unique to particular frozen soil; and S_k and S_c are arbitrarily selected settlement and settlement rate, respectively, which are introduced into the equation to put it into normalized form. The four experimental parameters $\sigma_k, K, \sigma_c,$ and n in equation (2) can be obtained by plotting pseudoinstantaneous deformation and steady state settlement rates, versus the applied stress in a log - log plot.

Equation (2) can be rewritten as

$$s(t) = B_1(\sigma_d)^k + B_2(\sigma_d)^n t \tag{3}$$

where $B_1 = C_1 S_k / \sigma_k^k, B_2 = C_2 S_c / \sigma_c^n$

Phukan (1982) investigated the creep behavior of ice-rich frozen soil samples obtained from various regions of Alaska.

In the new synthesis presented here, these data as well as some of the available data on ice are reviewed, and the assumed creep parameters for ice-rich silt are summarized in Table 1.

TABLE 1
 SUMMARY OF CREEP PARAMETERS FOR ICE-RICH SILT

Temperature Range (°C)	B1 (KPa ^{-k} x cm)	K	B2 (KPa ⁻ⁿ x ⁻¹ cm)	n
0 to -1	10 ⁻²	1.5	5 x 10 ⁻⁶	2.7
-1 to -3	5 x 10 ⁻⁴	1.9	0.7 x 10 ⁻⁶	2.7

Using equation (3) and Table 1, it is now possible to predict the deformation rates under constant embankment load on ice-rich permafrost.

In order to introduce some cross-check between the theoretical treatment described above and field measurements of embankment settlement, it is important to compare the predictions offered by this preliminary analysis with the recorded data presented in Figure 5.

From the embankment construction data, the average deviator stress below the midsections at sta. 166+75 and 170+00 may be calculated as 71.4 and 88.2 KPa, respectively, and the temperature range is about -0.5°C. Using the creep parameters of ice-rich soils (Table 1), equation (3) may be used to predict the settlement of the embankment. The range of settlement calculated for the embankment for different time periods agree with the measured information plotted in Figure 5.

The foregoing analysis for the creep settlements of embankment in ice-rich permafrost employed assumptions concerning the uniformity of soil conditions and temperatures. Moreover, it was assumed that the embankment maintained its geometry (no significant change in height). This was done to preserve the simplicity of the treatment, and it is encouraging to observe the

reasonable success of the method in predicting field behavior.

Clearly, the embankment design on ice-rich permafrost will involve limiting the height of embankment and thereby stress to keep the settlement within allowable limits. Obviously, the temperature beneath the embankment must also be maintained below the freezing temperature.

CONCLUSIONS

An analysis has been developed for the prediction of settlement for embankment built on ice-rich frozen soils. As more creep data for frozen soils of varying ice contents become available, the creep parameters for the settlement equation synthesized here may be modified to reflect the properties of the supported soil beneath the embankment. This will result in a more rational basis for the settlement calculation.

From a practical point of view, it is most important that the effects of disturbance of the ground thermal regime (due to construction operations or naturally occurring changes in terrain conditions and climate), which may result in significant settlement with time, be duly considered in the design of embankment in ice-rich permafrost. Moreover, depending on the existing temperature and ice content of founded frozen materials, the height of the embankment (reflecting stress) may be limited to maintain the embankment settlement within an acceptable range. More information on creep parameters of frozen soils at different stress levels is required to limit the maximum height of embankment that can be built so that only negligible deformation with time occurs.

Between 1980 and 1982 a total of 65 seasonal frost mounds were observed at several localities in the North Fork Pass, interior northern Yukon. The majority were of the frost blister variety, although icing blisters and icing mounds also occurred. The largest was 3.5 m high. Several persisted for more than 1 year and a few experienced reactivation and further growth in a second winter. Stratigraphic investigations, together with ice fabric analyses, suggest the mounds result from the freezing of suprapermafrost groundwaters during winter freezeback under conditions of high hydraulic potential. Piezometers, installed in areas of active mound formation, indicate pressures ranging from 40 to 80 kPa are associated with mounds 1-2 m high.

INTRODUCTION

Seasonal frost mounds are a groundwater discharge phenomenon resulting from increased hydraulic potentials developed by suprapermafrost groundwater in the active layer during winter freezeback. They form a distinct group of ephemeral and unstable winter landforms.

Although their occurrence has been widely reported in arctic North America (e.g., Brown and Berg 1980, p. 29, 82; Leffingwell 1919, p. 158; Muller 1945, p. 59; Porsild 1938, p. 47; Sharp 1942; Toth 1972, p. 161, 162; Zoltai and Johnson 1978, p. 24, 27, 51), only a few studies describe them in detail (e.g., van Everdingen 1978, 1982; van Everdingen and Banner 1979). In some instances, seasonal frost mounds have been confused with palsas (e.g., Hughes et al 1972, p. 38; Maarleveld 1965, p. 10-11) and they should also be distinguished from other types of short-lived ice-cored mounds which occur in tundra regions (e.g., French 1971). In the USSR, seasonal frost mounds have been the subject of several in-depth investigations (e.g., Shumskii 1964; see Williams 1965, p. 100, 103, 211-212).

Within this context, this paper documents the occurrence and internal structure of seasonal frost mounds in the North Fork Pass area of the Ogilvie Mountains, interior Yukon Territory (64°35'N, 138°18'W). At intervals between September 1980 and July 1982, the growth and decay patterns of more than 65 seasonal frost mounds were observed. The measurement of hydraulic pressures associated with mound activity is also reported.

STUDY AREA

The seasonal frost mounds described here occur in several locations in the North Fork Pass area between kilometers 82 and 86 of the Dempster Highway (Figure 1). The elevation of the pass is 1,370 m a.s.l. The mean annual air temperature is approximately -8°C and average precipitation is 480 mm. The area is mapped by Brown (1978) as being in the most northern zone of discontinuous

FIGURE 1 Location map of North Fork Pass, interior Yukon, showing sites (1-7) where seasonal frost mounds occur.

permafrost. However, according to borehole data (Foothills Pipe Lines [Yukon] Ltd. 1978), permafrost temperatures immediately north of the North Fork Pass are between -8°C and -5°C below an active layer which varies from 0.3 m to 2.0 m thick depending on site conditions. The boundary between continuous and discontinuous permafrost may be just

south of the pass at an elevation of approximately 1,000 m a.s.l. (Harris et al. 1983).

Various landforms diagnostic of permafrost conditions are present in the vicinity of the pass. These include ice wedge polygons, poorly sorted circles and stripes, beaded drainage and small thermokarst ponds. Solifluction is widespread on valley side slopes above 1,450 m a.s.l. Vegetation consists, for the most part, of shrub and tussock tundra in the valley bottom and alpine tundra on the valley side slopes.

MORPHOLOGY AND SETTING

At least 7 localities of frost mound activity have been identified (see Figure 1), all of which are associated with cold mineralized perennial springs. The mounds occur at or below the break of slope between the valley side and the floodplain of the East Blackstone River. The break of slope is hydrologically significant since it approximates the intersection point between the water table and

the ground surface. Frost blisters usually form in organic-rich silts covered by a layer of peat and/or tundra vegetation (Figure 2a) while icing mounds and blisters (Figure 2b) form in the icings that result from winter overflow caused by spring discharge. In all localities, alluvial fan deposits, formed where small tributary channels join the main valley, cover the lower valley slopes and serve as primary aquifers. The angles of slope of all sites range between 2° and 10° . Since the mounds occur on both sides of the valley, aspect does not appear to be a critical factor in their distribution. However, aspect may influence the timing of mound activity, since freezeback occurs earlier on northeast facing slopes. This limits the availability of groundwater and may explain why the largest icings occur on the northwest side of the valley (sites 1, 3, and 4; see Figure 1). The largest mounds, by contrast, occur at sites 5 and 6 on the northeast side of the valley (see Figures 1 and 2a), and are associated with the steepest local relief (i.e., highest hydraulic potentials).

FIGURE 3 Diagram showing the internal stratigraphy of three frost blisters. (A) Frost blister 1-2. (B) Frost blister 1-15. (C) Frost blister 1-4. Ice fabric diagrams from vertical thin sections are plotted on Schmidt equal area, lower hemisphere projections. For description of stratigraphy, see text.

Mound heights range from 0.5 m to 3.5 m while long-axis basal diameters range from 3 m to 70 m, often oriented parallel to the local slope. In general, the seasonal frost mounds of the North Fork Pass area are smaller than those described elsewhere (e.g., Lewis 1962; van Everdingen 1978, 1982). On the other hand, their frequency of occurrence exceeds all others previously cited.

In plan the mounds may be either circular, elongate, lobate, or complex. The mound profile is frequently modified by dilation cracks up to 35 cm wide, and by slumping or collapse caused by melting of the ice core (see Figures 2c and 2d). Scattered lumps of organic material observed incorporated within the icings indicate that explosive rupture may have occurred in some instances. Frost mounds were observed to survive the summer with minimal degradation or thaw. Some were reactivated the following winter; in one instance, reactivation resulted in a doubling of both mound height and length.

INTERNAL STRUCTURE

Stratigraphic investigation, along with detailed process studies, provides one method of distinguishing between seasonal frost mounds and other morphologically similar frost mound phenomena such as palsas.

Frost mound stratigraphy was determined either mechanically using a motor-driven coring unit and light drilling equipment, or manually by excavating along dilation cracks and areas of collapse.

The typical mound stratigraphy is summarized by the following generalized sequence. This is also illustrated in Figure 3 which shows the internal structures of three mounds located at site 1 (see Figure 1). All are covered by a surface vegetation mat which, during winter, is also covered by varying thicknesses of packed snow or icing ice. Beneath the surface organic layer is a thin (10-50 cm thick) layer of peat grading into organic-rich silt. This contact between the ice and silt is sharp. In many mounds, the ice is layered and includes bands of gas bubbles and some sediment inclusions. Gas inclusions range from small and spherical to vertically oriented and elongate bubbles, as much as 1 cm in diameter and 3-4 cm long. In some small blisters less than 1.0 m high, the mound is solid; the ice core forms an epigenetic ice body unconformably overlying frozen ice-rich sediments. By contrast, the larger frost blisters have cores consisting of one or more layers of clear ice which are usually arched over a water-filled chamber. Typically, the thickness of ice varies between 10 and 50 cm and the height of the chamber ranges from 20 to 70 cm. The horizontal dimensions of the ice core are difficult to document as are the sizes and shapes of the interior water chambers. Based on the drilling and

sectioning undertaken, it appears that the shape of the ice core resembles the surface expression of the mound, while the water chamber is low and lens shaped. During winter drilling, water encountered in the chamber was found to be clear and sometimes slushy; during the summer the water was murky and dirty. On several occasions in summer drilling an empty chamber was observed, where frost mound rupture the previous winter had presumably resulted in drainage. The sediment located beneath the ice core consists of in situ layers of frozen organic silt and silty sand with gravel. The bottom of the ice core probably correlates with the top of the frost table at the time the mound formed. Frost blisters 1-2 and 1-15 (see Figure 3) are typical of this general stratigraphy.

Frost blister 1-4, however, incorporates at least two ice-rich sediment layers in the ice core (see Figure 3). These separated ice of visibly different crystal and bubble characteristics. This mound was observed to experience reactivation during the 1980-1981 winter, following its initial formation the previous winter. The sequence of sediment-rich and clear ice, present in the lower part of the core, may represent a multiple cycle of mound growth where water with a high suspended sediment content was injected either between existing layers of ice or into a nearly totally frozen ice core.

Ice fabric studies (see Figure 3) also suggest that the mounds result from the injection of water rather than ice segregation, as might be expected if they were in palsas. Ice crystal orientations were measured using a four-axis universal stage (Langway 1958). Two fabric patterns are differentiated: first, a chill zone of small ice crystals with c-axis orientations forms a loose girdle parallel to compositional layering and perpendicular to growth direction; and second, the fabric is characterized at depth by large (0.5-2.0 cm diameter) vertically oriented long columnar crystals formed parallel to their growth direction. A preferred c-axis orientation normal to the growth direction was also observed. This fabric pattern is similar to that described for lake ice or injection ice (Gell 1978; Shumskii 1964) and might be expected in the freezing of a closed water-filled chamber.

HYDRAULIC CONDITIONS

Although the origin of these features is well known in general terms (e.g., Muller 1945, p. 59-60; van Everdingen 1978, p. 273-274), the details of their growth mechanism will normally reflect site-specific hydrologic conditions.

During drilling of several mounds in September 1981, it was noted that when the water-filled chamber was penetrated, trapped gases were released. On at least one occasion, sufficient pressure was present to temporarily force water 15 cm up the borehole. Presumably, these water pressures represented residual pressures associated with the hydraulic potentials necessary for mound growth the previous winter. Accordingly, piezometers were inserted in several actively growing mounds during March 1982. The piezometer consisted of a PVC standpipe containing silicone oil which

was closed at the top and had a flexible rubber diaphragm at the bottom. A simple pressure meter was attached to the top. Although any gas pressures contained within the mound were released upon penetration of the cavity by the drill, the insertion of the piezometer enabled measurement of any hydraulic potential that subsequently developed. A foam collar, attached to the piezometer, ensured a complete seal. Maximum values recorded over a 7-day period in four frost mounds, all between 1.0 and 2.0 m high (Figure 4), ranged between 40 and 80 kPa. Highest potentials were recorded in the two icing blisters (1-23 and 1-24) while the two frost blisters (1-25 and 1-26) were significantly lower. This may reflect the different tensile strengths of the confining materials but equally may indicate different hydraulic gradients at the four localities.

FIGURE 4 Diagram showing hydraulic potentials recorded at four seasonal frost mounds, North Fork Pass, March 16-23, 1982.

DISCUSSION

Similar measurements of hydraulic potentials associated with seasonal frost mounds have not been reported previously in the literature, although V. G. Petrov (see Williams 1965, p. 160) attempted to deduce the pressures involved via the depression of the freezing point of water inside a mound. However, van Everdingen (1982), using assumed densities of confining materials at Bear Rock, N.W.T., inferred that the minimum hydraulic potential necessary to form a 2.9 m high mound was 35.5 kPa, and for a 4.9 m high mound was 56.8 kPa. Although these calculations do not consider the planimetric dimensions of the mounds, if it is assumed that there is a general relationship between mound height and overall dimensions, it would appear that the maximum potentials recorded at the North Fork Pass exceed the minimum values assumed to operate at Bear Rock. At North Fork Pass, using similar values to those of van Everdingen (1982), a frost mound 2.0 m high (e.g., 1-26) would require a minimum pressure of 38.7 kPa. Since we observed pressures as high as 52 kPa at this mound, we assume that the difference reflects the resistance

to deformation of the confining materials. We do not think that higher hydraulic pressures exist in the North Fork Pass area, since the maximum dimensions of the mounds and the discharge of the perennial springs are considerably less than at Bear Rock. Instead, the presence of peat and organic-rich silts in the North Fork Pass are not conducive to the retention of high hydraulic potentials because the threshold values for mound rupture will be relatively low. On the other hand, the number of frost mounds exceeds that of the Bear Rock locality. It may be that the generally shallower active layer in the North Fork Pass, the dispersed nature of the springs, and the variability of freezeback at the high elevation all favor the formation of small, but numerous, mounds.

CONCLUSIONS

The occurrence of seasonal frost mounds is relatively common in the North Fork Pass area. They reflect suitable site-specific conditions of ground-water discharge, climate and the presence of permafrost as an impermeable lower boundary to ground-water movement. Stratigraphic studies indicate that the mounds possess an internal structure which differentiates them from palsas. The ice core, as illustrated by ice fabric and isotope analyses, indicates injection and freezing of water under conditions of high hydraulic potentials.

The direct measurement of the hydraulic potentials associated with seasonal frost mound activity is possible using a simple piezometer apparatus. Although more measurements are required from a wider range of localities, the data presented in this paper suggest that potentials of between 40 and 80 kPa are necessary to form mounds 2.0 m high. Large mounds probably require higher potentials.

CRYOLITHOGENESIS AS A TYPE OF LITHOGENESIS

A. I. Popov

Faculty of Geography,
Moscow State University, USSR

The paper examines a special, climatically controlled type of lithogenesis, namely cryolithogenesis. This zonal type of lithogenesis is dictated by the processes of cryodiagenesis and cryohypergenesis, occurring specifically in the polar and subpolar zones. Typical cryolithogenic products of cryodiagenesis and cryohypergenesis are distinguished, along with the corresponding peculiarities of their geographical distribution. Some critical comments are presented with regard to certain alternate existing concepts of cryolithogenesis.

Recognition of cryolithogenesis as an independent climatic type of lithogenesis was a logical consequence of elucidation of the role of cryogenic processes in the earth's crust (Popov 1967). The variety of interpretations of the concept of cryolithogenesis in the literature, however, requires a return to this subject.

Lithogenesis is not only the formation of sedimentary rocks, but also the formation of weathering crusts; all transformations of primary and secondary rocks under subaerial and subaqueous conditions, i.e., under thermodynamic conditions at shallow depths, characterized by low temperatures and low pressure, should be attributed to it. All the processes of exogenic rock-formation under the effect of sedimentogenesis, diagenesis and weathering are thus processes of lithogenesis. The intensity and the zonal character of the processes of lithogenesis are determined by physical-geographical conditions that vary from one natural zone to another.

Catagenesis, metagenesis and metamorphism correspond to different thermodynamic conditions characterized by high temperatures and higher pressure. Such conditions are caused by endogenic factors and are not subject to natural zonation.

Because cryogenic processes are exogenic processes, cryolithogenesis is a part of general lithogenesis.

The cryogenic processes should be regarded as processes of diagenesis and weathering which develop under the near-surface thermodynamic conditions; they have no continuation under the thermodynamic conditions of catagenesis, the subsequent stage of transformation of earlier-formed rocks.

Cryolithogenesis is active in polar, subpolar and high mountain regions of both the Northern and Southern Hemispheres.

Arid lithogenesis develops under dry conditions and humid lithogenesis under sufficiently wet conditions; cryolithogenesis occurs under the action of ice and water that changes its phase periodically. According to all data available, the ice type of lithogenesis (Strakhov 1960) should be regarded as cryolithogenesis (Popov 1967).

Diagenesis should be understood not only as the physical-chemical equilibration of sediment in a

subaqueous medium (Strakhov 1960), but also as the physical-mechanical equilibration in both the subaqueous and subaerial media, viz., compaction, relative dehydration, and squeezing out of free water and migration of loosely-bound water (Shvetsov 1958, Rukhin 1969, Shantser 1966, Lomtadze 1970, and others). Consequently, cryogenic processes mainly responsible for physical-mechanical transformations in sediments and rocks and contributing to their long-term consolidation should be understood as diagenesis (cryodiagenesis). Under cryolithogenesis, the thermodynamic factor of diagenesis, i.e. water crystallization, suppresses the physical-chemical equilibration but does not exclude it altogether.

Cryodiagenesis is the long-term, irreversible freezing of moist sediments and dispersed rocks; ice forms in these substrates as an authigenic mineral. Cryodiagenesis influences the aleuropelitic series of these sediments and rocks, which is expressed in relative dehydration of mineral aggregates during migration of both free and loosely-bound water, in their intravoluminal contraction and the formation, as a rule, of various types of ice streaks which form the characteristic cryogenic textures of a diagenetized perennially frozen rock. No appreciable changes occur in the mechanical makeup of the sediment or rock. Cryodiagenesis of coarsely dispersed rocks (sands and the like) is a simpler process associated with fixation of freezing free water in situ, with forcing it out of the freezing front, with formation of a massive cryogenic texture or centers of ice-formation that do not markedly disturb the structure of coarse sediments, and also with retaining the initial mechanical composition of coarse clastic and other materials. The formation of massive wedge-ice lattices in dispersed rocks during the successive frost cracking should also be referred to the category of phenomena of cryodiagenesis. Also included here should be the formation of the ice cores of pingos and palsas.

As the gravitational compaction of a dispersed rock develops during its subsidence and dehydration, the effects of cryodiagenesis cease at the stage of complete disappearance of loosely bound water whose presence and ability to migrate

represents the most important factor of cryodiagenesis. The freezing of a moist aleuropelitic rock that underwent general diagenesis and had not frozen previously, but had become only moderately consolidated, retaining the loosely-bound water capable of cryogenic migration, is a process of diagenesis with all the mentioned cryotextural aftereffects. The freezing of such a rock is not a transition to the stage of catagenesis; it is only a pause in the common diagenesis of the rock, during which originate new, cryodiagenetic processes whose textural features superimpose upon the textural features of the preceding pre-cryogenic diagenesis. Thus, cryodiagenesis can manifest itself as the primary diagenesis when sediments, which did not undergo diagenesis before, freeze, but it can also act as secondary, superimposed diagenesis, when rocks freeze which did undergo general diagenesis but which did not become heavily consolidated and retained loosely-bound water capable of cryogenic migration (Popov 1967).

Cryodiagenesis also manifests itself by similar cryotextural effects in longterm, irreversible freezing of unconsolidated moist clayey and coarser weathering deposits. In this case, cryodiagenesis appears as posteluvial diagenesis.

Clastic formations stand out as products of cryogenic weathering in cold regions of the earth; they result from physical disintegration of crystalline, metamorphic and consolidated sedimentary rocks. Silty formations also form through cryogenic weathering as an ultimate result of disintegration of the sand and coarser fraction and aggregation of the clay fraction.

Cryogenic weathering is manifested most fully by systematic, seasonal or diurnal freezing-thawing of rocks. Two basic mechanisms of cryogenic destruction of rocks are then taking place: (1) cryogenic weathering proper as a result of the wedging action of ice in relatively large fissures and pores, which causes the formation of coarse detritus (cryoclastites, such as blocks, rubble and coarse sand), and (2) cryohydrational weathering (Konishchev 1977) due to the variation in pressure in thin water films in microfissures, which is the result of phase changes which cause the formation of the silty and fine-sandy fraction (cryopelite). Cryopelite is the end product of cryogenic weathering.

Cryogenic weathering resulting in the formation of cryoclastites and cryopelites is restricted to the horizon of seasonal freezing-thawing. The epigenetic freezing of crystalline, metamorphic and compact sedimentary rocks (sandstones, aleuropelites, argillites, limestones), when a perennially frozen rock is being formed, is also, in the end, a process of destruction. During this process, mainly free water freezes in fissures due to tectonic processes or denudation that relieve the rock mass of its load. The subsequent possible thawing of these rocks (perhaps in a short period of time or in hundreds or thousands of years) would necessarily lead to their destruction and disintegration. Therefore the process of freezing of compact bedrocks should be regarded as a process of the initial cryogenic weathering and also as a process that prepares these rocks for destruction; such perennially frozen rocks should be called "rocks of cryogenic pre-destruction."

The process of nivation is a process of cryogenic weathering. It occurs on rock surfaces under the conditions of diurnal changes of phase (ice-water) in the peripheral, intensively moistened zone in the immediate vicinity of snowpatches and glaciers. Silty nival fine material is the product of nivation.

The regelational type of weathering occurring at the contact of a glacier bed and the underlying rock is an independent type of cryogenic weathering. This type of weathering produces characteristically a so-called regelational, fine silt (Moskalevsky 1978) which constitutes the bulk of the fine material in ground moraines. While glaciers are second, after rivers, in the volume of load (Gurrels and Mackenzie 1974), the cryogenic process should be considered as one of the most important factors in the complex geological activity of glaciers.

Cryogenic weathering (cryohypergenesis) is diverse, and involves at least four types.

On the basis of the preceding discussion, the products of cryodiagenesis are the following: (1) polymineral dispersed ice-rich rocks, i.e., cryolitites, and (2) monomineral ice rocks (veined, injectional, etc.), i.e., cryolites. The products of cryogenic weathering, i.e., of cryohypergenesis, are as follows: (1) rocks of cryogenic pre-destruction, such as perennially frozen masses of crystalline and other compact rocks; (2) cryoclastites, i.e., initial products of cryogenic destruction, such as blocks, rubble and sand; and (3) cryopelites, i.e., end products of cryohypergenesis, namely, silty loessial fine material. The products of cryohypergenesis are components of a distinctive cryogenic crust of weathering.

A number of authors substantiated the delimitation of "polar lithogenesis" (Lapina et al. 1968, Danilov 1978); the conditions of sedimentogenesis in polar seas are the main criterion, while the processes of lithogenesis under continental conditions are considerably less important.

The well-known specificity of sedimentation in the seas of the cold zone takes place more appreciably on the shelf than outside it. However, Strakhov (1976) concluded that there was no single polar type of lithogenesis that would include both polar land and seas. The lithogenesis of sediments over the major part of polar waters is mainly the lithogenesis of an oceanic humid type that does not differ essentially from the oceanic type of lithogenesis at middle latitudes.

In conclusion, only the direct influence of ice or of systematic phase changes on sediments and rocks determines the classification of a territory or a water area under cryolithogenesis. The indirect effects of floating ice on sediments (transport of boulders), the presence of salt brines, and other such phenomena without direct influence of ice on sediments and rocks cannot be regarded as factors of cryolithogenesis.

A definition of cryolithogenesis as a sedimentary process inherent to the cold regions of the earth has been proposed (Gasnov 1976). Under that definition, all cryogenic processes that are not immediately associated with sedimentation are not regarded as components of cryolithogenesis, but are understood as phenomena of cryogenesis.

In my opinion, the restriction of cryolitho-

genesis to participation of cryogenic factors in the process of sedimentation, i.e., in the formation of syngenetic frozen rock masses, is erroneous because a number of links within the complex process of cryolithogenesis such as cryogenic weathering, freezing of bedrock, cryodiagenesis of unconsolidated or poorly consolidated rocks with epigenetic freezing are omitted.

It is only through consideration of the climatically preconditioned specificity of diagenesis and weathering that one can determine properly the type of lithogenesis, in our case, cryolithogenesis, including cryodiagenesis and cryogenic weathering (cryohypergenesis).

Researchers regard cryolithogenesis as a sedimentary process because of the strict succession between the areas of denudation, transportation of material, and its accumulation in the terminal runoff basins. This approach is permissible when this succession is well developed, i.e., when there is a causal interrelationship between the areas of drift, transportation and accumulation. However, as we know now, such succession and interrelationship is very inextensive within the zone of cryolithogenesis. Also, the manifestation of cryolithogenesis in time is relatively restricted—from the end of the Pliocene to the Holocene inclusive.

Based on sufficiently extensive field data, I have concluded that cryogenic rocks and their complexes are formed under the conditions of a limited group of processes inherent in the areas of predominant denudation, predominant accumulation, and relative stabilization of the surfaces undisturbed by drift or material accumulation (Popov 1958). Each specific area is characterized by its own complex of cryogenic rocks, which may fail to reach into another area. On the Taymyr Peninsula, for example, under the conditions of denudation and downslope material movement, deposition of the displaced products of cryogenic weathering and their local accumulation took place on slopes and at the slope bases, in depressions and in small river valleys during long periods of time corresponding to the major time periods of the Pleistocene. There are pertinent examples referring to the other two mentioned areas, viz., areas of predominant accumulation and of relative stabilization of accumulation and drift of cryogenic material.

Apparently, the conclusion is true that lithogenesis in general and cryolithogenesis in particular can be realized both successively in stages from the drift sources to the terminal runoff basins and, to a considerable degree, through closed development within the areas of predominant denudation, predominant accumulation, and relative stabilization of surfaces without drift or accumulation or complete continuity between them.

Under the conditions of accumulation (in large river valleys, in deltas and in the sea), the self-containment of the type of formation of cryogenic rocks and its relative independence of the adjacent areas of denudation and drift of the cryogenic weathering products are particularly expressive. The following materials enter such accumulation areas: material formed cryogenically on water divides, products of river-washout of the Pre-Quaternary and Quaternary "non-cryogenic"

rocks, considerable percentage of the present-day organic materials which are mainly vegetative, part of sediment runoff, and non-volcanogenic and volcanogenic eolian materials. All these become components of the deposits of the terminal runoff basins and major river valleys as a sum of non-cryogenic and cryogenic products, and it is far from being clear which of these components will prevail in each particular case. This is greatly confusing for those researchers who are studying only products of cryolithogenesis in marine sediments of the polar basin.

Observations showed that during both sub-aqueous and subaerial sedimentation in the Arctic, cryogenic weathering in a thin active layer (0.2 to 0.5 m) only weakly "reprocesses" the accumulated material; cryodiagenesis fixes its initial composition and changes only its mechanical properties and the texture due to ice segregation. Therefore the mixed composition of such a cryogenically diagenitized rock may show few or no traces of previous cryogenic weathering at the stage of denudation or at the place of accumulation. The areas of accumulation and the local areas of cryogenic denudation in the Arctic and Subarctic lack direct and close continuity.

Fully independent cryogenic, mainly cryo-eluvial rock formation proceeds under the conditions of relative stabilization of the surfaces not subject to drift or material accumulation; there is often no input or output of material underway in these areas. This is illustrated by considerable areas of some plateaus, vast drainage divides of the great lowlands, and old terraces of the major river valleys. Under such conditions, the exogenic process at the stage of cryogenic weathering with a thin cryogenic weathering crust is clearly autonomous; an example are loessial formations of loessial mantle loams.

The closure of processes and products of cryolithogenesis within the areas of denudation and drift, and the well-known autonomy of cryogenic exogeny under the conditions of denudation and slope migration were already discussed.

The rate of the processes of formation of the products of cryogenic denudation and cryogenic weathering crust should also be taken into account. Contrary to the rather widely accepted high rates of denudation and, in general, high rates of development of exogenic processes in permafrost and tundra regions, the data available show irrefutably that in reality the areas of stable cooling are characterized by relative retardation of these processes and the high rates are an exception. It must be concluded that one cycle of cryogenic denudation, transportation and accumulation can sometimes extend over a period of time corresponding to the Pleistocene, i.e., over the entire epoch of the existence of permafrost and the climate under which cryolithogenesis occurs. Hence the inertness and the relative conservatism of materials that form are moved and accumulate in the course of cryolithogenesis, and the long time they take to reach the terminal runoff water basins.

The epigenetic freezing of both Pre-Quaternary and Quaternary rocks should be mentioned; this is a process bearing no relation to either the immediate cryogenic denudation, drift, or accumulation.

As was already shown, this is either a process of cryodiagenesis or of the initial cryogenic weathering, i.e., cryogenic pre-destruction that can operate for a relatively long time.

It was established earlier that cryolithogenesis occurs in the area of stable cooling of the earth; this area coincides with the permafrost regime. But it is known that cryolithogenesis is manifested also in the areas of only seasonal freezing, outside the limits of permafrost occurrence. It is displayed here only as cryogenic weathering. This is the area of predominantly humid lithogenesis, and cryolithogenesis is active here only under certain conditions. This zone with a combination of the processes of humid and cryogenic lithogenesis should be probably named a cryohumid zone and referred to the area of unstable cooling.

The recognition of cryolithogenesis as an independent type of lithogenesis (along with the arid and humid types) is supported by the following circumstance. While in the zones of arid and humid lithogenesis the major lithogenesis agent is water and the product is a solid mineral constituent (transformed sediments and materials of weathering crust), in the zone of cryolithogenesis the major lithogenesis agent is ice, and the main product is also ice which is accompanied by important solid mineral products of cryolithogenesis. This unity of agent and product places the zone of cryolithogenesis into a special position; the cryohumid zone with its exclusive cryogenic weathering is an exception.

Ice formation imparts clearly expressed individual features to sediments and all rocks and preconditions their originality in terms of lithology and facies. Freezing accompanies other geological processes in the cold zone, such as erosion, water accumulation, etc. To a considerable degree, freezing directs all exogenic geological processes along a new, specific path. Besides, freezing fixed as permafrost represents a limit for the usual subsequent processes of rock alteration at positive temperatures, e.g., for diagenesis and catagenesis.

It should be noted that frozen rocks and underground ice do not enter any of the general lithological classifications, which by itself is an indication of their special, exclusive position. Their seeming ephemerality and relative instability under the thermodynamic conditions of the earth cannot be the reason for such exclusion. Under the conditions of the Arctic, in many regions of the Subarctic and in the Antarctic, many underground ice formations remain relatively unaltered during tens and hundreds of thousands of years and have undoubtedly a right to be singled out as a special group of rocks. The cryogenic processes causing most appreciable changes in the zone of hypergenesis of the cold regions of the earth acted during the entire Upper Cenozoic era upon considerable areas of dry land in the cold stages of the Pleistocene.

THE EFFECT OF HYDROLOGY ON GROUND FREEZING IN A WATERSHED WITH ORGANIC TERRAIN

Jonathan S. Price

Department of Civil Engineering, University of Saskatchewan
Saskatoon, Saskatchewan, Canada S7N 0W0

This is an investigation into factors affecting seasonal frost penetration in organic and inorganic terrains including the effect of the water table on freezing. Five different terrain types were instrumented with frost gauges and snow stakes. Piezometers were used to record water table fluctuations, and soil thermistors were used to determine temperature gradient and heat flux. Frost penetration among sites, and variation of frost depth within sites was investigated. Where the water table was at the surface and considerable flow occurred through upper layers, circulation of water reduced the rate of freezing but caused cooling to occur more rapidly in deeper layers, but where little flow was observed, cooling of lower layers lagged considerably, resulting in more rapid frost penetration in upper layers. Freezing of positive and negative relief elements was different for bogs and fens. Here again, the elevation of the water table was largely responsible.

INTRODUCTION

An assortment of terrain types both organic and inorganic can occur within one watershed. In this paper the term "terrain" is used to define a geographical area typified by the soil type, vegetation and hydrologic characteristics (for example bog or fen). The characteristics of each terrain type can result in a variety of freezing patterns in response to similar macroclimatic stimuli. During winter, the hydrologic and freezing regimes of a particular terrain type are interdependent. Price and FitzGibbon (1982) have shown that in organic terrain where the water table is at or near the surface when freezing begins, the pattern of subsurface drainage and runoff are affected. They noted in both mineral terrain and organic soils with deeper water tables, freezing has little or no effect on local hydrology. Obviously, the reverse is also true. The presence of the water table at the surface will have a strong effect on freezing. Thermal conductivity is directly proportional to soil moisture. Higher specific heat of moist soils, however, demands greater energy loss for cooling and freezing. Thus peat which is moist but not saturated experiences rapid freezing (Tyrtikov 1959). The role of water overlying permafrost in organic terrain was investigated by Ryden and Kostov (1980) who found freezing rates in depressed (wetter) areas to be 20% slower than in areas which were elevated.

The freezing of sphagnum hummocks proceeds more quickly than freezing of adjacent depressions. Brown and Williams (1972) and Romanov (1961) found higher moisture content of depressions to be partly responsible. Romanov (1961) also found that the increased surface area of hummocks promoted a more rapid cooling. A similar pattern of freezing in ridge-trough microrelief of ribbed fen was noted by Romanov (1961). He found deeper frost in ribs (than in troughs) but with less ice (water) content, hence, equivalent "frozen mass."

In addition to the effect of hydrological conditions on freezing, the physical and mechanical properties of the soil and vegetation are important. Brown and Williams (1972) found mineral soils to have thermal conductivity roughly an order of magnitude greater than dry peat. This results in greater annual amplitude in soil temperature for mineral terrains. This paper is an investigation of the hydrological properties which affect the formation and penetration of ground frost in a watershed containing large areas of organic terrain.

THE STUDY AREA

A 17.4 km² watershed located in Nipawin Provincial Park, Saskatchewan (lat. 53° 55' N, long. 104° 45' W) was instrumented for the winter of 1981-1982. Located north of the 0°C mean annual isotherm, it is on the southern fringe of the zone of scattered permafrost. The mean annual precipitation is 440 mm (133 mm snow) (Fisheries and Environment Canada 1978). The area is gently to moderately rolling, and is underlain with a relatively impermeable glacial till which is blanketed by a 120-200 cm sand layer. No permafrost was encountered in this basin.

The watershed (shown in Figure 1) contains five distinct terrain types consisting of mineral terrain (Site 1), wet low-lying bog (Site 2a), sedge fen (Site 2b), dry high-moor bog (Site 3), and ribbed fen (Site 4). Organic terrains account for 35% of the area of the watershed. On well drained mineral terrain (sandy soil) the dominant vegetation is white spruce (*Picea glauca*) and jack pine (*Pinus banksiana*) with some aspen (*Populus tremuloids*). Black spruce (*Picea mariana*) and occasional balsam poplar (*Populus balsamifera*) dominate lower lying areas on mineral terrain. There is generally a 70 to 80% canopy cover and a ground cover of feather moss (*Pleurozium schreberi*). Open areas have scattered jack pine and are covered with a 5 cm mat of lichens.

METHODS

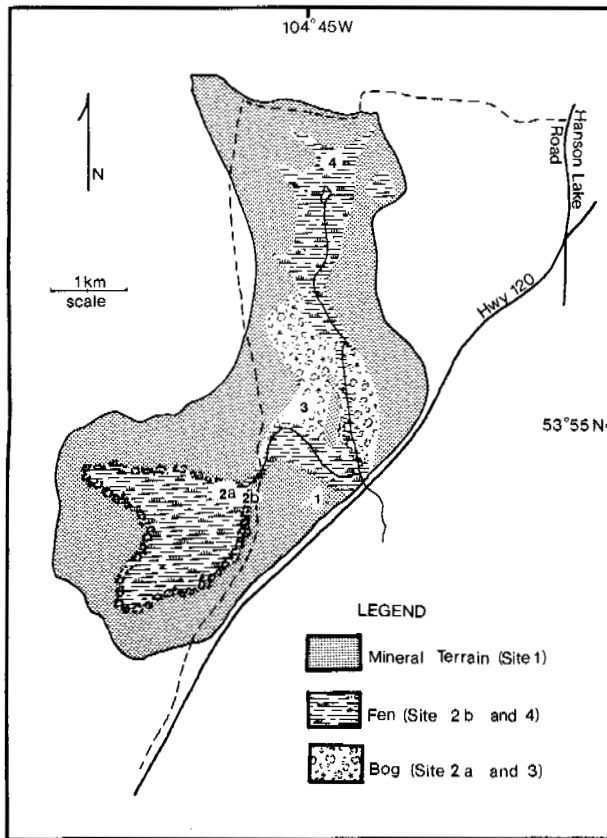

Figure 1 The study area.

The wet bog (Site 2a) has a poorly developed hummocky microtopography formed from sphagnum moss (*Sphagnum fuscum*) and is covered with Labrador tea (*Ledum groenlandicum*). It has 20 to 50% canopy cover composed of black spruce and tamarack (*Larix laricina*). Mean peat thickness is 165 cm. The water table was very close to the surface with small pools in some depressions. The dry bog (Site 3) has a 60–80% hummocky ground cover, comprised primarily of sphagnum mosses, with Labrador tea on the hummocks. Mean peat thickness is 140 cm, and the water table was 20–30 cm below the surface (of the depressions) at the onset of winter.

The open sedge fen (Site 2b) has low relief and is dominated by *Carex* (sedges) with some willow (*Salix*) and alder (*Alnus*) shrubs at the edges. The mean peat thickness is 170 cm and the water table was at or above the surface. Considerable flow was observed over the fen at high water levels during the autumn. Ribbed fen (Site 4) consists of alternating rib-trough microtopography, orientated perpendicular to the general direction of flow. Low *Carex* (sedges) grow in the troughs, with willow and alder shrubs and sedges growing on the ribs. Ribs are spaced 3–5 m apart and are 20–50 m in length and 10–20 cm in height. Mean peat thickness is 180 cm and the water table was at the surface of the troughs prior to freeze-up.

A recording piezometer was installed in all sample areas except for the wet bog (Site 2a). The piezometer tube was constructed from a 10 cm diameter plastic pipe extending 1.5 m below the soil surface, and 0.5 m above. The above ground section of the piezometer was covered by an insulated housing (R 12 fiberglass insulation), and an ethylene glycol - methyl alcohol solution was poured into the tube with a small quantity of light oil (to prevent evaporation of the alcohol). This was largely successful in preventing the piezometer from failing due to freezing. A stage recorder in a wooden housing recorded the water level in the tube.

Each site had 10 frost gauges (Rickard and Brown 1972) and 10 snow stakes along a transect. At each station along the transect one frost gauge and one snow stake were located adjacently. Stations were located from 5 to 10 m apart or as specified below. On mineral terrain (Site 1), five frost tubes and five snow stakes were situated under the forest canopy, and five each in the open. On the high bog (Site 3) they were located alternately on hummock and depression, and similarly for rib and trough in the ribbed fen. A transect of 20 snow stakes and 20 frost gauges extended from the low bog (Site 2a) over the adjoining fen (Site 2b), oriented perpendicular to the direction of flow.

At each site one or two sets of thermistors were implanted in the soil at depths of 10, 60, and 120 cm to measure temperature. A mercury in steel probe and recording thermograph was also used in the sedge fen (Site 2b) with probes at 10 and 60 cm. Air temperature data were recorded at Site 3, and had to be supplemented with records from the LaRonge weather station (125 km to the north west) due to instrument malfunction. Correlation of LaRonge temperatures with on site temperatures was $r^2 = 0.98$.

RESULTS AND DISCUSSION

Depth and standard deviation of frost penetration are shown in Figure 2 for each terrain type. Considerable variation in frost depth was displayed within both the mineral terrain and the high (dry) bog. In both of these terrains, the water table remained below the freezing front (see Figure 3). Much less variability was observed for the fens and the low bog, where the water table elevation was at or above the surface at least during the first few months of winter, and the freezing front was in contact with saturated peat at all times. This is shown for the fens (Site 2b and Site 4) in Figure 3. It was found that movement of water through the saturated zone imported heat to the soil (Figure 4). On 17 October, which was the last day of positive mean daily temperatures for 1981, the temperature profile for the fens differed markedly from those of the mineral and bog terrains (Figure 4). In mineral and bog terrains, the soil was nearly isothermal. In the bogs, cool temperatures existed at depth because of slow heating over the

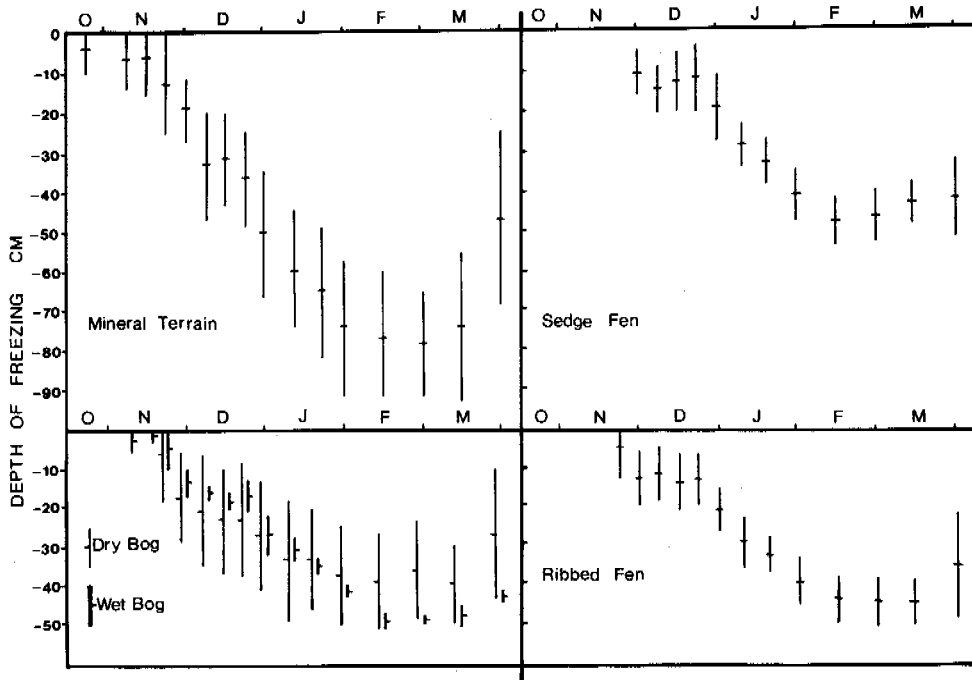

Figure 2 Depth and standard deviation of freezing of five different terrain types.

Figure 3 Elevation of water in the piezometer and depth of freezing for four terrain types.

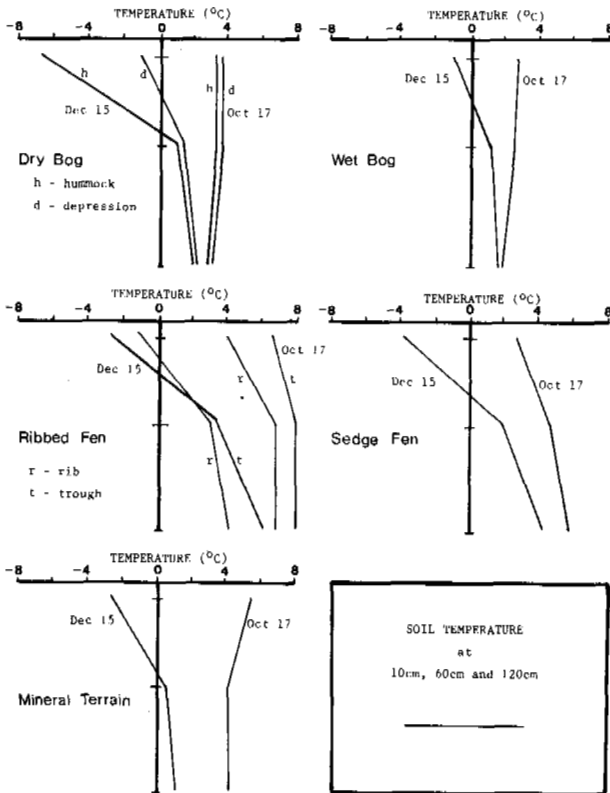

Figure 4 Ground temperature profiles for five terrain types on 17 October and 15 December.

summer. Insulative properties of surface mosses when dry, and slow drainage inherent to bogs minimized heat exchange. Water in the fens, on the contrary, experienced greater volumes of flow on and within surface layers and in the underlying mineral aquifer, allowing greater heat exchange than in the bogs. Additionally, the saturated fen surface provided little insulative cover, and the unforested condition permitted greater direct solar radiation receipt. Consequently, warmer temperatures prevailed in the fens, particularly at depth.

By 15 December, 436 negative degree-days had accumulated. From inspection of the temperature profiles shown for this date (Figure 4), it is evident that in the bogs most of the heat lost was from the surface layers, and cooling of deeper layers was slow, whereas in the fens, flowing water provided the mechanism for more rapid heat exchange. In the mineral site, large changes in surface and basal temperatures for the dates given (in Figure 4) reflect the greater thermal conductivity and lower volumetric heat capacity of mineral soils.

Frost penetration at each site was affected by the variable height of surface features with respect to the water table, vegetation characteristics, and snow accumulation patterns. Discussion of these effects is presented site by site.

Mineral Terrain

On the mineral terrain both frost depth and snow depth were found to be significantly different between forested and open sites. The difference between mean values were tested with t-test at a 95% significance level. Snow accumulation was 50% greater in the open area than under the dense black spruce due to canopy interception. Nevertheless, on mineral terrain, significantly greater frost penetration occurred in the open areas than in the forested location (see Figure 5). This is contrary to Baldwin's (1956) and Tyrtikov's (1959) suggestion that deeper frost occurs under dense coniferous forests. Although snow cover is normally important in reducing the depth of the frozen layer, the effect of the forest microclimate cannot be overlooked. Longwave radiation emitted by forest biomass is an important source of energy for the snowpack and ground in the forest ecosystem (Jeffrey 1968). Additionally, lower wind velocities in the forest reduces sensible heat exchange. FitzGibbon (1976) found windspeed in similar forest conditions near Schefferville, Quebec to be 7.06 km/hr lower than in the open. Here, a combination of these factors was sufficient to result in significantly less frost in the forested area. The difference in snow density between open and forested sites sampled was not significant ($n = 10$). The moss cover in the forest appeared to have some influence on frost penetration, with less frost forming beneath moss covered soil than in ground covered by lichen.

Figure 5 Freezing and snow depth for mineral terrain (top), dry bog (centre) and ribbed fen (lower).

In the mineral terrain the frost depth reached its maximum by 28 February and then began to degrade for the remainder of the winter, even though 43 continuous subfreezing days followed totalling 486 freezing degree-days. This was a result of the rising water table in the mineral aquifer caused by icing of the drainage channel 250 m away. The rising water table can be seen from Figure 3. The water in the aquifer had sufficient heat energy to cause thawing of frost at that location, and raise the temperature at 120 cm depth by 3°C between 14 February and 15 March.

Wet Bog

In the wet bog (Site 2a) the water table was close to the surface at the time of freeze-up. Because of the relatively low microrelief and slow subsurface drainage, ground freezing showed little variability among sampling stations (Figure 2). Snow depth also showed a very low standard deviation. The average rate of frost penetration was 4 mm/day, as compared to 7 mm/day reported by Ryden and Kostov in a depressed (wet) area underlain by permafrost in Sweden. The lower rates of freezing encountered here are in part due to the fact that permafrost was not present. Initial freezing was slower than in the dry bog (Site 3) because of the high volumetric heat capacity of saturated peat. The rate of frost penetration remained relatively constant when compared to the dry bog (Figure 2), as a result of the physical homogeneity of the site, and the constant saturated moisture conditions experienced at the freezing front. Upward heat transfer from lower layers was slight as reflected by the temperature profiles (Figure 4). The heat flux also remained reasonably constant over the winter, and only dropping slightly in response to thicker snow cover.

Sedge Fen

In the sedge fen (Site 2b) there was little surface microrelief across the transect. The water table was at or above the surface prior to freeze-up. The weekly accumulation of snow was evenly distributed across the transect with standard deviation generally half of that for frost depth. Variability in frost depth, was related to zones of higher subsurface water flow. Shallower freezing was noted to occur where most surface water flow was observed prior to winter. Frost depth in these zones was typically 10-20 cm less than in other parts of the fen. This was of considerable importance to winter drainage because it maintained a subsurface "channel" in the most active hydrological layer (i.e. the upper layers of peat have the highest hydraulic conductivity, whereas lower layers are almost impermeable).

An 11.4 mm (water equivalent) snowfall occurring between 20 and 23 December reduced the temperature gradient of the fen and caused the temperature 10 cm below the peat surface to rise 2.2°C (while mean daily air temperature dropped). In high flow zones, total degradation of the frost layer occurred (depth of frozen layer was initially 10 to 13 cm) and the average thaw for the transect was 4.9 cm. This illustrates the large thermal capacity of the fen.

In the sedge fen the frozen layer not only extended downward, but grew upward from the primary freezing surface as a result of flooding and subsequent freezing of the lower snow layers which became saturated by water. Water seepage onto the surface was caused by a) hydraulic pressure created by the expulsion of water from the peat as it froze, b) increased hydrostatic pressure created by the overburden pressure exerted by the snowpack c) artesian pressure formed as a result of the impermeable frozen layer which constricted inflowing water beneath (Price and FitzGibbon 1982). The rising hydrostatic pressure in the fens is evident from Figure 3.

Dry Bog

In the dry bog there was a deep water table relative to the sphagnum hummocks. Similar moisture content was measured in both positive and negative relief elements, hence specific heat and thermal conductivity were also similar. Under such conditions, Romanov (1961) found freezing intensity to depend exclusively on surface morphology during the early winter before the accumulation of a snow cover. Hummocks, which have greater surface area, experienced deeper and more rapid freezing than depressions (Figure 5). Here, the heat flux ratio of positive to negative relief elements was 2.1:1 between 15 to 29 November. Additionally, the difference between snow depth on hummocks vs. depressions was not significant until after 31 January, which indicates snow cover may not have been as important as surface form or proximity to the water table (no data is available on snow density during this period). Between 31 January and 15 February the heat flux for positive and negative relief elements was nearly equivalent as was freezing intensity.

In the dry bog (Site 3) the mean rate of frost penetration was initially higher than in the wet bog (Site 2a) due to the lower volumetric heat capacity of the drier surface. As the freezing front approached the water table, the increased volumetric heat capacity of peat at the freezing front resulted in slower freezing.

Ribbed Fen

Prior to freezing (17 October), ribs were cooler than troughs (Figure 4), but by 15 December the upper layers of the trough were considerably cooler than ribs, and by 31 January the troughs were cooler throughout the vertical profile. The heat flux for troughs was 3.5 times greater than for ribs between 15 to 29 November. Although the saturated condition of the troughs resulted in a higher volumetric heat capacity than ribs, freezing occurred first in troughs and penetrated more rapidly (Figure 5).

On 15 December, three (of five) frost gauges on ribs were unfrozen while mean frost depth in troughs was 19.4 cm. There was some evidence that the water table level in ribs rose slightly, and that water circulation through ribs might have been important in delaying freezing. It is possible that lateral flow may have occurred in

ribs as deeper freezing in adjacent troughs (in addition to their already lower position with respect to the water table) presented a barrier to flow in the normal downslope direction. This might explain the pools of unfrozen water that were observed at the edge of the fen in early winter.

From 15 February onward, the difference in frost depth for ribs and troughs was no longer significant. This coincided with the period of rapidly diminishing water inflows (as evidenced by the falling piezometric water levels shown in Figure 3) and with frost depths in ribs and troughs exceeding 40 cm. With freezing at this depth the hydrologically most active layer described by Romanov (1961) becomes inert, resulting in similar conditions at the freezing front in ribs and troughs. As the deepening snowpack provided greater insulation, and as water circulation at the freezing front was minimized, the rate of frost penetration in positive and negative elements became similar.

CONCLUSIONS

Several generalizations on the effect of the groundwater table on frost penetration can be made. Where the groundwater table is deep, it has little effect on the freezing process, but as the freezing front approaches the water table, the freezing rate slows considerably. Frost which has already formed may degenerate if the water table rises or a thick, low density snowpack accumulates. Where the water table is close to the surface and water experiences little flow, fairly homogeneous freezing occurs. If the water table is at or above the surface and considerable subsurface flow occurs (as in fens), the patterns of freezing can be complex. Water flowing beneath the frozen surface inhibits deep frost penetration. The effect of snow as an insulator is important but can be overshadowed by other local conditions such as forest cover, depth to the water table, or surface morphology of relief elements.

PEDIMENTATION AND FLUVIAL DISSECTION IN PERMAFROST REGIONS
WITH SPECIAL REFERENCE TO NW-CANADA

Kuno Priesnitz and Ekkehard Schunke

Department of Geography, University of Göttingen,
Federal Republic of Germany

The paper deals with the question, whether under periglacial conditions the destruction of pediments by fluvial dissection or the formation of pediments are prevailing processes. Studies on this problem were carried out mainly in the Mackenzie and in the central Richardson Mountains, in areas, which since the beginning of the Quaternary period are subject to periglacial but not to glacial conditions. Pediplains are common in the whole area. Most of them are thought to be periglacial pediplanation surfaces (cryopediments). The aim of the paper is to report observations about the main processes causing the formation of these pediments by backwearing (intense slope retreat of the adjacent steep slopes by mass wasting and rill-wash, solifluction and sheet wash activity, favoured by the surplus water from the steep relief and nivation on the upper parts of the pediplains, transport of the debris across the pediments into the main rivers). Fluvial action is different in areas not yet affected by the dissection caused by isostatic uplift and in the marginal areas, where this dissection is very intense. Outside the recently dissected parts there is no competition between cryoplanation and fluvial activity.

INTRODUCTION

In climatic geomorphology, the approach exists to make a distinction between the climatomorphic zones dominated by planation (formation of plains) and those dominated by dissection (formation of valleys) (e.g. Büdel 1971, 1977, 1982). With perhaps the exception of the humid tropics, no geomorphic zone generates so much controversy over the prevailing style of erosion as the arctic periglacial zone. The extreme positions are that the dominant geomorphic tendency in the periglacial zone is (1) "excessive valley-cutting" ("exzessive Talbildung", Büdel 1977, 1982) or (2) most intense pediplanation (Dedkov 1965).

Studies on these problems were made in 1978 and 1981 in the Mackenzie and Richardson Mountains, especially in the central Richardson Mountains accessible by the Dempster Highway (an area of continuous permafrost), in the eastern and western foothills of both ranges and around the "Plains of Abraham" in the Canyon Ranges, SW of Norman Wells (an area of discontinuous permafrost). Comparative observations were made in the Brooks Range near Atigun Pass, in several parts of Alaska, including the Arctic Slope, and in the Canadian Archipelago.

The main criterion in selecting these study areas was that they have been subject to periglacial conditions since the beginning of the Quaternary period without being glaciated at any time (cf. Hughes 1969, Denny 1970, Douglas 1972, Prest et al. 1974). Thus, if there exists any "convenient natural test site" (Büdel 1982:63) for meeting pure and mature periglacial features, it is here that we will find it. Many of the difficulties in climatic geomorphology arise from the comparison of forms of different age and maturity and from neglect of the time factor (cf. Brunsden 1980 and Douglas 1980). Areas in which a recent change in the general modeling style has occurred, as, e.g., those subject to

periglacial conditions for only a few thousand years since the end of Pleistocene glaciation, may be well suited for process research, for studies on short lived microforms or on modeling tendencies, but they are not so well suited to demonstrate what the typical climatomorphic relief (including mesoforms and macroforms) may be. In this regard the unglaciated regions of NW-Canada and Alaska offer ideal conditions.

Pediplains—in the strictly descriptive sense of gently sloping surfaces (1° - 10°) at the foot of higher mountains—are very common in the mentioned area. Their frequency and ubiquity suggests that the non-climatic environmental conditions leading to their formation are common and unspecific:

1. They occur at different altitudes. Many of them start right from the valley bottoms or the lowest terraces of the large rivers. At medium altitudes of 300-900 m, they are most frequent. The highest observed pediplains (not cryoplanation terraces) are situated at 1,300 m in the Mackenzie Mountains. The formal difference between the planation surfaces described here and the better known cryoplanation terraces lies in their sizes and their positions relative to the mountain slope, not in their absolute altitudes (cf. Czudek and Demek 1970, French 1976:155 ff.).

2. A strict dependence on permafrost could not be established: Frequency and appearance as well as evidence of active backwearing (see below) have been observed to be the same both in areas with continuous permafrost (northern Richardson Mountains, about 67° N) and in areas with discontinuous permafrost (Ft. Simpson area, surroundings of the Plains of Abraham in the Mackenzie Mountains near 64° N). Though it appears plausible that the processes causing cryoplanation are favored by permafrost, our observations seem to agree more with the views of Demek (1969:56 ff.) than with those of Rejer and

Péwé (1976:107 ff.).

3. A dependence on lithology could not be established either. Pediplains cut rocks of all kinds and ages: Cambrian schists in the southern Richardson Mountains, dolomites of Ordovician and Silurian age, as well as Devonian sandstones and shales in the Plains of Abraham area and sandstones, siltstones, and shales of Devonian, Mississippian, and lower Cretaceous age in the Richardson Mountains foothills.

4. As to the general orographic position, three types of pediplains may be distinguished, piedmont pediments, valley pediments and intermontane pediments (classification by Mensching 1958, 1973) (Figures 1 and 2).

FIGURE 1 Cryopediment with sharp upper limit and inclination of 2° - 4° , about 4 km wide; crossed by shallow valleys. Little Keel River Valley, North of "Plains of Abraham," Mackenzie Mountains.

FIGURE 2 Narrow valley-cryopediment showing dissection by box-shaped valley. Bedrock (Upper Devonian sandstone) is cut sharply by pediment. Central Richardson Mountains ($66^{\circ}50'N$).

The features which suggest the morphogenesis of the pediplains are described in the following three sections. These treat, first, the steep slopes delimiting the pediplains at the upper end, second, the pediplains themselves and the processes acting on their surfaces and, finally, the valleys to

which the pediplains usually run.

FIGURE 3 Mountain slope dissected by steep V-shaped valleys into triangular sections. Pediment interrupted by Carcajou Lake in the course of Little Keel River, a canyonlike incised tributary of Carcajou River, Mackenzie Mountains.

THE STEEP RELIEF AT THE UPPER MARGIN OF THE PEDIPLAINS

The marginal chains of the Mackenzie and Richardson Mountains mostly have the character of hogback mountains at 1,100-1,600 m elevation.

The characteristic traits of the relief are that the mountain sides are deeply cut by V-shaped valleys, independent of the structure. The valleys have steep rectilinear slopes of about 30° , very steep longitudinal profiles and, despite that, often flat floors.

Erosion in these valleys is obviously very intense. On the slopes, mass wasting and rillwash dominate, with episodic runoff and gravel transport by meltwater in the valley bottoms. Valley-erosion cuts down to the local erosion base and then develops widening flat floors without any change in the slope processes and slope profiles. Thus, small and large valleys are characterized by the same slope angles of about 30° and finally the whole mountain slope becomes dissected into very characteristic triangular facets (Figure 3).

The same processes operate on these "triangular slopes" (cf. Büdel 1977:72) as on the valley slopes, namely frost wedging, mass wasting, and rillwash, and cause very intense backwearing.

THE PEDIPLAINS

The important supply of frost debris from above does not lead to accumulation at the foot of the slope for denudational activity at the upper edge of the pediplains is capable of keeping the foot of the steep slopes clean. Commonly the upper limit of the pediplain is marked by a sharp knickpoint, most exceptions being structurally controlled. The processes responsible for this denudational cleaning of the upper edge of the pediplains are solifluction and sheetwash, which were both observed directly and deduced from micro-forms,

FIGURE 4 Oblique view from aeroplane showing sharp upper end of cryopediment and forms giving evidence of active solifluction and sheetwash. NW of the "Plains of Abraham," Mackenzie Mountains.

FIGURE 5 Cryopediments with pediment passes and inselberglike mountain remnants. Vegetation marks now inactive transport-paths directed toward very shallow valleys. NE footregion of the "Plains of Abraham," Mackenzie Mountains.

transport patterns, and sediment structures, e.g. on pediplains at the south side of Little Keel River (Plains of Abraham), and in the upper ends of many valley pediments in the central Richardson Mountains (cf. Figure 4).

The main factor aiding all types of solifluction and sheetwash in this orographic position is the increased water supply, caused by surface runoff from the steep slopes and by meltwater from snow trapped in the mountainfoot concavity.

The upper parts of the pediplains have usually been found to be slightly fan-shaped, with slope angles varying from 6° - 12° . This allows solifluction and sheetwash to deliver debris to stream channels in a short distance. We have seldom observed that the entire pediplain is an active "slope of transportation" (cf. French 1976:156); most debris transport is done after a short distance of nonlinear transport by the rivers crossing the pediplains (cf. Figure 5). These rivers are:

- small runoff channels not connected to the mountain drainage and not eroding at all;
- rivers coming from the V-shaped or flat-floored valleys of the adjacent mountains, heavily charged with sediment (these are characterized by braided channels, either eroding only weakly or more often flowing above the pediplain level through accumulations of their own sediments);
- some rivers derived from areas in the adjacent mountains which do not supply detritus, e.g., some quartzite areas in the McDermott syncline of the Mackenzie Mountains. These rivers are able to cut shallow box-shaped valleys into the pediplain—5 m being the maximum observed depth cut into solid rock. These valleys expose the sharply cut bedrock core of the pediments, overlain by a fanglomerate of 0.5-3 m thickness.

The lower parts of the pediplains, with slope angles of 1° - 5° , are usually inactive with surfaces characterized by patterned ground, lichen-covered stones, or dense and undisturbed tundra vegetation.

Given our observations of structure, genesis, and erosional intensity, as well as the probable duration of periglacial erosion in these areas,

most of the pediplains in all probability are cryopediments in the sense of Macar (1969:138) and Czudek and Demek (1970:101; 1973) or cryoplanation forms following Bryan (1946:639 ff.) and Demek (1963). The morphographic and morphogenetic criteria described in these references—most of them are summarized by French (1976:155 ff.)—fit the observed forms surprisingly well.

Since we lack studies over a long period and sediments which would provide independent age estimates for the cryoplanation surfaces, we can only evaluate the probability whether or not periglacial processes would be capable of producing pediplains (including those several kilometers wide) in the time available. The main view against a genesis in cryoplanation is that which considers the pediplains as Tertiary forms which have been preserved or only slightly modified by Quaternary processes (cf. Büdel 1971, Washburn 1979:237 ff.). Arguments to refute such a view include the following facts.

High levels interpreted as Tertiary relic surfaces in several parts of Yukon (cf. Bostock 1972), e.g., in the Wernecke and Ogilvie Mountains, lie clearly at a higher elevation than the cryopediments and are dissected by the V-shaped valleys and the steep frost slopes above the pediments.

The known glaciation limits and the "rather meagre understanding of changing climates of central Yukon during the Quaternary" (Foscolos et al. 1977: 1; cf. Bostock 1966, Hughes et al. 1969, Zoltai and Tarnocai 1974) suggest that, during most of the Quaternary, there must have been some kind of a periglacial climate in the Mackenzie and Richardson Mountains. Consequently, careful extrapolation of present morphodynamic rates to the entire Quaternary may be possible. Extrapolating comparable studies of periglacial denudation (cf. French 1976: 148, 172) and taking into account the age of those planation surfaces which can be dated (cf. Demek 1969, Reger and Péwé 1976, Washburn 1979:240), it may be argued that even the largest pediplains in the non-glaciated parts of NW-Canada and Alaska (with the exception of the North Slope) can be ex-

plained by the present cryoplanation rates. Thus, the actual relief of this never-glaciated area may be considered as one of the most pure and mature periglacial reliefs in the world.

Cryoplanation is not only a process of widening of preexisting plains. As demonstrated by the research on cryoplanation terraces (as compiled recently by Karrasch 1972) and our own observations in many periglacial areas, the slightest concavity at the foot of a slope can start (by backwearing effects) the development of a frost cliff/frost slope, and a cryoplanation terrace/cryopediment.

In this context, the main problems which remain to be solved seem to be (1) the reconstruction of the Tertiary relief, (2) the Quaternary history with its fluctuations of the periglacial climate and their geomorphic effects and (3) quantitative studies of periglacial backwearing rates and cryopediment growth.

THE VALLEYS

The valley network of the Mackenzie and Richardson Mountains appears on the ground as well as on air photographs and LANDSAT imagery to consist of two overlapping river systems: an older one with wide shallow valleys originating in the center of the mountain ranges, and a younger, more sharply incised one, which is growing retrogressively at the expense of the older one.

It seems evident, that the intense erosion causing the younger valley system follows recent uplifts, by glacial rebound as well as by tectonics. Recent isostatic uplift is estimated at about 100-200 m for the Richardson Mountains.

The southern Mackenzie Mountains are believed to have been recently uplifted even more: in the Nahanni River area by as much as 485 m in postglacial time (Ford 1973). The upper valleys, not yet affected by retrogressive dissection, are shallow and flat-floored with depths of 2-3 m, 10 m at the maximum, and widths of the broad gravel fills of up to more than hundred meters. The rivers swing in anastomosing channels over the whole width of the valley floor, locally undercutting the banks and locally restricted by the gravel fans of tributary rivers.

The adjacent parts of the pediments are the oldest, inactive sections which suggests that the rivers have been flowing at the same level since the beginning of the pediment formation. They are used to capacity by their gravel load and have no tendency to downward cutting.

The tributary rivers of the Mackenzie and the Peel River which are presently incising have a totally different appearance. Deep, narrow box-shaped canyons up to 100 m deep (note the "Canyon Ranges") are common. The Nahanni Canyon, with rock walls of more than 1,000 m in places, represents a most impressive example of the vertical erosion achieved by an antecedent river.

Fluvial activity is in general limited to short runoff periods during the snowmelt season (lasting several weeks to several months depending on latitude) and exceptional heavy rain events. Glacier and baseflow runoffs are morphologically of secondary importance. Our assessment of fluvial activity in a longterm periglacial environment is that,

because the runoff is concentrated into short periods, the rivers are capable of enormous erosion rates. This explains the overrating of periglacial vertical erosion by Büdel (int. al. 1982: "zone of excessive valley-cutting") and others, who have generalized from areas of recent isostatic uplift as, e.g., Spitsbergen.

The "normal case" in the sense of climatic geomorphology seems to be that the energy of a comparatively very steep longitudinal gradient (up to several degrees) is needed for the through-transport of the heavy frost debris load. There seems to exist a long-term equilibrium between different and seemingly antagonistic tendencies (formation of plains versus formation of valleys), which allows the conclusion that under stable conditions the actual surface is to be considered as mature in a climatic-geomorphological sense as well as in a Davisian sense. Only in the steepest headwater regions or after a break in the equilibrium profile does considerable vertical erosion take place.

The threshold value of the gradient of rivers used to capacity by the through-transport and of vertically eroding rivers depends of course not only on climatic but also on other environmental factors as, e.g., petrography and on the age of the actual relief.

ALPINE PERMAFROST IN TIAN SHAN, CHINA

Qiu Guoqing, Huang Yizhi, and Li Zuofu

Lanzhou Institute of Glaciology and Cryopedology, Academia Sinica
People's Republic of China

The distribution of permafrost in Tian Shan depends chiefly on vertical zonation. Because of local conditions, the lower limit of permafrost varies from place to place: the lowest limit is 2700 m on north-facing slopes and 3100 m on south-facing slopes, about 1000 m below the local snow line. In general, the lower limit descends 171 m with each 1° increase in latitude and 10.6 m with each degree of increase in longitude. Alpine permafrost can be divided into three zones: unstable permafrost, transitional permafrost, and stable permafrost. The map of permafrost distribution in Tian Shan is based on temperature observations in bore holes, field observations of cryogenic phenomena, and interpretation of aerial photographs. The development of ground ice in coarse-grained sediments, both buried glacial ice and segregated ice, is a peculiarity of Tian Shan. Under the stone stripes, rock circles, and frost-heaved rocks, massive ground ice is found. An old moraine with a silt content of less than 15% has proved to be rich in ice.

In China, the Tian Shan stretches for 1700 km west to east and is 100-300 km wide from south to north. There are many ridges and fault basins controlled by the WNW and ENE tectonic lines and other factors. Most of the Tian Shan consists of metamorphic and igneous rocks. Ridge crests generally exceed 4000 m a.s.l.; the highest summit, Tomor Peak in the west, is 7443 m. Local relative relief is usually 3000 m or more, so vertical zonation of air temperature, precipitation, and landscape is inevitable.

The mean annual air temperature decreases with elevation. The gradient is 0.33°-0.37°C/100 m between 1830 and 3000 m a.s.l., and 0.61°-0.66°C/100 m between 3000 and 4000 m (Zhang and Xie 1962).

In general, there are two zones with high precipitation: the first is coincident with the forest-steppe zone (about 1800-2500 m), with precipitation of about 600 mm/year; the second lies at the snow line, with precipitation of from 500-700 to more than 1000 mm/year. About 90% of the annual precipitation is concentrated in the period from April to October. Observations show that the precipitation decreases from west to east.

With rising elevation, a series of landscapes is encountered, namely, desert and semidesert, forest-steppe, subalpine-alpine meadow, and cold desert. Their boundaries vary with slope orientation, latitude, and longitude.

All these affect the characteristics of permafrost distribution.

PERMAFROST DISTRIBUTION

The total area of permafrost in the Tian Shan of China is about 63,000 km² (Figure 1). The distribution shows both vertical zonation and latitudinal and longitudinal variations.

According to observations and 4 years of ground temperature measurements in the Kuyxian Pass region of the middle Tian Shan, the lower limit of alpine permafrost is at 2700 m on north-facing slopes and 3100 m on south-facing slopes (Qiu and Zhang 1981). The lower limit varies, however, because of differences in relief, surface cover, geologic-lithologic characteristics, and precipitation, and does not coincide with a particular contour line (Table 1). Despite variation, the lower limit always lies in the subalpine-alpine meadow zone, higher than the local tree line, and is 900-1200 m lower than the snow line. These characteristics, together with the distribution of cryogenetic phenomena, are useful aids when mapping permafrost through the interpretation of aerial photographs (Figure 1).

The thickness, temperature, and stability of the permafrost and the depth of the active layer varies with elevation. Usually, the depth of seasonally frozen ground is 1-2 m at 1000 m a.s.l. and becomes 4-5 m adjacent to the lower limit of permafrost, while the active layer in the permafrost region is 4-5 m thick in the vicinity of the lower limit, becoming <2 m in the stable permafrost area of the high mountains. Generally, there are three zones of alpine permafrost: the unstable zone, the transitional zone, and the stable zone.

Adjacent to the lower limit, the perennially frozen ground has a mean annual temperature of -0.1° to -0.2°C, so it is very unstable. For example, in the Kuyxian Pass region, the rainfall in 1972 was 100 mm higher than normal, and the permafrost table observed in drill hole F5 descended to a depth of 3.5 m. In 1973-1975, annual precipitation was normal, and the permafrost table gradually returned to a depth of 2.7 m (Figure 2).

However, at high altitudes, for example at 3200 m in the Kuyxian Pass region, the permafrost is as

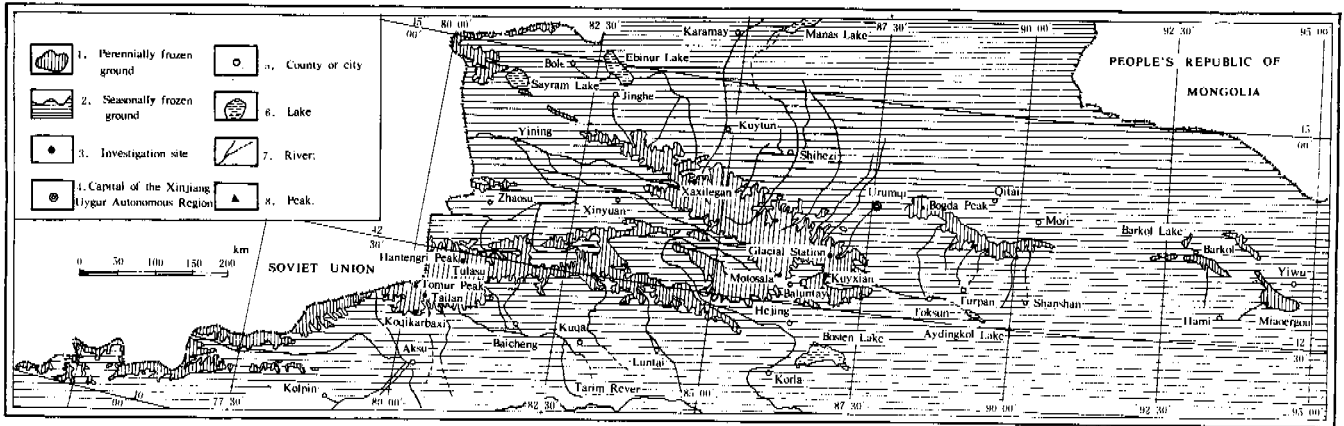

FIGURE 1 Distribution of frozen ground in Tian Shan, West China.

TABLE 1 Selected data on the lower limit of alpine permafrost in the Tian Shan.

Site	Location	Elevation of permafrost lower limit (m), slope facing					Elevation of glacial terminus (m)	Elevation of snow line (m), slope facing		Vertical distance between permafrost lower limit and snow line (m)
		N	NE/NW	E/W	SW/SE	S		N	S	
Miaoergou	43°00'N 94°15'E			2950			3600		4200 (SW)	1250
Kuyxian Pass	42°56'N 86°53'E	2700				3100	3700	3900	4100	1100
Source of Urumqi River	43°07'N 87°00'E	2900				3250	3600	3800	4200	925

FIGURE 2 Isotherm of drill holes F5 and D198 in the Kuyxian Pass region.

much as 100 m thick and has a mean annual ground temperature of -2°C , which can be defined as stable permafrost. As a result, the level of the permafrost table did not change during the same 4-year period no matter how much the rainfall fluctuated (Figure 2). Moreover, in 1981 the temperature at the level of zero annual amplitude remained the same as that measured in 1973. Gorbunov (1978) assumed that at 7000 m the ground temperature might be as low as -20° to -25°C , but the presence of such highly stable permafrost remains to be proven.

In the transitional zone, between the unstable and stable zones, permafrost thicknesses increase 20 m for each 100-m increase in elevation at Miaoergou in the east and 50 m for each 100 m at the source of the Urumqi River in the central region.

Because the lower limit of alpine permafrost varies in altitude and the width of the transitional zone varies from place to place, it is impossible to associate the boundaries of the three zones with specific elevations. Nevertheless, binary regression analysis provides the following equation for prediction of the elevation of the lower permafrost limit:

$$H = 11089.5 - 10.6X - 171.2Y$$

where H = elevation of lower limit (m)
X = longitude (°)
Y = latitude (°)

The correlation coefficient of this equation is 0.915. This equation shows that the latitudinal variation of the lower limit of permafrost is -171.2 m/lat. 1°N, which differs from the data presented by Fujii and Higuchi (1978) and Zhou and Guo (1978). This equation also shows a longitudinal variation of -10.6 m/long. 1°E, which might be caused by the decrease of precipitation from west to east. Since the Tian Shan extends through 21° of longitude (from 74° to 95°E), the longitudinal variation of the limit should not be omitted.

GROUND ICE

The development of ground ice in the Tian Shan depends on geologic-geomorphologic conditions. There are few ice veins in the cracks of the frozen bedrock; permafrost is usually ice-poor on scree slopes and in the gravel and pebbles in well-sorted alluvial fans because they are well drained. Permafrost in clayey soils on gentle slopes, in intermontane depressions, and in hollows at the boundary between alluvial fans is usually rich in ground ice (Qiu and Zhang 1981).

The following discussion is concerned with ground ice in coarse-grained sediments, which may be a peculiarity of the Tian Shan.

Exogenous Ground Ice

At the source of the Urumqi River, buried ice occurs in Little Ice Age moraines. A 10-m-thick buried glacial ice body is exposed in a natural cave of the ice-cored end moraine of Glacier 6. The ice is preserved by the protection of the debris mantle. In addition, the Tomor-type glacier, which has a great deal of avalanche cover and a superglacial moraine, forms similar kinds of buried glacial ice.

Another kind of buried ice is from buried snow. For example, on the south slope of Haxilegan, a snow deposit was covered by artificial waste rocks in May 1977, and in a year it had become a 20-50 cm ice layer. It appears that buried "snow-ice" may be formed in places with thick snow deposit and frequent rock avalanches in west Tian Shan.

Endogenous Ground Ice

(1) Segregated ground ice in sediments rich in fine-grained materials: The deluvial-solifluctional deposits in the Tian Shan are usually poorly sorted,

and segregated ice will form if there is an appropriate water supply. For example, in well D-135, on a gentle slope adjacent to a steep cliff in the Kuyxian Pass region, it was found that a deluvial sandy clay layer containing 25-35% gravels and pebbles is underlain by a deluvial debris (slope wash) layer with 21-31% fines. The upper layer has a netted-stratified cryogenetic structure (mineral layers separated by ice veins and horizontal ice layers) with a volumetric ice content of 60%, and the debris layer has a conglomeratic cryogenetic structure (debris cemented by ice lenses) with a volumetric ice content of 55%. This kind of ground ice has been found in many places in the Tian Shan.

(2) Segregated ground ice in glaciofluvial-deluvial deposits with alternative beds of coarse and fine-grained material: This kind of ice occurs in a swampy lowland at the source of the Urumqi River. As a result of syngenetic frost action, a thick ice layer (>50 cm) with a volumetric ice content of 95% has formed beneath the new permafrost table (old earth surface, as indicated by the presence of humic materials and decayed roots). Due to the impermeability of the massive ground ice, the active layer is usually saturated and therefore experiences strong frost heaving. This results in many frost-sorting phenomena on the slopes and the swampy lowland, including upheaving stones (Figure 3), stone stripes (Figure 4), and rock circles. According to pit observations, the sorted stones are standing in the principal frost-heaving zone of the active layer, and between the base of the sorted stones and the permafrost table there is an undisturbed zone. This demonstrates that frost sorting is directly related to the heaving process that occurs in the active layer.

(3) Ground ice in coarse-grained deposits: In the Kuyxian Pass region, a 110-m-thick permafrost layer occurs in the Alaxigongjin Moraine that is rich in ice lenses and ice horizons and has a stratified conglomeratic cryogenetic structure. Based on its depositional characteristics and cryogenetic structure, as seen in drill hole samples, Qiu and Zhang (1981) pointed out that this is a syngenetic permafrost formed in association with sediment aggradation during glacier advance and recession, and the ice layers there differ from buried glacial ice.

There are two logical explanations for how such ground ice could form in a sediment containing such

FIGURE 3 Upfreezing stone and the underlying permafrost.

FIGURE 4 Section of large stone stripe.

a small amount of fine-grained material (the percentage of <0.1 mm grains is no more than 10% in general); repeated ice formation over an extended period of time, and the poor permeability of ice-rich frozen ground.

During sediment aggradation and after glacier melting, the sediments remain in a cold climatic environment and undergo frost action with the formation of ice crystals. At the initial stage of the sediment freezing, moisture migration might be insignificant; however, with ice crystal formation, the porosity of the soil may gradually diminish. Then water would migrate from places with higher temperature to those with lower temperature, and from places with thicker unfrozen water films surrounding ice crystals or soil grains to places with thinner unfrozen water films. After a long period of repeated ice segregation, ice lenses and ice horizons would be formed.

Soil permeability may decrease as ice forms at depth. With the aggregation of permafrost, gravitational water might freeze at the base of the active layer and form ice horizons joined to the underlying frozen ground.

CONCLUSIONS

Distribution of permafrost in the Tian Shan depends chiefly upon elevation. With increasing elevation, three permafrost zones may be recognized: an unstable permafrost zone with mean annual ground temperatures t_{cp} of -0.1° to -0.2°C and a thick-

ness less than 20 m; a stable permafrost zone with t_{cp} below -2°C and permafrost >100 m; and a transitional zone between them. The lower limit of alpine permafrost and the boundaries between zones vary and do not coincide with particular contour lines.

The lower limit of permafrost shows latitudinal and longitudinal variations. For each 1° of latitude to the north, the lower limit drops 171 m; and with each 1° of longitude to the east, the lower limit drops 10 m.

Several kinds of ground ice develop in coarse sediments, with ice contents as high as 50-95%, a characteristic that may be a peculiarity of the Tian Shan.

ACKNOWLEDGMENT

Thaw depths, soil temperatures, and vegetation cover were measured between 1978 and 1982 in tussock tundra on burns representing current, 1,2,3,4,5,7,8,9, and 10 year old fires in either the Seward Peninsula or the Noatak River areas of Alaska. Percentage increase of thaw in tussock tundra on flat terrain was 10-40% during the first 5 years following fire with a possible peak at 2 years and a return nearly to prefire thaw depths by the tenth year. Thaw depths following fire were significantly deeper in tussock tundra on slopes (> 5%) than on flatter terrain. Tussock tundra soil temperatures were significantly higher in a 3-5 week old burn than in an unburned control, but were similar to the control in a 10 year old burn. Increases in vascular plant cover following fire in tussock tundra averaged 10% per year during the 10 years following fire and could account for decreases in thawing and soil temperatures over this time. Other factors, such as seasonal time of burning, thickness of the soil organic horizons and tussock density, vary regionally and may affect postfire thawing. Prolonged deeper thawing found in burned white spruce taiga emphasizes the importance of vegetation recovery for ameliorating postfire thawing regimes.

INTRODUCTION

Lightning-caused tundra fires constitute a natural form of arctic vegetation and soil disturbance which potentially can produce active layer changes and permafrost degradation. Individual fires as large as 980 km² have been reported (Racine 1979), and more than 3,800 km² burned in northwest Alaska in 1977, alone. Although it is clear that permafrost conditions could be affected over large areas, relatively little is known about how fire affects active layer thicknesses and soil temperatures of tundra, particularly with respect to changes over time spans of as many as 10 years (Viereck and Schandelmeier 1980).

Our study reports active layer thickness measurements from burns up to 10 years old in northwest Alaska and attempts to construct a vegetation-soil thaw word model to describe ecosystem changes due to natural fire. Between 1978 and 1982 we made measurements of thaw depths and vegetation cover at a wide variety of sites representing 2 week to 10 year old burns in the Seward Peninsula or Noatak River areas (Figure 1). By surveying a wide range of burned sites in northwest Alaska, we attempted to obtain data that would permit us to propose hypotheses which suggest how quickly and by what mechanisms the permafrost responds to fire.

The available information on fire-permafrost relationships has been summarized recently by Viereck and Schandelmeier (1980) and Brown and Grave (1979). Long term information (8-20 years) for active layer changes following taiga fires has been presented by Viereck (1981) for

interior Alaska and by Mackay (1977) and Black and Bliss (1978) for northern Canada at Inuvik. These reviews indicate that there are relatively few long term measurements of thaw depths following tundra fires in Alaska. Much of the research to date has dealt with the first and second year postfire thaw measurements, such as those by Wein and Bliss (1973), Brown et al. (1969), Racine (1981), and Hall et al (1978), which for tussock tundra, generally show increases of 10-40% over controls. Continued monitoring by Johnson and Viereck (in this volume) of thaw depths over 5 years following a 1977 tundra fire on the North Slope represents some of the longest monitoring of postfire thaw patterns in tundra that is available.

STUDY AREAS

The Noatak River and Seward Peninsula study areas are located above and below the Arctic Circle, respectively, and are at or near the boundary between tundra and taiga in northwest Alaska (Figure 1). White spruce (*Picea glauca*) forests extend into the southeastern base of the Seward Peninsula and into the lower drainages of the Noatak watershed. In all other respects, both areas are arctic in character with continuous permafrost. Mean annual temperatures are about -8° to -5° C and annual precipitation probably ranges between 22 and 50 cm (Racine 1979).

The Noatak River drains over 33,600 km² of the western Brooks Range as it courses primarily westerly through a 644 km long, generally broad

lowland that separates the Brooks Range into two smaller mountain groups. Elevations vary from sea level where the river enters Kotzebue Sound to over 1,830 m in the mountains, with about 66% of the watershed occurring below 610 m elevation. Lowland areas (below 610 m) are generally covered with tussock tundra with patches of white spruce forest along the lower reaches of the river. Soils are slightly acidic and have surface organic layers in the intertussock spaces of 5-14 cm thickness.

The generally lower than 914 m, 320 km by 192 km Seward Peninsula consists of rolling uplands, interior basins, coastal lowlands, and a central mountain range. Deep silty loess deposits cover much of the area, and soils generally are moderately to highly acidic, with organic matter thicknesses in the intertussock spaces of up to 20-30 cm. Sedge tussock tundra is dominant on the rolling gentle slopes, with willow shrub thickets along drainageways and

sedge wet meadows on poorly drained flats.

The known fire history for the Seward Peninsula has been reviewed by Racine (1979) and that for the Noatak by Racine et al (in preparation). Tundra fires have been fairly extensive in both areas during the 1970's. An estimated 3,000 km² burned in the Seward Peninsula in July 1977 and 640 km² burned during 1977 in the Noatak basin. Based on present data, tundra fires appear to be of more frequent occurrence in these two areas than elsewhere in arctic Alaska.

Eight different burns representing 1971 (1), 1972 (2), 1977 (3), and 1982 (2) fires were visited in the Seward, Noatak, or both (Table 1, Figure 1). All of the Noatak River fires visited were located near the river in the lower to middle part of the watershed below an elevation of 305 m. Seward Peninsula sites included Imuruk Lake and Utica Creek on a large (940 km²) 1977 burn, a 1971 burn at Coffee Creek about 75 miles north of Nome, and a second 1977 burn at Arctic River in the northwestern part of the peninsula. Data from these fires were supplemented with information on unburned tundra vegetation and soils obtained in 1973 by Racine and Anderson (1979) and Holowaychuk and Smeck (1979) in the Seward Peninsula and by Ugolini and Walters (1974) in the Noatak River area.

METHODS

Thaw depths were measured with a steel probe pushed vertically into the ground until stopped by the frost table. Therefore, rather than measuring the distance to the 0° C isotherm in the soil, we measured the distance to an ice-cemented surface. Thaw depths were measured both from the ground surface (active layer thickness) and/or from a horizontal reference string tied tightly between two stakes 5-10 m apart. Also recorded was the distance from the string to the ground surface so that profile cross sections of both the ground surface and the frost table could be constructed to examine interrelationships and the roughness of both. When probing in tussock tundra, the type of surface (live or dead tussock, intertussock space, frost scar, etc.) through which the probe passed was recorded each time. Soil temperatures were measured with a YSI Telethermometer and a long steel thermistor probe.

Probing was carried out in conjunction with plant cover, density, and biomass sampling in 1 m x 1 m plots or along transects extending from unburned into burned tundra. One thaw depth measurement was taken in the center of each 1 m x 1 m plot, and in most plots 4 additional measurements were taken midway between the center and the corners of the plot. At 3 Seward Peninsula sites (Table 1), thaw depths and vegetation were sampled once in each of 3 years following a 1977 fire. In addition, prefire (1973) thaw and vegetation measurements were obtained by Racine (1979) and Holowaychuk and Smeck (1979) at the Seward Peninsula-Imuruk Lake sites. During July and August of either or both 1981 and 1982, several sites in the Noatak

area (Table 1) were probed at 10-14 day intervals. Additional one-time depth-of-thaw measurements were obtained at remote sites in both the Noatak and Seward Peninsula, representing both burned and unburned tundra.

RESULTS

Depth of Thaw

Because thaw depths vary seasonally and with surficial conditions of soil texture, exposure, drainage and vegetation cover, we found it necessary to control these variables as much as possible to permit detection of the effects of fire on thawing. We achieved this control by limiting our discussion primarily to tussock vegetation on 2 types of terrain: on flats (slopes less than 5%) and on slopes (angles of 5% or more). Because we could not obtain unburned (control) thaw measurements at all burn sites and because measurements were taken at the different sites in different years and at different stages in the progression of summer thawing, we constructed composite seasonal thaw curves for unburned (control) tussock tundra in the Seward Peninsula (Figure 2) and the Noatak (Figure 3).

FIGURE 2 Thaw depths in burned and unburned tussock tundra in the Seward Peninsula at different times during the summer, on different slope angles (< 5% vs. > 5%), and for varying number of years since fire.

Seward Peninsula. Although the unburned thaw depth measurements were obtained in different years and at different sites, the resultant curve appears to define fairly well ($r^2 = .96$) the seasonal thaw pattern for unburned (control) tussock tundra on flat terrain in the Seward Peninsula (Figure 2). By plotting thaw depths similarly measured in relatively flat tussock tundra sites in the Seward Peninsula representing 1, 2, 3, 7, 8, and 10 years following fire (Figure 2), we can determine that the depth of thaw increased by a maxi-

imum of 30-40% by the second year following fire, after which it returned nearly to control levels by the seventh, eighth, and tenth years.

Burned tussock tundra sites on steeper slopes showed a much greater and probably longer lasting thawing response (Figure 2). Without a reliable control for these sloping sites, we are unable to compute the actual percentage increase in thawing due to fire for these slopes. In 1 case, however, we found increased thawing of over 100% 1 year after a fire on a steep, 12-13% slope.

Noatak River. The unburned (control) thaw curve for the Noatak River area (Figure 3) was constructed from a composite of several thaw curves obtained by monitoring thaw at unburned sites through portions of the 1981 and 1982 summer thaw seasons. We also used 1960 thaw data from Ogotoruk Creek at Cape Thompson (Johnson 1963), west of the Noatak study area. The composite curve is similar to that determined for the Seward Peninsula, with a daily rate of thaw of 0.4-0.5 cm per day for both areas.

Thaw depth measurements in July-August 1982 on a June 1982 tussock tundra burn in the Noatak show a first year increase in thaw of 20-30%. On a nearby 10 year old tussock tundra burn, thaw depths were only 10-15% deeper than the control. Three, 4 and 5 year old burned tussock tundra sites were thawed 16-22% deeper than the control. Other 4 and 5 year old burned tussock tundra sites sampled in the Noatak were located on slopes greater than 5%, for which no

FIGURE 3 Thaw depths in burned and unburned tussock tundra in the Noatak River watershed at different times during the summer, on different slope angles (< 5% vs. > 5%), and for varying numbers of years since fire. For symbols see Figure 2. Unburned 1960 tussock tundra thaw measurements for Ogotoruk Creek Valley, Alaska are from Johnson (1963).

unburned control curve was available. In agreement with the Seward findings, we found that these burns thawed more deeply than burns on flat tussock tundra sites.

Based on our limited measurements and those of Ugolini and Walters (1974), we conclude that thaw depths in unburned white spruce stands in the Noatak are shallow and similar to those in unburned tussock tundra (Figure 3). In contrast, we measured thawing in a spruce area burned 5 years earlier that was 2 times deeper than in an adjacent unburned stand.

Soil Temperatures

To examine the thermal characteristics of the observed initial increase in thawing followed by a return to nearly prefire levels by the tenth year, we obtained measurements of soil temperatures in unburned, recently burned (1982), and 10 year old burned (1972) tussock tundra sites in the Noatak River area (Table 2). Temperatures at depths of 10 cm below the unburned intertussock ground surface occurred in the range of 2°-5° C. In contrast, temperatures 10 cm below the tops of surrounding unburned tussocks were 11°-13° C, which indicates a 6°-8° C temperature difference between the tussocks and intertussock spaces.

During a clear warm period in July 1982 we found intertussock soil temperatures were 7°-10° C at 10 cm depths in recently burned (June 1982) tussock tundra. These values were significantly higher by 3°-5° C than in the unburned controls (Table 2, $t = 7.0$, $p \leq 0.001$). Similarly, tussock temperatures at 10 cm below the tussock top also were warmer than in unburned tussocks by 5°-8° C during this period ($t = 6.7$, $p \leq 0.001$). Likewise, soil temperatures during July 1982 at 20 cm depths were significantly lower by 2.7° in unburned intertussock spaces than in recently burned intertussock spaces ($t = 8.9$, $p \leq 0.001$). Lastly, during the warm July 1982 period, temperatures at 10 cm depths in tussocks and intertussock

spaces of tundra burned 10 years ago were not significantly higher than the unburned control (Table 2), but were significantly lower by 3°-4° C than temperatures at comparable depths in the recent burn ($t = 5.1$; $p \leq 0.001$).

Such differences were ephemeral, however, and depended on weather conditions. With the onset of rains and cool, cloudy weather in August, we detected little temperature difference between the recently burned area and the unburned control (Table 2).

DISCUSSION AND CONCLUSIONS

Role of Revegetation

The results presented here suggest that, following fire in tussock tundra on level terrain, active layer thicknesses and soil temperatures rise relatively rapidly and then return to preburn levels within as few as ten years. We hypothesize that this relatively rapid recovery is due largely to a rapid reestablishment of graminoid cover following fire (Figure 4).

At one Noatak River tussock tundra site burned in 1977, and probably representing an old drained lake basin, live vascular plant cover had reached levels of 75-90% in five years, due to the rapid regrowth mainly of *E. vaginatum* (36%) and *Betula nana* (26%). Six weeks after a June 21, 1982 tussock tundra fire on the Noatak River (Figure 1), we measured cover of 40% contributed mainly by regrowth of *E. vaginatum* tussocks which had leaf lengths of 20 to 30 cm by the end of July. Such data show how quickly *E. vaginatum* leaves can grow to overhang and shade the intertussock spaces, increasing reflection and reducing the penetration of radiation.

Racine et al. (in preparation) found that about one half of the recorded tundra fires between 1956 and 1981 in the Noatak watershed occurred during June, with the other half occurring during July. For those June burns

FIGURE 4 Percent cover and percent increase in thaw depth in relation to time since fire in tussock tundra.

followed by favorable growing conditions, the rapid regrowth of sedges as described above could reduce heat absorption and increase surface albedo relatively quickly. In contrast, data from mid to late July burns indicate slower rates of revegetation: in the Noatak by the end of July live vascular plant cover on a mid-July burn had reached only about 10% with *E. vaginatum* leaf lengths of only 4-9 cm; following the late July 1977 Kokolik River burn on the North Slope of Alaska, Hall et al. (1978) reported only 5-10% vascular plant cover regrowth by the end of August 1977. These observations suggest that vegetation regrowth does not contribute to reduction of heat absorption and increase of albedo in the same year of a mid-summer fire. These differences in system response to timing of fire suggest that there also may be some difference in rate of recovery of the permafrost table.

Role of Organic Thickness

In addition to influences of revegetation on postfire thawing patterns, the thickness of the intertussock organic soil horizon remaining after fire further controls the rate of postfire permafrost recovery. Our measurements suggest that in the Seward Peninsula, tussock tundra generally has deeper organic horizon thicknesses (20-30 cm) and greater sphagnum moss cover than in the Noatak, where tussock tundra organic horizons are only 10-14 cm and sphagnum is less common. In the Seward Peninsula on most tussock tundra sites, less than 5 cm of this organic horizon is lost in a fire (Racine 1977) and, as a result, the increase in thaw 7-10 years after fire is proportionally lower in the Seward Peninsula sites than in the Noatak sites (Figure 4). Based on this finding, we suggest that postfire buildup of the organic horizons is not rapid enough to account for the observed rapidity of postfire stabilization.

Role of Slope

On slopes greater than 5%, postfire thawing was always deeper than in tussock tundra on flats. Unfortunately, without an adequate unburned control for such slopes, we cannot determine percent increases in thaw due to fire. We hypothesize that the increased thawing we found on slopes may relate to greater drainage and insolation which would result in greater drying, leading to greater fire-caused fuel consumption and damage to vegetation and underlying organic soil horizons. Delayed revegetation due to slower plant growth rates where tussocks are absent or sparse may prolong periods of increased susceptibility to thawing while increased insolation at the soil surface may produce greater thawing. We generally have found prefire tussock density and cover to be lower, and the burning to be more severe, on slopes than on flats, so that slopes would not benefit as much from the combination of rapid tussock regrowth and survival of an insulating organic horizon. In addition, the shrubs that are proportionately more abundant in the intertussock spaces of tussock tundra on steeper slopes usually do not contribute significantly to regrowth of cover (25% or more) until at least 7-10 years after fire. Lastly, although bryophytes (e.g., *Ceratodon purpurea*, *Marchantia polymorpha*) can develop high cover rapidly on burned sites, we do not believe that they significantly reduce the ability of soil to thaw and may actually slow the development of a vascular plant cover.

Tundra/Taiga Comparison

Viereck (1981) suggests that thaw stabilization following fire may be more rapid in arctic regions of Alaska with low mean annual temperatures (-8° to -9° C) than in taiga areas of interior Alaska having higher mean annual temperatures (-3.5° C). However, our results from burned tundra flats and slopes of the Noatak River and Seward Peninsula areas suggest that recovery of the prefire permafrost table may be delayed significantly where surface revegetation is slow, and that regrowth of the vegetation is a function of the preexisting vegetation, slope characteristics, and timing of the fire.

ACKNOWLEDGEMENTS

Our tundra fire studies were carried out between 1978 and 1981 in the Seward Peninsula through support from the Bureau of Land Management (BLM), U.S. Army Cold Regions Research and Engineering Laboratory (CRREL), National Park Service (NPS) and Earthwatch; and in 1981 and 1982 in the Noatak through support from the U.S. Man and the Biosphere program, NPS, and Earthwatch. We thank the several reviewers of the draft manuscript who provided valuable comments and suggestions.

DISTRIBUTION AND GEOLOGY OF GROUND ICE ALONG THE YUKON PORTION OF THE ALASKA HIGHWAY GAS PIPELINE

V. N. Rampton¹, J. R. Ellwood², and R. D. Thomas¹

¹Terrain Analysis and Mapping Services Ltd., Carp, Ontario, Canada K0A 1L0

²Foothills Pipe Lines (Yukon) Ltd., Calgary, Alberta, Canada T2P 2V7

Ground ice occurs within specific geologic environments along the Alaska Highway Gas Pipeline in the Yukon Territory. At shallow depths, ice is commonly in the form of ice lenses (aggradational); rarely in the form of ice wedges. Great thicknesses of aggradational ice are present where thick fine-grained postglacial sediments have accumulated. Epigenetic ground ice has formed in fine-grained sediments under poorly drained ground adjacent to streams, lakes, swamps, ponds and drainageways. It has also formed in fine-grained sediments draped over truncated permeable strata, in fine-grained sediments complexly interbedded with coarse-grained sediments and in fine-grained sediments adjacent to bedrock valley walls. Generally, epigenetic ground ice has formed in environments where ample groundwater has been supplied to aggrading permafrost tables, environments characterized by high groundwater gradients.

INTRODUCTION

The Alaska Highway Gas Pipeline parallels the Alaska Highway in the Yukon Territory (Figure 1). It follows mainly valleys and lowlands. All terrain except the first 5 km has been glaciated. However, distribution of permafrost and variations in local geology, most specifically the past and present hydrogeologic environment, governs the distribution of ground ice.

Figure 1: The Alaska Highway Gas Pipeline Route through Yukon.

Investigations conducted along the pipeline right-of-way indicate that more than 80% of the terrain traversed north of Kluane Lake is perennially frozen, that significantly less than one-half of the terrain traversed between Kluane Lake and Takhini River (KP 379) is perennially frozen, that less than 20% of the terrain traversed between Takhini River and KP 653 is perennially frozen; and that less than 5% of the terrain traversed south of KP 653 is perennially

frozen (Table 1). Ground ice is found in different concentrations throughout most frozen ground, but it is only present in high concentrations in specific geologic environments.

Ground ice is most abundant in the following permafrost environments: (1) shallow depths--mainly aggradational ice and locally ice wedges (ground ice classification according to Mackay 1972); (2) areas of fine-grained postglacial deposits--alluvium and eolian silt; (3) poorly drained areas adjacent to surface water--mainly swamps, lakes and streams; (4) areas where near surface fine-grained strata receive groundwater recharge from permeable strata; (5) valley bottoms having extensive fine-grained sediments adjacent to bedrock valley walls; and (6) disintegration moraines--complexes of glacial deposits formed on stagnant glacial ice.

SHALLOW GROUND ICE

Ice lenses occur frequently in the upper 2-4 m where permafrost is present (Table 1), especially where fine-grained sediments overlie coarse-textured sediments. Typical areas occur north of Kluane Lake between KP's 133 and 221 (cf. 78-CS-2 in Figure 2) where till and glaciofluvial deposits are adjacent to broad braided channels or outwash plains, which provided moderate amounts of loess upon deglaciation. During deglaciation permafrost began to aggrade and an active layer was established. As loess was deposited, the base of the active layer rose and water perched on the permafrost in the fall eventually became incorporated into the top of the permafrost. In areas where loess has been re-deposited by slopewash, aggradational ice is similarly incorporated into the profile.

Aggradation ice has also been incorporated into the profile where the active layer has thickened and thinned due to effects of climatic changes, forest fires and mass wastage. Peat beds in a sequence of icy colluvium (mainly re-worked loess)

Figure 2: Bore hole logs for 78-CS-2(T) and 76-01-1. Peat (Pt), loess (OL, SM) and volcanic ash (VA) in 78-CS-2(T) show high moisture contents (right-hand column) whereas the underlying glacial drift have low moisture contents except for the upper few metres. Thick organic-rich loess (Pt-OL, ML) in 76-01-1 shows high moisture contents throughout its thickness. USC - Unified Soil Classification; Dp - Depth; PFC - Permafrost Classification; MC - Moisture Content.

and peat on a slope at the Quill Creek test site have been dated at 10,600 ± 170 (BGS-738), 6,340 ± 140 (BGS-739) and 3,670 ± 120 (BGS-751). This suggests that thaw intervals occurred shortly

after 10,600 B.P., 6,400 B.P. and 3,700 B.P. allowing material to be eroded downslope. At sites of deposition the active layer rose and ice lenses were incorporated into the profile. Not only has aggradational ice developed here, but it also must have developed in flat areas where the active layer thickened and thinned without sediment accumulation. Climate may have been warmer than present between about 10,000 and 3,500 years B.P. and then subsequently was cooler than present until recently (Denton and Stuiver 1967, Rampton 1970). The White River Ash (deposited about 1,220 years ago (Hughes et al. 1962)) shows no sign of movement at the Quill Creek test Site (KP 155) and throughout the area; this suggests frigid conditions and general landscape stability since its deposition.

Ice wedges are present in some areas north of Kluane Lake. Polygonal patterns (their surface expression) can be recognized on air photos of terrain underlain by fine-grained sediments near the Alaska border. Further south where ice wedges are weakly active or inactive, they are present in peat near White River and in the subsurface at the Quill Creek test site (Figure 3). At the latter location the larger ice wedges are relic as they are buried by alluvium, volcanic ash and organics. Ice wedges are rarely present in coarse-textured fluvial deposits and drift; e.g., Hughes et al. (1962) noted polygonal trenches developing on morainic topography stripped of its organic cover near KP 50.

EOLIAN AND ALLUVIAL ENVIRONMENTS NORTH OF KLUANE LAKE

Postglacial eolian and fluvial activity has resulted in the accumulation of thick fine-grained deposits, especially in areas where sources of wind-blown loess are close at hand (Rampton 1981).

For example, silt blowing off the Donjek River's braided floodplain (KP 140) onto moss-covered substrata has resulted in the buildup of organic-rich and icy loess to depths of over 7 m (cf. 76-0-1 in Figure 2). The continuous rain of loess upon the landscape plus alluvial action and fluctuations in climate leading to mass wastage have also resulted in redeposition of fine-grained alluvium in valley bottoms during postglacial time. As shown by the nature of the permafrost and high moisture contents in borehole log 81-01-060 (Figure 4), ice lenses are very common in the more than 10 m of fine-grained organic sediment that accumulated on an imperfectly drained alluvial plain during the last 8,000 years. Variable thicknesses of icy organic-rich fine-grained alluvium, which cap gently-sloping coarse-textured sediments in other places (e.g. between KP's 25-40, 55-71, 75-125, and 169-213), generally have similar origins.

Ice lenses are also associated with thin beds of fine-grained sediments within coarse-textured alluvial fans. This ice probably has an epigenetic origin following abandonment of the fan by surface and subsurface water flow, which would tend to maintain unfrozen ground conditions.

Of special note is the distal edge of a large alluvial fan north of Beaver Creek where organics and fine-grained alluvium overlie gravel and sand (KP 7-16). Groundwater movement through this fan has maintained relatively high subsurface temperatures. At the toe of the alluvial fan where it abuts against bedrock, springs and taliks have developed because of warmish water being forced to the surface there. Ground ice is restricted to the organics and fine-grained alluvium due to the groundwater flow (cf. 80-11-010 in Figure 4). Ground ice here is probably epigenetic, as the area has been subjected to a number of thermokarst cycles.

PERMAFROST ENVIRONMENTS ADJACENT TO SURFACE WATER

In sporadic permafrost south of Kluane Lake, ground ice is abundant where ample groundwater has been supplied to aggrading permafrost through the subsurface from water bodies or from groundwater moving toward these water bodies. Under normal conditions, the aggrading permafrost table is isolated from a water supply by the initiation of permafrost development, but where water bodies occupy taliks, water can be laterally supplied to the permafrost table (Figure 5). Thus extensive ice lensing and massive ice is often found adjacent to swamps, ponds, lakes, rivers and drainageways.

Massive ice and ice lenses under palsa-type mounds extend to depths of 9 m near Sulphur Lake (KP 258) and to depths of 4-5 m near Jake's Corner (KP 504) and Morely River (KP 614-625) in areas adjacent to ponds or swampy areas in broad poorly drained depressions (Figure 6). Groundwater must have moved from the ponds (commonly of thermokarst origin) or from the taliks underlying the ponds to an aggrading permafrost table in the adjacent terrain. Permafrost and ground ice has probably aggraded and degraded intermittently during post-glacial time, as witnessed by active thermokarst at these localities.

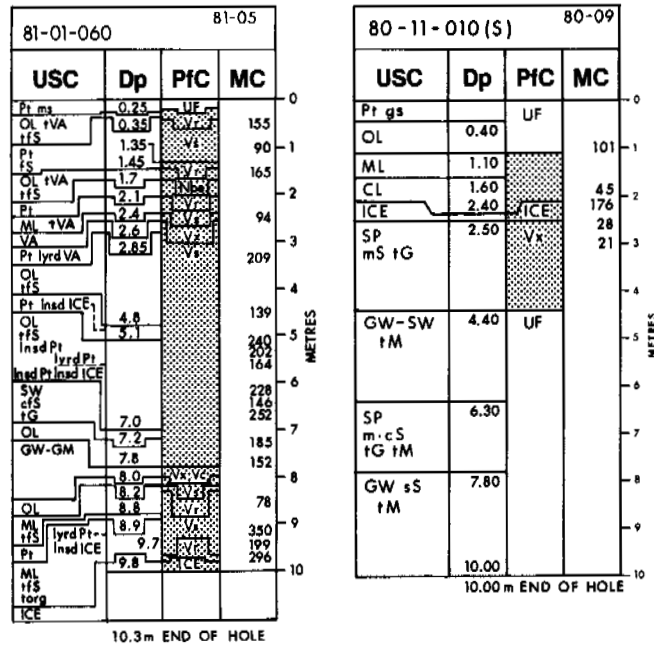

Figure 4: Borehole logs for 81-01-060 and 80-11-010(S). See Figure 2 for explanation of USC, Dp, Pfc, MC.

Figure 5: Ground water conditions in areas of aggrading permafrost where no surface water body is present ("normal conditions") and with surface water body present. Note that water may flow to or from water body depending upon position of water table.

Abundant ice lenses and massive ice are present in sediments underlying low terraces adjacent to Pine Creek (KP 288.5), Marshall Creek (KP 300), Aishihik River (KP 315) and McClintock River (KP 466.5). At Marshall Creek and Aishihik River, ground ice is found in sediments underlying flood

Figure 6: Logs of boreholes drilled adjacent to ponds or poorly drained ground near Sulphur Lake (80-P/L-C-15B) and Morley River (79S-D17). Drill holes on well-drained uplands adjacent to 80-P/L-C-15B are characterized by low ice contents. See Figure 2 for explanation of USC, Dp, Pfc, MC.

Figure 8: Ground conditions underlying terrain adjacent to McClintock River and Marsh Lake. See Figure 7 for borehole explanation.

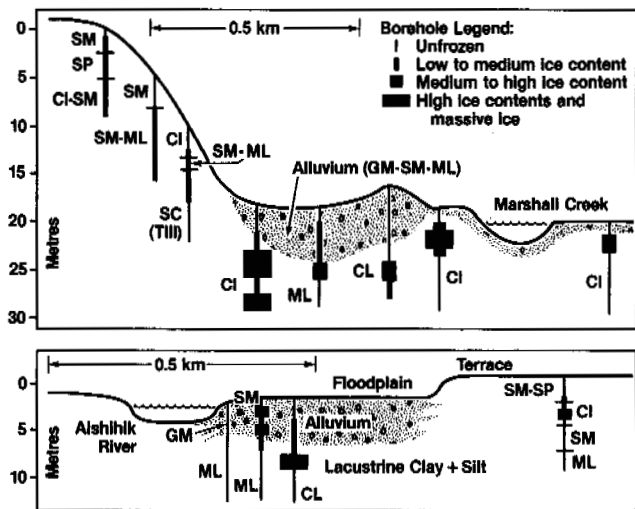

Figure 7: Ground conditions underlying Marshall Creek and Aishihik River terraces and floodplains. See Table 1 for quantification of ice contents.

plains and low terraces to depths of 9 and 6 m, respectively (Figure 7). Permafrost aggradation and the formation of ground ice at these localities has undoubtedly occurred after the formation of the postglacial terraces and floodplain, as the ground immediately under the stream creating these landforms would have been thawed at that time. The ground ice has developed in zones of high groundwater gradients; whether the area is one of

discharge to the streams, recharge from the streams or varies according to season is not known. Clearly however, ample water was being provided to the aggrading permafrost table.

Near McClintock River (KP 466.5), ice lenses and massive ice have developed to depths of 9 m in glaciolacustrine clays and silts that underlie lacustrine and eolian sands (Figure 8). Ice underlying the lacustrine plains postdates the drainage of the late-glacial lake; ice underlying the terraces postdates their formation. The abundance of ground ice can be explained by an ample supply of water moving short distances from the water bodies (river or lake) along sand partings in the clays to an aggrading permafrost table in the lacustrine sediments. Ground ice present to depths of 6.5 m under an isolated palsa-like mound in the large alluvial-lacustrine complex near Marsh Lake's outlet (KP 460) probably developed similarly.

PERMAFROST ENVIRONMENTS ADJACENT TO AREAS OF GROUNDWATER DISCHARGE

Ice lenses are common in the lacustrine clays and clayey tills that form the near-surface substrata on the slope west of Pine Creek (KP 288). Here lacustrine sediments blanket a valley bottom (Figure 9). Erosion of unconsolidated deposits by stream and glacier action to form the valley truncated permeable strata and allowed groundwater to be discharged on the surface of the slope as evidenced by springs at the base of scarps along the slope. Thus ample groundwater was supplied quickly to any aggrading permafrost table on the lower slope. Massive ice in sediments east of Cracker Creek (KP 334) may have a similar origin.

Unconsolidated sediments forming the moderately sloping banks of major stream valleys, e.g., the Marshall Creek valley (KP 299) and the Takhini River valley (KP 379), also contain ground with

Figure 9: Ground conditions underlying slope to west of Pine Creek. See Table 1 for quantification of ice contents.

high ice contents, which may be due to groundwater discharge. At Takhini River, geophysics and drilling outlined a wedge of frozen low-permeability clays with high ice contents (Figure 10). However, exposures along the Takhini River show sand partings and bands of silty fine sands interbedded in the glaciolacustrine sequence. Probably, groundwater moving through these more permeable strata created a damp environment on the river banks. This allowed vegetation favorable to permafrost aggradation to flourish. Groundwater continued to flow to the aggrading permafrost table, and ice lenses and massive ice developed. Obstructions of groundwater flow lines by the permafrost would cause the groundwater to move above and below the initial permafrost pod, and cause icy permafrost to form at some height above stream level and the original level of the groundwater discharge.

PERMAFROST ENVIRONMENTS ADJACENT TO BEDROCK VALLEY WALLS

Large areas near the base of extensive bedrock valley walls are underlain by massive ground ice to depths exceeding 9 m in the Takhini and Medenhall River (KP 359) valley bottoms. These areas are marked by an abundance of thermokarst depressions.

Permafrost probably formed immediately after drainage of the glacial lake, especially near the base of valley walls where moist conditions would prevail. Water falling on the surrounding bedrock-cored uplands entered the groundwater system by seeping directly into the bedrock or through permeable strata on the bedrock surface. This water was probably discharged at the base of the valley walls or flowed through sediments to incised streams as idealized in Figure 11. Thus strata at the base of the aggrading permafrost were saturated by groundwater from the surrounding

Figure 10: Ground conditions in west bank of Takhini River. See Table 1 for quantification of ice contents.

uplands in a zone of high groundwater gradients, and ground ice formed as the permafrost aggraded.

Areas where permeable sandy beds are interbedded with the silts and clays are most favorable for the accumulation of ground ice, as water can quickly move toward the aggrading permafrost table. This may be the case in the Mendenhall River valley, where currents may have deposited sandy belts when the valley acted as an outlet for the glacial lake within the Mendenhall and Takhini River valleys. In the Takhini River valley, areas of high ground ice are most common near bedrock valley walls, especially where the base of the adjacent valley walls is covered by permeable sandy tills or glaciofluvial sands and gravels. Perhaps the glaciofluvial sediments are interlayered with the glaciolacustrine sediments and act as a medium for groundwater movement to aggrading permafrost. Lacustrine sediments in the central part of valleys appear relatively free of ground ice, as has been documented by boreholes west of the Mendenhall River crossing.

DISINTEGRATION MORAINES

Part of the route between Enger Lakes and White River (KP 40-KP 63) crosses disintegration moraine (Rampton 1971) characterized by discontinuous lenses and beds of interbedded diamicton (till), silt, sand, and gravel (Figure 12) in an area of relatively continuous permafrost. Thick ice lenses and massive ice are common to depths of over 20 m. Many strata are probably inclined and vertical due to melt-out of dead ice containing much englacial debris and underlying much supraglacial debris and to depositional and deformational processes common to the terminal zone of glaciers. The diamicton (till) in the disintegration moraines is commonly loose and coarse-textured. This complex configuration of strata allows groundwater to flow through

Figure 11: Diagrammatic cross-section showing conditions leading to ground ice formation during permafrost aggradation in glaciolacustrine sediments at base of bedrock valley walls.

permeable sediments to focii of ground ice formation during permafrost aggradation. The complex configuration of strata has led to a very irregular distribution of ground ice as illustrated in Figure 12.

Most ground ice is probably epigenetic, although possible occurrences of relict glacier ice cannot be discounted. During glaciation the 0°C isotherm probably rose to the base of the glacier. Permafrost would then degrade subglacially, and melt any ground ice previously present. During deglaciation permafrost would immediately begin to aggrade and water would be conducted to focii of ground ice formation via permeable strata from lakes, ponds or the saturated taliks underlying them. Alternately, subglacial meltwater from basal melting of the decaying glacier may have been driven through permeable strata by the hydraulic gradient created by glacier overburden thickness; much as has been envisaged for the formation of massive ice in the Mackenzie-Beaufort region (Rampton 1974).

CONCLUSIONS

Ground ice has developed along the pipeline route throughout late glacial and postglacial time (approximately the last 13,000 years). Ground ice most commonly occurs as aggradational ice or epigenetic ice. Aggradational ice is most extensive where water is perched upon a rising permafrost table, either where the table is rising due to aftereffects of forest fires, mass wastage or changing climatic conditions or where continuous deposition of fine-grained materials is occurring. Epigenetic ice is most extensive where ample groundwater is available and can be transmitted via permeable strata or under high groundwater gradients to an aggrading permafrost table. This usually occurs adjacent to rivers, lakes, ponds, and permeable taliks or in discharge areas adjacent to truncated unconsolidated sequences or bedrock valley walls.

A MATHEMATICAL MODEL FOR PATTERNED GROUND:
SORTED POLYGONS AND STRIPES, AND UNDERWATER POLYGONS

R. J. Ray,¹ W. B. Krantz,¹ T. N. Caine,² and R. D. Gunn³

Laramie, Wyoming 82071 USA

This paper presents a model in which Rayleigh convection of the water in an active layer is responsible for the regularity, size, and shape of some types of sorted patterned ground. These convection cells result in uneven melting of the underlying ice front during thawing. The resulting undulatory ice front provides a pattern of which sorted stone polygons and stripes are the "fossil mirror." The model predicts the width to depth-of-sorting ratio for sorted patterned ground. Furthermore, the model predicts the existence and width to depth-of-sorting ratio of underwater sorted polygons. These predictions are corroborated with field study data from both "normal" and underwater sorted polygons.

INTRODUCTION

Sorted patterned ground is a periglacial phenomenon which displays many unusual and oftentimes strikingly beautiful characteristics. Near perfectly hexagonal stone polygons (Figure 1) are common in remote locations above timberline in the highest mountains and even at sea level in the arctic. Sorted polygon widths range from a few centimeters up to giant forms of 10 m or more (Washburn 1980 p. 142). Networks of regular, sorted polygons often transform into parallel, sorted stripes as the terrain changes to sloped. Furthermore, the impressive regularity of sorted patterned ground may extend over several square kilometers at a single site (Richmond 1949).

Among the most interesting sorted patterned ground features are the nearly constant width to

depth-of-sorting ratios for any size form and the occurrence of sorted polygons on the bottom of shallow lakes or ponds. Meinardus (1912) noticed that the characteristic width of sorted patterned ground increases as the depth-of-sorting increases. Sorted polygons, which presumably have been formed underwater, have been reported (e.g., Jennings 1960) and in fact often occur at the bottom of a pond or lake at lower elevations than "normal" sorted patterned ground.

This paper presents a Rayleigh convection model for the regularity of sorted patterned ground which explains these unusual characteristics including the prediction of the width to depth ratio of a broad class of sorted polygons observed both above and below water. The scope of this paper is as follows. First, a brief review of previous models for sorted patterned ground formation is given. Next, a new model for the regularity of sorted patterned ground is presented. This convection model then is supported with width and depth-of-sorting measurements of both "normal" and underwater sorted polygons. Finally, many interesting characteristics of sorted patterned ground are explained with the use of this model.

It is generally agreed that the origin of patterned ground is polygenetic (Caine 1972). There are many mechanisms which can cause a homogeneous mixture of small and large stones to become sorted or segregated through frost action: cryostatic pressure, differential frost heave, and upfreezing of stones are possible mechanisms (Washburn 1956). Other models for sorted patterned ground formation invoke some sort of cracking by desiccation, or thermal contraction in seasonally frozen ground or permafrost (Washburn 1980 p. 156).

Although all these processes do occur in nature, it is generally agreed that they are inadequate in explaining the regularity of all sorted forms. The noncracking mechanisms require an initial regularity of some kind to be developed in the soil prior to sorting. The cracking mechanisms yield crack

FIGURE 1 Relict sorted polygon, Arapahoe Pass, Front Range of Colorado. Stone polygon is approximately 3 m across.

networks too small (desiccation cracking) or too large (permafrost cracking) to explain most sorted polygons or stripes. Furthermore, none of these mechanisms can adequately explain the constant width to depth-of-sorting ratio in sorted polygons, the transition from sorted polygons to sorted stripes, the increase in depth-of-sorting with depth of the active layer, the regularity of polygon networks or the occurrence of sorted polygons underwater.

The model presented here suggests that thermally driven convection or "Rayleigh" convection of the water in the active layer can explain the interesting characteristics of a broad class of sorted patterned ground. Rayleigh convection has been advanced as an explanation for sorted patterned ground before. Nordenskjöld (1909) suggested that sorted polygons are a result of convection currents in the ground due to the temperature difference between the surface of the frost table and the surface of the thawed ground. Low (1925) and Gripp (1926, 1927, 1929) proposed that currents capable of lifting stones occurred due to the density inversion of water between 273 K and 277 K. However, Elton (1927) showed that the flow caused by this density difference is too weak to carry stones. The model developed in this paper, while involving Rayleigh convection, is substantially different from the convection models discussed above.

RAYLEIGH CONVECTION MODEL FOR SORTED PATTERNED GROUND REGULARITY

This section discusses the implications Rayleigh convection cells in an active layer would have toward sorted patterned ground formation. First, the new model for inducing regularity in the active layer is discussed. Then, a summary of the principal results of the mathematical analysis for the onset of Rayleigh convection cells in the active layer is given. It should be emphasized that this model in no way attempts to explain the entire formation process of sorted patterned ground; rather, it provides a mechanism for the occurrence of regularity in the active layer.

Formation of Undulatory Ice Front by Rayleigh Convection

During the warmer months, the top portion of the permafrost melts to form the active layer. The active layer is thus water-saturated earth bounded below by thawing, but still-frozen, soil at 273 K and bounded above by either air or standing water if it lies below a shallow lake or pond. For modeling purposes, it is assumed that the upper surface is at or near 277 K. This situation often occurs naturally (e.g., Ives 1973, Washburn 1980 p. 59); situations where the surface temperature is different from 277 K are easily incorporated into the theory (see Ray et al. 1983). It is well known that in this temperature range, the density of water increases with temperature, reaching a maximum value at 277 K.

Since the density of the water near the upper surface (at 277 K) is greater than that near the lower ice-liquid interface (at 273 K), the system is potentially unstable and will tend to form

convection cells (Figure 2). Lord Rayleigh (Strutt 1916) showed that convection cells do not form in every fluid layer with an inverse density stratification. The onset of convection cells is controlled by opposing forces. The density gradient and corresponding buoyancy forces must be large enough to force the fluid to circulate. The viscous drag, which in an active layer is a function of the viscosity of the water and the permeability of the soil, must be small enough to avoid damping out the circulation cells. This criterion is commonly expressed in terms of a critical value of the Rayleigh number (Ra), a dimensionless parameter defined as the ratio of the buoyancy force divided by the product of the viscous drag and the rate of heat conduction:

$$Ra \equiv \frac{\rho_c^2 C_p \beta \Delta T k g L}{\lambda_s \mu} \quad (1)$$

where ρ_c is the density of the fluid at its reference temperature (water at 273 K), C_p is the heat capacity at constant pressure, β is the thermal expansion coefficient, ΔT is the temperature difference imposed across the depth L , k is the permeability, g is the gravitational acceleration, λ_s is the thermal conductivity, and μ is the shear viscosity. Any parameter which makes the Rayleigh number large contributes to the formation of Rayleigh convection cells. The critical Rayleigh number, above which the onset of convection cells will occur in the active layer, will be given when the results of the mathematical analysis are summarized.

With the aid of these Rayleigh instability arguments, a sequence of events is now proposed for the formation of sorted polygons. First, it is assumed that the permeability, k , of the soil is initially too low for the density inversion to result in Rayleigh convection cells; that is, the k which appears in the numerator of Equation (1) is so small that the Rayleigh number is below its critical value. The thickness of the active layer is often nearly the same each year (Ives 1973,

FIGURE 2 Two-dimensional cross-section of hexagonal Rayleigh convection cells in the active layer. Note the resulting uneven melting of the permafrost front.

Washburn 1980 p. 59). Frost heave causes vertical (the primary degree of freedom for movement) expansion of the active layer. On thawing, it does not settle to its original density; that is, it stays slightly lofted. Corte (1962) has shown experimentally that up to 10% increase in volume of the active layer can result from as few as 10 freeze-thaw cycles. Application of the Blake-Kozeny equation (Bird et al. 1960 p. 199) indicates that a 10% volume increase can result in an increase in permeability of nearly 70%. After many such freeze-thaw cycles, the active layer will have lofted enough to reach a permeability which allows the critical Rayleigh number to be reached. If the 4 K temperature difference is present across the active layer, all properties appearing in Equation (1) will be nearly constant except the permeability, k , and the depth, L .

Attaining the critical Rayleigh number then is first possible when the nonconstant parameters in the Rayleigh number reach their extreme values; that is, k is large enough to achieve the onset of convection when L is at its maximum (deepest annual thaw). Note here that the Rayleigh number is largest when the upper surface temperature is at or near 277 K. This implies that convection cells will be initiated at that time of the year when the upper surface temperature is about 277 K.

Earlier models which attempted to explain the regularity of patterned ground by Rayleigh convection were based on the contention that these weak circulatory currents could cause direct movement of the larger stones which form the borders of sorted polygons. The model developed in this paper is not based on any argument that Rayleigh convection cells can move stones directly to effect a sorting process. In contrast, this model contends that Rayleigh convection determines the regularity indirectly through its influence on the shape of the ice front which underlies the water-saturated porous medium.

The influence of Rayleigh convection on the shape of the underlying ice front was ignored in earlier Rayleigh convection models which attempted to explain patterned ground regularity. The Rayleigh convection cells determine the shape of the underlying ice front because they induce uneven heat transfer to this front. In regions of downflow, the transport of warmer water from the upper surface to the ice front will cause increased melting; conversely, in regions of upflow, the transport of colder water from the ice front will retard melting. Figure 2 shows a schematic of the two-dimensional cross-section of the resulting undulatory ice front. Note the ice "peaks" under the upflow regions and the ice "valleys" under the downflow regions. It can be proven that the plan form configuration of the Rayleigh convection cells will be hexagonal.

The presence of hexagonal undulations on the thaw front then influences any sorting processes which are slowly occurring in time such that the sorting mirrors the pattern of the underlying ice front. This could occur by any one or combination of possible sorting mechanisms such as cryostatic pressure, differential frost heave, and primary frost sorting. This paper does not attempt to determine which mechanism or combination of mechanisms causes the sorting process to mirror the

patterned ice front. Indeed it is not possible to infer from the field data taken in this study which mechanism caused the sorting. However, it is possible to determine if the geometry and characteristic spacing of the patterned ground correspond to that which would be induced by an undulatory ice front caused by Rayleigh convection. If this model for explaining the regularity of patterned ground is correct, then the ratio of the polygon width to depth-of-sorting should be equal to the width to depth ratio predicted by the mathematical model assuming that the depth-of-sorting is nearly equal to the depth of the active layer when free convection is initiated.

Summary of Principal Results From Mathematical Analysis

In order to determine the critical Rayleigh number above which convection will occur and the corresponding convection cell width to depth ratio, a linear stability analysis was carried out. Although this analysis is straightforward, it is quite lengthy and hence only the principal results can be summarized here. The interested reader desiring more details of the analysis is referred to Ray (1981) or Ray et al. (1983).

The governing equations for fluid flow and heat transfer in the unstably stratified active layer are Darcy's law, the equations of motion, the thermal energy equation, and the equation of continuity. Also, an equation of state is required which describes the increase of water density with temperature between 273 K and 277 K. The boundary conditions needed to solve these equations correspond to specified temperatures of 273 K and 277 K at the lower and upper boundaries, respectively. In addition, in the case of "normal" polygons formed in an active layer bounded above by air, the upper and lower boundaries are assumed to be impermeable. In the case of underwater polygons, this latter condition is relaxed at the upper boundary; this leads to dramatically different predictions. In addition, for both "normal" and underwater polygons, an energy balance condition must be satisfied at the lower ice front boundary which is allowed to be compliant in that it can deform in response to the convection cells. The resulting linear stability theory solution is novel in allowing for this compliant boundary.

This system of equations and boundary conditions is solved using the formalism of linear stability theory. For the case of "normal" polygons, linear stability theory predicts a critical Rayleigh number $Ra_C = 27.1$ for the inception of convection cells and a corresponding convection cell width to depth ratio given by

$$\frac{\lambda}{L} = 3.81 \quad (2)$$

For the case of parallel stripes on a slope, theory predicts a critical Rayleigh number of $Ra_C = 27.1/\cos \phi$, where ϕ is the angle of inclination. The corresponding width to depth ratio is then in the range $2.68 \leq \lambda/L \leq 3.81$, depending on the slope angle and the magnitude of the subsurface flow in the active layer.

Sorted stone polygons formed underwater are

predicted to have a smaller critical Rayleigh number ($Ra_c = 17.1$) and a correspondingly higher width to depth ratio:

$$\frac{\lambda}{L} = 5.07 \quad (3)$$

Theoretical considerations suggest that this ratio may depend on the water depth. However, we have insufficient data to warrant refining the theory at this time.

These results allow prediction of the conditions for which convection cells will form. When the physical parameters of an active layer bounded above by air yield a Rayleigh number just above 27.1 (i.e., the permeability is large enough for flow), convection cells should form which have a width to depth ratio of about 3.8. When the Rayleigh number of an active layer below a shallow lake or pond goes just above 17.1, convection cells with a width to depth ratio of about 5.1 should form.

FIELD STUDIES

The field studies were designed to test the hypothesis that the regularity of sorted patterned ground corresponds to that predicted for Rayleigh convection cells. This would suggest that Rayleigh convection in the active layer is responsible for the observed regularity of sorted patterned ground. If Rayleigh convection is involved in sorted polygon inception, it would have occurred long ago in relict sites that are now polygonally patterned; however, sites about to form sorted polygons are very difficult to identify. For this reason, the field studies presented below focused on measurements of existing sorted polygons as a test of the Rayleigh convection hypothesis.

Two sets of data were collected. Figure 3 is a plot of 18 data points taken from a wide range of "normal" sorted polygon sizes, that is, where the active layer was bordered above by air. The dark points are diurnal small polygon data whereas the light points are data for polygons formed over longer time periods. The characteristic width is an average of center-to-center measurements for several adjacent polygons. The depth was found by trenching through the stone border of a polygon, then measuring from undisturbed ground reference level to the bottom of the sorted border, or to the point where the stones were no longer oriented vertically. A linear regression of these data yields a slope of 3.6 and an intercept of 0.041 m with a correlation coefficient of 0.98. This slope of 3.6 agrees reasonably well with the theoretical value of 3.8 given by Equation (2).

The data plotted in Figure 4 are from measurements taken in the manner described above for polygons appearing on the bottom of shallow lakes or ponds. A linear regression fit of these data yields a slope of 5.7 with an intercept of -0.18 m and a correlation coefficient of 0.94. This slope agrees reasonably well with the value of 5.1 given by Equation (3).

FIGURE 3 "Normal" sorted polygons: Characteristic width versus depth-of-sorting. The dark points are data from diurnal sorted polygons.

FIGURE 4 Underwater sorted polygons: characteristic width versus depth-of-sorting.

DISCUSSION

The excellent agreement between measured and predicted values of the width to depth ratios for both normal and underwater polygons provides convincing support for the hypothesis that Rayleigh convection in the active layer was responsible for the regularity of the sorted patterned ground studied here. This Rayleigh convection model can also explain many other characteristics of patterned ground. For example, the constant width to depth-of-sorting ratio observed for "normal" sorted

polygons follows from the fact that for any depth active layer, the critical convection cell width to depth ratio is 3.81. This then explains the wide range in sorted patterned ground sizes since thinner active layers will produce smaller polygons.

Since theory predicts that Rayleigh convection cells will be hexagonal in a horizontal active layer, this implies that the mirroring stone polygons also will tend toward this shape. Many investigators have noticed this preferred shape of sorted polygons, especially in smaller, diurnal forms (see Ray et al. 1983). The regularity and extent of some sorted patterned ground networks suggest that, when conditions are conducive to Rayleigh convection on any part of a site, they probably prevail throughout the site.

The transition from sorted polygons to sorted stripes is predicted by the Rayleigh convection model as well. It is well known in thermal convection theory that as a saturated porous medium undergoing Rayleigh convection is tilted from the horizontal, the three-dimensional, polygonal convection cells, which occur in the flat configuration, become two-dimensional roll cells oriented downslope (Combarous and Bories 1975). In a sloped active layer, such two-dimensional roll cells would melt the ice-water interface into troughs and ridges running parallel to the fall line. The resulting sorted forms would then be parallel sorted stripes (Ray et al. 1983). The fact that the critical Rayleigh number is predicted to increase with slope angle may explain in part why stripes are not observed on steeper slopes.

Finally, the occurrence of underwater sorted polygons can be explained in light of the Rayleigh convection model. Figure 5 shows a network of underwater polygons on the bed of a shallow lake in the Snowy Range of Wyoming. Freezing of a shallow pond in a periglacial environment will extend into the bed below it and produce an active layer which is bordered above by standing water during thaw conditions.

Figure 4 shows that the measured width to depth ratio for underwater polygons is seen to agree remarkably well with the value of 5.1 predicted by the Rayleigh convection model. Note that the

FIGURE 5 Underwater sorted polygons, Snowy Range of Wyoming. Polygons are approximately 0.8 m wide.

predicted critical Rayleigh number for underwater polygons is 17.7 as opposed to 27.1 for "normal" polygons. This implies that underwater sorted polygons may be observed under less constraining conditions than "normal" patterned ground (i.e., lower permeability, shallower active layer, reduced temperature gradient). Throughout the Southern Rockies, most large active sorted polygons are on the beds of ephemeral ponds. Commonly these polygons do not continue onto the shore above the high water level and may be found at elevations several hundred meters lower than those of "normal" polygons (Ray 1981 p. 230).

CONCLUSIONS

The model presented here hypothesizes that the regularity, size, and shape of some types of sorted patterned ground can be explained by Rayleigh convection cells in the active layer. The model predicts a width to depth-of-sorting ratio of 3.8 for "normal" sorted polygons and a width to depth-of-sorting ratio of 5.1 for underwater sorted polygons which compare favorably with field measurements of 3.6 and 5.7, respectively. Finally, many interesting characteristics of sorted patterned ground can be explained by this Rayleigh convection model.

ACKNOWLEDGMENTS

The authors wish to acknowledge financial support provided for these studies by the National Science Foundation (grant DPP-8210156). A seed grant for the field studies was provided by the Council for Research and Creative Work of the University of Colorado. One of the authors (RJR) was partially supported during this work by a Dean's Graduate School Fellowship from the University of Colorado. Finally, the authors wish to acknowledge Ms. Ellen M. Romig and Mr. Dennis L. Ehmsen for their assistance in preparing the final manuscript and figures and Mr. David Newbold for his help in the field program.

GELIFLUCTION DEPOSITS AS SOURCES OF PALEOENVIRONMENTAL INFORMATION

Richard E. Reanier and Fiorenzo C. Ugolini
College of Forest Resources, University of Washington
Seattle, Washington 98195 USA

A gelifluction lobe above treeline at Walker Lake in the Brooks Range of Alaska was examined for pedological and palynological evidence of the expansion of the boreal forest during the Holocene. Soil pits excavated to the base of the active layer (1 m) revealed organic rich material consisting of ancient vegetation buried by the advancing lobe front. Laminations, platy soil structure, slickensided soil peds, and "plough marks" from pebbles in this organic-rich deposit indicate basal sliding is an important component of downslope movement. Radiocarbon dates obtained from buried organics indicate a relatively constant lobe advance rate of about 3.21 mm yr⁻¹ throughout much of the Holocene. A paleosol buried beneath the advancing lobe shows that a degree of soil development comparable to that of modern soils of the area was achieved by about 3,200 years B.P. Pollen spectra from the buried organic layer differ markedly from the regional lake pollen record, but give evidence that the treeline has recently advanced to its modern position during the past 5,000 years, and has not been more expanded in the past. We conclude that gelifluction deposits contain valuable paleoenvironmental data for studies of vegetation history and soil development. Such deposits are particularly important in geomorphic situations where lakes and bogs are absent and site-specific information is required.

INTRODUCTION

Historically, studies of periglacial phenomena have concentrated on geomorphic description and on analysis of physical properties and processes involved in landform development (Washburn 1980). Paleoenvironmental uses of periglacial landforms generally have been restricted to regional inferences about former climates from the presence of relict landforms. Climatic inferences are based upon analogy with climatic parameters associated with similar active landforms. Gelifluction, the gradual downslope flow of water-saturated soil in permafrost affected regions, results in such periglacial landforms as gelifluction sheets, benches, lobes, and streams (Washburn 1980). Benedict (1976) suggested that deposits buried beneath advancing gelifluction features should provide high-resolution palynological and pedological records.

As part of a multidisciplinary study of Holocene treeline changes in the southern Brooks Range of Alaska (Brubaker et al. 1983, Garfinkel and Brubaker 1980, Goldstein 1981, Ugolini et al. 1981, 1982), we examined gelifluction lobes as potential sources of information on treeline fluctuation. If the treeline had expanded beyond its present limit during the Holocene, as it did in northern Canada (Bryson et al. 1965, Ritchie and Spear 1982), we reasoned that gelifluction deposits near the treeline would contain a record of that expansion. We report here the results of palynological and pedological investigations of one lobe located above Walker Lake (67°9'N, 154°22'W) in the south central Brooks Range of Alaska (Figure 1).

STUDY AREA

The Walker Lake study area was selected because of its well-defined treeline and

FIGURE 1 Map of study area.

noncalcareous parent material suitable for pedogenic studies and ¹⁴C dating. The south facing slope where our study was centered is composed of low grade quartz-muscovite schist of Paleozoic age (Nelson and Grybeck 1981). The slope is mantled to an altitude of about 525 m by drift of the late Wisconsin Walker Lake glaciation (Figure 1), but was overridden by the earlier and more extensive Itkillik and Kobuk glaciations (Hamilton 1982). Walker Lake is near the boreal forest and shrub tundra transition. The altitudinal limit of continuous forest occurs at about 550 m at the study site. White spruce (*Picea glauca*) dominates the forest at treeline and in well-drained areas, while black spruce (*Picea mariana*) dominates the poorly drained areas at lower altitudes. Quaking aspen (*Populus tremuloides*) and paper birch (*Betula papyrifera*) are secondary tree species. Ericaceous shrubs and lichens are common in the forest understory and in the shrub tundra above treeline. Alder

(*Alnus crispa*) and willow (*Salix* spp.) are locally abundant in draws and along stream banks. The area is within the zone of discontinuous permafrost (Brown and Péwé 1973).

The gelifluction lobe examined here is located at an altitude of 620 m, approximately 70 m above the limit of continuous forest (Figures 1 and 2). It is about 35 m in axial length with the axis oriented downslope at 175° azimuth. The surface gradient is 14° and the lobe is from 1 to 1.5 m thick. Active layer thickness in midsummer is about 1 m. It is a turf-banked lobe (Benedict 1976) with a continuous cover of shrub tundra. Although the lobe is located above the continuous forest limit, a solitary white spruce grows on the lobe near its western margin 13 m upslope from the lobe front, and several white spruce seedlings are present.

METHODS

Five trenches were opened along the lobe axis in order to examine the internal structure of the lobe (Figure 2). Soil profiles were described in each trench and one of the profiles was selected for laboratory chemical analyses. Fabric measurements were made in this same profile. Soil description followed standard methods (cf. Ugolini et al. 1981). Soil textural analysis utilized standard sieve techniques for the fraction coarser than 4 ϕ and a Sedigraph 5000D particle size analyzer for the fines after pretreatment for organic matter and iron removal. Soil chemical analyses were made on the air-dry soil fraction finer than -1 ϕ (2 mm). Details of the analytical

procedures are given in Ugolini et al. (1981). Samples of the buried organic deposit were taken for pollen analysis and ^{14}C dating (Figure 2). Radiocarbon samples were stored at 3°C, air-dried, and carefully examined under magnification to remove any rootlets prior to submission for dating. The dates were run by Beta Analytic, Inc. after dispersion in hot HCl to remove carbonates and have been normalized to -25 per mil ^{13}C . Pollen samples were processed by standard acetolysis techniques (Faegri and Iverson 1975). Extracted pollen was mounted in silicone oil and counted under 400X magnification until at least 300 grains were identified in each sample.

RESULTS AND DISCUSSION

Structural Analyses

Fabric measurements taken from 100 stones between 25 and 75 cm below the surface at the soil profile location (Figure 2) show long-axis orientation parallel to the lobe axis (Figure 3). The mean fabric dip angle is 26.6° with an angular deviation of 12.0° as compared with a lobe surface gradient of about 14°. The mean fabric azimuth is 178.5° with an angular deviation of 42.0°, while the lobe axis azimuth was estimated to be 175° true. Such fabric orientations are commonly found in gelifluction deposits (Benedict 1976), and have been taken as evidence of active lobe movement.

Although the exact mechanism of gelifluction movement, whether by flow or by sliding along shear planes, remains undetermined (Washburn

FIGURE 2 Longitudinal section of gelifluction lobe showing sample locations (black dots) and soil profile location, and a plot of radiocarbon age and distance from lobe front.

FIGURE 3 Scatter plot of fabric measurements.

1980), basal sliding appears to be an important component of downslope movement of this lobe. The soil structure of the lobe material is dominated by fine to very fine platy structure (Table 1), the development of which is favored by ice segregation that preferentially forms planes parallel to the soil surface (Benedict 1976). Such planes are potential places for sliding to occur as the active layer thaws. Detailed field examination of the still-frozen Alb horizon revealed apparent glide planes separated by thin segregation ice lenses. The soil peds had shiny, slickensided surfaces due to the orientation of fine muscovite plates. Occasional stones protruding into the organic horizon from the overlying C2 horizon had left striae and "plough marks" several cm long in the Alb material.

Rates of Movement

Radiocarbon dates of $1,830 \pm 50$ years B.P. (Beta-2840), $4,010 \pm 60$ years B.P. (Beta-2645), and $6,610 \pm 100$ years B.P. (Beta-2840) were obtained from the buried organic horizon 4.1, 12.4, and 20.6 m from the lobe front, respectively. A plot of these dates (including the present) against distance from the lobe front is linear ($r^2=0.99$) and indicates a relatively constant rate of movement of about 3.21 mm yr^{-1} throughout most of the Holocene at the time resolution examined here (Figure 2). This compares with other reported northern hemisphere basal movement rates determined by ^{14}C dating ranging from 0.6 to 10 mm yr^{-1} (Benedict 1976, Alexander and Price 1980). No attempt was made to correct for calendar age or for mean residence time of soil carbon as others have done (Benedict 1970) because of differences among calibration curves and the apparent unreliability of ^{14}C ages less than about 500 B.P. (Stuiver 1982). However, the use of reasonable estimates of residence time (300-500 yr) in the regression would tend to somewhat increase both the movement rate and correlation.

Pedological Analyses

Soils of the study area have been characterized by Ugolini et al. (1981). The soils are weakly podzolized; those displaying albic horizons fail to meet the spodic horizon chemical requirements of the Soil Taxonomy (Soil Survey Staff 1975), and are classified as Dystric Cryochrepts together with similar soils lacking albic horizons. Soils of the gelifluction lobe lack albic horizons, except immediately beneath the

FIGURE 4 Particle size distribution in soil profile.

single white spruce tree. Detailed morphological and chemical analyses of a profile extending through the lobe to the paleosol beneath (Figure 2) are presented in Table 1. The Alb horizon (buried surface horizon) of the paleosol is very dark grayish brown in color and contains an amount of readily oxidizable carbon (C) exceeded only by that of the modern surface horizon. C is lower in the B2bf horizon than in the modern B2 horizon, perhaps as a result of in situ oxidization after burial. A similar trend is seen in the humified carbon fraction (C_p). As measured by electrical conductivity (EC), ionic strength similarly shows a peak in the Alb horizon but is nearly an order of magnitude lower in the buried than in the modern solum. However, both Na-dithionite and Na-pyrophosphate extractable Fe and Al reach peak values in the paleosol, suggesting the preburial soil was at least as well developed as the modern soil. Carbon and extractable sesquioxide values for other soils near treeline in the study area are comparable to levels reported here (Ugolini et al. 1981). The interpolated time of burial of this portion of the paleosol, and therefore the date of cessation of surficial pedogenesis, is 3,200 years ago (Figure 2), by which time the Holocene soils above treeline had evidently reached modern levels of development.

The particle size distributions of the soil horizons for material finer than -4ϕ show strikingly similar modes in the medium silt (5 to 6ϕ) and in the pebble (-4 to -2ϕ) size classes (Figure 4). The bimodal pattern may result from comminution of the quartz-muscovite schist during gelification itself, or may be a distribution inherited from till (cf. Dreimanis and Vagners 1971). The particle size distributions generally show the poor sorting characteristic of gelification deposits. Despite the overall similarities, the two A1 horizons differ from the other horizons in having relatively more material in the silt and clay fractions (5 to 12ϕ) and less material in the sand and gravel fractions (-4 to 5ϕ). This result is

consistent with greater rates of both physical and chemical weathering in the surface horizons.

Pollen Analyses

At the outset of this investigation it became obvious that the reliability of pollen data from gelification deposits needed to be tested. Pollen from lake cores has been "smoothed" by mixing in the water column before deposition on the lake bottom. However, soil pollen may reflect microscale heterogeneity in plant distributions, so that samples of the same age from the same locality may have dissimilar pollen spectra. Accordingly, we examined paired samples of the buried organic material taken from points about 0.5 m apart on a line normal to the lobe axis to see if contemporaneous samples had similar spectra. The sample pairs were taken from distances of 0.2, 1.5, 4.1, 9.6, 12.6, and 20.6 m from the lobe front (Figure 2). Using a multinomial homogeneity test reported by Mosimann (1965; test A7), we evaluated the null hypothesis that the pairs had the same true proportions of the seven pollen types in Figure 5. In five of the six pairs the hypotheses of homogeneity was rejected at the 0.05 level of significance. Gramineae (grasses) Cyperaceae (sedges), and *Artemisia* typically contribute the highest individual terms to the total chi-square, reflecting the higher heterogeneity of these taxa. This is understandable since these are anemophilous taxa producing large amounts of pollen and all grow locally on the lobe today. The chance proximity of such plants to the portion of soil that eventually becomes a "sample" may explain the higher heterogeneity of these taxa in the pollen spectra. When these three taxa are excluded from the test, the homogeneity hypothesis is not rejected in any case at the 0.05 level. These results indicate that the interpretation of changes in the relative abundances of Gramineae, Cyperaceae, and *Artemisia* must be made with caution.

Pollen preservation in the gelification lobe samples is generally poor in relation to normal preservation in lake pollen records. Pollen degradation in the lobe takes the form of both crumpling and corrosion; degradation generally increases with sample age. However, even in the oldest samples some well preserved grains were encountered, and in the youngest samples poorly preserved grains were found. Of the taxa in Figure 5, Cyperaceae and Gramineae seemed most susceptible to corrosion and are possibly underrepresented in the samples, while *Picea* pollen seemed relatively unaffected by corrosion. Fragile *Juniperus* pollen was not preserved in the lobe deposits, although *Juniperus communis* is common on the lobe today. However, a *Juniperus* needle was recovered from the 4,000 year old sample, suggesting that this species was present at the site throughout the record.

Brubaker et al. (1983) have recently completed a detailed study of late Wisconsin and Holocene vegetation changes in the central Brooks Range based on lake pollen records. The major vegetation changes in the region occur prior to the beginning of our gelification lobe record at 6,600 years B.P. The exception is the establishment of

the boreal forest at the south shore of Walker Lake about 5,000 years B.P. Otherwise, this younger portion of the record is conspicuous by its lack of change.

Pollen spectra from the buried organic layer show systematic departures from those of the regional lacustrine record. In contrast to the regional spectra, *Artemisia* pollen percentages dominate those of other taxa throughout the gelifluction lobe record, reaching levels of 40-60% of the pollen sum (Figure 5). Pollen of Ericaceae and Gramineae are insignificant components of the regional spectra, but reach much higher levels in the gelifluction deposit. *Betula* percentages are perhaps half those of the lake records. Spores of *Lycopodium* and monolet spores of the Filicales (ferns) dominate the total pollen throughout the gelifluction lobe record, exceeding 90% of the total microfossils in the oldest sample (Figure 5). This may result in part from differential preservation due to the high resistance of these spores (along with conifer pollen) to both corrosion and oxidation (Havinga 1967). However these spores are common in surface litter samples from the study area, and increases in these types in the regional record between 8,000 and 10,000 B.P. have been interpreted as increasing abundances of *Lycopodium* and ferns in the vegetation (Brubaker et al. 1983).

In addition to these overall differences between the two records, changes in the pollen percentages of specific taxa are seen in the lobe record which do not occur in the lake pollen record. Gramineae pollen percentages reach a minor peak in the 3,200 year old samples. Both Ericaceae and Cyperaceae percentages increase in the gelifluction lobe samples younger than 1,800 years. *Picea* pollen is absent from the 6,600 year old gelifluction lobe sample, consistent with the very low regional *Picea* percentages at this time. The arrival of the boreal forest at the south shore of Walker Lake at about 5,000 years B.P. is accompanied by lake pollen *Picea* percentages of about 20% that remain relatively constant to the present. In the gelifluction lobe, *Picea* percentages of 1-2% occur in the 4,000 and 3,200 year old samples. Samples younger than 1,800 years from the lobe have *Picea* percentages between 5 and 10%, while modern surface litter samples from the lobe have percentages between 14 and 21%. In the absence of any change recorded in the lake record, these increases in *Picea* percentages in the gelifluction lobe record suggest treeline has advanced recently to its modern position from lake shore altitudes (200 m) where it stood about 5,000 years B.P. Latitudinal treeline in the Alatna River valley (35 km east of Walker Lake) apparently reached its modern position about 1,500 years ago (Brubaker

FIGURE 5 Pollen percentage diagram from the buried organic layer of the gelifluction lobe.

et al. 1983). Modern treelines at Walker Lake and in the Alatna valley are both at about 550 m altitude, although the treeline on the Alatna River is about 50 km farther north.

CONCLUSIONS

The degree of soil development exhibited by the buried paleosol and the *Picea* pollen percentages that suggest a recent increase of treeline to its modern altitude both indicate that treeline did not expand beyond its modern position during the Holocene. This conclusion was reached by others solely on the basis of soil (Ugolini et al. 1981) and lake pollen (Brubaker et al. 1983) data. We have also shown that basal sliding is an important component of gelifluction lobe movement at this site. This study has demonstrated that gelifluction deposits are useful sources of paleoenvironmental data. Paleosols preserved beneath advancing lobes contain information about past degrees of soil development. The advancing lobe front buries organic matter which can be used to date lobe activity and to calculate past rates of movement. The buried organic material contains a fossil pollen record useful in documenting past vegetation changes.

Shortcomings in the use of gelifluction deposits in paleoenvironmental studies include the excessive labor required to excavate samples, pollen spectra heterogeneity resulting from the effects of nearby individual plants, and the poor degree of pollen preservation which may bias the record. However, gelifluction deposits are frequently found in locations where lakes are absent, and may be the only available source of paleoenvironmental data. Additionally, gelifluction pollen records can complement lake pollen records by providing information about local vegetation not recorded in the lake records.

INVESTIGATION OF THE AIR CONVECTION PILE
AS A PERMAFROST PROTECTION DEVICE

R. L. Reid^{1,3} and A. L. Evans^{2,3}

Tennessee, Knoxville, Tennessee 37916 USA

Winter performance and summer characteristics were measured for the air convection pile permafrost protection device. Velocity and temperature profiles were measured in the tube and annulus of air convection piles having below ground lengths of 3 m (10 ft) and 6 m (20 ft) containing 0.25 m (10 in) diameter tubes concentric with a 0.46 m (18 in) diameter outer piles. It was found that there was turbulent flow in both the tube and annulus and that the thermal performance could be expressed in terms of Nusselt and Rayleigh numbers by the equation $Nu = 0.21 Ra^{0.29}$ for temperature differences between permafrost and ambient air temperature exceeding 14°C (25°F). In another 3 m (10 ft) pile, ice formation rates were measured under simulated summer conditions. It was found that a maximum ice thickness of 3.8 cm (1.5 in) is obtained and that the rate of formation is very slow for aboveground heights of about 2 m (7 ft) or more. Although the air is conceptually stagnant during summer, air movement was detected in the device for surface winds exceeding 2.0 m/s (4.5 mph) for the 3 m (10 ft) pile and 4.5 m/s (10 mph) for the 6 m (20 ft) pile.

INTRODUCTION

Thermal protection of permafrost is a well-recognized concern whenever construction of any type is contemplated in arctic and subarctic regions. The removal of naturally insulating vegetation can cause increased melt depths for permafrost in the summer and possible lack of refreezing in the winter. This potential problem was identified early in the planning for the Trans-Alaska Pipeline and a vigorous program was undertaken to find the most effective permafrost protection device (Jahns et al, 1973).

There are two obvious means of protecting permafrost in pipeline projects. These both involve active refrigeration. One method is to cool the fluid before it is pumped into the pipeline and the other method is to refrigerate the outside of the pipeline along its entire passage through permafrost. The first method is feasible for a gas but not a liquid since fluid friction is much higher with the liquid pipeline necessitating periodic and large amounts of cooling along the pipeline route. Refrigerating the pipeline wall is possible with both liquid and gas pipelines, but is extremely costly. This technique was used in the Trans-Alaska Pipeline in sections where pipeline elevation above the permafrost was not possible.

Elevating and insulating a pipeline removes most of the direct heating problem but not the indirect effect caused by the removal of vegetation during construction. This problem also arises whenever buildings, highways, or any other

type of construction is attempted in permafrost regions. One method of protecting the permafrost is to install passive devices in the permafrost that will transport heat out of the permafrost in winter, when the permafrost temperature exceeds ambient temperature, to refreeze and possibly subfreeze the permafrost. These devices should cease operation in the summer when the permafrost is colder than ambient air. These devices can operate through transport of a gas, a liquid, or liquid and vapor through a phase change (heat pipes). Several different devices of all three types were tested by Galate, et al (1973) to determine overall heat removal rates. The type of device ultimately selected for the pipeline was a heat pipe although it was among the most costly devices. An air device, commonly known as the air convection pile, was not chosen for the Trans-Alaska Pipeline because of the lack of a detailed understanding of its performance and because of concerns about possible summer problems. Although the heat pipe had higher heat removal rates in the laboratory tests, Galate (1975) showed that both devices exceeded a minimum heat removal rate set by computer simulations for installations in permafrost. Because the air convection pile is so inexpensive compared to heat pipes (about one-tenth the cost) and because it has a potential of a longer service life, research has continued on the performance and characteristics of the air convection pile.

The air convection pile is an open system, tube-in-tube device that is installed in permafrost at depths of 3 - 18 m (10 - 60 ft). As

shown in Figure 1, an aboveground head section keeps precipitation out of the pile and allows passage of ambient air through the pile where, in winter, the warmer permafrost heats the air in the annulus causing air to enter the tube, pass down to the bottom, rise up the annulus, and exit back to the environment. The outer tube is typically 0.46 m (18 in) diameter and can be made of heavy gauge steel if the pile is to support an above ground load. The inner tube is typically a thin gauge material, 0.25 m (10 in) in diameter, and extends nearly to the bottom of the pile leaving only 0.15 m (6 in) of clearance. A support arm can be attached to the aboveground section if a load is to be supported as in an elevated pipeline.

FIGURE 1 The air convection pile.

Even though the construction of the air convection pile is very simple, the heat and mass transfer mechanisms are actually very complicated. Although the driving force is natural convection, there is unequal heating of the annulus because of radiation heat transfer from the outer pile to the inner tube which provides heat for both the tube and the annulus. Also the tube flow acts as a drag on the annular flow and there are entrance effects in both the tube and annulus. The experiments by Galate (1975) were done in a heated calorimeter bath with a refrigerated chamber over the aboveground head and measured only the overall thermal performance in the device. No measurements were made of the velocity or temperature profiles in the device. An early mathematical model developed by Reid et al (1975) predicted temperature and velocity profiles as well as thermal performance based on assumed heat transfer modes in the tube and annulus. One objective of the study reported here was to perform detailed velocity and temperature measurements as well as measure overall performance to better understand the heat and mass transfer mechanisms and to develop correlations based on the observed mechanisms and data.

The concerns relative to the summer behavior of the air convection pile were that (1) because of the very low pressure drops through the pile, it might be susceptible to wind induced forced convection, and (2) moisture might enter the pile by diffusion and/or condensation, forming ice at the frost line, and possibly completely blocking the air flow through the pile in the following winter, when the air temperature falls below the permafrost temperature. Galate (1975) reported some observations of the first effect but provided no data as to a possible threshold velocity or magnitude of the effect. Additional objectives of the study reported here were to investigate possible ice formation and wind induced circulation during summer.

THERMAL PERFORMANCE

A full-scale prototype air convection pile was constructed and instrumented. Since the predominant driving force for the flow is the temperature difference between the permafrost and the ambient air, it was decided to simplify the apparatus by using ambient room air as the source and heating the outer pile wall. The difference in temperature level of the experiments relative to arctic conditions was correlated by the Rayleigh number as discussed below. A simulated below ground section was constructed of galvanized ducting, wrapped with copper tubing, and covered with insulation as shown in Figure 2. This section was built to be expandable and data were taken for both 3 m (10 ft) and 6 m (20 ft) depths. A hot water supply system which could control and measure the temperature and flow rate of the water was constructed. The inner tube and head assembly were also constructed from galvanized sheet and tubing.

FIGURE 2 Test configuration.

Details of the instrumentation and experimental method were reported previously by Evans and Reid (1982). Velocity and temperature profiles obtained by hot wire anemometer and thermocouple traverses were reported for the 3 m (10 ft) heated length in the same reference. The velocity measurements were complicated by the discovery of low-frequency turbulent flow (4-28 Hz). This required signal conditioning and linearization to obtain the true time average velocity at each point.

Velocity and temperature profiles were measured at three vertical positions in the pile. A typical velocity profile at the bottom of the tube is shown in Figure 3 along with the curve calculated for fully developed turbulent flow from Kays (1966). Profiles at upstream sections were

FIGURE 3 Velocity profile in the tube.

somewhat different, showing the flow progressing to a fully developed state. Figure 4 shows a measured profile at the top of the annulus along with calculated curves for fully developed laminar and turbulent flow in an annulus from Knudsen and Katz (1958). It can be seen that the profile resembles neither laminar or turbulent flow. At lower (upstream) locations, the profiles were basically of the same shape. Typical dimensionless temperature profiles are given in Figure 5.

FIGURE 4 Velocity profile in the annulus.

The dimensionless temperature, θ , is defined as

$$\theta = \frac{T - T_1}{T_w - T_1}$$

where T_1 = ambient air temperature and T_w = outer pile wall temperature. The dimensionless radial

position Y is defined such that $Y = 0$ is the outer pile wall and $Y = 1.0$ is the centerline of the pile. (The tube wall is located at $Y \approx 0.44$.)

FIGURE 5 Temperature Profiles

The shape of the velocity profile in Figure 4 does not resemble fully developed turbulent flow because of the unequal heating from the walls and the strong coupling of the momentum and energy equation through the buoyancy force. There are three distinct regions in each profile. From the tube wall, at $Y = 0.44$, is an inner boundary layer developing off the tube wall. From $Y = 0.4$ to 0.075 then is core type of flow in which the velocity increases linearly with Y . Finally for $Y < 0.075$ there is an outer boundary layer being generated off the outer pile wall at $Y = 0$. The maximum velocity occurs at $Y = 0.05$, 1.1 cm (0.45 in) from the outer wall. The profiles taken at the bottom to the pile showed this general profile is already almost fully developed only a short distance of the annulus. This is due to the high amplitude of the turbulence at this point generated by the turn of the flow at the bottom of the pile.

Average velocities in the tube and annulus as a function of temperature difference between the ambient and outer pile wall are shown in Figure 6. The overall heat removal rates are shown in Figure 7.

FIGURE 6 Average velocities in the Tube and Annulus.

The data for the 6 m (20 ft) below ground section were not reported in the previous reference, but the velocity and temperature profiles were similar in shape as for the 3 m (10 ft) section. The velocities and overall heat removal rates are also given in Figures 6 and 7, for the 6 m (20 ft) pile.

FIGURE 7 Overall heat removal rate for the air convection pile.

Since the measurements of air convection pile performance were made at a higher temperature level than occurs with permafrost, the ΔT between pile wall and inlet air temperature in the laboratory does not correspond directly with the ΔT that would be measured in a field application. The important parameter that governs the driving force for heat transfer is the Rayleigh number, defined as:

$$(Ra)_r = \frac{g\beta\Delta T r^3}{\alpha\nu}$$

where

- g = gravitational acceleration
- β = volume coefficient of expansion
- ΔT = temperature difference between inlet air and outer pile wall
- r = radius of the pile
- α = thermal diffusivity
- ν = kinematic viscosity.

The relationship between the Rayleigh number and arctic ΔT assuming a permafrost temperature of 0°C (32°F) is shown in Figure 8. The results for the heat transfer rate can also be expressed in a dimensionless form by the Nusselt number, which is defined as:

$$(Nu)_r = \frac{Qr}{A\Delta Tk}$$

where

- Q = heat transfer rate
- A = heated area of the pile (outside wall + bottom)
- k = thermal conductivity.

FIGURE 8 Relationship between Rayleigh number and arctic ΔT .

The plot of $(Nu)_r$ versus $(Ra)_r$ for the results of these experiments and the results of Galate et al. (1973) are shown in Figure 9. All the results fall on the same curve since the pile is equally effective per unit length for any total length of pile. For the same ΔT , the total heat transfer will be twice as great for a pile of twice the length because of the heated area factor in the Nusselt number as shown above. Above a Rayleigh number of about 2.5×10^7 ($\log (Ra)_r = 7.4$, arctic $\Delta T = 14^\circ\text{C}$ (25°F)), the curve is approximately a straight line which is determined by the equation:

$$(Nu)_r = 0.21 (Ra)_r^{0.29} \tag{1}$$

The results for Q predicted from equation (1) and shown in Figure 9 are about 10% lower than given by Galate (1976) for a 3 m (10 ft) air convection pile. As shown in the same reference, the air convection pile has a heat removal rate about 30% lower than that attained by heat pipes. However, as discussed earlier, both types of device exceed a minimum required for permafrost installation. This is because the heat transfer to the permafrost is governed by a series of thermal resistances which include the thermal resistance in the soil and the thermal resistance from the pile to the ambient air. The latter resistance is zero for the air convection pile but not zero for heat pipes. Also the thermal resistance in the soil is large and may dominate the other resistances. The important result is

that the less expensive air convection pile provides adequate thermal protection of the permafrost.

FIGURE 9 Nusselt number versus Rayleigh number.

FROST AND ICE FORMATION

As discussed earlier, one concern about the air convection pile was that ice might form on the walls of the pile during summer. It was postulated that the ice could bridge the annulus of the pile and prevent or delay the start up of the pile the next winter. Therefore, a study was undertaken to determine the degree of frost and ice formation in the annulus of the pile under arctic conditions and to obtain a method or methods to reduce or stop the ice formation.

To determine the effects and the amounts of ice formation another 3.05 m (10 ft) model of an air convection pile and a simple environmental chamber were constructed as described by Reid et al (1982). The pile wall was refrigerated and the environmental chamber temperature controlled to simulate actual arctic conditions.

During a test the following parameters were monitored and recorded: pile wall and inner tube temperature, chamber humidity and temperature, ice thickness, volume and final mass, and the annulus concentration gradient. The ice thickness was measured by a profilometer riding on a track attached to the tube wall. From the profiles, the ice volumes were determined by integrating the cross section and revolving it about an axis. The final ice mass was found by letting the ice melt at the end of a test and weighing the resulting water. The chamber humidity and the annulus concentration gradient were determined using an hygrometer system which gave a reading in percent relative humidity. The percent relative humidity was converted to absolute humidity ratio using the dry bulb temperature and psychrometric chart.

Detailed results from this study were given in the paper by Reid et al (1982). Two important observations can be made from the results. First, the rate of ice formation is relatively insensitive to ambient humidity, but is very

sensitive to the length of air convection pile above the ground surface. Vertical humidity traverses in the annulus showed a concentration gradient consistent with this observation since the diffusion path length is larger for longer unheated necks. The second observation is that the maximum ice thickness levels off at 3.8 cm (1.5 in) after 25-30 days. It was postulated that the maximum possible ice thickness is governed by a conduction, convection, and radiation heat transfer balance. That is, after the ice obtains a certain thickness no further increase in this thickness is possible at that point due to the surface temperatures not being low enough for any moisture to freeze to ice. The ice will continue to increase in thickness on levels where the thickness is less than the maximum possible ice thickness. This was verified by the data which showed that the ice volume was still increasing when the maximum ice thickness had leveled out. Another concern with ice formation is whether a partial blockage will prevent the pile from starting to operate during the following winter. A test designed for the thermal performance apparatus using an inflatable bag showed that partial blockage would not prevent winter operation. Approximate calculations have also shown that ice may sublimate out of the pile in 10 - 50 days during the winter depending on the amount of blockage.

The conclusion from this part of the study was that ice formation should not be a problem under stagnant air conditions since the maximum ice thickness will be 3.8 cm (1.5 in). However, added protection can be obtained by always using an aboveground height of at least 2.1 m (7 ft) which includes 1.4 m (4.5 ft) for the neck and 0.7 m (2.5 ft) for the inlet and outlet section.

EFFECT OF SUMMER WIND

As mentioned earlier, another concern during summer was that wind blowing across the pile head might cause circulation of ambient air through the device causing additional permafrost melting. The same experimental apparatus as was used for simulated winter performance testing was used for this study. However, the hot water supply was replaced by a chiller to cool the pile wall approximately 6.5 C (11.7 F) below the ambient temperature in the laboratory. A large air supply was constructed which included straightener tubes to provide a relatively uniform flow field. The wind speed was slowly increased while the hot wire anemometer probes were being monitored and the wind speed was recorded at which flow just started in the air convection pile. This critical wind speed was 2.0 m/s (4.5 mph) for the 3 m (10.0 ft) pile and 4.5 m/s (10.0 mph) for the 6 m (20 ft) pile. The rate of heat transfer from the air to the pile wall was measured for the 10 ft pile at a wind speed of 4.5 m/s (10.0 mph). A mass flow rate of 0.0133 kg/s (1.75 pound mass/min) and a heat transfer rate of 9.6 W (32.9 BTU/hr) were measured. These measurements were not made for the 6 m (20 ft) pile because of the inadequacy of the chiller to cool the pile for the long period of time necessary to make the traverses.

The important observation in this section is that for piles of 6 m (20 ft) in depth, summer induced circulation may not be a problem since winds will seldom exceed 4.5 m/s (10 mph). It appears that this effect may be approximately linear such that piles of 12 m depth or greater may not be wind sensitive because winds above 9 m/s (20 mph) are rare in summer. Further data are needed, however, to fully define the effect of summer winds.

SUMMARY

Prototype 3 m (10 ft) and 6 m (20 ft) air convection piles were constructed and performance was measured as a function of Rayleigh number. These results are given in Figure 9 and equation (1) with the relationship between Rayleigh number and arctic ΔT shown in Figure 8. Measured velocity profiles showed turbulent flow in both the tube and annulus.

An additional 3 m (10 ft) prototype pile was placed in an environmental chamber simulating summer conditions and the rate of ice formation monitored as a function of chamber humidity and uncooled neck length (height that protrudes above ground). It was found that the maximum ice thickness in the 10 cm (4 in) annulus would be 3.8 cm (1.5 in). The rate of ice formation was only weakly dependent on chamber humidity but decreased greatly as the uncooled neck length was increased such that very low rates were obtained if the height above ground surface was 2.1 m (7 ft).

The pile was shown to be wind sensitive under summer conditions but this effect was very dependent on below ground length. Since flow did not start until the wind velocity equaled 4.5 m/s (10 mph) in the 6 m (20 ft) pile, wind sensitivity may be negligible for longer piles.

SOME EXPERIMENTAL RESULTS ON SNOW COMPACTION

Eugenio Retamal

Geotechnical Division, Institute of Research
& Testing Materials (IDIEM), Universidad de
Chile, Plaza Ercilla 883, Santiago, Chile

This paper presents the results of snow field compaction at snow temperatures near 0°C and some stress-strain properties obtained from rigid plate load and unconfined compression tests. The data and results of some load tests performed at outer Antarctica are also presented.

INTRODUCTION

In the most southern part of continental Chile (lat. 45°-55°S) and in areas sufficiently separated from the sea, there are large areas covered with snow almost all year round with ambient temperatures characteristically fluctuating between -10° and +5°C. These temperatures gradually diminish toward the inner part of the southern cone of South America and also toward the south. The systematic diminution of temperature means that at the Shetland Islands the average annual isotherm is -2°C and at Margarita Bay (lat. 68°10'S, long. 67°05'W) it is -6°C. During summer the isotherm at the Shetland Islands is 1°C, at Margarita Bay it is 0°C, and in winter it is -7° and -14°C, respectively. Toward the inner part of the Antarctic continent, temperatures constantly diminish, and they change abruptly when the coastal areas are left behind.

Therefore human activities in these areas require aerial transportation, and consequently, there is need of methods to increase the bearing capacity of snow and of working techniques for the construction of airfields on deep to not very thick snow. Of special interest is the case of snow temperatures near 0°C since there are very few experimental data dealing with snow in the temperature range -5°C to the melting point, which is of importance for Chile.

This paper adds data obtained from field compaction of snow in the vicinities of the Lonquimay Vulcan in a test field located at 1,400 m above sea level and data for tests performed at the Collins Glacier, King George Island (Shetland Islands).

TESTS AT LONQUIMAY

The Lonquimay Vulcan, 2,860 m high, is located in the southern Andes Mountains (lat. 38°26'S, long. 71°14'W). An area was selected near its south slope and 1,400 m high because of temperature similarities with the Antarctic Peninsula.

Two types of test fields were constructed using a Bomag BW 75 S, two steel wheel roller with a gross weight of 928 kg. The first type of test field was built by just passing the roller without vibration over the existing natural snow, which had a total thickness of about 80 cm. For the first five passes the roller was assisted by a

system of cables and winches and by a thin rubber carpet 10 m by 1.2 m put over the snow surface. From the fifth pass the roller was able to operate in a self moving way with or without the rubber carpet and without assistance from the cable-winch system. In Figure 1 is presented the experimental curve of the variation of unit weight of snow of the upper part versus the number of passes.

A second type of test field was built using an excavation of about 8 m by 1.5 m in plan area and filling it, from the hard soil surface, with compacted snow. For this purpose the first layer of loose snow was put over the existing soil with a loose thickness of about 20 cm and then compacted using the roller, which passed over the rubber carpet during the first 4-5 passes. In this way a test field 8 m long by 1.2-1.5 m wide with a total height of about 80 cm was built. On the surface of the test field several vertical load tests were performed using a 30 cm diameter rigid load plate. The results of a typical test are presented in Figure 2. In Figure 3 is shown the variation of the tangent deformation modulus E vs. time (Tangent modulus is obtained from the straight parts of the curves of Figure 2 which have similar slopes). To obtain the value of E the classical equation was used:

$$E = \frac{q_s B (1 - \mu^2)}{\rho} I_\rho$$

where

- q_s = total intensity of contact pressure
- B = diameter, 30 cm
- μ = Poisson's ratio; 0.35 considered for this case
- I_ρ = influence factor, $\pi/4$
- ρ = measured settlement

In Figure 4 the results of unconfined compression tests are shown. The tests were performed with samples taken from the test field and with different degrees of compaction.

TESTS AT COLLINS GLACIER

Collins Glacier is located at King George Island. Tests were performed during winter over a multilayer system of metamorphic snow and ice.

Vertical rigid plate load tests were performed at different bottom levels of two pits during their excavation. These pits were also used for getting the stratigraphy of the snow-ice system shown in Table 1.

TABLE 1 Stratigraphy of the Pits.

PIT	DEPTH (cm)	DESCRIPTION
1	0-33	Loose snow
	33-36	Ice
	36-170	Intercalated thin layers (1-5 cm) of medium to hard snow and ice layers
2	0-37	Loose snow
	37-47	Medium to hard snow
	47-52	Hard ice
	52-85	Medium snow
	85-90	Ice
	90-93	Loose snow
	93-95	Ice
	95-105	Loose to medium snow
	105-108	Ice
	108-127	Medium snow
	127-185	Ice

In Figure 5 are shown the results of a vertical load test performed at a depth of 33 cm in Pit 1. In Figure 6 can be seen the variation of the deformation modulus E , obtained as a secant modulus between the origin and a settlement of 0.1 and 0.2 cm, versus time. In Figure 7 are presented the data of a load test at a depth of 40 cm in Pit 2. In Figure 8 is shown the variation of E versus time if E is obtained as a secant modulus in the curves of Figure 7, and in Figure 9 the variation of the modulus of deformation if E is obtained as a tangent modulus for large settlements from the same curves. Finally in Figure 10 is presented the variation of E in a deeper load test performed in Pit 2 if E is obtained as a tangent modulus for large settlements.

COMMENTS AND CONCLUSIONS

It can be seen that snow, under the conditions described, can be compacted using light equipment and that with 5-10 passes of the roller used it is possible to get a unit weight of about $6.5-7 \text{ kN/m}^3$. Probably with heavy equipment, such as a heavy rubber-tired roller, the results would be better.

The influence depth of compaction for the roller used was between 15 and 20 cm. Vibrations were not useful for compacting snow.

The values of E are highly contaminated with creep, which is a very important factor in snow and ice behavior under load. As a consequence, the load speed is of great

importance.

Experimental work at Collins Glacier shows that under a first layer of loose snow of about 35-40 cm, at the time and under the conditions of the field tests, there is a multilayer system of ice and snow and its deformation modulus E , also affected by considerable creep, is comparable to the same modulus as that of a soft to hard clay, depending on time. This level could be a relatively good subbase for upper layers of compacted snow for skiways and probably as a runway for emergencies or restricted use. It is convenient to point out that the temperature of deeper layers of the glacier tend to diminish, and consequently their engineering properties tend to improve.

From the load tests at Collins Glacier and also from the same tests on compacted snow it seems that the applied pressure-settlement behavior could be represented by a bilinear system with E_{sec} and E_{tg} approximately independent of time at least for $t < 10-15$ min according to Figure 11. In this figure, q_L would vary with time. If it is supposed that for landings $t = 0$, the deformation would be defined for E_{sec} , E_{tg} , and q_L .

POWER LINES IN THE ARCTIC AND SUBARCTIC -- EXPERIENCE IN ALASKA

Robert W. Retherford

International Engineering Company, Inc., 813 D Street, Anchorage, Alaska 99502 USA

There is a substantial background of experience on the design, construction, and operation of power lines on and in the frozen earth of Alaska. This paper contains a digest of mostly successful examples of Alaska power line elements operating with the frozen earth. The paper considers footings, anchors, structures, conductor and electric grounding. Examples are taken from operating power systems which serve the small village (50 consumers); the large urban/rural community (50,000 consumers); and a number of federal, state and industry installations.

INTRODUCTION

Ice, snow, wind, heat and cold make and remake the frozen earth of the world's northern latitudes. Much of Alaska is in this region so its residents must deal with those changing elements (Eaton et al 1975). Power line construction and operation has grown with Alaska's development and gained experience in living with this environment.

Long-term weather records do not exist in most of Alaska. Experience has also shown that climates may differ drastically with small changes in location and elevation. Skill in reading the evidence of nature is then important in decision-making which may radically alter the feasibility of projects.

Differences in the weather criteria chosen for the design of electric lines listed herein arise partly from the subjectivity that results from these conditions. Other differences in the terrain, flora and fauna of a line location provide the challenge that encourages innovative solutions to match the variety of Alaska's earth and sea.

The overload capacity design factors chosen to assure reliability in a power line are influenced by the value of the affected product or service. For example: Loss of power to the Prudhoe Bay oil fields could shut down a cash flow of \$2 million/hr. while the loss of hydroelectric power to a typical community of Southeast Alaska might require replacement by using diesel fuel costing about \$1,000/hr.

The experience described is with power lines in Alaska, although not all are located within a strict permafrost regime. Examples are included for footings, anchors, structures, conductors, and grounding.

ALASKA POWER LINES

The key map (Figure 3) shows the approximate location of a selected group of power lines. Table 1 lists the lines, general data, and a key indicator pointing to specific experience described in more detail in the text.

SPECIFIC EXPERIENCE ITEMS

Footings

Many conventional footing designs are in use on the power lines of Alaska, such as grillages, concrete, and tamped earth where the soil conditions allow. In permafrost regions there are often stable soils where these designs are acceptable. Examples of designs used where the freeze-thaw cycle operates in unstable soil are illustrated by a photo or drawing and/or text in this section.

(1) Gravel backfill for wood-pole installations has been used successfully. Using local soil instead has produced severe frost-jacking in many installations. Figure 1 shows a typical gravel backfill construction unit, which has been used on Lines 4, 12, and 14.

(2) A bogshoe composed of a crosslog and outriggers to stabilize pole structures in muskeg has been used with limited success. The shoe works, but if frost jacking takes place on the pole, the whole assembly will tip with the prevailing winds. The design, shown in Figure 2, is used on line 3.

(3) Use of piling to reinforce poles or provide suitable pole stubs has a successful history. Figure 4 shows a typical installation for an H-frame wood pole line. These units have been used on lines 3, 4, and 5. Single and multiple steel H-pile have been used successfully for metal tower footings in muskeg and permafrost soils on lines 8, 11, 13 and for anchors on line 16 (Proctor and Meyers 1978).

- 3/ 2.54 cm. radial ice + 0.192 KPa of wind at -18°C
- 4/ Additional criteria also used for design in specific locations or for extreme conditions.

* Refer to numbered paragraphs in text.

FIGURE 4 Reinforcing piling on wood poles ice encrusted tide flat

(4) A three-legged bogshoe (tripod) with a sliding necklace around the pole is in use on lines where severe frost action causes differential movement of pole and bogshoe (Figure 5).

(5) A sand-water slurry has been successful as backfill in regions of cold (-12°C) permafrost. The slurry is prepared and delivered unfrozen to each pole site where it is poured into the pole holes of the temporarily supported structure and allowed to freeze.

Line 10 used this backfill.

(6) Extra depth of setting for poles installed in permafrost has worked well in many installations. A rule, referred to as the "... old Tsytoovich rule..." (Sanger 1969), says that embedment in permafrost should be twice the thickness of the active (freeze-thaw) zone. With this guideline, extra depth has been used successfully with and without gravel backfill (see (1) above). Lines 10, 12, and 14 use extra-depth.

FIGURE 5 Tripod bogshoe with sliding necklace

(7) Pole bearing plates attached to poles or pole stubs (Figure 6) are being utilized in some installations in permafrost. Experience has been mixed with such devices (Sanger 1969). New efforts are reported, where the strength of the installation is increased by attaching plates to poles using spiked grid fasteners.

(8) A plastic boot for poles or pole stubs has been used in a few installations with mixed results. The purpose is to reduce the friction at the interface between the active layer and the pole or stub. This boot is installed on line 7 (Breckenfelder and Osborn 1965). See Figure 7.

(9) Soil stabilization using "self-powered" heat transfer devices to remove heat from soil is believed to have been started in Alaska in the 1950s by two individuals on separate tracks, a Salcha River homesteader named J. C. Balch, and an engineer named E. L. Long. The Balch tube (a liquid convection system), the Long pile (a liquid/

FIGURE 6 Pole bearing plates for foundation stabilization

FIGURE 7 Pile boot for wood pole stub stabilization

vapor convection system) and subsequent "frost tubes" have been applied to Alaska power line footings with success since that time. Three commercial products used today with power lines in Alaska are those manufactured by Arctic Foundations, Inc. of Anchorage, AK, Thermodynamics, Inc. of Seattle, WA and McDonnell-Douglas Astronautics Company in Richland, WA. A sketch of a typical installation is included as Figure 8. Line 14 uses some of these devices.

(10) A screw anchor footing has been used with varied results for aluminum towers on line 7 (Breckenfelder and Osborn 1965). Figure 9 is a sketch of the footing, and Figure 10 shows a footing which failed when one anchor jacked more than another. Other footings in this design continue to be successful.

(11) A concrete pad resting on a gravel pad on unstable ground has been successful in providing a stable footing for guyed metal towers. Figure 11 shows such a unit replacing a former failed screw anchor footing on line 7.

FIGURE 8 Cryo anchor for power pole stabilization

FIGURE 9 Tripod screw anchor tower footing

Structures

Conventional structures as known from standard practice in other areas such as single wood poles (lines 2, 3, 4, 5, 6, 12, and 14), guyed-Y (line 9), and four-legged self-supporting galvanized steel (lines 2, 3, 7, and 9) have been used for Alaska power lines. Rugged terrain, weather related phenomena, and effects of operating in permafrost soils have spawned innovative designs. One of the oldest power lines in Alaska (line 1) has experienced a broad range of these conditions. The perseverance of the operators of the line has generated numerous innovations (see Conductor) in their continuing efforts to maintain the line and adapt it to the environment (Wallenburg 1915, and Baum 1916). Severe wind, snow, and ice on high, steep slopes and ridges resulted in relocation of sections of line 1 and 9 to better sites. Some other unusual designs are described as follows:

(15) A few of the original steel towers of line 1 were subjected to creeping snow fields and severe unbalanced loading from broken conductors under heavy ice loads. Successful repair and preventive maintenance was accomplished by using timber splints to protect and reinforce the steel legs.

FIGURE 13 X-braced 4 pole wood structure

(16) A four-legged, X-braced wood pole structure was used on line 1 to resist the snow creep and high winds at other locations (Figure 13).

(17) Following the 1964 earthquake, emergency replacement of failed power line structures was made using a gravity-stabilized tripod arrangement (line 3). This structure was later used on a new line in a muskeg swamp (line 5). See Figure 14.

(18) Strong winds moving up slope across a power line near Kodiak (line 6) lifted the conductor to make contact with its supporting cross-arm. A strut insulator added prevents excessive swing.

(19) The four-way guyed-Y tower of line 7 was installed in many locations

FIGURE 14 115 kV tripod gravity stabilized structure

FIGURE 10 Screw anchor tower footing

FIGURE 11 Concrete pad on gravel

Anchors

Many conventional soil anchors used as standard practice in other areas are installed on power lines in Alaska. Examples include expanding anchors, cone anchors, plate anchors, and log anchors. As with footings, stable soil allows these practices even in permafrost regions. With unstable soils and permafrost some examples of successful anchoring techniques are described as follows:

(12) Prior to the advent of the power installed screw anchors a low grade concrete (or soil cement) backfill used to encase a conventional anchor (log, plate, etc.) placed in a watery, muskeg bog would give excellent results. The weight of approximately 1.2 to 2.4 m³ of concrete and its ability to flow into the weave of fibre, muck and water and then set up has developed 5.5 to 11 tons of working strength. A number of these anchors on line 3 have survived the great Alaska earthquake of 1964.

(13) The power installed screw anchor has been used with success in muskeg and a variety of permafrost. It is believed that the screw anchor has first been tested and used in dense till on line 7 in 1965 (King and Crory 1965). Other installations followed as more powerful drilling motors became available (Retherford and King 1970). Anchors of this type are in use on lines 7, 8, 11, 12, 13, 14, and 17 (see Figure 12).

(14) Some permafrost soils are so hard that techniques for placing anchors include predrilling of a reduced size hole into which a screw anchor is installed. Line 12 has such anchors.

FIGURE 12 Screw anchor reinforced helix for glacial till

FIGURE 15 Guy safety link

where the frost conditions could produce different movements of tower footings and guys (Figures 9 and 10). A guy safety link was provided to allow a measured amount of slack to be added to a guy upon failure of a shear pin (Breckenfelder and Osborn 1965). See Figure 15.

(20) A guyed, hinged X-shaped metal tower design (Figure 16) was developed to provide a flexible structure tolerant of differential movements of tower footings and guy anchors. The guy yoke system allows unbalanced forces to distribute smoothly through the tower structural system with yoke failure prior to tower damage. Aluminum lattice and steel tube configurations have been used on lines 8, 11, 13, 16, and 17 (Rankin and Retherford 1967, LaRue and Retherford 1977).

(21) A guyed, hinged pi-shaped metal tower design using a guy yoke system similar to the X-tower described in (20) above is being used on lines with extremely long spans in the rugged fjords of southeastern Alaska. (Steeby et al 1979).

(22) A gravity stabilized A-frame structure was developed for use on roadless terrain and permafrost lands. It is part of a single wire electric power delivery system to minimize costs of electric lines in remote areas (Bettine and Retherford 1981, Retherford et al 1982). See Figure 17.

FIGURE 16 Guyed and hinged X-tower tubular steel

Conductor

A few unique experiences with power conductors in Alaska are described.

(23) Very heavy icing of the power conductors at high elevations (1000 m) on line 1 resulted in the installation of copper clad steel conductors with relatively high resistance so that electric current could heat the conductor and prevent the formation of ice (Baum 1916). This successful solution is produced by controlling the reactive current exchange between ends of the line. See Figure 18.

(24) A wooden ground-lay utilidor enclosing primary, secondary, and grounding conductors has been in use since 1971 on line 18 with unsatisfactory performance. This duct originally replaced cables plowed into the ground, which were destroyed the action of the seasonal frost. Such a duct lying on the earth is difficult to protect from damage. A steel ground-lay utilidor replacing the wooden one has been under test since 1978 with improved results.

FIGURE 17 Gravity stabilized A-frame

Grounding

Grounding of electric systems in Alaska is accomplished

- as in other areas - through earth electrodes which are designed for the soil resistivity found. Large regions of Alaska have permanently frozen soils with a very high resistivity. One such area is Prudhoe Bay (line 10), and it has been given special attention by the operator - Sohio Alaska Petroleum Co. Another special situation is that of the single wire ground return electric transmission system now being demonstrated (Retherford et al 1982, Eaton 1974 and 1975). The following paragraphs describe some specific experiences regarding grounding:

(26) The 69 kV transmission system at Prudhoe Bay carries a neutral (ground wire) under the phase conductors and a phase wire "catcher" on

FIGURE 18 Heated conductor required

each structure to provide support and grounding should phase conductors come loose from insulators (line 10 Figure 25). The underrunning ground conductor provides for faster, surer relaying and added safeguards against accidental contact of phase conductors.

(27) The single wire ground return transmission line, in operation between Bethel and Napakiak, Alaska since 1980 (line 15) has primary earth connections at each end. At Bethel an abandoned steel well casing about 60 m deep extending through permafrost into other layers of soil provides a resistance of about 3.6 ohms. The electrode system at Napakiak consists of eight ground rods about 10 m long and 10 m apart connected by a 107 mm² bare copper wire in a trench about 0.6 m deep and provides a resistance of about 2.9 ohms. This ground grid is installed in a thaw bulb near the Kuskokwim River. Eaton (1975) suggests that if a hemispheric contact zone between a thaw bulb and permafrost is assumed, resistance (R) of the thaw bulb/permafrost contact can be estimated as follows:

$$R = p/2 \pi r$$

where

p = resistivity of the permafrost

r = radius of the hemisphere

Identification of thawed zones within permafrost by electro-magnetic techniques was suggested and demonstrated on line 15 by D. Gropp (Gropp 1977). This method makes a rapid location of suitable thaw bulbs for further investigation as potential grounding electrodes in permafrost zones possible.

THE ROLE OF SPECIFIC SURFACE AREA AND RELATED INDEX PROPERTIES
IN THE FROST HEAVE SUSCEPTIBILITY OF SOILS

Ross D. Rieke¹, Ted S. Vinson², and Daniel W. Mageau³

¹Hart-Crowser & Associates, Inc., Seattle, WA 98102 USA

²Dept. of Civil Engineering, Oregon State University, Corvallis, OR 97331 USA

³R and M Consultants, Inc., Fairbanks, AK 99701 USA

Soil properties important to the frost heave phenomenon must be identified to establish which index property tests can aid in evaluating frost heave susceptibility. Following a consideration of existing frost heave theories, the frost heave mechanism was identified as being fundamentally related to the specific surface area of the soil. Specific surface area may be related to index property test results, specifically, the liquid limit and the clay mineralogy of the fine fraction. Laboratory frost heave tests were performed to develop relationships between index properties and frost heave susceptibility. Tests were performed on soil mixtures consisting of uniform sand with 5%, 10%, and 20% fines of different mineralogic composition, representing a range of specific surface areas. Over 30 frost heave tests were conducted on 11 distinct soil mixtures. The frost heave test consisted of freezing a soil column and noting the intake of water into the specimen as well as the frost heave. Using the concept of segregation potential, the frost heave susceptibility of a soil was found to increase with increasing percentages of fines, decreasing activity of the fine fraction, and, for a specific fine fraction mineralogy, increasing liquid limit of the fine fraction.

INTRODUCTION

Throughout the history of the development of frost heave theories, the specific surface area has been identified, either directly or indirectly, as a soil property important to the frost heave mechanism. Taber (1930) noted the importance of the size and shape of the soil particle to frost heave. Beskow (1935) noted Taber's theories and further considered the importance of the adsorbed layer of water on the surface of the soil particle. Using relationships between grain size, adsorbed water, and frost heave, Beskow developed one of the first frost heave susceptibility criteria.

Modern researchers have continued to note the specific surface area as a fundamental soil property in the frost heave mechanism. The models presented by Miller (1972, 1978) and Takagi (1980) indirectly identify the surface area characteristics of a soil as playing an important role in frost heave behavior. They suggested that water flowing to a forming ice lens must pass through a "frozen fringe" or "zone of diffused freezing," where free pore water is frozen. These concepts, along with present theories regarding flow through frozen soil (Hoekstra and Miller 1967), suggest that specific surface area is indeed important in the frost heave mechanism. Konrad and Morgenstern (1980, 1981) further suggest the importance of the frozen fringe. They found that the permeability of the frozen fringe was a controlling factor in the frost heave response of soils. Since Hoekstra and Miller (1967) suggest that the ease with which water migrates through frozen soil is related to the continuity of adsorbed water layers on the soil particle surfaces, Konrad and Morgenstern's theory indirectly notes the influence of specific

surface area on the frost heave mechanism.

The relationships between specific surface area and index property tests are well known. By considering the fundamental nature of the Atterberg Limits (ASTM 423-66 and D424-59) and soil grain size distributions (ASTM D4422-63), the significance of the specific surface area to these index properties may be demonstrated. Specifically, Graboska-Olszewska (1970) concluded that the liquid limit of a soil (ASTM 423-66) is intimately related to its specific surface area. The relationship of grain size distributions to specific surface area may be inferred by noting the relationship of surface area to soil particle size and assumed particle shape.

In an attempt to better define the role of specific surface area and related index properties to the frost heave susceptibility of soils, a laboratory testing program was undertaken. The frost heave response of several soil mixtures representing a range of specific surface areas was determined in a frost heave test cell. Relationships between frost heave susceptibility, specific surface area, and Atterberg Limits were derived for the soils considered in the study. The results of the study are presented herein.

DESCRIPTION OF TEST SYSTEM AND PROCEDURES

The frost heave test consisted of freezing a soil specimen and noting the intake of water into the specimen as well as the change in vertical height. No attempt was made to duplicate field conditions in the laboratory test program. Although it is desirable to apply the results of this and other laboratory investigations to actual field situations, only relative frost heave sus-

ceptibilities, as measured in the laboratory, were determined. The frost heave tests were performed under "worst case" conditions to minimize the influence of variables other than specific surface area. To achieve conditions that were most conducive to frost heaving, the specimen was saturated and the free water surface was maintained at approximately the same level as the frost front.

The soils used in the laboratory study consisted of an extremely uniform fine sand (Astoria Sand), Hanover Silt with the plus No. 200 sieve (0.74 mm) sizes removed, and relatively pure kaolinite and montmorillonite. The D_{10} of the Astoria sand was .14 mm with a C_u of 1.4. The D_{10} of the silt was .006 mm with a C_u of 3.8. Kaolinite and montmorillonite were obtained from the Clay Mineral Society of America (CMSA), Columbia, Missouri. The specific surface areas for the kaolinite and montmorillonite were provided by the CMSA. The specific surface area of Hanover Silt was determined by considering its grain size distribution and employing specific surface area calculation procedures given by the Asphalt Institute (1979).

The frost heave cell used in this investigation is an adaptation of the cell described by Mageau (1978). The frost heave cell consists of a 30.5 cm (12.0 in.) long by 10.2 cm (4.0 in.) I.D., by 15.2 cm (6.0 in.) O.D. nylon barrel. The specimen is placed inside the cell and an aluminum top cap and bottom plate serve as constant temperature boundaries. The temperatures of the top cap and bottom plate are maintained at constant values by circulating constant temperature fluids through heat exchange mazes within the cap and plate. To aid in the boundary temperature control and to prevent radial heat flow, the cell was placed in a refrigerator whose temperature was maintained at approximately 2°C (36°F). A 50 ml (7.75 in.³) buret was connected to the water intake line and the flow of water into or out of the specimen during a test was noted by the change in the water level in the buret. The change in the height (reflecting frost heave) of the specimen during the test was measured with a linear variable differential transformer (LVDT). The temperature along the length of the specimen was monitored with thermistors adjacent to the soil embedded in the wall of the frost heave cell barrel. Prior to freezing, the specimen was consolidated one-dimensionally under 50 kPa (7 psi) pressure and allowed to reach thermal equilibrium with the ambient refrigerator temperature.

INTERPRETATION OF FROST HEAVE TEST RESULTS

In conjunction with the development of a mechanistic frost heave theory, Konrad and Morgenstern (1980, 1981) presented a parameter referred to as the segregation potential (SP_o), which was defined as:

$$SP_o = \frac{V_o}{\text{grad } T} \quad (1)$$

in which,

SP_o = segregation potential

V_o = water intake flux

grad T = temperature gradient across the frozen fringe.

At near steady-state conditions (i.e., very small frost penetration rate) this parameter, as determined in a frost heave test, was found to be constant for a given soil when the suction at the frost front is small (i.e., a small depth of unfrozen soil).

Further, they developed a relationship between segregation potential and the permeability of the frozen fringe such that the frost heave characteristics of a soil can be related to its segregation potential as determined under controlled laboratory test conditions. Specifically, a high segregation potential implies a high frost susceptibility. To compare the frost heave susceptibilities of various soils one needs only to compare segregation potential values as determined in the laboratory. A detailed explanation of the determination of SP_o from laboratory results is given by Mageau and Sherman in this volume.

TEST PROGRAM AND RESULTS

A total of 31 frost heave tests were performed on various combinations of sand, silt, and different types of clay. Astoria sand was used in each test together with fine fractions consisting of various combinations of silt, montmorillonite, poorly crystallized kaolinite, and well-crystallized kaolinite. Mixtures containing 5%, 10%, and 20% fine material were considered. In mixtures with a specific percentage of fines, the composition of the fine fraction was varied by considering different combinations of silt, montmorillonite, and the two types of kaolinite. The specific surface areas for the soil mixtures were determined as the weighted summation of specific surface areas for the various soil types comprising the mixture.

The segregation potential was calculated for each frost heave test using the measured intake of water and the temperature gradient in the frozen fringe. Thermistors close to the estimated location of the frozen fringe were used to establish the temperature gradient (Rieke 1982). The results from Test 21 were chosen to illustrate typical results. Figures 1, 2, and 3 show the frost front penetration versus time, water intake and heave versus time, and temperature gradients, respectively, during Test 21.

Table 1 presents the results of the 31 frost heave tests and liquid limit tests performed on the various mixtures of fines. Figures 4 and 5 show a well-defined relationship between segregation potential (SP_o) and specific surface area. Liquid limit versus specific surface area relationships for the three types of clay-silt combinations are shown in Figure 6.

Frost heave and index property tests were also performed on a specimen of silty sand (SM) obtained from a site on the North Slope of Alaska to allow a preliminary comparison to be made between the artificially prepared laboratory materials used in this investigation and remolded natural soils. The results of the frost heave and index

DISCUSSION OF TEST RESULTS

Figures 4 and 5 show a strong correlation between segregation potential and specific surface area for soil mixtures with fine fractions consisting of montmorillonite-silt, poorly crystallized kaolinite-silt (PK), and well-crystallized kaolinite-silt (WK). A strong correlation between

FIGURE 4 Segregation potential versus specific surface area for montmorillonite mixtures.

FIGURE 5 Segregation potential versus specific surface area for kaolinite mixtures.

FIGURE 6 Liquid limit versus specific surface area.

FIGURE 7 Segregation potential versus liquid limit of fine fraction for all tests.

liquid limit of the fine fraction and the specific surface area of the fines is shown in Figure 6. From these relationships and the fact that the specific surface area of the specimen is strongly dependent upon the specific surface area of the fine fraction, it may be inferred that a fundamental relationship exists between the segregation potential and the liquid limit of the fine fraction for all of the soil mixtures considered.

Figure 7 shows the segregation potential versus the liquid limit of the fine fraction for montmorillonite-silt fines, poorly crystallized kaolinite-silt, and well-crystallized kaolinite-silt fines, respectively. The results presented indicate the percent fines has a much larger influence on the segregation potential than the liquid limit.

The results shown in Figure 7 also indicate that segregation potential is a function of the clay mineralogy of the fine fraction. It appears that mixtures with well-crystallized kaolinite exhibit greater segregation potentials than mix-

tures with montmorillonite. The segregation potential of mixtures with poorly crystallized kaolinite were intermediate to the other clay mineral mixtures.

These observations suggest that the frost heave susceptibility is dependent on the clay mineralogy of the soil. A convenient index property to identify the predominant clay mineral in a soil mass is the activity. The activity is classically defined as follows:

$$\text{Activity, } A = \frac{\text{Plasticity Index}}{\% \text{ by weight finer than } 2\mu} \quad (2)$$

(i.e. % clay sizes)

The definition of activity used in this investigation is different from that given in Eq. (2) in that the liquid limit is employed in the numerator in place of the plasticity index. Also, the activity is associated with the fine fraction only, rather than the entire sample. Thus,

$$\text{Liquid Limit Activity of the fine fraction, } A_{LL} = \frac{\text{LL of fine fraction, } L_{ff}}{\% \text{ clay sizes in fine fraction}} \quad (3)$$

Considering the relative values of A_{LL} for calcium montmorillonite, poorly crystallized kaolinite and well-crystallized kaolinite, it is suggested that as the activity of the clay mineral in the soil decreases, the segregation potential and, hence, frost heave susceptibility increases. This conclusion is consistent with observations made by Lambe et al. (1969), who found that clays with high activities, specifically Na-montmorillonite, decreased frost heave when added to frost susceptible materials.

Because the segregation potential is strongly influenced by the percentage of fines in the soil and the liquid limit activity of the clay minerals in the fine fraction it is possible to develop a general parameter that relates index test results to segregation potential values. It was noted that the segregation potential increased as the percentage of fines (% minus No. 200 sieve (0.74 mm) increased, that is:

$$SP_o \propto \% \text{ fines} \quad (4)$$

It was also noted that as the liquid limit activity of the fine fraction increased, the segregation potential decreased, that is:

$$SP_o \propto \frac{1}{A_{LL}} \quad (5)$$

Combining Eqs. (4) and (5):

$$SP_o \propto \frac{\% \text{ fines}}{A_{LL}} \quad (6a)$$

$$SP_o \propto \frac{\% \text{ fines}}{LL_{ff} / \% \text{ clay sizes in fine fraction}} \quad (6b)$$

$$SP_o \propto \frac{(\% \text{ fines})(\% \text{ clay sizes in fine fraction})}{LL_{ff}} \quad (6c)$$

Let us define the right side of Eq. (6c) as the fines factor, R_f , that is:

$$R_f = \frac{(\% \text{ fines})(\% \text{ clay sizes in fine fraction})}{LL_{ff}} \quad (7)$$

The fines factor was calculated for each test and the results are presented in Table 1. Figure 8 shows a strong correlation between R_f and segregation potential. Also included in Figure 8 are the results of a frost heave test and index property tests performed on the field sample. It is encouraging to find a good correlation between the segregation potential and R_f for the natural soil. Thus, for the soils considered in this investigation, the results from index property tests (sieve analysis, liquid limits, and hydrometer analysis) may be related to the segregation potential with a reasonable degree of confidence.

As it is presently defined, R_f is the result of observations of test data and the attempt to relate the results of the observations to a common parameter. Thus R_f is an empirical parameter.

FIGURE 8 Segregation potential versus fines factor, R_f .

Empirical relations are useful in that they can serve to give an estimate of a desired parameter. In this regard R_f may aid in the more complicated problem of identifying frost susceptible soils under field conditions. Another role that empirical parameters can fulfill is in contributing to the development of a more fundamental understanding of the phenomena with which they are associated. This role is possible only if one is familiar with the basic development of the empirical parameter. Following this philosophy, the fundamental soil properties that affect R_f may be analyzed with respect to improving our understanding of existing frost heave models.

In the model presented by Konrad and Morgenstern (1980), the amount of the unfrozen film water between the surface of a clay particle and the frozen pore water is directly related to the ease with which water flows through the frozen fringe. Since the permeability of the frozen fringe was identified as the critical factor influencing the segregation potential of saturated soils, the abundance of unfrozen film water has a direct bearing on the frost heave susceptibility of the soil. The test results indicate, however, that although montmorillonite has a higher unfrozen water content than kaolinite, kaolinite has consistently higher segregation potentials. This fact suggests that the permeability of the frozen fringe is not solely a function of the abundance of unfrozen film water. Specifically, the ease with which water migrates through the frozen fringe is related to the rigidity of the unfrozen water films. Noting that the rigidity of the adsorbed water layers in kaolinite is less than that of adsorbed layers in montmorillonite (Grim 1962), the permeability of the frozen fringe should be greater for kaolinite than for

montmorillonite.

R_f considers the effect of the unfrozen film water rigidity upon the segregation potential by noting that clays with low activities, such as kaolinite, have less rigid unfrozen water films and, hence, higher frozen fringe permeabilities and segregation potentials. Thus, assuming that the liquid limit activity of the fine fraction as defined in this investigation is an acceptable parameter to distinguish the rigidity of the unfrozen films, it can be seen that:

$$SP_o \propto \frac{1}{A_{LL}} \quad (8)$$

This is identical to Eq. (5) that was initially used to develop R_f .

The specific surface area of a soil may be considered to be a function of the amount and nature of the fines in the soil. This is reasonable since the fine fraction, owing to the small grain sizes, controls the specific surface area of the soil. More specifically, the extreme values of specific surface area for clay greatly influence the specific surface area of a soil mass. Therefore, it is reasonable to expect a relation between the amount of fines in the soil and the continuity of the unfrozen water films, hence, the permeability of the frozen fringe. Noting the influence of the frozen fringe permeability on the segregation potential, the relationship between the amount of fines in a soil and the segregation potential of the soil may be expressed approximately as:

$$SP_o \propto \% \text{ fines} \quad (9)$$

This relation is identical to that presented as Eq. (4) in the development of R_f .

SUMMARY AND CONCLUSIONS

Over 30 frost heave tests were conducted on 11 distinct soil mixtures. Using the concept of segregation potential, the frost heave susceptibility of a soil was found to increase with increasing percentages of fines, decreasing activity of the fine fraction, and for a specific fine fraction mineralogy, increasing liquid limit of the fine fraction. These relationships were summarized by introducing a term referred to as the fines factor, R_f , (re Eq. (7)). The fines factor allows index property test results to be related directly to the frost susceptibility of a soil, owing to the strong correlation found between segregation potential and the fines factor. Based on an analysis of the fines factor it may be demonstrated that the permeability of the frozen fringe and, hence, a soil's tendency to heave, are a function of not only specific surface area but also the mineralogy of the fine fraction. It is hypothesized that fine fractions with highly active clay minerals have less mobile unfrozen water films in the frozen fringe resulting in a reduced frozen fringe permeability.

ACKNOWLEDGMENT

The studies described herein were supported in part by the Department of Civil Engineering, Oregon State University. The support of the department is gratefully acknowledged. The efforts of Laurie Campbell and Nancy Platz, who assisted in the preparation of this paper, are greatly appreciated.

DETERMINATION OF THE THERMAL PROPERTIES OF FROZEN SOILS

D. W. Riseborough, M. W. Smith and D. H. Halliwell
Geotechnical Science Laboratories, Geography Department
Carleton University, Ottawa Canada K1S 5B6

This paper describes the development of a method for determining soil thermal properties (conductivity and diffusivity) at temperatures close to 0°C, based upon the transient heat flow from a cylindrical copper probe. A very small heat input and a very sensitive temperature measurement system allow the maximum temperature change in the soil sample to be kept to less than 0.1°C. The soil sample is first cooled to about -10°C, to ensure ice nucleation, and then determinations are done at closely spaced intervals on a warming curve. At each temperature, a least squares regression on the time-temperature data is used to determine the soil properties. The analytical solution is sensitive to both the soil conductivity and the apparent heat capacity; therefore the latter is also determined independently using the unfrozen water content curve obtained via time domain reflectometry. Results for two saturated silts are presented.

INTRODUCTION

In the temperature range just below 0°C, the thermal properties of soils containing water can change significantly with small changes in temperature. As the volume fractions of ice and water are temperature dependent, methods requiring prolonged and substantial heating of a soil sample cause a change in the properties being measured. Because of such limitations it has not been possible to reliably determine the thermal properties of soils in the temperature range 0°C to -2°C (e.g., Penner 1970). Unfortunately, for many practical studies of soil thermal regimes it is precisely this range of temperatures which is of concern. Kay et al. (1981) do present results for thermal conductivity, for one soil, at a temperature of -0.7°C.

This paper describes two stages of development of a technique, based on transient heat flow from a cylindrical probe, for the determination of the thermal properties of frozen soils (conductivity and diffusivity) in the temperature range 0°C to -2°C, as well as beyond this.

Typically, conductivity probes are designed on the basis of a theoretical heat flow model which assumes a line heat source, with heat capacity of zero and infinite thermal conductivity (see Farouki 1981). This approach requires that the sample be heated continuously, until a rate of temperature rise which is linear with the logarithm of time is attained. The slope of T versus log(t) is then used to determine the conductivity. In frozen soils close to 0°C, this procedure is not feasible, since the unfrozen water content of fine-grained soils changes rapidly with small changes in temperature. As water changes phase, latent heat of fusion is absorbed or released. The apparent heat capacity of the soil is a function of the rate at which the change of state occurs, and this rate is a function of temperature. Also, ice and water differ in thermal conductivity. Therefore, as the volume fractions of ice and water are temperature

dependent, the thermal properties of the soil mixture must change accordingly. Thus, any method requiring prolonged heating of a soil sample will cause a change in the properties being measured.

THE "CONDUCTIVITY" PROBE

The design of the probe is based on the analytical model of transient heat flow from a cylinder of infinite conductivity given by Jaeger (1956):

$$\Delta T = (Q/\lambda) \cdot G(\alpha, \tau) \quad (1)$$

where ΔT is the temperature change at the probe-soil interface and

$$G(\alpha, \tau) = (2\alpha^2/\pi^3) \cdot \int_0^\infty \frac{1 - \exp(-\tau u^2)}{u^3 \nabla(u)} du \quad (2)$$

where

$$\nabla(u) = (u \cdot J_0(u) + \alpha \cdot J_1(u))^2 + (u \cdot Y_0(u) + \alpha \cdot Y_1(u))^2 \quad (3)$$

and

$$\alpha = 2C/C_0, \quad \tau = \kappa t/a^2 \quad (4)$$

All symbols are defined in the notation list at the end of the paper. This formulation assumes perfect thermal contact between the probe and the soil. For a cooling period following a short pulse of heat, temperature change can be analyzed by the following:

$$G(\alpha, \tau) = (2\alpha^2/\pi^3). \quad (5)$$

$$\int_0^{\infty} \frac{\exp(-(\tau-\tau_0)u^2) - \exp(-\tau u^2)}{u^3 \tau(u)} du$$

for $\tau > \tau_0$, and where $\tau_0 = \kappa t_0/a^2$ is the length of the heating period. Both the pulse method (equation 5) and the continuous heating method (equation 2) have been tested in our experiments.

In the theory for the standard needle probe, $G(\alpha, \tau)$ is simplified by assuming that the probe heat capacity and radius are zero, and by the use for sufficiently large times (e.g., see Farouki 1981). To use the method for smaller times - i.e. to limit ΔT and/or to determine the diffusivity - the complete form of $G(\alpha, \tau)$ must be used. A sensitivity analysis of $G(\alpha, \tau)$, using the parameters for our probe, indicated that the pulse method is primarily sensitive to soil conductivity, whereas the continuous heating method is strongly sensitive to both conductivity and diffusivity.

The probe radius and heat capacity enter into the solution of $G(\alpha, \tau)$, and therefore must be accurately known. The model also assumes that the thermal conductivity of the probe is infinite; in practice, this means the true conductivity must be very large relative to the conductivity of the material under test.

The probe, made of copper ($\lambda = 380 \text{ W m}^{-1} \text{ C}^{-1}$), is 220 mm long and 6.0 mm in diameter. Heat flows out radially from a coil of constantan resistance wire wound on a small copper rod which is inserted in a hole bored along the length of the probe; silicon heat sink compound was used to ensure good thermal contact. The temperature at the probe-soil interface is measured with a thin foil thermocouple (Omega type CO1-T) referenced to the temperature bath. Temperature is recorded via a nanovoltmeter (Keithley Model 181) with a sensitivity of $\pm 50 \text{ nV}$. A small input of heat and the very sensitive temperature measurement system ($\pm 0.001^\circ\text{C}$) allow the maximum temperature rise in the soil sample to be kept to 0.1°C . This requires that the experiment be protected from thermal and electrical disturbances. The measurement system is guarded and grounded, and connections are protected from thermocouple effects. The system is shown in Figure 1.

A least squares regression is performed on the time-temperature record to determine the best fit of the soil thermal properties to these data. The method proved reliable in test materials (water in a weak gelatin solution, and ice).

In addition to the probe measurements, the unfrozen water content (θ_u) versus temperature (T) relationship, is determined for the soil, using the technique of time domain reflectometry, (TDR), (see Patterson and Smith 1981). These data are used to calculate the soil apparent heat capacity, which is then used to constrain the solution for conductivity from the heat probe data. So far, the technique has been applied to saturated samples, in order to reduce the possibility of moisture migration, and to ensure effectively zero contact resistance.

EXPERIMENTAL METHODS

Thermal property determinations have been undertaken for remolded samples of Caen silt and Castor sandy loam. (Pertinent physical properties for these soils are summarized in Figure 2). The soil sample was first frozen to about -10°C (to ensure ice nucleation), and thermal property determinations were made at various temperatures on a warming cycle.

A TDR probe was also inserted in the soil sample for determination of θ_u at each temperature (see Figure 2). Soil apparent heat capacity, (C_a) was calculated from:

$$C_a(T) = C_m(T) + L_f \cdot \left(\frac{d\theta_u}{dT} \right)_T \quad (6)$$

where $C_m(T)$ is the volumetric heat capacity of the soil-ice-water mixture, L_f is the latent heat of fusion, V_w is the specific volume of water, and $(d\theta_u/dT)$ is the slope of the unfrozen water content curve at temperature T.

Determinations were first performed for Caen silt, using the pulse method. The procedure followed was to heat the probe for a short period (typically 15 s) and then allow it to cool to its original temperature. The temperatures during the cooling period were used to solve for the soil thermal properties via the regression procedure. However, at temperatures above -1°C , an unexpected problem was encountered. The time-temperature trace was higher for successive runs at the same temperature (Figure 3), thus yielding non repeatable results (cf. Kay et al. 1981).

This can be explained by hysteresis in the unfrozen water content temperature relationship (see Patterson and Smith 1981). When a sample is heated for the first time at any temperature, the warming curve of the unfrozen water content relationship is followed. However, once the sample begins to cool it will not return along this curve, but will follow some intermediate curve (Figure 4). When it is heated again it will follow a new warming curve, to return on another scanning curve, and so on. This interpretation was examined by placing a sample of Caen silt in a temperature controlled bath ($\pm 0.01^\circ\text{C}$) and subjecting it to alternating temperatures between -0.6°C and -0.25°C . Values of θ_u , determined using TDR (Figure 4), indicated hysteresis between successive runs at the same temperature. While the effect of hysteresis on the volume fractions of ice and water is small, its effect on the apparent heat capacity (which depends on $d\theta_u/dT$) will be large because of differences in $d\theta_u/dT$ on heating and cooling, and between successive runs.

Figure 5 shows a plot of conductivity versus T as determined for the Caen silt sample using the pulse method. At each temperature, the highest value of conductivity was determined on the first run, with values generally declining for each successive run. Successive values of conductivity were calculated using a value for C_a which became increasingly erroneous. Whilst the trend

in conductivity values determined for the first run at each temperature seems consistent, the results above -3.9°C are unreliable.

It is concluded, therefore, that the heat pulse method cannot be used to determine soil thermal properties where hysteresis in the unfrozen water content relationship is large. The alternative method chosen was to heat the probe continuously for about 3 min, but at a very low rate (less than 1 W m^{-1}), in order, again, to limit the temperature rise to less than 0.1°C . Whilst it would be preferable to carry out a number of determinations at any one temperature, the hysteresis effect described above does not allow this. Instead, the procedure followed was to perform conductivity determinations at closely spaced temperatures on a warming cycle.

A sensitivity analysis of equation (2) for conductivity, diffusivity and heat capacity showed that markedly different combinations of these properties can produce probe heating curves which are indistinguishable, within the limits of measurement accuracy. Attempts to determine all properties simultaneously, therefore, are prone to error, since an incorrect estimate of one property will be offset by incorrect estimates of the other properties. The only property that can be determined independently is C_a . However, as $d\theta_u/dT$ approaches infinity (i.e. at very warm freezing temperatures), it becomes impossible to accurately estimate C_a . Therefore, the analytical procedure followed was to evaluate all three thermal properties, and satisfy the following criteria.

1. The thermal properties combine to produce the observed heating curve (to within $\pm 0.01^{\circ}\text{C}$).
2. Each property plots as a smooth function of temperature (which seems physically reasonable.)

The data were first analysed without constraining the solution to $G(\alpha, \tau)$ for any of the thermal properties. The results of this were plotted. The calculated heat capacities were compared to those estimated using the TDR freezing characteristic data. A smoothed function was fitted to the combined heat capacity data. The smoothed values were then used to constrain $G(\alpha, \tau)$ in the determination of conductivity.

The results of this procedure are shown in Figures 6, 7, 8. Some scatter still remains in the values for conductivity, although the plot of diffusivity determinations is most satisfactory. For conductivity, the scatter is greatest at temperatures above -1°C ; in this range, $d\theta_u/dT$ changes rapidly (see Figure 2), affecting estimates of C_a , hence λ . It appears that the accuracy of the method is limited by the accuracy with which $d\theta_u/dT$ (hence C_a) can be determined. Determination of more points on the θ_u versus T relationship, or direct (calorimetric) measurement of C_a , might improve the estimates. Kay et al. (1981) also present a method for determining soil thermal properties which requires knowledge of C_a . However, the only results they present above -2°C , are at -0.7°C . They indicate a wide scatter in their values.

It appears that the conductivity value at -1.9°C is simply anomalous, since estimates of

C_a in this range should be reliable (where $d\theta_u/dT$ is small).

Finally, perhaps the best estimates of the thermal properties are achieved when all three plot as smooth functions (such as the line indicated in Figure 6). Therefore, additional smoothing might be justifiable, with a third criterion that the trend line passes through the values at 0° and -5°C , say. At these temperatures, the results are probably most accurate.

CONCLUSIONS

The continuous heating method described in this paper extends the temperature range for which the thermal properties of frozen soils can be determined. However, at temperatures where C_a changes rapidly, or becomes very large, further refinement in analysing the results may be desirable. The heat pulse method cannot be used in the range 0° to -2°C , because of hysteresis in the unfrozen water content versus temperature relationship.

NOTATION

T	= temperature.
ΔT	= temperature rise.
Q	= heat input per unit length.
λ	= soil thermal conductivity.
κ	= soil thermal diffusivity.
C	= soil volumetric heat capacity.
C_a	= apparent heat capacity.
C_o	= volumetric heat capacity of the probe.
a	= radius of the probe.
t	= time.
t_o	= length of heating period (pulse method).
τ	= $\kappa t/a^2$.
α	= $2.C/C_o$.
θ_u	= unfrozen water content (by volume).
$\exp(x)$	= e^x .
$J_n(x)$, $Y_n(x)$	= Bessel functions of order n , of the first and second kinds, respectively.

ROCK STREAM DESCRIPTION*

N. N. Romanovskii and A. I. Tyurin

Geology Department, Moscow State University
Moscow, USSR

The authors have investigated rock streams by analyzing the frozen materials of which they are composed. On the basis of abundant data it was shown that rock streams are not chaotic accumulations of coarse material as was earlier considered but orderly geodynamic systems evolving according to certain rules. Three hypsometric belts have been distinguished, merging one into the next in orderly fashion. Each of these belts consists of a strictly defined combination of facies and subfacies differing both in structure and in the range of factors affecting its movement. The range of sediments occurring in a rock stream depends on its genesis, stage of development, and geological and geomorphological peculiarities. The data obtained by the authors have enabled them to elaborate scientifically substantiated recommendations as to the building of engineering structures on rock streams or in their zones of impact and to approach environmental protection in a rational fashion.

In recent years rock-stream (felsenmeer) research has acquired a great practical importance. This is connected with the intensive economic development of the regions which are subject to rock stream formation. Rock streams often have great areal extent. For instance, the areas occupied by rock streams in parts of Southern Yakutia and Northern Transbaikalia are as follows: (1) 1 to 5% in depressions and in other regions with weak bedrock, (2) 25 to 60% on Jurassic quartzite-like sandstones, and (3) 60 to 80% in the golets/alpine belt on Proterozoic and Archean metamorphic rocks.

The structure of rock streams is not uniform, and the processes leading to the formation of the coarse-fragmented material, its movement on slopes, and accumulation at the foot are also diverse. Various types of description (cryogenic, thermogenic, and sometimes hydrogenic) are among constantly active processes of movement of coarse-fragmented material of rock streams; the accompanying processes are frost heaving of fragments, viscoplastic flow of interstitial ice, and creep of the fragmented material in the seasonally thawed layer along the icy base. Each of these processes can act in certain parts of the rock stream and be absent in others, and have a direct interrelation with the structure of their profile. Different parts of rock streams are characterized by definite relationships between the thicknesses of the coarse-fragmented material and seasonally thawed layer by specific cryogenic structure, and by morphology.

It is possible to approach the study of rock streams using the method of frozen ground-facies analysis. The facies of rock streams were distinguished on the basis of the uniformity of the landforms and on morphology. General direction of the processes forming and transforming the coarse-fragmented material served as a principal character to distinguish the facies. Within the same facies it was necessary to distinguish subfacies on the basis of structural characteristics of the rock stream body in the cross-section (according to the presence or absence of silt horizons, character of sorting

of fragments, cryogenic structure, relationships of its thickness with depths of the seasonally thawed and seasonally frozen layers and a set of movement factors).

In rock streams, which are mobile slope formations, three main "belts" are distinguished downslope. First, there is the belt of mobilization of coarse-fragmented material, its preparation for movement. There are still no rock streams as such, but an accumulation of coarse-fragmented material is formed that consequently is entrained into motion. The belt of mobilization is followed by the belt of rock streams *sensu stricto*, i.e. by mobile and rocky slopes and streams. Active movement (transit) of the rock stream mantle takes place here. The third belt is that of accumulation of coarse-fragmented material where movement downslope diminishes or stops completely. Internment or burial of rock streams by deposits of various origin, and their reworking by exogenic processes and transformation into other formations takes place here. In each belt a number of facies are distinguished which are grouped into three categories on the basis of their role in rock stream formation and for convenience of analysis: (1) facies of external supply belt, (2) facies of transit belt and (3) those of the accumulation belt.

The facies of external supply belt of rock streams may vary greatly with the geological structure of the area, the history of its development, and the relationships of the depths of the seasonally thawed and seasonally frozen layer and the mantle of loose deposits.

The facies of the external supply belt of rock streams pass downslope into those of the belt of movement (transit) of coarse-fragmented material. (1) The facies of the rock stream slope, (2) a group of facies of rock stream flows and (3) a group of facies of structural rock stream slopes are distinguished within the latter belt.

Facies of the rock stream slope is widely distributed within the study area. It is confined to

*See Editor's note on last page.

slopes between 3-10° and 30-35° in angle. The width of the rock stream is usually greater than or commensurable with its length, and the morphology of its surface is uniform.

The suffosion-destructive subfacies is characterized by coarse-fragmented material, represented by blocks, rubble and grus. It has weak sorting and passes into broken rock at the base. In the lower layers of coarse fragmented material occurs a small amount of filler which consists of sand of varied particle size and silty sandy loam. Because the thickness of the rock stream is less than the depth of the seasonally thawed or seasonally frozen layer, the bedrock is subjected to intense cryogenic weathering. The movement of coarse-fragmented material occurs mainly due to thermogenic and cryogenic desorption. Of great significance are disintegration of coarse fragmented material, its movement resulting from frost sorting, and suffosional removal of fines.

According to the observations in the Chulman Depression, the rate of movement of sandstone fragments of this subfacies on the surface of a slope with steepness of 25° is up to 2 cm/yr. Rapid movements of material do not occur. Creeping semi-disintegrated bedrock blocks are encountered within the suffosion-destructive subfacies which develops below the slump block facies.

The golets ice subfacies (in the rock stream slope facies) is usually located hypsometrically below the suffosion-destructive subfacies. The boundary between them has a complex configuration and is ill-defined in the microrelief of rock streams. The structure of rock streams of the golets ice subfacies is characterized by frost sorting of coarse-fragmented material without matrix in the seasonally thawed layer and by an ice-soil layer consisting of bedrock fragments cemented by golets ice below the seasonally thawed layer base. The ice content within this layer is different. In some cases ice fills only the voids in the coarse-fragmental material; in others, the rock mantle is "inflated", i.e. the blocks, rubble and grus are surrounded by the ice and the volume ice content reaches 70-90%. The golets ice includes small lenses of fines, layers and lenses of ice which differ in color, structure, content of mineral admixtures, and air bubbles of various shape. Small lenses of sand often duplicate the contours of bedrock blocks located in the ice. Flattened bedrock blocks change their orientation within the cross section of the ice-soil layer. In its lower part the planes of the fragments duplicate the position of the rocks in an undisturbed state. In the upper part of the section the position of the block planes approximates the direction of the general inclination of the slope surface. This is apparently a consequence of movement of the blocks in the ice-soil layer due to plastic deformations which are indicated by the structures of the enveloping ice.

The ice-soil layer includes planes marked by sprinkling of sand material and increased content of air bubbles that have a different dip with respect to the slope: subvertical, into the depth of the slope and along its dip. The genesis of these disturbances is apparently related to ruptures of the ice-soil layer as a result of volume-gradient deformations and to stress release occurring during

movement of the coarse-fragmented material. These ruptures apparently play an important role in movement of rock streams.

The golets ice subfacies is characterized by processes of plastic flow of the ice-soil layer, and slow movement and slides of the coarse-fragmented material along the icy base. Such slides usually occur locally in places where the seasonally thawed layer base is sufficiently even, without a high content of large blocks frozen into the ice layer, which would hold the rock stream material even on steep slopes.

The accumulation of the golets ice in the perennially frozen base of a rock stream is possible while the mantle of coarse-fragmented material remains relatively constant or increases in thickness. Weathering and the disintegration and removal of fines downward is compensated by the more rapid transport of the fragmented material from above from the external or internal supply belts of the rock stream.

In the study area, the rate of movement of the fragmented surface material ranges from 1 to 3 cm/yr (the average being 2 cm/yr). The described golets ice subfacies is characterized by greater rates of creep of the fragmental mantle, in years of an increase of its thickness, and by rapid debris slides primarily on steep parts of the slope and on slopes undercut by rivers. The nonuniform movements of the rocks of the fragmented mantle of the golets ice subfacies leads to thawing, slumping and occurrence of depressions on some parts of the rock stream slope and, conversely, to an increase of the thickness of the fragmented mantle or to golets ice formation at the seasonally thawed layer base on other parts of the rock stream slope.

The siltation subfacies is confined to the lower parts of rock stream slopes and to the less steep parts of rock stream slopes with insignificant elongation or complex relief.

The cross sections of the rock streams which belong to this facies are composed of poorly sorted coarse fragmented material without filler to the depth of 0.2-0.5 to 1.0 m. Lower in the section occurs a layer of the coarse-fragmented material with dispersed filler whose content may reach 60-70%. Usually in the summer, the fines in the seasonally thawed layer are saturated and in a quick ground condition. In a frozen state the horizon has a massive and irregular lense-like bedded cryostructure. The thickness of the horizon with dispersed fines increases downslope. The seasonally thawed layer thickness does not exceed 1.5 m in this subfacies. Also within this subfacies, thermogenic desorption acts in the layer without filler and cryogenic desorption occurs in the entire seasonally thawed layer; heaving of the fragmented material, viscoplastic flow of the layer with fines, deluvial subsurface washouts, and accumulation of fines occur. Rapid movements and slides after heavy rains are also associated with this subfacies; these occur both on a wide front along with formation of depressions parallel to the slopes, and locally, forming stripes of the coarse-fragmented material. Local movement results in the occurrence of grooves of different length and width, with the cirques of separation in the upper part and heaved cones of indistinct shape in the lower one. Heaving of separated fragments also occurs.

The measured rate of heaving ranges from 2 to 20 mm/yr.

Facial variations occur either independently in short rock streams, or in combination, regularly replacing one another in long rock streams. Replacement of facies and subfacies in time occurs too. Replacement of subfacies is an objectively existing process determined by various conditions, such as resistance of rocks to weathering, steepness of slopes, undercutting of slopes by rivers, etc., as well as by climatic and frozen ground factors. Within the study area, the following combination of subfacies is most often encountered in the mature rock stream slope facies. The suffosion-destructive facies is located in the upper part of the rock stream slope. Hypsometrically lower there is the golets ice subfacies turning into the siltation one at the foot.

In the initial stage the facies of the rock stream slope is represented only by the suffosion-destructive subfacies which takes up the entire rock stream. The rock stream increases in length and thickness. As the thickness of the rock stream enlarges through both weathering of rocks and suffosion of fines, the rock porosity becomes higher and the quantity of golets ice being formed annually in the rock stream increases. The ice content is highest in the lower part of the section which is most washed out and characterized by maximum porosity. The increase in ice content leads to a reduction of the thickness of the seasonally thawed layer and to the transition of its lower part into perennially frozen ground. Consequently, the golets ice subfacies starts to form in the lower part of the rock stream slope. The growth of the golets ice subfacies proceeds upslope similarly to the "backward erosion". In cases where weathering of hard bedrock results in the formation of a small quantity of fines which are easily removed by surface runoff, the golets ice subfacies may replace the suffosion-destructive one completely. In this case, the belt of rock stream movement (transit) is again represented by only one subfacies.

Finally, the siltation subfacies is formed, irrespective of rock strength in the lower part of the rock streams developing on slopes not undercut by rivers. On rocks that are more resistant to erosion the siltation subfacies appears later, and develops more slowly than on less resistant rocks. The area of the siltation subfacies increases upslope at the expense of the other subfacies. In this case the rate of its formation decreases gradually, practically ceasing at a certain level. The remaining part of the rock stream, which is represented by the suffosion-destructive or the golets ice subfacies, is usually small and weathering of rocks within its limits cannot support the development of the siltation subfacies. If the amount of fines removed by the surface runoff is large, the siltation subfacies may replace all subfacies located upslope. Finally, the rock stream is degraded. However, hard rocks and high moisture content of the deposits may cause heaving of the coarse-fragmented material and the revival of the rock stream.

There is a group of rock stream flow facies. The rock stream flow facies include narrow, linearly extended rock streams the width of which is

considerably smaller than their length. Within the study area, the rock stream-flows are represented by three facies: (1) rock stream rills, (2) rock stream rampart flow and (3) rock stream stripes. The distinctive features of the rock stream flow facies are: (1) the concentrated, directed movement of the coarse-fragmented material, (2) differences in structure not only downslope but also in the transverse section; these differences are related to orienting effect of the banks of the flow and other factors. Formation of rock stream-flows is determined by the occurrence of fractures extended downslope in the rock, or by systems of frost polygons (usually following tectonic cracks); the cracks following the surface gradient are most reworked (weathered, washed out, etc.). Because of this, the rock stream flow facies has slump blocks and the subfacies of differential weathering of rocks as an external supply belt.

The rock stream rill is represented by extended rock streams the width of which varies from 3 to 4 to several tens of meters; the side parts are raised compared to the axial part.

Within the boundaries of Southern Yakutia and Northern Transbaikalia, rock stream rill takes place along the lines of frost cracks where intense processes of suffosion of fines occurs. In this case the size of the cells in the network of polygons exceeds 15m; the large distance between the cracks prevents formation of the rock stream slope facies. The width of the rock stream rills varies from 3 to 6 m. The rock stream rill facies often occurs in depressions. This is most typical of Transbaikalia and Stanovoe Nagore Mountains.

The rock stream stripe facies is represented by linear, elongated, flat rock streams, which are not distinguishable in the relief of the slopes, are without a pronounced concentration of the flow of supra-permafrost water and without intensive suffosion. The cross section of the rock stream stripe subfacies is determined by its genesis and the stage of development. Depending on this it may or may not have a channel. If a channel is not formed, the cross section of the facies is filled almost completely with fines. For example, such facies are formed as a result of destruction of rock remnants, the banded coarse-fragmented material of which is shifted downslope. In the relief of the slope, the subfacies has the shape of the rock stream. The fragments are placed on their sides, their long axes oriented along the dip of the slope. Frost sorting is apparent in the cross section. If the rock stream stripe facies is formed on loose deposits the thickness of which exceeds the depth of the seasonally thawed or seasonally frozen layer, the rock stream flow appears to immerse into the slope according to its denudation. Coarse-fragments of the loose deposits composing the slope are included in the subfacies.

The rock stream rampart-flow facies represents elongated rock streams with an elevated central part and a depressed peripheral part. Characteristically, on steep areas and in the upper parts of slopes the immobile banks of the rock stream are raised as much as 1 m. On relatively flat areas and in the lower parts of the slopes the ramparts-flows form well defined positive micro-

relief. The sides of blocks are oriented along the dip of the slope; in the transverse section the blocks diverge fan-like from the center to the periphery. Distinct frost sorting of fragmented material is encountered in the vertical section. At the base of the seasonally thawed layer, the space between fragments is filled with saturated fines. The thickness of the horizon with fines increases downslope. An icy layer is usually found below the seasonally thawed layer without fines. In the upper parts of the rampart flows the seasonally thawed layer depth often exceeds the thickness of the rock stream mantle and the seasonally thawed layer includes broken rock. This is a typical suffosion-destructive subfacies. The occurrence of the greater part of the rock stream rampart-flow on a viscoplastic and heavily iced base leads to constant formation of debris slides and, consequently, to a change in configuration of the seasonally thawed layer base.

In many respects the structure and dynamics of the rock stream rampart facies are determined by the genesis of the rock stream. Within Southern Yakutia and Northern Transbaikalia, the formation of the rock-stream rampart facies (as well as of those of the rock stream rill and stripe) is closely associated both with weathering of bedrocks along tectonic lines and frost cracks and with the heaving of fragments to the surface. Surface runoff is concentrated in frost cracks penetrating considerably deep into the bedrock and follows its initial jointing. Periodical temperature fluctuations which extend deep along the cracks and high degree of water accumulation intensify weathering processes. Following the growth of veins of the coarse-fragmented material along the lines of cracks, the fragments start slowly move downslope and to be squeezed out toward the sides of polygons by heaving of ice formed in the seasonally thawed (seasonally frozen) layer, through temperature deformations, suffosional cones of finely-fragmented debris, gravitation and other factors. The rate of displacement of fragments is up to 1.5 cm/yr along the dip of a 6° steep slope and up to 1.2 cm/yr along the trend. Therefore, the growth of veins of the coarse-fragmented material brings about a specific qualitative change - transformation of veins into the rock stream.

There is a group of facies of structural rock stream slopes. These include a series of rock streams distributed in regions where presently or in the recent geological past, were active processes of frost riving and formation of polygonal-veined structures both in rocks and semirocks. Facies variations of this group of rock streams are formed by complex effects of rock stream formation processes on the rocky substrate composed of polygonal blocks. The intensity of rock stream formation is different on blocks and in depressions between them. The character of the forming rock streams varies with lithological characteristics of the rock, the intensity of surface runoff, and the depth of the seasonally thawed or seasonally frozen layer. This allows the recognition of a series of facies.

The facies of concealed-polygonal rock stream slopes is formed on surface of hard rock outcrops denuded of loose mantle and destroyed by a system of cracks. The most intense processes of frost

weathering are encountered along cracks. The surface runoff is concentrated within the cracks and "pockets" of the deeper weathering zones are formed in the bedrock. In this way, the mantle of the rock stream fragmented material forms on the slope; its thickness is different in different parts. The thickness of the coarse-fragmented mantle both in the cracks and above the block-polygons changes as follows:

- (1) 1.0-1.5 m in the upper part of the rock stream slope;
- (2) 2.5-3.5 and 1.0-1.5 m in the middle part of the slope;
- (3) in the lower part of the slope the thicknesses are similar and range from 2.5-3.0 m.

The relief of the facies is represented by a rock stream slope of medium steepness with the solid mantle of the coarse-fragmented material and with sink holes linearly extending downward. The fragments in the sink holes are of maximum size. In cross section the facies represents a series of furrows filled with coarse-fragmented material. In the downslope there are not only changes in relationships of different thicknesses of the coarse-fragmented material along the cracks and on the blocks, but also changes in the cross section structure and in the relationships of thicknesses of the fragmental mantle and the seasonally thawed (seasonally frozen) layer. This allows a recognition of a series of subfacies within the given facies. These subfacies are of complex nature. On the one hand, there are certain areas of which the structure is similar to that of the suffosion-destructive subfacies; grinding of rocks composing the seasonally thawed layer continues within the limits of blocks-polygons. At the same time, parts of subfacies with golets ice form along the lines of furrows.

The facies of banded concealed-polygonal rock stream slopes is represented by coarse-fragmented mantle with an uneven surface showing alternation of the fragmented material ramparts (the arrangement of which coincides with the trend of the slope) and relatively smoothed inter-polygonal areas. Elevation of ramparts above the surface ranges from 20 to 30 cm, reaching a meter in some cases. The width of the ramparts varies from 1 to 3 m. The surface of some ramparts is only slightly convex. Very coarse structure of jointing at the surface is an important character of the ramparts. The ramparts are often characterized by high porosity and look open. Downslope they become less distinct. In certain cases they merge.

Two cases of formation of this facies should be distinguished. (1) Along the polygonal network of ancient frost cracks in weathered bedrock forms a large amount of dispersed material (40-70%; sandy loam, loam) from which the fragments are heaved to the surface. (2) Bedrock is overlain by the mantle of loose deposits the thickness of which is less than that of the seasonally thawed or seasonally frozen layer. These loose deposits are subjected to frost riving. As a result, polygons with a medium size of 4x4 to 6x6 m have been formed. The surface runoff is concentrated along the polygonal depressions and zones of weathering are formed in underlying rocks. Higher moisture content in these depressions promotes intense heaving of fragmented material trending along the surface and

causes formation of veins of the coarse-fragmented material. If the depth of seasonally thawing or freezing exceeds the thickness of the mantle of loose deposits, the growth of veins leads to formation of ramparts of coarse-fragmented material on the surface; the width of these ramparts is 4 to 5 m, and the height varies from 0.5 to 1.5 m. The coarse-fragmented mantle closes over the polygons. The structure of the facies of banded concealed-polygonal rock stream slopes is specific. A distinct asymmetric system representing alteration of veins of fragmented material and blocks-polygons appears under the coarse-fragmented material mantle. The thickness of veins coinciding with the trend of the slope reaches 2.5 to 3.0 m, and their width 2 to 3 m. The size of the veins extending downslope is considerably smaller. A series of subfacies can be recognized within this facies. Certain structure of the fragmented material composition and its processing is characteristic of the subfacies in which the destruction of rocks, included in the seasonally thawed layer is completed. The fragments of maximum size are located along the cracks and from the surface, as though enveloping the polygons.

The rate of and factors causing the movement of the fragmented mantle and coarse-fragmented mantle material is different in the different parts of the facies. The rate of the mantle movement on slopes with a steepness of 15° is about 0.4 cm/yr above polygonal remnants, and reaches about 1.5 cm/yr in the sinks extending downslope.

The present work is regarded as a first attempt at the facies analysis of rock streams. The authors have concluded that a systematic study of the mechanisms of movement of rock streams and evaluation of their engineering geologic characteristics should be carried out only when their specific facies variations are taken into account.

Rock streams are mobile slope formations having certain genesis, ordered structure and specific mechanisms of movement characteristic only to them. Our frozen ground-facies analysis has confirmed the necessity of distinguishing them as a specific genetic type of slope formations - that of the rock stream desertion.

Editor's note: Desertion is defined as a surficial creep deposit which results from a volume change such as is caused by frost heave and or swelling. It is a zonal type of deposit, not identical to either solifluction or gelifluction. Reference: Poppe, V. and J.E. Brown, 1976. Subsurface investigation and geotechnical evaluation of the site of the Fairbanks wastewater treatment facility identified the soil profile, the extent of frozen ground, and other pertinent geotechnical parameters necessary for design and construction considerations. Primary geotechnical-related concerns included thaw settlement, extent of overexcavation, and minimizing groundwater infiltration into the excavation. The overlying ice-rich silt stratum was considered to be unsuitable for proposed site development because of its high thaw strain potential. The underlying gravel-sand stratum was considered to be suitable for foundation bearing, although the potential for limited thaw strain and seismically induced dynamic densification were of concern. From all indications, the structure has not exhibited any significant settlement during the period of operation. An example of differential movement attributed to a possible combination of soil thawing and heaving occurred when subsequent placement of the septic disposal building partially on silt outside the original excavation and backfill limits resulted in significant tilting of the structure.

INTRODUCTION

Prior to statehood, development of facilities within the Fairbanks floodplain region was typically accomplished on locations of unfrozen floodplain granular deposits. Notable exceptions are those documented in the literature by Terzaghi (1952) and Waterhouse and Sills (1952) on the Ladd Field (Fort Wainwright) power plant, by Terzaghi (1952) on the Eielson AFB hanger, and by Philleo (1966) on the University Park School addition. Site or performance data on other and more recent construction accomplished on frozen portions of these floodplain gravels have not been readily accessible or published. This paper presents, in case history format, information on site conditions at the Fairbanks wastewater treatment facility.

Based on overall project requirements, consultants for the City of Fairbanks selected the proposed sewage treatment plant site on the east side of Peger Road, approximately 7.2 km (4.5 mi.) from downtown Fairbanks (see Figures 1 and 2). Specific geotechnical concerns with proposed development at the site focused on defining: (1) the extent and limits of frozen ground, (2) surface water and subsurface groundwater conditions, (3) physical behavior of the soils (particularly frozen soil consolidation upon thawing and densification under dynamic loading), and (4) a sufficient area of frozen ground delineated so that the building could be positioned to allow all excavation "in the dry."

The wastewater treatment building, having approximate plant dimensions of 115.8 m (380 ft.) by 100.6 m (330 ft.), is a one-story concrete structure with below-ground areas for clarifiers, chlorinators, and sludge handling equipment. The building has multiple floor levels ranging from approximately 7.6 m (25 ft.) below to about 1.5 m (5 ft.) above the original ground surface. The

approximate top of gravel and bottom of floor slab elevations are shown in Figure 3.

Thermal degradation of the frozen soils at the site, both during construction and throughout facility operational life, required that design should accommodate time-dependent changes associated with anticipated ground deformation. Pre-construction information indicated that development of the site was feasible; construction of the main facility was begun in late 1973 and was completed in 1976. Site instrumentation to monitor ground deformation was not installed. Performance of the building to date appears to be satisfactory, at least in terms of static thaw settlement. The potential effect of any dynamically induced settlement associated with any densification resulting from significant ground shaking remains unknown.

SITE CONDITIONS

General Topography and Geologic Setting

The sewage treatment plant site lies on an abandoned portion of the Tanana River floodplain, approximately 548.6 m (1,800 ft.) north of the active braided floodplain. The natural ground surface is relatively flat except for a few depressed thaw ponds and partially filled sloughs. The building site occupies an area between a thaw pond to the south and a marshy area to the north. Vegetation in the area is generally grass tussocks, moss, low brush, scattered groves of willows, and a few scattered birch, black spruce, and alder. Site construction grading has resulted in much of the area now being covered with granular fill with a relatively uniform surface.

Subsurface Soils

Subsurface soils at the site were identified in terms of two major soil strata; these being

(1) surficial ice-rich organic silts and (2) underlying clean (lower silt content), relatively ice-free gravels and sands. All borings drilled in the immediate vicinity of the defined building site indicated soils were frozen below the 2-3-foot active layer to total depth drilled. Boring locations are shown in Figure 2 and a log of Test Hole F-12 is presented in Figure 5.

Ice-rich organic silt extended from original ground surface to depths varying from 1.07 m (3.5 ft.) to 3.81 m (12.5 ft.). The natural moisture content of samples from these silts was high, (ranging from 10% to 61% and dry densities of the frozen samples were relatively low, ranging from 913 kg/cu.m (57 pcf) to 1,410 kg/cu.m (88 pcf).

The underlying gravel-sand stratum was found to alternate between sandy zones and gravelly zones. Moisture contents of the gravel-sand samples ranged from 7% to 31%; the sand density range was from 1,426 kg/cu.m (89 pcf) to 1,570 kg/cu.m (98 pcf), and the gravel density range was from 1,922 kg/cu.m (120 pcf) to 2,243 kg/cu.m (140 pcf). Based on boring results, the lateral extent of the sand substrata was considered to be relatively smaller than that of the gravel. Some occasional minor silt seams were also encountered in the gravel-sand strata; however, their extent and influence was felt to be small.

Permafrost

Permafrost in the immediate area of the site was classified as discontinuous. The permafrost was considered to be warm (i.e. between -2.0 and 0°C) and therefore sensitive to surface disturbance of the natural vegetation. Thermokarst depressions, resulting from thaw of ice-rich organic silt soil, were evident in the surrounding area. Unfrozen soils were encountered at the edge of a thaw pond and along the southern boundary of the initially proposed building location. The unfrozen-frozen soil contact zone was delineated with subsequent drilling and the building location was shifted slightly more than 15.2 m (50 ft.) north in an attempt to position the building excavation limits entirely within an area of frozen soil.

The near-surface organic silt stratum generally was found to contain large amounts of visible ice within individual 6-inch sample increments, with estimates ranging from 0 to 100%. The ice existed as individual crystals, crystal aggregates, and lenses and veins up to 0.15 m (6 in.) thick. Little visible ice was observed in the sand and gravel strata. Much of the coarse granular material appeared to be clean (very low silt content) and dry frozen, with only minor amounts of ice in voids between sand and gravel particles.

Water Table and Surface Drainage

Excavation and below-ground construction activities had the potential of being more time-consuming and costly if the proposed work had to be accomplished with a high water table condition. Emphasis was placed on defining groundwater conditions and, as much as possible, verifying that placement of the building completely within a frozen core area would likely minimize water-

related problems that could result from infiltration through pervious zones or taliks during construction.

Surface drainage conditions in the immediate area were relatively poor due largely to the dense organic mat cover, the impervious nature of the frozen organic silt, and the flat terrain. While ponds did not exist directly within the building location, ponded water did exist, at least during the summer, in topographically low areas north and south of the site.

A high water level was found in the unfrozen soils at the edge of a thaw pond near the south boundary of the proposed building excavation. It was considered possible that the level of the water reflected a hydrostatic water table that could provide an almost infinite supply of water that might flood the excavation.

A number of test holes were drilled to further delineate and verify the extent of the frozen zone within which it was proposed to locate the building. Test Holes F-5 through F-11 were drilled to locate the northern boundary of the previously mentioned pond. Only Test Hole F-9 encountered unfrozen ground and high groundwater conditions.

DESIGN CONSIDERATIONS

General Concerns

The effect of construction of major facilities on ice-rich fine-grained frozen soils and the effect of consequent thaw-induced subsidence have been reported in numerous documents. Although a number of projects have been constructed on frozen granular deposits, only limited information has been published on the thaw settlement performance of frozen coarse-grained material within the Fairbanks area of the Tanana River floodplain deposits. The general perception that these granular deposits can be assumed to be thaw stable, such as presented by Pewe (1982) and in the Trans Alaska Pipeline System stipulations (1974), is relative; it is cautioned that thaw performance must be related directly to structure tolerances and site-specific conditions.

Some engineering problems that might result from thaw of these coarse granular materials and require assessment are described below.

- (1) The extent of consolidation resulting from thawing of frozen gravel and sand is primarily dependent upon soil density, ice content and silt content derived from soil deposition processes and past depositional history. The influence of soil arching in reducing thaw settlement within the soil mass through stress and strain redistribution is also important; however, any subsequent earthquake-induced dynamic densification, may cause further settlement.
- (2) Thawed granular material, with low-to-moderate densities, may liquefy when subjected to earthquake-induced shear stresses.
- (3) Substantial lateral pressures and buoyancy effects may develop against below-ground structures and walls as the soil thaws and densifies around a building and as probable

perched ground or trapped surface water surrounds the structure.

Construction problems related to frozen coarse granular deposits involve several concerns.

- (1) Excavation procedures and economic removal of frozen silt and bonded vs. unbonded frozen gravel. The influence of frozen soil temperature (warm vs. cold) and time of year can critically influence the extent of excavation effort and related earthwork economics.
- (2) Earthwork operations "in the wet" are typically more costly than when performed "in the dry." When operations are planned to be performed in the dry, water infiltration into the excavation may adversely alter or impede planned excavation efforts or schedules, particularly when attempted during the winter construction period.

Thaw Consolidation

Field tests performed with the consultant supervision of Karl Terzaghi (1952) in the early 1950s on the power plant at Ladd Field provide important practical in situ data on the thaw consolidation behavior of the Tanana floodplain frozen granular deposits. Laboratory thaw consolidation tests made on the frozen granular cores obtained from the Fairbanks wastewater treatment facility site reported by Wellman and Nelson (1972) and laboratory and in situ field tests accomplished during studies on thaw performance of related frozen granular material for the Trans Alaska Pipeline System route, reported by Luscher and Afifi (1973) and Nelson et al. (in this volume) have provided further confirmation of potential thaw consolidation behavior.

Results of laboratory uniaxial thaw consolidation tests performed on frozen coarse-grained samples obtained from the site are summarized in Table 1. All frozen core samples were recovered using diamond core barrels with refrigerated diesel oil as a drilling fluid. The fluid was maintained at temperatures slightly below freezing (approximately equal to in situ temperatures). The recovered cores were 75 mm (3 in.) in diameter and, depending on sample condition, core segments had a length-to-diameter ratio ranging from 1 to 2.

The uniaxial thaw consolidation tests were performed according to the following procedures. Sample preparation was accomplished in a cold room; frozen core samples up to 4 in. long were fitted into rigid cylindrical rings after being trimmed to planar surfaces and to a 63.5 mm (2.5 in.) diameter. The samples were then brought into the -6.6°C testing room, loaded uniaxially in a constant air pressure loading frame under a pressure approximately equal to the sample overburden weight and then thawed. One-end drainage of any excess meltwater was permitted through a porous stone placed on top of the sample.

In general, the gravels were found to have frozen dry densities greater than 1,922 kg/cu.m (120 pcf) and the assumption was made that higher density, clean gravels (approximately less than 5% silt content) of alluvial origin exhibited little

if any consolidation upon thawing. The sandy layers within the granular stratum gave some cause for concern because the recovered samples were found to have lower frozen dry densities, sometimes as low as 1,442 kg/cu.m (90 pcf). The thaw consolidation tests reported in Table 1 were performed on the sand samples obtained from the sand substrata intermixed with the gravel-sand stratum.

The results of the thaw consolidation tests indicated that limited static compression of the sand samples occurred during thaw under equivalent overburden load. The minimum recorded strain was 0.2% while the maximum strain value was 3.5%. These results compare reasonably well with those found for similar materials tested in the laboratory during the Trans Alaska Pipeline System routes studies. Potential additional strain effects resulting from dynamic loading were not assessed during either of these laboratory test programs.

Earthquake Concerns

The effect of earthquake ground motions was assessed with regard to potential for dynamically induced densification of the granular material and to the susceptibility of the material to liquefaction. The gravel substrata within the sand-gravel stratum were not considered to be susceptible to liquefaction since in their frozen state they were found to be at approximately 70-90% of their maximum relative thaw state density.

Because of limited sample material availability, evaluation of the sand substrata was based on two relative density tests (ASTM Specification D2049-69) performed on a composite sand sample with a unified soil classification of SP. The results of the tests and a list of individual samples that formed the composite sample are included in Table 2. Also included in this tabulation are the computed relative density values of all test hole samples having gradations similar to the composite sample. Engineering analysis of the sand samples' relative densities (average relative density approximately 44%) and the in situ stress and water table conditions based on Seed et al. (1971) (1972) indicated that the sands could withstand an earthquake with the equivalent of 10 stress cycles of approximately 0.1 g peak acceleration before liquefaction might occur.

Since occurrence of moderate-scale earthquakes (Richter magnitude 5.5 to 7.0) were anticipated in the immediate area and during the 30-year project design life and because of the number of variables involved, it was assumed that dynamic settlement could cause the sands to densify to approximately 70% of their maximum relative density. This increase in density implied a consolidation strain of about 4% in the sand substrata. Assessment of the approximate upper limit extent of equivalent vertical sand substrata indicated that about 3 m (10 ft.) of looser sand might be involved within the upper 12.1 m (40 ft.) of influence area for expected long-term thaw degradation below the building. Thus, it was felt that this equivalent thickness of sand could result in an upper limit of about 0.12 m (0.4 ft.) of total settlement.

Experience obtained from the Ladd Field power plant site also provides some additional in situ ground performance data for the same type of deposit. Although detailed site and sample data were not reviewed, information presented by Waterhouse and Sills (1952) indicated the frozen ground area of the Ladd Field power plant "to be composed of river-deposited stratified sandy gravel, the porosity and grain size of which varied erratically." The porosity, ranging from 15% to 40%, averaged 25% and the silt content had an average of 6%. The in situ thaw test site was reported by them to have produced approximately 0.4% static thaw strain for 6.1 m (20 ft.) of thaw, and dynamic ground-shaking effects generated by controlled blasting produced an average additional strain of 1.3% and thus a total thaw consolidation strain of approximately 1.7%. Terzaghi (1952) indicated "the measured value decreased from 1.8% at a depth of 3.9 m (13 ft.) below original ground surface to very small values at a depth of 9.1 m (30 ft.). He also reported relatively similar results from one test performed at the site of a large hangar at Eielson AFB. Here, maximum thaw strain near ground surface was found to be 2.5% and became negligible at depth.

CONCLUSIONS

It was recommended that the frozen silt be removed from within the entire plant area and excavation extend down into the gravel-sand stratum at least 1.52 m (5 ft.) below footing or floor slab grade, whichever resulted in a lower elevation. The proposed building bottom-of-slab elevation together with the approximate elevation of the ice-silt/gravel-sand strata interface, indicated in Figure 3. These soil strata are shown on the selected profile section in Figure 4. Given consideration of anticipated ground thawing during the construction and operational period and the influence of soil arching at greater depth, it was estimated that under static loading conditions the maximum total and the differential settlement would be on the order of approximately 25.4 mm (1 in.) and 19.1 mm (0.75 in.), respectively. Under earthquake loading conditions, it was felt that total and differential settlement would be increased by about 50.8 mm (2 in.).

Construction excavation was completed during the 1974-1975 winter season. Earthwork excavation was accomplished in the dry using dozers with ripper teeth (to break up the frozen soil) without encountering any significant difficulty or ground-water problems. Granular backfill was subsequently placed and compacted as specified to the approximate slab base elevations shown in Figure 3.

The Fairbanks wastewater treatment facility was completed in 1976 and the structure has not been reported to exhibit any evident deformation because of ground settlement; however, the potential compaction influence resulting from earthquake-induced ground shaking remains unknown.

In late 1975, construction of the septic disposal building was begun separate from the main treatment plant. This building, with footing excavations barely visible in the May 1, 1976, air

photo of Figure 1, was placed at the edge but within the originally identified frozen ground segment; however, total excavation of the organic silt stratum apparently had not extended to this area.

Differential movement was noted in late 1976 and subsequent subsurface investigation Fowler (1977) revealed that some of the organic silt stratum had not been removed below footing depth within most of the building area. Differential movement of 0.12 m (0.4 ft.) was measured at that time. This building deformation was attributed to a possible combination of thawing of any frozen portions and frost heaving of unfrozen portions of the organic silt stratum found in three of the four test holes drilled in 1977 adjacent to the footings and at each corner of the 5.5 m (18 ft.) by 9.8 m (32 ft.) building. As reported in Pewe (1982), subsequent corrective measures, extension of concrete piers to bearing on the gravel stratum and placement of a horizontal blanket of insulation at the base and around the building perimeter have apparently stabilized the building movement.

ACTIVE LAYER ENERGY EXCHANGE IN WET AND
 DRY TUNDRA OF THE HUDSON BAY LOWLANDS

Wayne R. Rouse

Department of Geography, McMaster University, Hamilton, Ontario, Canada L8S 4K1

Results of weekly calculations of ground heat flux for Churchill, Manitoba, made from September 1981 to December 1982 are presented. Measurement sites included a variety of well-drained upland, semiupland and wet lowland locations, a forested site, and an ice-cored palsa.

Net radiation, Q^* , was measured at representative sites in summer and at one site in winter with the latter measurement being applied with corrections to all sites. The ground heat flux, Q_G , was divided into sensible and latent heat components and was determined from soil moisture and temperature measurements.

Snow depths were shallow on open tundra sites and deep at the forested and a forest-influenced site. As a result, final snowmelt at the latter sites occurred 7 weeks later than at the former ones. Q^* was similar for all sites with a maximum variation of 14% from the all-site average. Active layer depths on upland sites were double those in the wet lowland. During the thaw season, Q_G was almost the same for all sites and averaged 12% of Q^* . Q_G during freezeback fully compensated for the net radiational heat loss in winter.

The similarity in Q_G for such a heterogeneous groups of sites is explained in terms of thermal conductivities and vertical temperature gradients. The results are seen as having some general applicability and show that Q_G is an important component of the surface energy balance.

INTRODUCTION

The energy expended in melting the active layer in permafrost terrain is important in determining the depth of the active layer, in determining how much ice in the active layer will be released to take part in hydrologic processes, and in influencing differences in frost table depths, which will determine the direction of subsurface water flow. The degree of thawing and the release of water is important in thermokarst activity. The magnitude of ground heat storage is important in calculating how much energy remains for other processes, such as evaporation and sensible heating of the air. At least some of the energy absorbed during the thaw season will be released during freezeback and will ameliorate surface heat loss and be a thermal input to the base of a snowpack.

The ground heat flux, Q_G , might be expected to be variable according to terrain type, groundwater content, and the depth and longevity of snow cover. For example, in the Churchill area, an early study by Brown-Beckel (1957) indicated that active layers in different terrain types could vary from 55 to 335 cm in nonrocky soils. The depth of winter snow cover has been shown to strongly affect active layer depths by a number of researchers as summarized by Outcalt and Brown (1977). At snow depths and snowpack longevity are highly variable depending on vegetation type and topography is well known and is documented for the high arctic at Resolute by Woo and Marsh (1978) and in the subarctic at Schefferville by Adams and Roulet (1982).

There are a number of ways that Q_G can be measured or estimated. In addition to direct measurement with heat flux plates, which are not reliable in permafrost terrain, there is the vertical gradient approach in which

$$Q_G = k \frac{\Delta T}{\Delta z} \quad (1)$$

where k is the thermal conductivity and $\Delta T/\Delta z$ is a time-averaged vertical temperature gradient in the soil. Inherent problems in the practical application of this approach for long-term estimates involve experimental difficulties in determining k and the fact that it varies over time with changing soil ice and water content.

An alternate and preferred approach is to calculate the heat storage over time as

$$Q_G = C(\Delta T/\Delta t)\Delta z + L_f \quad (2)$$

in which L_f is the latent heat of fusion involved in the thawing and freezing of soil water, C is soil heat capacity, and ΔT is the temperature change over the time period Δt averaged for a depth increment Δz , which ideally operates between the soil surface and the depth to the base of the annual thermocline. In equation (2), L_f can be determined from the volume and temperature of soil water (ice), and $\Delta T/\Delta t$ can be measured with few technical problems. C , however, must be divided into its component parts in which

$$C = C_s X_s + C_w X_w + C_i X_i \quad (3)$$

where C is heat capacity, X is volume fraction of the soil, and s , w , and i refer to soil solids, water, and ice, respectively. C for sands, clay, and peat of varying density will be constant for a given site and horizon and can be obtained from the determinations of Kersten (1949). X_s can be determined by mechanical analysis or from $[1 - X_w(\text{SAT})]$, where $X_w(\text{SAT})$ is the saturated volumetric water content. It too is constant for a given site and horizon. X_w and X_i are the only important variables in equation (3) and must be measured. It is also important that one is able to differentiate between water and ice because C_w is more than twice the magnitude of C_i . It should be noted that because soil air has such a small heat capacity it

can be ignored in equation (3).

This study employs equations (2) and (3) to determine the ground heat storage at eight sites of very different characteristics in the Hudson Bay lowlands near Churchill, Manitoba and relates this storage to measured and estimated net radiation at these sites. The study period extended from September 1981 to December 1982 and calculations are presented for weekly periods.

METHODS

Site

Churchill (lat. 58.75°N, long. 94.08°W) is located on the southwest coast of Hudson Bay in an area that possesses a tundra landscape and a climate similar in many respects to low arctic areas across the continent. Hudson Bay is ice-locked along this coast from mid-November to mid-June, and drifting ice frequently lingers offshore until the end of July. Thus in spite of its relatively low latitude the terrestrial snow cover persists on average until late May and cold air temperatures until July. The vegetation consists of short grass, shrubs, and ground lichen on upland raised beach systems, thick sedge grass growing on surface peat in wet lowland areas, which constitute the bulk of the landscape, and scattered open forest development, especially on upland ridges. This forest development, although similar morphologically to the tree line, represents an outlier since further inland and to the south the trees disappear until the main tree line is encountered. Soils range from deep sands underlain by clay in the beach ridges to clays overlain by peat, which can be up to 0.5 m thick in the low-lying areas.

The research reported in this paper was undertaken at a location 2 km inland from Hudson Bay at eight select sites along two separate transects as shown in Figure 1. Table 1 gives their characteristics. Transect 1 was located exclusively in open tundra. Site 1A, located on the upland beach system, consisted of deep sands down to 2 m, which represents the terminal depth of measurement for all sites. It has a 5 cm organic surface layer overlain by a dominant short grass vegetation. This terrain is well-drained and there is no surface runoff even during the heaviest rains. Site 1B is on the side slope of the beach ridge and consists of a 10 cm organic horizon overlying sand to 90 cm, which in turn gives way to clay down to the terminal depth. Vegetation consists of grasses, lichens, shrubs and mosses. Site 1B never has surface water but as thawing progresses, significant ponding of water above the frost table occurs. Sites 1C and 1D are similar except the latter has water at the surface throughout the summer, whereas the former undergoes some surface drying between rainstorms. Both sites have a 25 cm peat layer directly overlying clay. Vegetation is almost exclusively a thick sedge grass.

Transect 2 has more variety in its landscape features. 2A is located in an open forest on the upland ridge. The soils are similar to 1A except the surface organic layer is a little thicker. The trees are stunted black spruce with an average height of 6 m and an average trunk spacing of 2 m. Understorey vegetation consists of shrubs and assorted lichen species. Site 2A acts as a snow trap accumulating a deep snowpack by late winter, which persists past the middle of June. Because soils

FIGURE 1 Research sites with a plan view of the basin and cross-sections of transects 1 and 2 showing the maximum active layer depth and the depth of the suprapermafrost groundwater.

thaw as the snowpack ripens, there is little surface runoff and the soils are saturated at final snowmelt. Site 2B on the south-facing side slope is similar to 2A except that the layer of sandy soil is thinner and there are no trees. The effect of the forest is, however, important. By virtue of braking the speed of the winds, snow is deposited early and deep at this site. It is, in fact, only after a deep snowpack has developed that buildup proceeds at site 2A within the forest. The deep and longlasting snow cover has important effects in keeping soil warm and in reducing the yearly total of net radiation. Site 2C is a palsa mound and was chosen for its uniqueness. It rises about 1 m above the surrounding wetlands, averages 10 m in diameter, has similar surface vegetation to site 1A, has a deep insulating peat layer, and boasts a solid ice core throughout the summer. In winter the snow cover was late developing in contrast to other sites.

For purposes of presentation the soils are grouped into pairs having similar soil topographic characteristics: 1A-2A, 1B-2B, 1C-2C, 1D-2D. It is noted that while 1C and 2C have similar soil profiles, their topographies are very different. The sands and clays both have bulk densities averaging about $1.6 \times 10^3 \text{ kg/m}^3$ and porosities of .35 and

.40, respectively. The peats range in density from 0.2×10^3 at the surface to 0.4×10^3 at the peat-clay interface. Their porosities likewise range from 0.9 to 0.6.

The eight sites studied represent a very heterogeneous group of landscape types that are typical of those found elsewhere in the Hudson Bay lowlands, in central Keewatin, and in the Mackenzie Valley.

Measurement

Net radiation was measured with net pyrradiometers at sites 1A, 2A, 1C and 1D at 1 m above the ground and at site 2A at 1 m above the forest. The instruments were recently calibrated and should be accurate to within $\pm 10\%$. The measurement period at sites was from late April to early September. In the winter period, measurements were made at one site similar to 1A and applied to all other sites except 2A. At 2A estimates were made according to a regression of net radiation on solar radiation derived for the April early May period in 1982 and 1979 and applied to the months of February, March and April, when there is substantial tree canopy absorption of solar radiation leading to larger Q^* . As a result, yearly totals of Q^* are larger at site 2A than at other sites. The summer measurements at site 1A were applied to 1B and 2B, those at 1C to 2C, and those at 1D to 2D.

The most important variable in equations (2) and (3) is the soil water and soil ice term as it is involved in both the sensible heat exchange in the soil Q_{SH} and the latent heat exchange Q_{LF} . Soil moisture was measured with a neutron probe at increments of 20 cm replicated at each site. The probe was calibrated for sands, clays and peats using gravimetric comparison. Since the neutron probe measures the H ion concentration in the soil, it cannot differentiate between liquid water and ice, which is a drawback to this measurement method. Soil temperature readings made it apparent when the main zero curtain effect ended, as rapid cooling or warming ensued. However, an assumption was made that at -5°C all soil water was frozen and that at 1°C it was all thawed. Since at most sites soil temperatures at maximum active layer depth were at least -10°C , total freezing is probably a safe assumption. However, at 2B, the warm soil hovered around -5°C depending on depth and this could introduce error into the calculations.

Soil temperatures were measured with thermistors at depths of 5, 10, 25, 50, 100, 125, 150 and 175 cm at the sites with maximum active layer depths and from 100 to 125 cm depths at the other sites. Measurements of soil temperature were made daily from April through August and every second week during the freezeback period and the winter. Soil moisture was measured every three days during thaw and every two weeks in the winter.

Air temperature was measured continuously with an aspirated thermistor in summer and taken from Environment Canada measurements at the Churchill airport in winter. Net radiation and temperature data were integrated for half-hour periods in a digital recorder and stored on magnetic tape for computer analysis at McMaster University.

Snow depths were measured at the individual sites with a meter stick and during the thaw period a grid along transects 1 and 2 was sampled regularly. The maximum active layer depths, groundwater

depths, and topographic profiles shown in Figure 1, were obtained during an intensive field survey during a field course for senior students.

RESULTS

The mean monthly temperatures shown in Figure 2 indicate 5 months of thaw temperatures peaking in July-August around 11°C and 6 months of freezing temperatures reaching a minimum of -24°C in January. For the period of measurement the annual air temperature was -8.5°C . October is clearly a transitional season, with temperatures hovering around freezing; the winter period from November to April is clearly defined, as is the summer period May through September. Final snowmelt on the tundra was 3 weeks earlier than the long-term average, occurring at the end of April rather than near the end of May. Final melt in the forest in the third week in June is normal.

Rainfall, shown in Figure 3, occurred in October 1981 but was limited to the period May through September 1982. The yearly total was within 10% of the long-term average.

Snow depths are highly variable at different sites in normal fashion for the tundra. Table 1 indicates that the open tundra sites along transect 1 along with the palsa at site 2C accumulated the least snow as a result of wind erosion. This snow was deposited at the forested sites 2A and 2B, where depths in excess of 1 m were common. Site 2B was particularly notable for substantial snowpack development in early winter, and the effects on the ground temperature regime are evident. The snow at the forested sites persisted five weeks longer than at the tundra sites. Site 2D served as a minor accumulation area, with snow depths double those found at adjacent site 2C.

Seasonal net radiation totals are given in Table 1. The maximum yearly departure from the mean-measured Q^* for all sites was 14%. The forested site 2A has the largest net radiation, the result of a smaller albedo in winter, particularly during the high sun period in late winter. The minimum Q^* at site 2B resulted from the late-lying snowpack with its high albedo. Q^* measurements at the other sites are within 7% of each other and differences are largely accountable to different surface albedos. Positive net radiation at all sites except 2A begins in mid-March and persists into mid-October. For site 2A it begins about 5 weeks earlier due to strong canopy absorption of solar radiation, which is the topic of a separate report. At all sites except 2A and 2B there is an abrupt increase in Q^* that accompanies final snowmelt, and maximum values are reached in late June/early July. The negative Q^* in winter does not exceed 11% of the positive summer value and is substantially less for the forest.

As indicated in Figure 2 and Table 1, soil temperatures and active layer depths are highly variable between sites. The deepest active layers are achieved in the upland sandy soils at sites 1A and 2A and these are at least twice the depth of the wetter sites 1C, 1D, 2D, and the palsa at site 2C. The side slopes at 1B and 2B have intermediate depths, the latter being the deeper presumably due to its south slope exposure. The soils at site 2B have a longer thaw season due to early snow accumulation, which favours warm winter soil temperatures

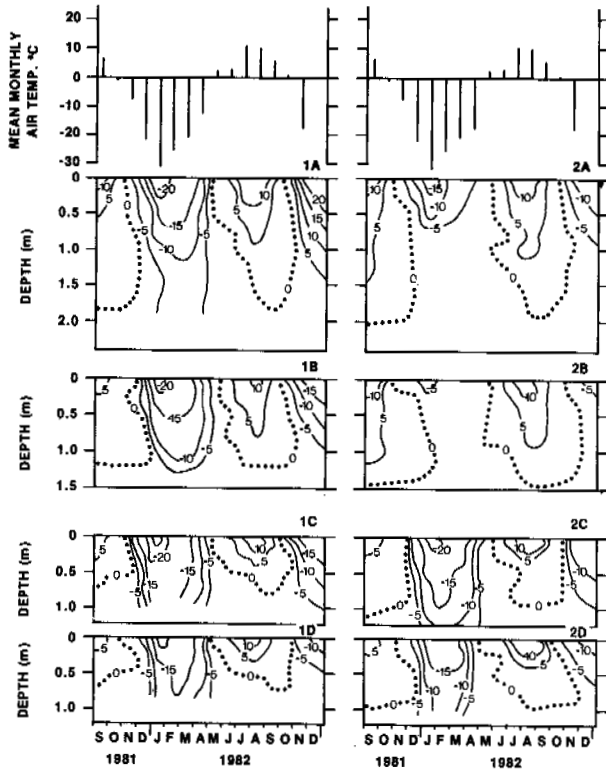

FIGURE 2 Monthly mean air temperature and the soil temperature at each site. Isotherms are at 5°C intervals. The dotted line denotes the position of the frost table.

and a prolonged zero curtain effect. At a depth of 0.5 m the coldest soils are those of the palsa at site 2C, and the warmest on an annual basis are at site 2B. The upland tundra site 1A has the largest annual temperature range.

Soil moisture is strongly influenced by soil type and topography and these are closely inter-related. The upland sites at 1A and 2A have gravel soils, and the lowland sites at 1D and 2D clay soils overlain by a thick layer of peat. Other sites are transitional between these extremes. Site 1A and 2A are the driest soils and also undergo the largest soil water loss from early to later

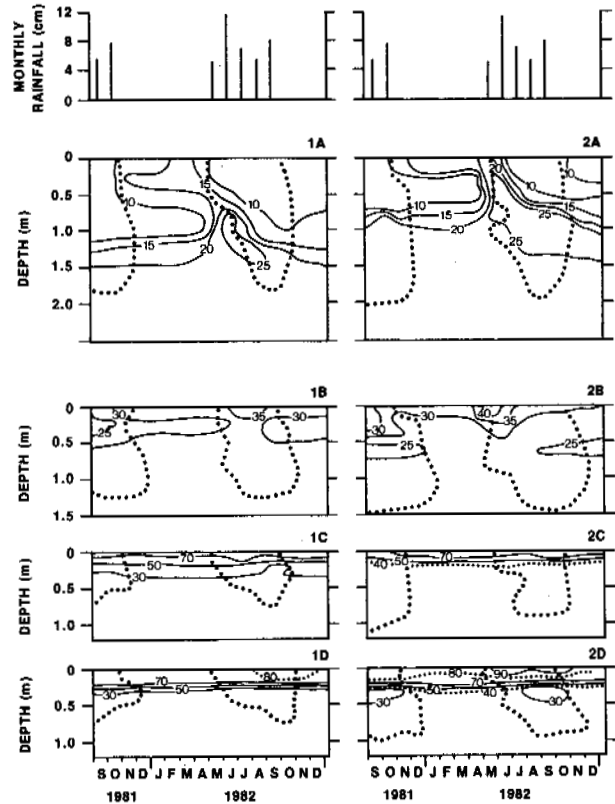

FIGURE 3 Total monthly rainfall and the volumetric soil moisture at each site. The isopleth interval is .05 in 1A, 2A, 1B, and 2B and .20 in 1C, 2C, 1D, and 2D, with fine dotted isopleths at nonregular intervals of 0.10 in the latter group.

freezeback is generally somewhat less than during thaw because, at least for this particular measurement period, the soils were drier in the fall than in the spring and the latent heat release was smaller. In terms of negative Q^* in winter, the heat released in the form of Q_G is equal to the radiational heat loss.

exactly compensates for winter season radiational heat loss associated with negative net radiation. The soil thus acts as a significant thermal regulator.

The similarity in total heat flux for such a variety of terrain types can be explained in terms of thermal conductivities and vertical temperature gradients and the large thermal conductivity of ice. The ice-rich wet sites thaw rapidly in spring due to large vertical temperature gradients and the large thermal conductivity of ice. However, with surface thawing the conductivity becomes that of saturated peat, which is not large, and the melting process is slowed, leading to shallow active layers. In contrast, the well-drained upland sandy soils remain moderately moist with less variable thermal conductivities and a more even thaw rate over the season. Because there is less ice to melt per unit volume, the active layers are deeper. Where the snow cover lies late in the forest-affected areas, thaw starts when the snow is still deep, because a temperature

.40, respectively. The peats range in density from 0.2×10^3 at the surface to 0.4×10^3 at the peat-clay interface. Their porosities likewise range from 0.9 to 0.6.

The eight sites studied represent a very heterogeneous group of landscape types that are typical of those found elsewhere in the Hudson Bay lowlands, in central Keewatin, and in the Mackenzie Valley.

Measurement

Net radiation was measured with net pyrradiometers at sites 1A, 2A, 1C and 1D at 1 m above the ground and at site 2A at 1 m above the forest. The instruments were recently calibrated and should be accurate to within $\pm 10\%$. The measurement period at sites was from late April to early September. In the winter period, measurements were made at one site similar to 1A and applied to all other sites except 2A. At 2A estimates were made according to a regression of net radiation on solar radiation derived for the April early May period in 1982 and 1979 and applied to the months of February, March and April, when there is substantial tree canopy absorption of solar radiation leading to larger Q^* . As a result, yearly totals of Q^* are larger at site 2A than at other sites. The summer measurements at site 1A were applied to 1B and 2B, those at 1C to 2C, and those at 1D to 2D.

The most important variable in equations (2) and (3) is the soil water and soil ice term as it is involved in both the sensible heat exchange in the soil Q_{SH} and the latent heat exchange Q_{LF} . Soil moisture was measured with a neutron probe at increments of 20 cm replicated at each site. The probe was calibrated for sands, clays and peats using gravimetric comparison. Since the neutron probe measures the H ion concentration in the soil, it cannot differentiate between liquid water and ice, which is a drawback to this measurement method. Soil temperature readings made it apparent when the main zero curtain effect ended, as rapid cooling or warming ensued. However, an assumption was made that at -5°C all soil water was frozen and that at 1°C it was all thawed. Since at most sites soil temperatures at maximum active layer depth were at least -10°C , total freezing is probably a safe assumption. However, at 2B, the warm soil hovered around -5°C depending on depth and this could introduce error into the calculations.

Soil temperatures were measured with thermistors at depths of 5, 10, 25, 50, 100, 125, 150 and 175 cm at the sites with maximum active layer depths and from 100 to 125 cm depths at the other sites. Measurements of soil temperature were made daily from April through August and every second week during the freezeback period and the winter. Soil moisture was measured every three days during thaw and every two weeks in the winter.

Air temperature was measured continuously with an aspirated thermistor in summer and taken from Environment Canada measurements at the Churchill airport in winter. Net radiation and temperature data were integrated for half-hour periods in a digital recorder and stored on magnetic tape for computer analysis at McMaster University.

Snow depths were measured at the individual sites with a meter stick and during the thaw period a grid along transects 1 and 2 was sampled regularly. The maximum active layer depths, groundwater

depths, and topographic profiles shown in Figure 1, were obtained during an intensive field survey during a field course for senior students.

RESULTS

The mean monthly temperatures shown in Figure 2 indicate 5 months of thaw temperatures peaking in July-August around 11°C and 6 months of freezing temperatures reaching a minimum of -24°C in January. For the period of measurement the annual air temperature was -8.5°C . October is clearly a transitional season, with temperatures hovering around freezing; the winter period from November to April is clearly defined, as is the summer period May through September. Final snowmelt on the tundra was 3 weeks earlier than the long-term average, occurring at the end of April rather than near the end of May. Final melt in the forest in the third week in June is normal.

Rainfall, shown in Figure 3, occurred in October 1981 but was limited to the period May through September 1982. The yearly total was within 10% of the long-term average.

Snow depths are highly variable at different sites in normal fashion for the tundra. Table 1 indicates that the open tundra sites along transect 1 along with the palsa at site 2C accumulated the least snow as a result of wind erosion. This snow was deposited at the forested sites 2A and 2B, where depths in excess of 1 m were common. Site 2B was particularly notable for substantial snowpack development in early winter, and the effects on the ground temperature regime are evident. The snow at the forested sites persisted five weeks longer than at the tundra sites. Site 2D served as a minor accumulation area, with snow depths double those found at adjacent site 2C.

Seasonal net radiation totals are given in Table 1. The maximum yearly departure from the mean-measured Q^* for all sites was 14%. The forested site 2A has the largest net radiation, the result of a smaller albedo in winter, particularly during the high sun period in late winter. The minimum Q^* at site 2B resulted from the late-lying snowpack with its high albedo. Q^* measurements at the other sites are within 7% of each other and differences are largely accountable to different surface albedos. Positive net radiation at all sites except 2A begins in mid-March and persists into mid-October. For site 2A it begins about 5 weeks earlier due to strong canopy absorption of solar radiation, which is the topic of a separate report. At all sites except 2A and 2B there is an abrupt increase in Q^* that accompanies final snowmelt, and maximum values are reached in late June/early July. The negative Q^* in winter does not exceed 11% of the positive summer value and is substantially less for the forest.

As indicated in Figure 2 and Table 1, soil temperatures and active layer depths are highly variable between sites. The deepest active layers are achieved in the upland sandy soils at sites 1A and 2A and these are at least twice the depth of the wetter sites 1C, 1D, 2D, and the palsa at site 2C. The side slopes at 1B and 2B have intermediate depths, the latter being the deeper presumably due to its south slope exposure. The soils at site 2B have a longer thaw season due to early snow accumulation, which favours warm winter soil temperatures

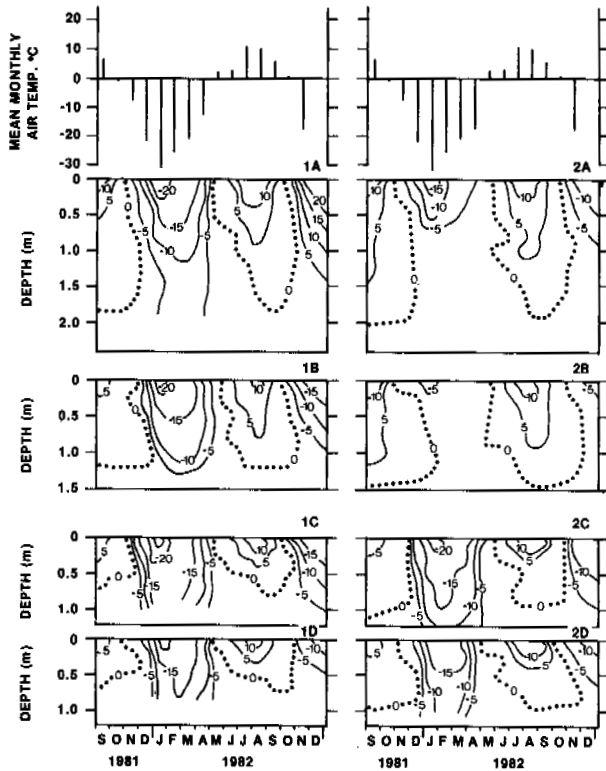

FIGURE 2 Monthly mean air temperature and the soil temperature at each site. Isotherms are at 5°C intervals. The dotted line denotes the position of the frost table.

and a prolonged zero curtain effect. At a depth of 0.5 m the coldest soils are those of the palsa at site 2C, and the warmest on an annual basis are at site 2B. The upland tundra site 1A has the largest annual temperature range.

Soil moisture is strongly influenced by soil type and topography and these are closely inter-related. The upland sites at 1A and 2A have gravel soils, and the lowland sites at 1D and 2D clay soils overlain by a thick layer of peat. Other sites are transitional between these extremes. Site 1A and 2A are the driest soils and also undergo the largest soil water loss from early to later summer. Sites 1D and 2D are the wettest sites with up to 90% soil moisture by volume in the surface organic layer, and they also show the least seasonal variability. The palsa site 2C is distinctive because the thick surface peat layer undergoes substantial summer drying.

The ground heat storage Q_G shown in Table 1 is subdivided into its components of the latent heat flux Q_{LF} and sensible heat component Q_{SH} . The following generalizations can be made. The wettest sites have the smallest latent heat exchange, which arises because they have the shallowest active layers and the largest temperature variation in the ice-rich near-surface permafrost. During the full thaw season Q_G makes up 10 to 13% the magnitude of Q^* . Early in the thaw season when both fluxes are large, the magnitude of Q_G is up to one-half that of Q^* . Total Q_G for all sites during the thaw season is very similar, with a maximum variability of 15% about the mean. The heat release during

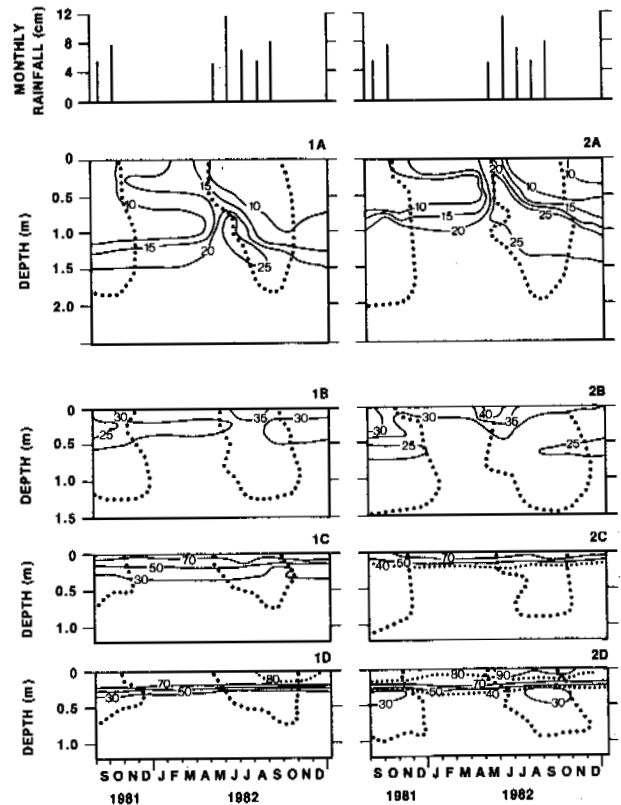

FIGURE 3 Total monthly rainfall and the volumetric soil moisture at each site. The isopleth interval is .05 in 1A, 2A, 1B, and 2B and .20 in 1C, 2C, 1D, and 2D, with fine dotted isopleths at nonregular intervals of 0.10 in the latter group.

freezeback is generally somewhat less than during thaw because, at least for this particular measurement period, the soils were drier in the fall than in the spring and the latent heat release was smaller. In terms of negative Q_G^* in winter, the heat released in the form of Q_G is equal to the radiational heat loss.

DISCUSSION

The most important results of this experiment are the large magnitude of Q_G in terms of Q^* and the uniformity of Q_G between sites. These sites are extremely varied in terms of vegetation type, soil type, soil moisture content, depth of active layer development, and depth and longevity of the snowpack.

In terms of the vertical heat transfer processes presented in equation (1) the two variables are the soil thermal conductivity k and the vertical temperature gradient $\Delta T/\Delta z$. The variable k is large for sands when they are even moderately wet and large for ice. It is moderate for wet clays and small for organic soils and for water and hence for saturated organic soils.

In early spring, k is large because the ground is frozen and $\Delta T/\Delta z$ across the atmospheric soil interface is large, so Q_G proceeds very rapidly,

Note: X_w is volumetric soil moisture; T is soil temperature; z(AL) is active layer depth; z_s is snow depth; Q_G is total soil heat flux; Q_{LF} is latent heat flux; Q^* is net radiation; TH is the thaw period; FB the freeze period. Fluxes are in MJ m⁻² for the period.

particularly in the ice-rich soils such as 1C, 1D, and 2D. Even beneath the snowpack (such as at sites 2A and 2B) thawing proceeds, since the snow is at 0°C and the frozen soil is < 0°C and has a large thermal conductivity, particularly when snow-melt refreezes in the top soil layers.

In terms of uniformity in the total heat flux between dry upland sites with a deep active layer and wet lowland sites with a shallow active layer it is useful to compare 1A and 1D. Table 2 shows that in May, Q_G at 1D is substantially larger than at 1A, in June they are about the same, and in July and August the heat flux at 1D is considerably less than at 1A. This can be interpreted in terms of the thermal conductivities that are largest at 1D early in the season when there is ice in the surface soil layers but become smaller than at 1A later in the season because of the smaller k of the saturated surface peat layer.

It is instructive to compare sites 1A and 2A. Although a thick snow layer dominates 2A until mid-June, the soil heat flux is greater than at 1A in both May and June and the forest soils are thawed to 1.3 m by final snowmelt. This rapid thawing is a response to large thermal conductivity in the moist sand and to the fact that the soils at depth

stay relatively warm throughout the winter. In July and August, Q_G at 2A is less than at 1A in spite of larger thermal conductivity because the vertical temperature gradients are less.

It is clear from Table 1 that neither the actual soil temperature nor the range of temperature change in the soil bears a relationship to the magnitude of the heat flux. Thus 2B, which is much warmer in winter than 1A, has the same magnitude of heat flux during the thaw season.

The soil stores summertime heat, which constitutes at least 10% of the net radiation flux. The release of this heat maintains relatively warm soils until the end of December and, in the event of a deep snow cover (as at 2B), throughout the winter season.

The results of this study should have more general applicability, since the varied terrain types studied are common in the Hudson Bay lowlands and in many areas of central Keewatin and the Mackenzie District. They are important to assessing evaporation using energy budget approaches, which often ignore Q_G in temperate latitude studies, but which cannot ignore it in permafrost areas. It is evident that warm soils can be achieved through effective thermal insulation of the surface in

Note: Q* is net radiation; Q_G is soil heat flux; Q_{LF} is soil latent heat flux. Flux values in MJ m⁻² month⁻¹; k is thermal conductivity through the top 25 cm of soil in Wm⁻¹°C⁻¹.

early fall, which would be at the end of August in the case of Churchill. This results in an augmentation of the thermal energy in the soil of at least 10% of the summer net radiation, as at site 2B.

CONCLUSIONS

As a result of much lesser snow depths final snowmelt on the open tundra preceded that in the forest by 7 weeks. However, snowmelt on the tundra was 3 weeks earlier than average. All other conditions were close to normal.

Net radiation was largest in the forest due to small albedos, especially in winter, and smallest at site 2B, where the longer-persisting snowpack maintained a large surface albedo into the summer solstice period. However, the maximum variation at any site was within 14% of the average. The total negative net radiation in winter did not exceed 11% of the positive summer total at any site.

Active layer depths in the sandy upland sites were double those of the lowland sites and, where snow accumulated early and stayed late, the soil presented the longest thaw season and warmest over all temperatures. Soil moisture was least on the upland sandy sites and also showed substantial summer drying, whereas in the wet sites it varied little over time and measured as large as 90% by volume in the surface low-density peat soils. The palsa was anomalous in many respects, having the coldest soils and also undergoing considerable drying in the surface peat layer.

During the thaw season, the ground heat storage was almost the same for all sites and averaged 12% of net radiation with site variations from 10 to 13%. Thus it is an important component in the energy balance at the surface. During freezeback, the heat energy released from the soil almost

exactly compensates for winter season radiational heat loss associated with negative net radiation. The soil thus acts as a significant thermal regulator.

The similarity in total heat flux for such a variety of terrain types can be explained in terms of thermal conductivities and vertical temperature gradients and the large thermal conductivity of ice. The ice-rich wet sites thaw rapidly in spring due to large vertical temperature gradients and the large thermal conductivity of ice. However, with surface thawing the conductivity becomes that of saturated peat, which is not large, and the melting process is slowed, leading to shallow active layers. In contrast, the well-drained upland sandy soils remain moderately moist with less variable thermal conductivities and a more even thaw rate over the season. Because there is less ice to melt per unit volume, the active layers are deeper. Where the snow cover lies late in the forest-affected areas, thaw starts when the snow is still deep, because a temperature gradient between warm snowpack and colder soils exists and the frozen soils have large thermal conductivities.

The results of this study are seen as having more general applicability for wet or moderately wet low arctic terrain, since the processes that favour a large and relatively uniform ground heat flux are universal.

DESIGN CONSIDERATIONS FOR LARGE STORAGE TANKS IN PERMAFROST AREAS

W. L. Ryan

Ott Water Engineers, Anchorage, Alaska 99503 USA

Large water and/or oil storage tanks (50,000 gal. or more) are usually necessary for camps, sites, or communities in the Arctic. The design, construction, and operational problems for over 40 large water storage tanks in arctic and subarctic Alaska are reviewed and summarized. The majority of the difficulties encountered with the tanks fall into three areas: foundations, interior painting, and outside insulation systems. Foundation settlement or heaving has proven to be the most widespread problem with large storage tanks. Unfrozen lenses, "warm" permafrost, and incorrect adfreeze strengths have all contributed to the several instances of settlement. Piling and gravel pads have both received widespread use, depending on local soil conditions and the availability of equipment and materials. Another very common problem is the failure of the interior painting systems. These failures have occurred with both the vinyl and epoxy paint systems and tend to be caused by the lack of adequate curing temperatures, inadequate ventilation during curing, and the individual layers being applied too thick.

INTRODUCTION

Large water and oil storage tanks are necessary for camps, sites, or communities in the Arctic. Water storage tanks have several characteristics which make them more difficult to design and maintain than oil storage tanks and, thus, will be emphasized in this paper. The majority of the difficulties encountered with the large storage tanks fall into three areas: foundations, interior painting, and outside insulation systems.

The majority of the tanks constructed over the past 10 years have been welded steel tanks with sprayed polyurethane foam insulation. Occasionally, "bladder" tanks and wood stave tanks with strapped-on boardstock insulation have also been used. Table 1 presents a summary of many of the major water storage tanks that have been constructed in the cold regions of Alaska. The problems (if any) that have been experienced with them are included, along with the construction costs of tanks constructed prior to 1980 adjusted to 1980 costs considering 7% per year inflation.

FOUNDATIONS

Foundation design is heavily dependent on the soil conditions at the site. Piling and gravel pads comprise most of the foundations utilized. The foundations have proven to be the most widespread problem encountered with large storage tanks in Alaska. The type of foundation used depends on several factors: permafrost presence (and its temperature) and soil properties; availability of construction materials such as gravel or piling; availability of equipment for construction; and the size and shape of the tank.

The presence of permafrost can simplify or complicate a foundation design. Due to the excessive weight that must be supported, hard-frozen, "cold" permafrost (less than -2°C) can best provide the support needed when using a pile foundation for

tanks. The load carrying capacity of a pile placed in cold permafrost is considerably greater than that of one in unfrozen ground, which must essentially rely on friction and/or end-bearing. In fact, in warmer soils (nonpermafrost), it is often not feasible to place sufficient piling under the tank to support the weight considering friction and/or end-bearing alone. In the absence of permafrost, a gravel pad or post and pad foundation is usually designed. In cold permafrost locations, piles are usually used unless large quantities of gravel are readily available. If sufficient gravel is available (a rare occurrence in much of Alaska's Arctic), a pad can be designed with sufficient thickness to prevent thawing of the underlying frozen ground due to heat lost from the tank. Insulation can be added to the pad to reduce the amount of gravel required. Only extruded polystyrene insulation should be used in tank foundations because it is the most resistant to deterioration by moisture.

The most difficult design situation is when "warm" permafrost (above -2°C) or permafrost with thawed "pockets" (talik) is encountered. Warm permafrost usually occurs near the southern limits of the continuous permafrost areas. Talik areas can occur in any location containing frozen ground but are most abundant in coastal areas, where they are often caused by a concentration of salts. This accentuates the importance of a detailed test drilling program. Test drilling must be carried out before foundations are designed to determine if thawed pockets do, in fact, exist. Piles having a portion of their length in the thawed area may not provide the support needed and settlement will result. The water storage tank location in Wainwright, Alaska, encountered this condition. It may have also been a contributing factor to the settling problems experienced with tanks in Barrow and Kaktovik, Alaska. In warm permafrost areas, the active layer is also deeper and longer piles will be required to obtain the same adfreeze strength for support.

Any construction activity at the ground surface can have a lasting effect on the depth of the active layer. This must be considered during pile design. The construction should be carefully carried out using mats or pads to protect the surface moss and to retain its insulating value. Any degradation of the permafrost can cause severe settling problems in high moisture content situations. Subsequent degradation can also be caused by heat lost through the tank bottom. In warm permafrost areas, it is even more important to insulate the permafrost from this heat or to provide air circulation under the tank to carry it away to the atmosphere. This is usually best accomplished by placing the tank on piling 1 or 2 m above the ground, but it can also be accomplished by a thick, insulated gravel pad containing pipes or culverts for the circulation of air. These pipes can be fitted with blowers which can force circulation through them in the winter, but they must be deactivated and the culverts plugged to prevent circulation during the summer.

There are other solutions which are not in wide use because of the high construction and/or operation and maintenance costs. Two examples of other methods which have been used to remove this heat before it melts the underlying frozen ground are: refrigeration lines laid directly in the pad, and forced air or self-acting thermo-piles.

The method of pile placement is critical. The primary objective is to place the pile in the ground with the least amount of thermal disturbance to the permafrost. The preferred method is to slightly underdrill a hole and drive the pile. The disadvantage of this method is that it requires pile driving equipment. Thus, most piles are placed using a drill-slurry back method. However, if not done carefully, this method can thaw the permafrost immediately around the hole and significantly extend the period of time needed for freeze-back. The piling can support only a small portion of the design load until the surrounding ground is frozen back and has dropped to the design temperature. In warm permafrost situations, this could take an entire winter or, more than one winter, depending on the thermal disturbance. With the drill-slurry back construction method, it is often necessary to mechanically freeze back the pile. It is essential that the temperature at various depths be determined prior to design and, if possible, at the time the ground is warmest. In calculating adfreeze bond strengths, differences in temperature from the top of the hole to the bottom should be integrated and not based only on an average temperature. The relationship between adfreeze strength and temperature is not linear.

Frost jacking of the piling in a tank foundation is not usually a problem because of the high loads. However, the design of a pile foundation must consider frost jacking prevention because it could be a problem if a tank should remain empty for a period of time. Frost heave can also create problems with the outer pile of a tank foundation which are usually only supporting a walkway that is not heavy enough to prevent the jacking.

Any coating, such as creosote, can significantly reduce the adfreeze strength and thus the load supporting capacity of a pile. This was a major contributing factor to the settlement problems encountered with a 2,160,000 liter water stor-

age tank constructed on piles in Barrow, Alaska. The use of a bond breaking material on the pile in the region of the active layer should be encouraged to prevent frost jacking. However, it must not extend into the permafrost, or the load supporting area of the pile.

The active method of tank foundation construction will not be discussed at great length here, as it is not often used. This method consists of prethawing with excavation and replacement of the thaw unstable frozen ground and designing the tank for a small amount of subsequent settling.

Creep of frozen ground can be a significant factor in a piling tank foundation because of the high loading. The magnitude of creep is very temperature dependent and, thus, is a greater problem in warm permafrost than cold permafrost.

Foundation costs are extremely variable depending on the availability of equipment and materials, the size of tank, and the permafrost conditions. Typical 1980 construction costs (U.S. dollars) of a foundation for a 1,900,000 liter tank would be around \$100,000 for a gravel pad (depending heavily on the availability of gravel) and \$200,000 for a pile foundation and floor system.

TANK DESIGN AND MATERIALS

The most widely used tank in remote arctic areas is welded steel. Wood stave tanks have been successfully used in the subarctic areas but they usually have more drawbacks than advantages in the Arctic. The disadvantages of wood stave tanks follow: (1) By design, they "weep" to maintain their overall water tightness. This can create problems in the winter and it makes them difficult to insulate effectively. (2) They will leak if they are not properly constructed and there seems to be a lack of people trained to assemble them correctly. (3) They are usually not cost effective in sizes larger than 375,000 liters. (4) Wood stave tanks are designed to be kept full at all times. This is not possible in many of the remote locations, especially where the tanks are operated on a fill and draw cycle. Impermeable liners have been used inside tanks. However, they are usually not very successful as human and ice damage can cause punctures.

Wood stave tanks do have the advantage of being easily transported into remote areas and specialized equipment is not usually required for assembly. The wood does provide a certain amount of insulation, also.

Concrete tanks are seldom used in the Alaskan Arctic. They require large quantities of high-quality aggregate and a solid, nonsettling foundation (rock), both of which are usually not available.

Steel tanks can be either bolted or welded. Bolted tanks are not as popular in larger sizes. Any damage during shipping can make it impossible to align the bolt holes during erection and increase the tendency of the seams to "seep". They do have the advantage, however, that the interior coatings can be baked on in the factory and then touched up in the field.

Welded steel tanks in smaller sizes (less than 75,000 liters) can be shipped to the site prefabricated, with no field welding required. However,

the larger tanks must be shipped in pieces and erected on site. Welders, qualified operators, and vacuum and radiographic equipment must be available to check for faulty welds.

At any location where the tank may remain empty or could reach the ambient temperature during the winter, special low-temperature welding procedures and steels with high impact strength at low temperatures should be used (ASTM A-516).

Steel tanks must also be painted, inside and out. Interior coatings have proven to be a major problem. Both vinyl and epoxy coatings have been used with varying success. Any interior treatment used in a tank storing potable water must be approved by the American Water Works Association (AWWA). The main problems that have occurred can be traced to improper application temperatures, solvent entrapment during curing, and the thickness of the individual coats. The keys to proper application appear to be assuring the surface is clean (sandblasted), dry, and warm (above 16°C), and that the total coating is applied in several thin coats instead of a few thicker ones. The AWWA, ASTM, and paint suppliers specifications should be consulted and followed. Exterior coatings are not as critical if sprayed-on urethane insulation is to cover the tank. In these cases, the outside is primed only, before applying the insulation.

Rubber "bladder" tanks have been used in some locations for oil and gasoline storage, usually on a temporary basis. Fiber glass tanks in the larger sizes are relatively new on the market and are not used extensively at the present time, but may be a consideration in the future.

Maintaining the water temperature above freezing in water storage tanks is a critical design consideration. Any ice forming in a tank can cause damage to coatings, attachments, controls, and even the tank itself. Heating systems and insulation should be designed to prohibit the formation of any ice and interior ladders and appurtenances should not be attached rigidly to the tank walls. Serious damage can result to the tank if ice should form on these fixtures. For example, the heat supply to a welded steel storage tank in Kotzebue, Alaska, failed, causing ice to form around the wall of the tank which included a stationary, interior ladder. Water continued to be drawn from the tank and the level dropped, leaving ice exposed. The hanging ice then broke loose and fell, tearing holes in the side of the tank where it pulled the ladder from the tank walls. The falling ice also damaged the bottom of the tank.

Surface ice can be prevented by operating the tank at a temperature above 4°C (point at which water is most dense), and wall icing can be prevented by keeping the contents mixed and above freezing. Outlet and inlet lines should be separated to help provide this circulation. Pumps should be utilized to provide circulation, if necessary.

INSULATION

All water storage tanks in arctic areas must be insulated or placed inside a heated building. Steel tank walls provide essentially no insulation value with the only "insulation" coming from the surrounding air film. Steel appurtenances should not penetrate the insulation, as ice will form on

the inside of the tank at the point of the thermal break.

Urethane and polystyrene are the most common insulations used for large water storage tanks. In any installation where the insulation is likely to be in contact with water, extruded polystyrene is recommended. A typical location would be in the gravel pad under the tank. Polystyrene must be applied as boardstock and cannot be sprayed on in the field as can urethane. Urethane has a somewhat better insulating value providing it has an airtight covering to prevent the loss of the freon gas filling the voids. However, if it is not tightly covered, the freon escapes and is replaced by air and urethane's insulating value becomes nearly identical to that of polystyrene. Urethane will break down faster than extruded polystyrene if it is exposed to moisture and freeze-thaw cycles or ultraviolet light (sunlight).

The preferred method of insulating is to spray urethane on in the field and cover it with a low molecular weight, butyl membrane for vapor seal and ultraviolet light protection and then with aluminum siding for physical protection. A critical consideration with this procedure in cold regions is the ambient temperatures. The air temperature must be above 10°C for proper application. The weather must be calm (no wind) when spraying. Even the slightest wind can waste large amounts of insulation and cause considerable damage to the surrounding property such as buildings and automobiles.

Another often-used method of insulating tanks is to strap or bond boardstock, either urethane or polystyrene, to the outside walls of the tank. This method can be used where the weather conditions are not suited for a spraying operation. Problems have been encountered in high wind areas where pieces of insulation have been blown from the tank. The insulation, and its covering, must be well strapped to the tank using clips welded to the outside tank walls. Also, spray or pour foam must be used to fill the cracks between the insulation boards before the outside covering is added.

Boardstock, preferably extruded polystyrene, should be used to insulate under the tank also. This is especially important for tanks on gravel pads in permafrost areas to prevent the lost heat from degrading the permafrost. The amount and type used will be determined by the specific conditions at the site.

The thickness of insulation needed will vary with the climate and heating costs at the location and can be determined through an economic analysis.

CONSTRUCTION COST

Typical tank costs are presented in the attached table, adjusted to 1980 construction costs using a 7% per year inflation factor. Tank costs since 1979 are actual costs in the year constructed. The variances in the unit costs can be attributed to changes in the cost of steel, the location of the tank, and the size of the tank. Foundation costs are not included. Typical specifications for interior painting systems and exterior insulation can be obtained from the author or John Delapp with the Alaska Area Native Health Service. Mr. Delapp also supplied cost and experience information for tanks constructed in 1982.

TABLE 1 Alaska Water Storage Tanks.

Location	Year Const.	Tank Dim. (meters)		Tank Size (liters [x10 ⁶])	Approx. Weight of Steel (kg.)	Cost (U.S. \$)*		Type of Use	Insulation Type, thickness, covering	Interior Paint	Ground Conditions	Foundation Type	Problems
		Dia.	Ht.			Total	\$/L.						
Kotzebue	1967	25	10.7	5.67	N/A	N/A	N/A	Continuous Use	Sprayed urethane 7.6 cm	Vinyl	Frozen gravel	Gravel pad	Need interior repainted. No settlement problems.
Wainwright	1971	25.6	7.3	3.79	N/A	N/A	N/A	Annual Fill	Banded urethane boards, 8.5 cm; cracks filled with sprayed urethane, covered with elastomeric material.	Vinyl	Frozen silts and organics	Wood piling	Experiencing gradual settlement. Insulation on roof popping off from settlement. Cracks opening on wall insulation.
Barrow	1975	21.3	6.1	2.16	57,143	401,800	0.185	Continuous Use	Spray urethane 8.9 cm walls, 12.7 cm top, butyl covering.	Epoxy (orig.) Repainted United "Vabar"	Frozen silts, organics, with some free ice.	Treated piling	100% inside repaint done 1981. Massive foundation settlement upon initial filling in 1978. Posts and pads installed to stop settlement in 1979.
Kivalina	1975	18.3	7.3	1.92	53,968	374,500	0.196	Annual Fill	Beadboard in gravel/foundation, 8.9 cm urethane boardstock walls, 10.2 cm urethane spray top, aluminum covering on walls.	Vinyl	Frozen gravel	Gravel pads	Originally boardstock roof blew off. Replaced with spray urethane.
Shungnak	1976	11.6	7.3	0.76	26,304	217,800	0.288	Monthly Fill	Sprayed urethane 8.9 cm, covered with butyl and paint.	Epoxy (orig.) now vinyl	Frozen sand overlain by 2 meters moist peat.	Gravel pad (removed peat)	Original epoxy rust "spotted" particularly at weld lanes. Tank repainted with vinyl in 1982.
Gambell	1976	9.1	6.1	0.38	16,780	122,200	0.322	Continuous Use	Sprayed urethane 8.9 cm, elastomeric coating. Aluminum sheathing installed 1981.	Epoxy	Pea gravel	Gravel	Interior paint failures recoated in 1981. Coating was "chalking" off and cracking. New paint is also blistered.
Savoonga	1976	9.1	6.1	0.38	16,780	138,000	0.365	Continuous Use	Sprayed urethane 8.9 cm, covered with elastomeric coating, aluminum sheathing installed in 1981.	Epoxy	Saturated frozen organics, ice lenses lava boulders.	Drill/drive steel pipe piles	Original interior paint failed. Recoated in 1981. Numerous small blisters developed after one year service of new paint.
Shishmaref	1976	12.8	9.1	1.14	33,107	231,000	0.203	Annual Fill	Sprayed urethane 8.9 cm covered with butyl.	Epoxy	Fine sand; probably frozen.	Sand pad	Interior inspected 1980. No major problems.
Grayling	1977	7.3	5.5	0.21	11,338	97,400	0.460	Continuous Use	Sprayed urethane 8.9 cm butyl.	Epoxy	Unfrozen silts and gravels.	Gravel pad	None known.
Twin Hills	1977	6.7	6.1	0.21	11,338	83,700	0.394	Continuous Use	Sprayed urethane 8.9 cm, butyl.	Epoxy	Unfrozen tundra mat overlain by thawed silts with some sand and gravel.	Gravel pad	None known.
Unalakleet	1977	24.4	6.1	3.78	99,320	346,700	0.092	Continuous Use	Sprayed urethane 8.9 cm, butyl.	Epoxy	Gravel	Gravel pad	Original paint failure interior. Repainted 1981. Recoating has blisters on floor.
Stebbins	1978	18.3	7.3	1.92	53,968	232,400	0.122	Annual Fill	Sprayed urethane 8.9 cm, butyl.	Epoxy	Sand & gravel gravel	Sand & gravel pad	None known.

CREEP OF FROZEN SOILS ON ROCK SLOPES

A. V. Sadovsky and G. I. Bondarenko

Research Institute of Foundations and Underground Structures,
Moscow, USSR

This article presents the result of experimental investigations into the creep of frozen materials on rock slopes. Analysis of field data revealed that creep in frozen waste heaps in northern regions is a typical rheological process. Laboratory investigations included two types of tests: simple shear tests and tests of shear-with-skewing. More than 400 samples of soil frozen to the rock were tested. The mechanics of shear were investigated and the formation of two zones was established: a zone of contact, and an overlying zone. By using the data from the experimental studies and from field observations it was possible to develop a method of calculating the rate of creep of frozen waste heaps on rock slopes and to predict the failure of these waste heaps.

The creep of frozen soils along the inclined rocky bed has something in common with flow of glaciers. But there are some differences due to peculiarities of deformabilities of ice and frozen soil. Ice flows practically under any load, but frozen soil flows when the load exceeds the threshold load corresponding to the onset of viscoplastic flow.

Several studies were made to investigate the processes of frozen soils deformability when they slide along the inclined rocky bed. The sliding of ten weathered rock masses was investigated and laboratory tests of frozen soils adfrozen to the rock material were conducted.

While mining is proceeding in the open manner in hilly regions weathered rock masses are thrown down on the rocky slopes. Low temperature causes quick cooling of blasted rock and an accumulation of a large reservoir of cold within it. The frozen state is the main peculiarity of weathered rock masses in the northern regions. The mean temperature of observed frozen masses on the rocky slopes ranges from -0.6°C to -1.0°C , the height of slopes ranges from 170 m to 400 m, and the angle of inclining ranges from 37° to 51° . After the mass volume increases to a certain value, the sliding begins. As a rule a period of deformation preceded the failure and creeping with constant speed lasted from 3 to 8 months. Analysis of field data showed the sliding of frozen masses to be the rheological process. Figure 1 shows the sliding to be a complicated process: the movement of "a" to the position of "a¹" shows the movement of the whole mass along the rocky slope, and shape of the mass surface during the sliding (curve a¹b¹c¹) reflects the creeping inside the mass.

More than 400 tests were conducted to investigate a long-term shear resistance of frozen soils adfrozen to the rock. Soil samples were prepared from coarse grained rock (maximal size of particles—5 mm). That soil was similar to sand, containing fine particles more than 8%; the water content was 0.13. Soil was adfrozen to the rock in the cold chamber with temperature -25°C . Then samples were kept during 15-18 hours at the testing

temperature. The roughness of the rock surface was formed by ac. HCl. The roughness degree was estimated as a sum of cavities (in mm) per 1 m of length. Shear devices PRS-1 developed by Sadovsky were used for tests.

First, it was necessary to determine if the rupture always occurred along the contacting surface. For that purpose shear tests were conducted on rocky samples at five values of roughness and the influence of roughness on the adfreeze resistance was investigated. It was shown that the roughness increased both parameters of the shear resistance: namely friction and cohesion. Empirical dependence of both parameters from the value of roughness was obtained.

The investigations have shown the process of deformability along the contact surface proceeds like the process of deformability within the frozen soil (2). Creep curves and long-term resistance of frozen soil decrease with time because the cohesion is the main source of long-term resistance decrease. The change in the friction angle with time and temperature is negligible. But there are some differences: the rupture along the contact surface occurs over a shorter period of time than the rupture within the soil under the same loads, i.e., each stage of the creep takes place over a shorter period along the contact surface and the shear resistance along the contact surface at any given time is less than that within the soil mass.

Two types of shear tests were conducted: shear (along the contact surface) and shear-to-skewing tests (general shear) (Figure 2).

In the shear-to-skewing test a certain volume of frozen soil was deformed. Total and by-contact shear linear deformations (strains) were measured. Angular deformations of soil were determined as a ratio of strains to the proper height, h, of the skewed layer. Constant strain rates were determined from creep curves (Figure 3). Experimental results indicate that rupture always occurred along the contact surface since the contact surface creep begins under less loads than the creep within the soil mass. As a result, tertiary creep (or progressive stage of creep) begins earlier than

that within the slide mass. For example, shear stress = 0.4 MPa led to creep with a contact strain rate equal to $1.4 \cdot 10^{-4} \text{ cm}^{-1}$, but at the same time strains inside the soil were gradually damping.

The relationship between the angular strain rate and shear stress within the loaded boundary (thickness h_c in Figure 2) layer may be described by Bingham-Schwedoff's relation:

$$\gamma = \frac{1}{\eta} (\tau - \tau_{\infty}) \quad (1)$$

where τ = acting stress;
 τ_{∞} = long-term resistance; and
 η = viscosity coefficient.

The viscosity coefficient for the boundary layer is practically equal to the viscosity coefficient for soil. Differences between strain rates of the boundary layer and of the soil are caused by differences of long-term resistances of abovementioned layers.

Linear slide speed (Figure 4), V , of any soil layer within the mass increases proportionally to distance from rocky bed and can be expressed by:

(a) for the boundary layer: as $V^c = \dot{\gamma}_c \cdot h_c$;

(b) for soil: as $V^s = \dot{\gamma}_s \cdot h_s$;

where h_c = thickness of the boundary layer, and
 h_s = distance from rocky bed to the soil layer.

Linear slide speed at the top surface of the sliding mass is equal to:

$$V = V^c + V^s \quad (2)$$

Experimental results confirmed that the rupture occurs after deformation reaches a definite value. It was observed that the rupture occurred only along the contact surface and the time until rupture is proportional to the strain rate along this contact surface. This fact brought forth the possibility of forecasting time until rupture by using experimental or field observed strain rates.

Experiments showed that two zones are formed in the sliding mass: namely, the boundary layer and the soil located above the boundary layer; viscosities of both zones are similar, but shear resistances are different. As a result, tertiary creep and subsequent rupture occur along the contact surface.

To determine strain rates of frozen masses of rock rubble, we analyzed the creep of a single homogeneous layer resting on bedrock which extends downward indefinitely. It was assumed that the slope deformation process proceeds as simple shear in the direction parallel to the bedrock surface and the mass of rock rubble is a homogeneous frozen soil. Shear stress produced by weight of mass can be written as:

$$\tau = \gamma_0 (H - y) \sin \alpha \quad (3)$$

where γ_0 = bulk density;
 H = thickness of the sliding mass;
 y = distance from bedrock to the layer being analyzed; and
 α = angle of inclination of bedrock surface.

It is known that the creep of frozen soil is caused by excess stress of: $\tau - \tau_{\infty}$, and for slopes:

$$\tau_{\infty} = C_{\infty} + \gamma_0 (H - y) \cos \alpha \cdot \text{tg} \phi_{\infty}.$$

Strain rate at the surface of the sliding mass (where $Y=H$) was determined from Stroganov's (4) and Maslov's solutions:

$$V^s = \frac{H-D}{\eta} \left[\gamma_0 \frac{H+D}{2} \cos \alpha (\text{tg} \alpha - \text{tg} \phi_{\infty}^s) - C_{\infty}^s \right] \quad (4)$$

$D = C_{\infty}^s \gamma_0 \cos \alpha (\text{tg} \alpha + \text{tg} \phi_{\infty}^s)$ — thickness of upper passive moving layer in which $\tau < \tau_{\infty}$.

Similar to equation 4 strain rate in the boundary layer is equal to:

$$V^c = \frac{h_c}{\eta} \left[\gamma_0 \left(H - \frac{h_c}{2} \right) \cos \alpha (\text{tg} \alpha - \text{tg} \phi_{\infty}^c) - C_{\infty}^s \right] \quad (5)$$

Strain rate on the surface of the sliding mass can be determined as a sum of a contact strain rate and a strain rate of the mass upper layer using formulas 2-5.

Calculations of strain rates for the secondary stage of creep were made using stress and deformation parameters determined from test results. Calculations showed that the creep speed of frozen heaps is very dependent on temperature. For example, an increase in temperature from -2°C to -1°C ($H=50$ m, $\alpha=50^{\circ}$) results in increasing the boundary layer strain rate from 0.35 to 32 mm per day and for the upper layer of the sliding mass, from 8 to 85 mm per day.

Comparison of both strain rates shows that strain rate inside the mass is to a great extent higher than contact strain rate. But if the temperature of the upper layers is below the temperature of the boundary layer, the creep inside the mass cannot begin. Since contact friction is less than friction inside the soil mass ($\phi_{\infty}^c = 18^{\circ}$ and $\phi_{\infty}^s = 32^{\circ}$), creep of the boundary layer can begin at a lesser angle of inclination of bedrock. For example, if $H=30$ m and the temperature is equal to 0.6°C , the contact creep begins at $\alpha=26^{\circ}$, but creep inside of the soil begins only at $\alpha=40^{\circ}$. This example shows how important it is to know the contact strain rate. Although very often the absolute value of the contact strain rate is small but the tertiary stage of creep develops along the contact surface.

It was mentioned that sliding of frozen masses of rubble begins after their volume increases to a certain value. The thickness of the mass to a greater degree influences the rate of strain. So, by increasing the thickness from 29 m to 40 m there will be an increase in the strain rate by more than ten times. This change in rate is in conformity with field observations of sliding masses of frozen rock rubble.

Figure 5 shows the graph describing the increasing sliding speed, V , of frozen mass in the process of increasing its thickness as the slide proceeds down the slope. Initial thickness of the sliding mass, H , at the beginning of the observation was 12 m, after 4 months, $H=20$ m, after 6 months $H=28$ m and after 8 months $H=34$ m. The intermittent line on the graph shows the observed speed and the solid line shows the calculated speed. Comparison of those two lines confirms the satisfactory results of this study.

CONCLUSION

(1) The sliding of frozen soils over bedrock is a typical rheological process including three states of creep.

(2) Two layers are formed in the sliding mass: namely, the boundary layer and the soil mass above this layer. Long-term resistance of the boundary layer, as a rule, is less than that inside of the soil mass. So the rupture occurs along the contact surface.

(3) The slide speed at the surface of frozen mass is the sum of a contact strain rate and the strain rate of the upper thickness of the sliding mass.

(4) The results of this study can be recommended for forecasting the strain rates of frozen soils on the inclined bedrock using creep characteristics of frozen soils (C_{∞}^S , $tg\phi_{\infty}^S$) and contact characteristics (C_{∞}^C , $tg\phi_{\infty}^C$).

ACCUMULATION OF PEAT CARBON IN THE ALASKA ARCTIC COASTAL PLAIN
AND ITS ROLE IN BIOLOGICAL PRODUCTIVITY

Donald M. Schell and Paul J. Ziemann

Institute of Water Resources, University of Alaska, Fairbanks, Alaska 99701

Terrestrial peat on the coastal plain of arctic Alaska is estimated to be accumulating at a rate equivalent to about $7-18 \text{ g C} \cdot \text{m}^{-2} \cdot \text{yr}^{-1}$, or 10-20% of the annual net carbon fixation. The accretion of root matter and surficial vegetation as peat is inversely proportional to microbial activity and grazing pressure by herbivores since the depth of the permafrost horizon responds to the insulative properties of the vegetative mat. Basal peats along the coastline in the vicinity of Prudhoe Bay range from 8,000-12,000 years B.P. and their stable carbon isotope ratios indicate that vascular plants and mosses contribute the bulk of the organic matter. The aquatic habitats of the tundra represent active sites for peat oxidation and conversion to faunal biomass. Inputs of peat occur via streambank erosion, thaw lake expansion and coalescence, and coastline inundation and erosion. Stable carbon isotope ratios and carbon dating of surface lake sediments indicate that peat, rather than algal production or recent terrestrial vegetation, constitutes the bulk of the organic matter.

INTRODUCTION

The revegetation of the arctic Alaska coastal plain (Figure 1) following the Pleistocene has resulted in a mantling of virtually the entire landform in a layer of organic matter ranging up to 3 m thick. Although the short growing season and low ambient temperatures have restrained plant life to a thin microrelief, the productivity supports abundant fauna. Actively growing vascular plants, bryophytes, and lichens, or standing dead plant material from the immediately preceding seasonal growth are the obvious sources of food for herbivores. The close coupling of primary production and the population dynamics of consumers such as caribou, lemmings, and insects have received intensive study by groups such as the International Biological Program (IBP) and by researchers assessing the impacts of oil industry development in the Prudhoe Bay region. These studies have produced complex models and budgets describing energy flow and compartmentalizing the carbon pools of the tundra biome. Excellent collections of papers describing these phenomena are available in volumes by Tieszen (1978), Hobbie (1980), Brown et al. (1980), and Sonesson (1980). In general, however, the models describing carbon movement in arctic tundra ecosystems use as end products (and loss to the ecosystem energetics) the evolution of carbon dioxide or peat in the permafrost layer. Superficially these are obvious losses--carbon dioxide is a complete recycling to a starting component, and peat is evident as an end product accumulating beneath the vegetative mat and in the permafrost. Although the formation of ice wedges and landforms related to polygonal tundra can alter or erode the peat mat, the ubiquitous layer of peat throughout the coastal plain attests to the accumulation of peat as a growing pool of stored and unavailable energy in tundra carbon flow.

We question the validity of this premise. Through the use of stable and radioactive carbon

isotope abundances in fauna from the coastal plain, we have demonstrated that the terrestrial and aquatic ecosystems are coupled through the production of peat and subsequent biological utilization (Schell 1983). The coastal tundra biome should not be viewed as separate terrestrial and aquatic ecosystems but instead considered as a whole with net energy flow from the terrestrial to the aquatic environment. Although Chapin et al. (1980) recognized the occurrence of this energy flow, they felt that the transfer represented only a minor fraction in the annual budget of the system and did not contribute to higher trophic level nutrition. In this paper we present estimates of the rates of carbon accumulation in coastal plain tundra and the subsequent movement from terrestrial to freshwater ecosystems. The role of peat carbon in the coastal plain ecosystem has been described elsewhere (Schell 1983). Details of the methodology are in Schell et al. (1982).

METHODS

Terrestrial Primary Production

The data obtained from the IBP site at Barrow (Webber 1978) and Devon Island (Muc 1973) for above and below ground primary production led us to estimate an annual net production of $88 \text{ g C}\cdot\text{m}^{-2}\cdot\text{yr}^{-1}$. Webber cautions that most studies have been in productive sites and that dry impoverished sites may be more significant in the arctic landscape. Therefore, we have selected the above value as a midrange estimate on a scale of tundra productivities.

Grazing, decay, and transport remove most of the fixed carbon from the tundra surface before incorporation into the peat layer, and quantitative estimation of the net accumulation is very difficult. Chapin et al. (1980) compare three techniques to approximate net carbon inputs to the Barrow tundra and found that during the study period a net increase occurred of between 40 and $120 \text{ g C}\cdot\text{m}^{-2}$. Since that rate would have accounted for the observed organic matter in the soil within as little as 160 years, production/utilization ratios probably vary widely from year to year and in response to microenvironments.

The difficulties inherent in areawide projection of carbon fluxes from data obtained at specific locations and the measurement noise resulting from localized process studies led us to abandon that approach in favor of a more generalized estimation of net carbon flux based upon soil organic matter, peat depth, and basal peat age. The calculated inputs were then

extrapolated areawide and compared to removal fluxes. Isotopic data were used independently to estimate the ecological significance of the physical processes.

Composition of Peat Soils

Detailed soil sections were taken at three sites near Simpson Lagoon, and several less detailed samplings were obtained from near Cape Halkett and from cut banks along the lower reaches of the Colville River. Additional data, previously collected from Simpson Lagoon (Lewellen 1973), are included here to illustrate the range of carbon contents involved.

Sample sites were chosen where erosion had exposed a fresh break in the permafrost. Pick and shovel were used to dig to undisturbed permafrost, and a vertical section was made at 10 cm intervals from beneath the vegetation surface mat to basal mineral soils. Samples were kept frozen until returned to the laboratory where moisture content was determined. Subsamples were analyzed for carbon, nitrogen, loss-on-ignition, radiocarbon content, and stable carbon isotope ratios.

Lake Sediments

Samples were collected either by Ekman dredge or by cores pushed by hand into the bottom, and sectioned horizontally in sufficient size to yield at least 5 g of carbon. After suspension in dilute hydrochloric acid to remove carbonates, samples were settled, decanted, rinsed with distilled water, and dried at 70°C in a vacuum oven.

Vegetation Samples for Isotopic Analysis

Fresh vegetation from tundra meadows, heaths, pond margins, and ponds was collected to establish current concentrations of radiocarbon and $^{13}\text{C}/^{12}\text{C}$ ratios in living primary producers. Samples were dried in vacuo at 80°C.

Fluvial Transport and Coastline Erosion

Riverbank, lakeshore, and coastline erosion constitute the major fluxes mobilizing peat incorporated into permafrost and dispersing it into a relatively warm oxygenated environment. Total quantities of particulate carbon in Colville River flow were calculated from U.S. Geological Survey (1979) data and from samples which we collected during the breakup period. These concentrations were extrapolated to include the entire Alaska Beaufort Sea drainages by multiplying the total slope runoff/Colville River runoff by factor of 1.7 (AEIDC 1974).

Samples of riverborne detritus for radiocarbon analyses were collected by suspending a 120 μm mesh plankton net in the Colville and Kuparuk rivers until sufficient material had been collected to assure 5 g of carbon. Samples were dried in vacuo prior to analysis.

Total organic carbon concentrations were determined by summing the dissolved organic carbon and the particulate fraction which was collected on precombusted glass fiber filters. Temporal coverage for the hydrologic year was limited to the breakup season and single samplings in July and August. However, the bulk of the transported matter is carried during the breakup flooding (Arnborg et al. 1967), and our sampling was concentrated in that period.

Coastline erosion arises from thermoerosional niching during storm surges, and subsequent collapse and dispersion of the tundra blocks. Input rates of organic matter were obtained by multiplying the total volume of tundra eroded by the average organic carbon content of soil profiles. Lake shorelines are also subject to erosion, but the rates are dependent upon the lake size (wind fetch) and shoreline type. Comparisons of airphotos revealed that lakeshores were eroding much more slowly than the nearby seacoast in response to the much greater variations in water levels and longer fetches in the marine environment. Small ponds appear to expand by subsidence and thermokarst formation at rates independent of wind stress until large enough for appreciable wave action. Changes in small lakes and ponds were not discernible in the airphoto sequence, and erosion is not believed to be a significant means of carbon input to the water column in ponds.

Lake Primary Production

The shallow thaw lakes of the Arctic are ultra-oligotrophic and much less productive than the surrounding tundra. The Barrow ponds, for example, average 10 $\text{g C}\cdot\text{m}^{-2}\cdot\text{yr}^{-1}$ (Alexander et al. 1980). Ikroavik Lake, a typical mid-sized thaw lake, was estimated to fix 4.5 $\text{g C}\cdot\text{m}^{-2}\cdot\text{yr}^{-1}$. Other arctic lakes, tabulated by Alexander et al.

(1980) ranged from <1 to 12.5 $\text{g C}\cdot\text{m}^{-2}\cdot\text{yr}^{-1}$ of phytoplankton production. Emergent macrophytes in the shallow margins of the lake are more productive per square meter than the lakes themselves in the cases noted above (Hobbie 1980). Benthic microalgae represent a larger carbon input than phytoplankton in the Barrow ponds, but little is known of their role in larger arctic lakes. Based upon the estimates of Alexander et al. (1980), we assigned an average production rate of 3 $\text{g C}\cdot\text{m}^{-2}\cdot\text{yr}^{-1}$ for benthic algae. The average primary production rate of coastal plain lakes (benthic and phytoplankton) was assumed at 8 $\text{g C}\cdot\text{m}^{-2}\cdot\text{yr}^{-1}$, a weighted mean for the ratio of large lakes (>1 km^2) to ponds wherein the higher production of benthic algae in the ponds is offset by a lower phytoplankton production. For calculation of coastal plain inputs, the area covered by lakes and ponds is taken as 50% of the total area (AEIDC 1975).

RESULTS

Major Annual Inputs of Carbon

Using the production estimates above, we calculated the magnitudes of these carbon inputs relative to each other and the major physically driven fluxes. At a mean annual primary production rate of 88 $\text{g C}\cdot\text{m}^{-2}\cdot\text{yr}^{-1}$, the terrestrial fixation far outstrips the aquatic. Given an equal distribution of aquatic and terrestrial area in the 75,000 km^2 coastal plain, 3.3 x 10⁹ kg C₀ is fixed by land plants compared to 0.3 x 10⁹ kg C in the lakes and ponds. Pond margins, with the highly productive emergent macrophytes, have been included with the terrestrial producers. Of this production, grazers consume approximately 10-20% of the carbon fixed during the first year, and decomposers (fungi, bacteria) remove much of the rest (Flanagan and Bunnell 1980) over the course of several following seasons. The organic matter remaining after grazing and decomposition constitutes the peat column accumulation for that year.

Table 1 lists the basal peat ages and carbon standing stock at four sites where the soil section accumulated in place (Lewellen 1973). Unlike unfrozen bogs wherein compaction tends to increase bulk densities with depth (Clymo 1978), the formation of permafrost and the high ice content of the soils maintain the density except at polygon margins where elastic deformation occurs as the ice wedge grows (Billings and Peterson 1980). Peat accumulated at mean rates of 0.18-0.23 $\text{mm}\cdot\text{yr}^{-1}$ or 7.4-18.3 $\text{g C}\cdot\text{m}^{-2}\cdot\text{yr}^{-1}$ in these sites. If these rates are representative, they imply that 8-21% of the terrestrially fixed carbon is annually incorporated into the peat layer; this corresponds to a net loss to the biosphere of 0.3-0.7 x 10⁹ kg C₀ $\cdot\text{yr}^{-1}$ in the coastal plain alone if no remobilization occurs.

In contrast, the surface sediments from Gooseneck Lake (70°40'N, 152°47'W) and Lake C-2 (68°28'N, 156°44.5'W) contained terrestrially

derived peat and yielded radiocarbon ages of 2,068 and 3,840 years B.P., indicating that the accumulation of recent carbon ceased as the thaw lake formed. Although the aquatic fixation rates add 0.3×10^6 kg C \cdot yr $^{-1}$ to the coastal lake ecosystem, utilization is nearly complete in the water column and surface sediments, leaving no excess for accumulation (Alexander et al. 1980).

The quantitative significance of the thaw lakes in the cycling of peat carbon remains uncertain. Shoreline erosion on large lakes from wave action disperses the peat across the bottom and into the water column. Airphotos clearly show plumes of eroding peat being spread by wave and current action across lakes. However, our coverage is too limited to allow an accurate estimate of the extent of lakes having sharply eroded banks. Almost all of the smaller lakes and many of the large lakes encroaching on previously drained thaw lake beds have very gently sloped margins protected by thick emergent vegetation. Here, apparently, thermokarst settling expands the lake size (Billings and Peterson 1980), and the tundra mat and underlying peat become the lake floor without being appreciably disturbed. The

core sample from Lake C-2 (Table 2) indicates that the sediments had not been mixed to much extent. If the sediment ages represent tundra submerged about 4,000 years ago, the accumulation rate would have been 0.16 mm \cdot yr $^{-1}$, very close to the rates obtained for the samples in Table 1. Once these thaw lakes drain, however, revegetation would cause resumption of peat accumulation with an age discontinuity occurring at the previous lake bottom level. All of the variables inherent in these processes prevent us from making a comfortable appraisal of the net flux of peat through the lake systems. Tentatively, however, we can approximate the magnitude. A shoreline erosion rate of 0.3 m \cdot yr $^{-1}$ on the ~500 lakes of $>2 \frac{1}{3}$ km diameter would thaw and suspend 1.5×10^5 m 3 \cdot yr $^{-1}$ in the water column using an eroding bank height of 0.25 m. This material would contain some 26×10^6 kg C, a small amount relative to other potential fluxes. We assume that erosion in the small lakes is negligible. Even allowing a severalfold error in this estimate does not change the flux size relative to inputs by carbon fixation or fluvial transport of peat.

NOTE: Carbon-13/12 ratios are expressed in per mil relative to Pee Dee Belemnite standard. Carbon-14 is expressed as the radiocarbon age or percent modern relative to 95% NBS oxalic acid standard, normalized to $\delta^{13}\text{C} = -25\text{‰}$.

Erosional and Fluvial Transport of Organic Carbon

The inputs of terrestrial carbon to the marine environment and their impact on nearshore marine food webs have been addressed elsewhere (Schell 1983). In order to estimate the major fluxes in the tundra ecosystem, the loss rates through erosion are included here. Several authors have measured coastline erosion rates (Lewellen 1970, 1973, Cannon and Rawlinson 1978, Hopkins and Hartz 1978), and S. Rawlinson (personal communication) has provided stratigraphic sections from approximately 100 sites along the Beaufort Sea coastline. Peat thicknesses are highly variable due to ice wedges and surficial relief, and usually range between 10 and 220 cm thick. The average peat thickness of 1.6 m found in areas of undisturbed accumulation contrasts with the overall average peat depth along the coast of 0.5 m. It was this latter value which we used to calculate the erosional losses. Based on eroded volumes, bulk (wet) densities and carbon content, we conclude that approximately 110×10^6 kg C \cdot yr $^{-1}$ is washed into the coastal marine waters. This flux results in mineralization process as microbial activity oxidizes the peat in the relatively warm, oxygenated waters (Schell et al. 1982).

Cut bank erosion and fluvial transport of peat are a major flux of terrestrial carbon to freshwater and marine food webs. The Colville River discharge (12×10^9 m 3 ·yr $^{-1}$), represents about 30% of the drainage to the Beaufort Sea. The total organic carbon concentrations ranged from an average high during the breakup season of 19.3 mg C \cdot l $^{-1}$ to 1.9 mg C \cdot l $^{-1}$ during the low water season in August. We used a weighted flow corrected concentration of 14 mg C \cdot l $^{-1}$ in calculating the average annual transport of 170×10^6 kg C \cdot yr $^{-1}$. Stable and radiocarbon analyses of the particulate matter collected in May and June from the Kuparuk and Colville Rivers confirmed that peat, not surficial vegetation, constitutes most of the suspended organics (Table 2). Significantly, of the two Colville River particulate samples, the first (collected during maximum tundra runoff) contained more recent matter than the latter sample. These samples are very close to the mean radiocarbon content of the peat soil sections (63% percent modern) (Schell 1983).

DISCUSSION

Peat accumulation on the coastal plain annually incorporates $280-690 \times 10^6$ kg C \cdot yr $^{-1}$ into the permafrost soils. If these rates are also similar to accumulation rates in more upland sites, the north slope of Alaska accumulates $1.6-3.9 \times 10^9$ kg C \cdot yr $^{-1}$ less the loss from fluvial and erosional transport. Figure 2 depicts these fluxes projected for the entire North Slope (200,000 km 2). Although the errors inherent are compounded and this model is probably correct only in magnitudes, it serves to illustrate that the loss of carbon to the aquatic environment is a major factor governing the net accumulation of peat in tundra. Since erosional processes are

widespread along the lakeshores and riverbanks, the aquatic biota have a readily available peat supply. Biological utilization of this refractory material by fungi and bacteria forms a trophic base upon which many of the apical organisms are ultimately dependent, and its availability on a year-round basis may increase its importance. Many shallow lakes and river channels where benthic algae would be more abundant are frozen to the bottom during winter months. Peat detritus collects in deeper quiet pools and lake basins, providing a perennially available source of food for insect larvae, which in turn are preyed upon by fish congregating in the ice-free deep waters. Butler et al. (1980), in assessing the energy requirements of chironomids, insect larvae heavily preyed upon by fishes and birds, concluded that they must be consuming detritus but could not conclusively demonstrate it in their situation. It appears, therefore, that even in situations where erosional inputs are small, the insect larvae take advantage of peat carbon along with the other sources available. The birds and fishes using the tundra lakes are thus assured of higher prey densities than would be normally available given the low and variable aquatic primary productivity of arctic lakes and ponds.

SOLID WASTE DISPOSAL
NATIONAL PETROLEUM RESERVE IN ALASKA

John F. Schindler
Environmental Affairs
Husky Oil-NPR Operations, Inc.
5333 Fairbanks Street Suite 10
Anchorage, Alaska 99502

The disposition of solid waste has always been a problem for twentieth century man and in the permafrost areas of the Arctic the problem is compounded. The most utilized option has been to backhaul the debris to urban areas for disposal or recycling. In the mid-1940's the Navy's exploration program brought tons of supplies to the north slope of Alaska. This logistics deluge continued through 1953 when the construction of the Air Force's Distant Early Warning (DEW) line began, and since, there have been many years of continued government activities and their concurrent supplies. Under the Navy and later the U.S. Department of the Interior (USGS) an attempt was made to clean up and consolidate this debris. In the winter of 1979-1980 a pilot project was undertaken to bury the debris at two sites. A Cat train would travel over approved trails to the designated burials during the winter months when such travel was environmentally safe. A D-8 Caterpillar tractor with blade and ripper tooth was used. The overburden was stripped to one side and then the hole was dug using tooth and blade. When the hole was deep enough to take the debris and still be covered by a minimum of 2 feet of fill, the debris was pushed in, compacted, and everything covered. Once covered, the overburden was spread again, the scar seeded and fertilized, and the seed and fertilizer walked in with the Cat tracks. A seed mixture high in tundra bluegrass seed and standard 10-20-10 fertilizer was employed. The high rate of survival of the original plants in the overburden was surprising and gratifying. Some burials were difficult to locate from the air after only two growing seasons.

INTRODUCTION

In the Arctic, as elsewhere, man's concern for the environment evolved over many years from an almost total lack of concern, to the present scientific and technical approach. The early Eskimos of the Arctic Slope were quite nomadic, following the good hunting of the season, and discarded their refuse a few feet from their dwellings. However, the wastes were almost totally organic in nature and therefore biodegradable; although this was the practice for centuries it left no lasting damage to the environment.

It was not until the intrusion of the twentieth century and the introduction of metal that solid waste in the Arctic became a real problem. The sanitary landfill practices of disposing of solid waste that is economically feasible in southern latitudes is extremely difficult in the north because of the permanently frozen ground. In addition, metals rust very slowly because the long season of cold severely limits the time available for the oxidation process. These factors, combined with the penchant of the Eskimo people to save scrap metals because they were exotic to their culture and therefore valuable, meant that it became the practice of all northern inhabitants to simply discard their solid wastes within sight of the front door. This practice of abandonment in place became the standard operating procedure for government agencies and private companies as well as individuals. The 55-gallon metal drum was so ubiquitous in the north it was referred to, only half in jest, as the official flower of the tundra.

The Early Exploration Program 1944-1953

On February 27, 1923, President Harding signed Executive Order No. 3797-A creating Naval Petroleum Reserve No. 4 (now the National Petroleum Reserve in Alaska or the NPRA). Actual exploration of NPR-4 did not begin until World War II. On February 5, 1944, the Director of the Naval Petroleum Reserves sent a proposal to the Secretary of the Navy for exploration and test well drilling. On June 2 the President formally approved the project. The exploration program was well under way by the end of the year and continued until 1953, when it was suspended.

During the exploration and during later military construction, environmental repercussions of operations on the North Slope were not a major concern of the military or the American public at large. Debris associated with the programs was simply abandoned in place. Although most of the major concentrations were left behind at several exploratory drilling sites, DEW line sites, and at support bases like Barrow and Umiat, additional debris, such as wastes from seismic and geodetic survey camps, piles of empty barrels at fuel cache sites, and discarded broken or replacement equipment parts at Cat train maintenance stops, were abandoned at numerous locations. These locations were not noted in any historical record, or, if they were, the record was lost.

Numerous other programs, although of less significant magnitude, generated accumulations of debris within the reserve. These include several federal agencies: the U.S. Bureau of Land Management, the U.S. Geological Survey, and the Fish and

Wildlife Service. State agencies, such as Fish and Game, have contributed a share, and private industry is not without blame.

The Exploration Program 1975-1982

The second exploration program was designed to be accomplished as much as possible during the winter months in order to minimize environmental impacts. Stipulations governed all operations and were based on the fact that even fragile tundra, when frozen under a foot of protective snow, is an exceedingly durable working platform.

Recent operations on the National Petroleum Reserve in Alaska were based from the 100-man camp at Lonely (POW-1). This camp was equipped with a chlorination/filtration plant to treat drinking water taken from nearby lakes and an extended aeration waste water treatment plant. The treated effluent was discharged to a small depression in the tundra. Sludge from the sewer plant, waste oils from camp operations, kitchen wastes, and combustible solid wastes were burned in the camp incinerator. The ashes, along with noncombustible materials, were disposed of in a State of Alaska approved sanitary landfill.

Drilling camps were, in essence, small versions of Camp Lonely without the sanitary landfill. All other utilities systems were about the same. Metal and ashes and any wastes beyond the capacities of the operating utilities were backhauled from the drilling camp to Camp Lonely for disposal in the appropriate manner.

Seismic and construction camps were mobile facilities, and the handling of utilities was accordingly different. Drinking water in the seismic camps came from melting snow or deep lakes when available. It was filtered and chlorinated. Some sewage facilities utilized electric incineration and others a physical chemical treatment system. Wastes were incinerated to the capacity of the units and otherwise backhauled to Lonely or a nearer facility.

Burn baskets were extensively utilized to open burn all wood and paper products. Putrescible wastes were disposed of in incinerators. Portable camps were allowed to dispose of small amounts of waste oils and other hydrocarbons by open burying under permits from the Alaska Department of Environmental Conservation.

Changes under Public Law 94-258

Although there existed environmental awareness and responsible management on the part of the Navy in the early stages of the exploration program, it wasn't until the Department of Interior assumed operational responsibility that the environmental program became more formally instituted. Public Law 94-258, the Naval Petroleum Reserves Production Act of 1976, transferred the exploration program from the Navy to the Department of Interior and charged the Secretary of the Interior to continue the exploration "in such a manner which will assure the maximum protection of . . . surface values to the extent consistent with the requirements of this Act for the exploration of the reserve" (Section 104.b). In response to this charge, the Department of the Interior instituted a Memorandum of Understanding (MOU) between the

Bureau of Land Management, responsible for overall management of the Reserve, and the U.S. Geological Survey, which was responsible for the exploration. The MOU outlines the responsibilities and the steps taken annually in preparation for the proposed exploration operations.

The first step each year was to write a preliminary annual plan of operations. This plan identified and located the wells to be drilled and any alternate locations proposed. This proposal also discussed the general overall operational plan, including such specifics as which construction groups would build which sites and when, how they would travel to the sites, be resupplied, etc. In addition, the drill rig to be used was identified and the target depth and time schedule delineated. This broad plan was circulated for comment to interested entities of federal, state, and local governments as well as private organizations.

Once the general plan of operation was established, a site-specific environmental assessment (EA) was prepared for each drill site. The information for the EAs was gathered concurrently with the engineering survey during the summer months. This meant that as the construction and drilling specifications were developed for each site the environmental concerns could be considered early in the engineering design process. Early recognition of environmental factors meant better engineering, more economical operations and excellent environmental protection.

Summer surveys included the gathering of topographical and soils information, the identification of water sources and borrow areas, and the preliminary layout of the construction sites. These areas were then checked for archeological resources, fisheries resources, rare or endangered species, wildlife disturbance, and socio-economic perturbations. If necessary, water sources were changed or schedules of withdrawal modified to protect fisheries resources and borrow sites were moved to avoid disturbing archeological values. If this was not feasible, the site was excavated by professional archeologists to remove the resources for museum study. In the cases of the special areas of the Utukok caribou calving grounds or the raptors nesting in the Colville River area, operational schedules could be adjusted to minimize or eliminate any possible discommodations. All of these environmental concerns were addressed and resolved in the environmental assessments specific to each site.

History of the Cleanup Program

During the late 1960s, the deteriorating quality of the environment became a concern to the American public. Environmental organizations pointed out problems and made increasing demands for action. Against this background, the remote Arctic Slope of Alaska did not escape notice. When interest began to focus on the area for its important potential new energy sources, especially the Prudhoe Bay discovery, the area's wildlife and unique environment became of increasing concern.

The Navy included funds in its 1971 budget to initiate a cleanup of debris from the earlier exploration and military construction programs. The first Navy efforts were accomplished by the

temporary assignment (2 weeks) of a company of SeaBees (CB - Construction Battalion) to the Barrow Camp in the fall of 1971. The manpower was used to police the immediate area of the camp and to manually pick up and stockpile as much debris as possible. Stockpiles were located on gravel beaches or roads where trucks and other equipment could be utilized.

Also in 1971, the oil industry operators of the Prudhoe Bay area initiated a summer cleanup program using rolligons on the tundra to pick up debris on the state lands that were under lease. This program was continued in the summers of 1972 and 1973.

The cleanup and rehabilitation program, initiated by the U.S. Navy in 1971, has continued in subsequent years. The Interior Department joined the effort during 1972 and conducted a cleanup program in the Barrow area. This program was unique in that a good deal of the work was conducted during the winter using small sleds pulled by snowmobiles.

In 1973, the Navy continued the effort with a program to clean up the Umiat Camp area. The low area east of the camp that had been used as a gravel source during exploration was used to receive the drums and debris, which were then covered with gravel. In addition, an effort was made to clean up the Point McIntyre area near Prudhoe Bay.

In the supplemental budget of the Congress for FY1974 the Navy was directed to begin a new exploration program in the reserve; the cleanup program was included as a line item in that budget. Efforts that spring centered on the Simpson Peninsula, and the debris was accumulated at the abandoned DEW line site, POW-A.

Early records of the cleanup program (1971-1975) are scattered and, although much cleanup was done, comprehensive annual reports were not prepared. Since Husky Oil-NPR Operations, Inc. assumed the responsibility (first under the Navy and later under the USGS) in December 1975, descriptions of the work accomplished have been somewhat more formalized.

The program continued under the Navy's direction until June 1, 1977, when jurisdiction of NPR-4 was transferred to the Secretary of the Interior, and the area was renamed the National Petroleum Reserve in Alaska (NPR). The Secretary of the Interior assumed all programs and responsibilities formerly under the Navy, including the ongoing program for the cleanup and rehabilitation. Within the Interior Department, the U.S. Geological Survey was designated as the lead agency and the cleanup program was conducted as an adjunct to the exploration drilling program on the NPR.

Cleanup-Summer 1976

During the summer of 1976, the cleanup program consisted of a great deal of hand labor. The major effort was picking up drums and debris and consolidating these materials at points accessible to vehicles, either immediately or later during winter when tundra traffic was possible. The cleanup program ran from June 28 to September 8 and a total of 331,300 pounds of debris were retrieved, 141,500 pounds of which were burned. In addition, 9,019 barrels were retrieved and stockpiled, 6,709 of these at POW-A. The area of cleanup stretched from Barrow to the Nechelik Channel of the Colville

River. The following sites were cleaned as well as smaller collections of drums and debris found between these locations:

Barrow Gas Fields	POW-1 (Camp Lonely)
Iko Bay Drill Site	E. Teshekpuk Drill Site
Simpson Test Wells	Pitt Point
POW-A	Halkett Drill Site
Alaktak	POW-B
West Topagoruk	Fish Creek Drill Site

Cleanup Program-FY 1977

A trial program was conducted during the fall of 1976 to test the economic feasibility of winter cleanup (winter was defined for these purposes as November 1 to January 31). To accomplish the winter work it was necessary to provide a self-sustaining camp for an 18-man crew. Skull Cliff, an abandoned LORAN navigational site about 24 mi. south-southwest of Barrow was selected for the test effort. The site consisted of abandoned buildings, supplies, debris, and a collapsed 625-ft. tower scattered over an area of approximately 6 square mi. Work was conducted from October 26 to December 15, 1976, and during this period 2,280 barrels and 2,000 pounds of debris were picked up. The subzero temperatures were not as much a problem as the lack of daylight. Hard-packed snow and reduced light made much of the debris difficult to locate. The frozen contents of the barrels made them impossible to empty and heavy to handle. The slow progress due to these factors coupled with a lengthy mobilization period increased the cost per unit work accomplished, until it was decided to abandon the winter effort.

In the spring of 1977, cleanup efforts were concentrated at three sites: POW-A, a former DEW line site, Simpson test well, drilled during the 1947 program, and the Topagoruk test wells from the 1951 program. It was decided to pick up the debris from the Simpson and Topagoruk sites and retrograde everything to POW-A. The final plans for the disposition of the debris had still not been settled, but locating the debris at POW-A allowed the additional option of backhaul via barge to the south 48. A portable barrel crusher was used to consolidate the bulk.

Operations were begun February 10 and were halted at the end of the first week of May. A total of 175 tons of debris were retrieved, 9,817 barrels were collected, and a total of 12,233 barrels were crushed (some of these having been retrieved previously). Although barrels were often filled with snow, covered, and frozen as in the fall work, the spring phase of the cleanup was more productive because of the increased daylight and the greater dependability and speed of the CATCO rolligons. In addition, many of the barrels at these sites were stacked above the frozen tundra and more accessible for retrieval.

Cleanup that summer was limited to the crushing of the barrels at POW-A and POW-B that had been stockpiled there that spring and during the previous summer's program. In addition, LIZ-C was cleaned up to prepare the site for use as a logistics base for the coming season of exploration.

In the FY 1977 program a total of 14,875 barrels were retrieved, 16,743 were crushed, and 485 tons of debris collected and burned or stockpiled.

Cleanup Program-FY 1978

The 1978 spring efforts at cleanup focused on the Skull Cliff and Topagoruk and East Topagoruk sites. Working out of Cat trains from April 1 through May 15, the cleanup crews stockpiled 2,120,000 pounds of debris on the beach at Skull Cliff. This included 236,000 pounds of tower, 200,000 pounds of crushed barrels, 1,380,000 pounds of cement and mud canisters from the exploratory program, and about 300,000 pounds of miscellaneous debris. Favorable weather contributed significantly to a highly productive season.

Summer cleanup of the old Navy sites commenced on June 8th and was accomplished at:

- Skull Cliff tower site
- Topagoruk and East Topagoruk
- Wolf Creek Test Wells 1, 2, and 3
- Weasel Creek Test Well
- Square Lake Test Well
- Titaluk Test Well
- Knifeblade Test Wells 1, 2, and 2A
- Mona Lisa Seismic Camp
- East Oumalik Test Well
- and an explosive cache discovered in the Ikipuk area

The summer's accomplishments were summarized as follows:

Barrels retrieved (uncrushed) 187,100 pounds

Barrels crushed	712,725 pounds
Combustible debris stockpiled	377,350 pounds
Combustible debris burned	924,310 pounds
Other debris	270,310 pounds

In excess of 1,235 tons of material and debris were burned or stockpiled.

Cleanup Program-FY 1979

Cleanup in FY 1979 was accomplished in the summer months only and the crews operated out of tent camps located near their work sites. This new method of operation proved to be very cost-effective because of the reduced helicopter and labor costs commuting to and from the work sites, and practically no lost time due to poor flying conditions. Work began at the old Brady site on the Kiligwa River with concurrent cleanup at Driftwood Creek and Liberator Lake. Efforts were then concentrated in the southeast area of the reserve. Combustibles that were stockpiled in 1978 were burned at Wolf Creek, Square Lake, Titaluk, and East Oumalik. Cleanup was accomplished at Fish Creek, Oumalik, Grandstand, and Gubic. The area of the Gubic test wells proved to have a great deal more debris than was originally estimated, including a burned-out rig, and the crews worked in the area for 32 days, better than one-third of the total summer's effort. During the summer of 1979 over 20 million pounds of debris were handled and a final 4,200,000 pounds of this material stockpiled for later burial.

Debris was stockpiled on dunnage on the tundra adjacent to possible burial sites. These sites were selected so as not to intercept any surface drainage, even the most ephemeral of water courses,

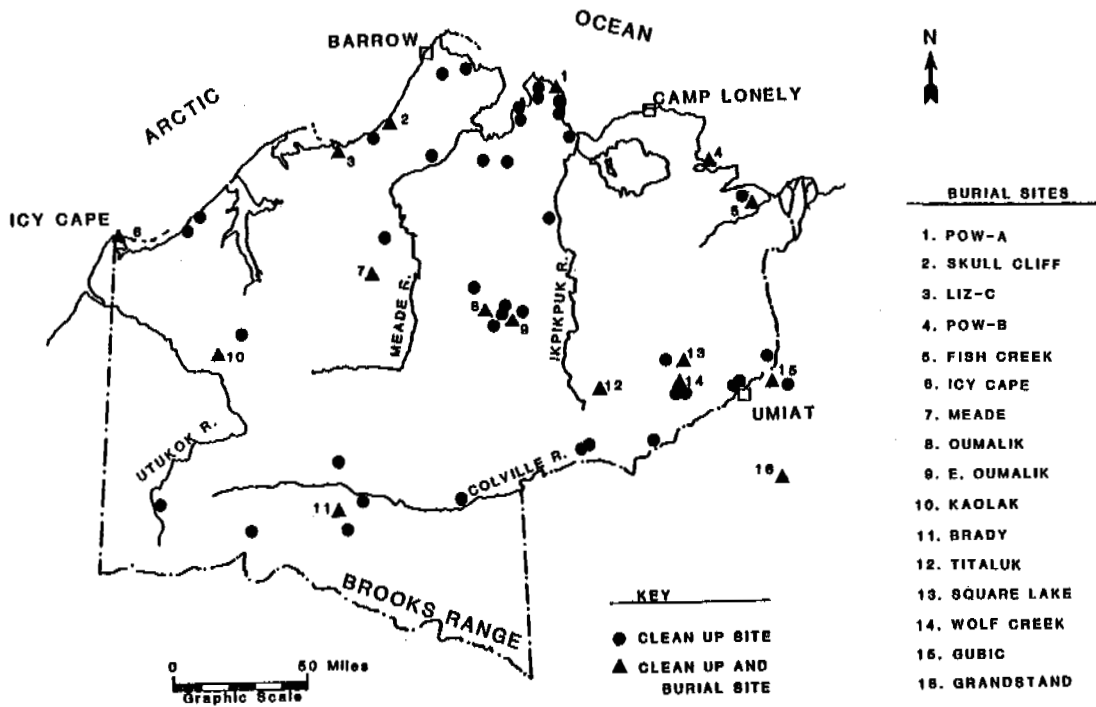

FIGURE 1 Cleanup and burial sites, National Petroleum Reserve in Alaska.

if possible. Any water erosion could uncover the buried debris and negate the entire program. The site was selected in relation to the surrounding terrain, on lower but not wet topography. The original intent was to avoid areas with soils of high ice content but subsurface ice is nearly ubiquitous on the North Slope, and once the program got under way the amount of ice did not seem to appreciably effect the cover of the debris. In actual practice, the presence of ice was desirable to ensure that ripping and excavation of the site was possible with the D-8 Cat. The lower sites were preferred as they were less visible and with more moisture, also easier to revegetate.

Cleanup Program-FY 1980

In the fall of 1979, the disposition of the consolidated debris from the cleanup of the old sites was still very much a question. It was decided to try burial at the two sites that were farthest from the ocean's edge as these would be expensive for marine retrograde. These sites were Grandstand and Gubic, both just off the reserve to the east and southeast of Umiat. The sites were on selected lands, so the prospect was discussed with the Bureau of Land Management and the prospective owner, the Arctic Slope Regional Corporation. When they agreed it was a feasible method of disposal, the permission of the Alaska Department of Environmental Conservation was obtained. A contract was let in early March 1980 for a Cat train with at least one D-8 Cat equipped with a ripper tooth and blade to do the burial effort. The idea was to strip away the organic overburden and stockpile it to one side; then excavate a pit of sufficient size to contain the debris; place the debris in the pit and compact it with the heavy equipment; and backfill with the original material so that a minimum of 2 ft. covered the debris. The overburden would then be spread over the site and seed and fertilizer distributed and walked in with the Cat. The effort went very smoothly.

The 1980 summer cleanup of old Navy sites and the cleanup and revegetation of drill sites of the current exploration program were combined under one contract. The season's operations got under way during the last week of May. An 18-man tent camp was set up at Oumalik; utilizing a Bell 205 helicopter for "lift" power to move the heavy timbers and other large debris, they began the cleanup of Oumalik, East Oumalik, Brady, Mona Lisa, and a number of new finds and old caches of explosives. The term "new finds" was used to designate any considerable amount of debris encountered locally within approximately 5 mi. of the site that was not scheduled in the work plan. It was decided to burn the explosives and their disposal was coordinated with the ADEC (Alaska Department of Environmental Conservation), the USGS, and other government authorities. By July 24, the tent camp was relocated to the Old Meade site and the crews helped with the cleanup at some current drill sites during the camp move.

Demobilization of the cleanup camp at Old Meade began on August 20 and the operation was out of the field by August 25. Although this was early according to schedules maintained in previous years, during the last days of operation, the camp was plagued by freezing water pipes and excess condensation in the tents. This season a total of 2,647,620 pounds of

debris was stockpiled for burial; 1,817,300 pounds consolidated at Oumalik and 830,320 pounds consolidated at Old Meade. New finds at Oumalik totaled an estimated 389,000 pounds, and at Old Meade they totaled approximately 51,000 pounds.

In late September 1980, an inspection was made of the burial sites that were finished the previous spring to check for any erosion or settlement problems due to thaw. None was found. One unanticipated advantage to the burial program that was discovered at this time was the high survival rate of the original site vegetation. When the overburden was stripped prior to the excavation it was stockpiled to one side and then used to cover the area after filling. Because the stockpile was exposed to the winds and cold for only a short time, usually less than 48 hrs., and then protected by a cover of blown snow soon after replacement, quite a few individual plants survived. The cover was a jumble of organic clods, but almost all showed signs of recovery of the original vegetation, including willows and birches. These survivors meant that the recovery of the natural vegetative cover would occur far more quickly than at sites that were seeded with grass species only.

Cleanup Program-FY 1981

The 1980 spring burial efforts were considered very successful, and it was decided to bury all the stockpiled debris. During the last few days of February, the burial contractor mobilized his Cat train and equipment to Koluktak via rolligon following previously cleared trails. Koluktak was chosen for a jumping-off point because there was an ongoing drilling operation there, complete with camp and airstrip, and the location was convenient to the first burial site. The program got under way on March 9, 1981.

The contractor's task was to travel overland to the sites where the debris from previous cleanup programs had been stockpiled. Locations for burial were designated and archeological and environmental clearances had been obtained earlier. The contractor operated as in the pilot program and burial was accomplished at:

East Oumalik	Square Lake
Oumalik	Old Fish Creek
Old Meade	POW-B (Kogru)
Titaluk	POW-A (Cape Simpson)
Wolf Creek	

Because deep snow conditions prevented the train from reaching Brady, the POW-A site was substituted at the end of the season. The program was finished by April 19, and the contractor demobilized the train overland to Deadhorse.

Since the summer of 1981 was possibly the last opportunity to accomplish environmental work under the exploration program, the work scope was expanded to complete as much as time and weather would allow. Cleanup began at miscellaneous minor sites in June. High winds and fog in the western part of the reserve slowed down the establishment of the cleanup tent camp at Icy Cape but the operation was finally in place by July 2. A second siege of winds up to 50 knots hampered work for another week. Icy Cape was finished by July 28 and the camp was moved to the Kaolak site. The old sites cleaned that season

were Icy Cape (LIZ-B), Peard Bay (LIZ-C), Kaolak, and numerous small finds.

Cleanup Program-FY 1982

The burial of the debris collected during the summer of 1981 was accomplished in the spring of 1982 at Skull Cliff, Brady, Kaolak, Icy Cape, and Peard Bay. The Skull Cliff operation was the major effort because an estimated 4,350,000 pounds of debris, which had been stockpiled on the beach for possible marine retrograde, had to be moved 1 mi. inland to the burial site. However, even with this rather large task, the program proceeded very smoothly. The contractor was working in the field on March 15, and began demobilization on April 17. Seed and fertilizer were applied to all sites as the crews departed.

REVEGETATION METHODS

The program for the revegetation of the burial sites was totally based on the program developed for the revegetation of the material (borrow) sites and drilling sites of the ongoing exploration effort. A review of the methods, materials, and reasons developed for that program is pertinent here.

Once a drilling site is cleaned up and any planned civil work accomplished, the site is ready for seeding. Active seeding is done prior to late June or the first of July and dormant seeding after the first freezing temperatures of the fall, usually late August. At the beginning of the exploration program, the first attempts at revegetation employed the grass seed mixtures utilized by Alyeska for the northern areas of the Trans-Alaska pipeline. This was a mix by weight of: 30% annual rye grass, 10% boreal fescue, 10% redbud, 20% nugget blue grass, and 30% arctared fescue. This was applied at the rate of 50 lbs. per acre and fertilized with a commercial chemical fertilizer 10-20-10 (nitrogen-phosphorous-potassium) applied at the rate of 600-650 lbs. per acre. Seed was walked in with Caterpillar tractor tracks, or dragged in with a piece of chain-link fence. This seed mix, fertilizer, and application rates were found to be moderately successful at inland sites and unsuccessful at coastal sites.

A review of the available literature revealed there were as many theories and methods of revegetation as there were reports. Advice ranged from planting willows and birch seedlings by hand, to lush seeding of grasses, to sparse seeding of grasses, to no planting or seeding at all, to very heavy fertilization, to no fertilization, or almost any combination of these.

The goal of the revegetation program was that the seed and fertilizer selected and the methods of application would produce growth that would prevent erosion, both wind and water, establish a vegetative cover, both for aesthetics and biohabitat, yet not establish such a thick vegetative cover as to deter the invasion of the original flora.

It was decided, in consultation with Drs. J. McKendrick and Wm. Mitchell of the University of Alaska Palmer Experiment Station, to use tundra bluegrass (*Poa glauca*), although the availability of this seed was quite limited. The bluegrass was used primarily in coastal areas, and a mix of tundra bluegrass, arctared fescue, nugget bluegrass, and

even annual rye was used in inland areas.

This native bluegrass species was grown from cultivars collected in the Sagwon Bluffs area of the Alyeska pipeline. Being native to the North Slope and the seed raised in Alaska, cultivation was very successful on the north slope. Using this seed also had the added advantage of not introducing an exotic into the ecosystem. The seed shows good growth success in both active and dormant seeding. It is an upright grass that grows in clumps of 4-8 or more stalks per base, which allows open space around the base of the plant for the invasion of native mosses, lichens, and grasses, yet prevents erosion. The height of the grass also enhances natural succession by providing a means of entrainment of local seeds.

The bluegrass seeds, or the seed mixture in inland areas, were dispersed at an application rate of 28-35 lb. per acre. This provided adequate coverage yet was not too dense as to prevent the return of other native species. All seed was applied with hand broadcasters, usually the type strapped to a man's chest or back.

For nutrients, the standard commercial shelf product, chemical fertilizer 10-20-10 or 10-20-20, proved to be completely adequate. Phosphorus was found to be severely limiting almost everywhere, so any fertilizer that was inexpensive, available, and provided phosphorus would do well. Not much advantage was found in greater amounts and lesser amounts did not appear to support adequate growth, so an application rate of 550-600 lb. per acre was decided upon. It was found that a second season's fertilizer application was very helpful in promoting increased survival. These were all qualitative observations. Random sampling of the pads and surrounding areas did not detect any significant increase in soil acidity that could be traced to the fertilizer.

SUMMARY AND CONCLUSIONS

The objective of the cleanup program was environmental enhancement through the removal of as much as possible of the evidences of man's activities. To promote this objective, all operational methods were designed to be protective of the environment.

Actual cleanup was best accomplished in summer when debris was not obscured by snow or frozen in the tundra. Retrieval was done manually with the assistance of a hoist-equipped helicopter. All overland traffic involving heavy equipment was restricted to the winter when the tundra was frozen and covered with a protective layer of snow.

Selection of burial sites was made to avoid any surface drainage channels and be located on low but not wet terrain. Subsurface ice content does not appreciably affect the burial results and generally makes easier digging. Revegetation should use native grass seed if at all possible. Tundra bluegrass (*Poa glauca*) proved to be the most adaptable to the greatest variety of North Slope sites. Any commercial fertilizer with phosphorus will promote growth.

The excavation/burial process should be done as quickly as possible to limit the time the tundra overburden is exposed to winds and freezing temperatures. If possible, replace the snow cover or promote the collection of blowing snow over the disturbed surface to promote an increased survival rate of individual plants.

SOME NONTRADITIONAL METHODS FOR SEISMIC INVESTIGATIONS IN PERMAFROST

B. M. Sedov

North-East Interdisciplinary Science Research Institute,
Academy of Sciences, Magadan, USSR

Small taliks and ice masses, both occurring at shallow depth, as well as other features make refraction and reflection techniques rather ineffective for permafrost studies. Through the use of data on the physics of ultrasonic oscillations and on seismic wave velocities and dynamics observed in permafrost areas, some nontraditional seismic exploration methods are suggested. They are based on converted mono- or polytype Rayleigh waves generated at the permafrost-talik boundaries, reverberations over ice layers, and other parameters. These methods enable us to enlarge the scope of permafrost research. Furthermore, the utilization of high-amplitude Rayleigh waves ensures environmental protection.

INTRODUCTION

In permafrost studies, seismic prospecting was used, for the first time, exactly 50 years ago (see Bonchkovsky et al. 1937). Refracted waves were utilized to determine the position of the upper permafrost and first P wave velocities were measured. Trial pits revealed that at depths of 1.5 m the seismic method exaggeration was equal to 4-7 cm. That was remarkable for the beginning. Since then seismic techniques have made considerable progress in permafrost research. A review of the tasks facing seismic exploration techniques was presented by Scott et al. (1979). Despite evident achievements, certain problems remain to be solved by permafrost scientists which are due to the following: First, taliks occurring in frozen terrain commonly have sizes comparable with seismic wave lengths; their boundaries are vertical or subvertical and crop out at the surface while the nearby thaw zones are overlain by a frozen active layer. Seismic velocities are found to be similar or identical in ice and frozen material. Detection of massive ice in such cases is not possible with ordinary refraction or reflection methods. To find more adequate solutions to the geocryologic problems confronting seismic exploration, certain nontraditional approaches are needed.

PREREQUISITES FOR NONTRADITIONAL METHODS

In permafrost areas, the seismic properties of loose rocks depend on both their lithology and their physical (thawed or frozen) condition. In the latter case, seismic waves are characterized by high velocities and frequencies, while Rayleigh waves have high amplitudes (Sedov 1976a). At the thaw-frozen rock boundary, the P wave acoustic impedance changes in a stepwise manner due to velocity variations (up to a factor of 2.9 or more for R 12 in sands). The contrast is even higher in frozen and dry rocks. At the ice-frozen rock boundary, a density-induced change of acoustic impedance is possible for P waves up to a factor of 1.7 in clay and up to 3.1 times in sand. Except

for the water-bottom boundary in marine seismic surveys, these conditions are not observed where permafrost is absent. The bottom effects on seismic waves are known widely (Burg et al. 1951). In ultrasonic physics, it has been shown that the energy of R waves is converted on rigidity-contrast (metal-air) surficial inhomogeneities (De Bremaeker 1958, Viktorov 1966). Seismologists have also suggested that R waves can be dispersed by both positive and negative relief features. However, in all these cases, solid matter contacted air, i.e. a medium that actually does not transfer energy but returns all the energy back to the solid body.

EXPERIMENTAL DATA

With due consideration of geoseismic peculiarities of permafrost as well as ultrasonic physics and seismological data, seismic wave fields have been studied over variously shaped and sized and genetically different taliks and ground ice masses as well as lithologically different permafrost sections. *In situ* investigations were undertaken for seismic wave velocities in low-temperature rocks and for their dependences on temperature, ice content, age, origin, peculiar changes at the talik-permafrost boundaries, and other features (Sedov 1976a). Seismogeologic type columns and effective two-dimension models have been elaborated for permafrost areas which took account of the rock physical condition and densities in the profile (Sedov 1976c).

In view of space limitations, only some non-traditional methods for seismic permafrost research are dealt with in this paper.

Figure 1 demonstrates the influence exerted by the talik-permafrost contact on the seismic wave field (Dyuryagin et al 1975, Sedov 1978). Criteria for its recognition are inferred experimentally. P and R waves excited in frozen rocks propagate into talik as longitudinal PP_0 and RP_0 waves without other type waves generated at the contact. From thaw rocks, P_0 wave transfers the energy

through the contact as a single-type P_0P wave and converted P_0R wave. Sound P_{air} wave forms converted P_{air} wave at the contact which propagates within the frozen rocks. As the waves impinge on the contact, it turns into a source of oscillations for the medium into which the energy is transferred. This is attended by velocity and frequency changes and by redistribution of the oscillation energy. For example, just as in the case of an explosion on frozen rocks, the P_0R wave amplitude is greater and its frequency smaller than those of the P_0P wave.

Whenever the horizontal extent of a talik (for instance, sub-channel talik) is comparable with the wave length, a different wave pattern can be observed. Figure 2 presents seismograms characteristic of the field over narrow (A) and broad (B) subchannel taliks overlain by a layer of seasonally frozen rocks measuring some 2.5 m in thickness (Sedov et al 1976). As the waves reach the taliks, they form converted PR and RP waves together with single-type passing waves, while the R wave forms, in addition, a RR wave. With other factors being equal, amplitudes of the PR, RP, and RR waves depend on the lateral extent of taliks.

Different-type high-amplitude converted waves are generated at the boundaries of sublacustrine taliks and from water cores of frost mounds, in steam-and-water thawing zones, pits, crack zones around blast holes, etc. Seismic wave fields over some of these inhomogeneous structures have been discussed previously (Roshchin et al 1975, Dombrovsky et al 1977, Sedov et al 1977). Despite the presence of similar features, each of the mentioned cases has its peculiar properties enabling recognition of an individual object.

The dependence of R-wave velocities on the lithology of perennially frozen rocks provides for determination of layer composition while pseudo-Rayleigh waves enable one to find the depths of occurrence and thicknesses, including the profiles where the velocities diminish downward (Sedov et al. 1978).

By changing the R wave length (changing the mass of charge or falling weight and vibrator effects) one can study the structure of perennially frozen rocks downward in the section. R waves have the greatest amplitudes with explosions on the surface. This enables one to reduce the amount of explosive used or, occasionally, to employ shocks or aerial explosions which spare the surficial layer of the ground.

Nontraditional seismic exploration methods have also been utilized in investigations of subpermafrost taliks occurring upon bedrock basements and covered by frozen rocks that are tens or even hundreds of meters thick (Bykov et al. 1978). Just as in the case of marine seismic surveys, water reverberations are observed above ground ice layers due to reflections of seismic waves from upper and lower boundaries (Sedov 1978). The "soft-bottom" formula and seismic velocities in the overlying frozen sediments enable one to determine the depth of the ice upper boundary with the aid of frequency value for the first reverberation wave. Ice thickness is found by the aid of the second reverberation wave and ice-related seismic velocities. Recognition of the second reverberation wave is facilitated by the oscillation

attenuations, which are more rapid in frozen materials than in ice.

CONCLUSIONS

The described nontraditional seismic exploration techniques provide for broader geocryologic research works.

Employment of higher-amplitude R waves results in less violent excitation sources, which may be replaced by above-ground blasts. This means a lesser environmental hazard and more permissive seismic exploration techniques.

Nontraditional methods are useful tools for investigation of subsurface taliks characterized by dynamic size changes.

ACKNOWLEDGMENTS

The author wishes to express his hearty thanks to E. M. Anisimov, G. I. Roshchin, G. F. Chulkov, and other coworkers for assisting in the author's field studies. Special thanks go to Yuri Stoma without whose assistance this paper would never appear in English.

ECOLOGICAL RELATIONSHIPS WITHIN THE DISCONTINUOUS PERMAFROST ZONE OF SOUTHERN YUKON TERRITORY

J.P. Senyk¹, E.T. Oswald²

¹Lands Directorate, Environment Canada, Pacific Forest Research Centre, Victoria, British Columbia, V8Z 1M5

²Canadian Forestry Service, Environment Canada, Pacific Forest Research Centre, Victoria, British Columbia, V8Z 1M5

Recognizing the immediate need for baseline resource information to cope with present and anticipated exploitation and development, an exploratory level integrated resource survey was undertaken in the Yukon Territory. This survey, which identified 22 broad scale ecosystems (Ecoregions), was succeeded by more detailed ecological land classification studies (Ecodistrict, Ecosection) in a number of locations throughout the southern part of the Territory. During these surveys a number of ecosystems containing perennially frozen soils and/or that evolved as a result of permafrost degradation were examined and characterized. Several of these are described and relationships between the various ecosystem components discussed.

INTRODUCTION

Ecological Land Classification is one approach to partitioning the earth's natural resources into geographically bounded "parcels" (ecosystems) that have certain biological and physical ties, continuity and homogeneity in terms of climate, terrain, bedrock, soil, vegetation, water and fauna. The system involves an interdisciplinary team of scientists, relies heavily on the interpretation of various forms of remotely sensed imagery and is hierarchical in nature, allowing for ecosystem definition at six levels of generalization (Figure 1) each of which provides information of appropriate scope and detail for a particular level of management.

Initial survey work in the Yukon Territory recognized 22 ecoregions (Oswald and Senyk 1977). Subsequently, more detailed surveys were conducted in some of the southern ecoregions (Figure 2) (Oswald, compiler. 1979; Senyk, et

al. 1981). These studies adopted the more or less formalized, hierarchical approach to ecological land classification of the Environmental Conservation Service Task Force (1981). Because the surveys conducted to date have been of an exploratory and reconnaissance nature, ecosystem recognition has been based largely on surface form, expression and composition of terrain, vegetation and water. Presence and surface expression of permafrost is used as an indicator of environmental condition,

and coupled with observable changes in other components of the ecosystem, supplies additional evidence for ecosystem differentiation. Patterned ground, such as circles, polygons and stripes and other features such as peat plateaux, palsas, surface collapse or thermokarst scars can often be related to distinct differences in local and to some extent regional climates.

Fire disturbance has been nearly universal in southern Yukon. Its effects have been to create a mosaic of biophysical patterns in various stages of succession. Forecasting stable conditions after disturbance is difficult, particularly when consideration is given to the development of perennially frozen soils concomitant with other components of the ecosystem.

DESCRIPTION OF AREA

Southern Yukon Territory is an area of rolling to hilly plateaux lands rimmed by high, rugged mountains on the southwest, north and east sides (Bostock 1965). The climate, described as subarctic continental (WAHL pers. comm.) shows the influence of the Pacific Ocean, specifically the Gulf of Alaska and the relatively frequent intrusion of mild air. Air flow is predominantly from the south and west, and as a result areas located to the south and west of mountain ranges receive considerably more cloud and precipitation than areas on the north and east sides. Annual precipitation increases in a northerly and easterly direction from about 220 mm per year immediately in the lee of the St. Elias and Coast Mountains to about 400 mm in the north and 750 mm in the Mackenzie Mountains to the east. Nearly half of the precipitation occurs during the summer months (June - August). Average annual temperatures decrease from about -1°C in the southwest to -7°C in the north and east. Temperature extremes increase in a northerly and easterly direction. These figures vary considerably with changes in elevation.

The area lies within the scattered and widespread permafrost subzones of the discontinuous permafrost zone, with the nearly continuous snow and ice covered St. Elias and Coast Mountains falling within a separate subzone (Brown in press) (Figure 3).

Except for the northwest corner, the area was glaciated during the Pleistocene (Hughes et al. 1969). Subsequently, nearly the entire area was covered with volcanic ash, which decreases in depth and particle size from the southwest to the east and north (Hughes et al. 1972).

Vegetation is typical of the northern sections of the Boreal Region (Rowe 1972), with Alpine Tundra occurring on all the higher elevation terrain. White spruce, lodgepole pine, alpine fir and black spruce are the common softwood species with tamarack having limited

FIGURE 3 Permafrost Subzones of Southern Yukon Territory

distribution; trembling aspen, balsam poplar and white birch are common hardwood tree species. White spruce occurs nearly universally throughout this part of the Yukon; black spruce is scarce to absent in the south centre. Tamarack is specific to the southeast, while alpine fir is present at the higher elevations throughout the eastern half. Lodgepole pine is common to abundant in east and central parts but generally absent in the west. Trembling aspen is common after fires throughout much of the area; balsam poplar on upland sites is most common in the west central part and white birch is scattered throughout, being mostly on cooler sites.

Soils in the southwest and south central parts are largely Eutric Brunisols, with Static and Turbic Cryosols occurring sporadically throughout but most commonly at higher elevations and in depressions (C.S.S.C. 1978). These grade to Dystric Brunisols and minor Luvisols and Podzols towards the east. Cryosols are common here in organic and imperfectly drained fine textured deposits at lower elevations. Cryosols become more prominent across the north occurring in a variety of materials and landscape positions. These are associated with Dystric and Eutric Brunisols and occasionally Podzols.

ECOLOGICAL RELATIONSHIPS

Mineral Soils

Permafrost occurs only sporadically at lower elevations, in the dry, warm climates in the lee of the Coast and St. Elias Mountains in the southwest and is confined largely to organic deposits, lower north aspect slope positions and fine textured soils. Of special interest in this area, are the thick glaciolacustrine deposits laid down during late Pleistocene time in the Takhini Valley (Lat. $60^{\circ} 45' \text{N}$, Long. $137^{\circ} 35' \text{W}$). In various locations throughout

the central part of this valley the deposits consist of silts and silty clay materials to a depth of 60 m and greater (Kindle 1953; Hughes et al. 1972). Thaw lakes or thermokarst depressions are abundant in this area and are clearly visible on conventional airborne imagery and, with careful visual observation, on satellite scenes. Part of the basin was burned approximately 25 years ago and present vegetation after disturbance consists largely of willow, aspen, grass and minor white spruce and lodgepole pine regeneration. The undisturbed portion supports open to closed stands of white spruce and minor aspen with a nearly continuous ground cover of moss. Soils are Static Cryosols and minor Eutric Brunisols (Senyk et al. 1981).

Though the thaw processes are far more active in parts of the disturbed area, they are also acting on the undisturbed ecosystem and appear to have been operative for a considerable period of time. The area where activity is most noticeable covers approximately 40 to 45 km². On the eastern fringes of the basin, relic or stabilized thaw ponds are evident, though not abundant (Figure 4). They are generally small, 10 to 15 m in diameter and mostly shallow, 1 to 2 m, in depth. Some of these were likely initiated during the building of the Alaska Highway with the resultant disturbance of the thermal equilibrium of the underlying permafrost, others are "natural", still others due to fire disturbance. The terrain surface is nearly flat to slightly mounded.

FIGURE 4 Stabilized thaw pond initiated during construction of Alaska Highway

Permafrost occurrence, ice content and form appears to vary considerably from east to west. In the central part of the basin, depressionalkali flats are common (Figure 5). These bear strong resemblance to the "alases" described in Washburn (1973). The terrain surrounding these depressions is only slightly mounded and contains abundant surface cracks with permafrost at

FIGURE 5 Alkali encrusted depressions similar to Alases.

depths slightly greater than 1 m (Figure 8). Vegetation surrounding these depressions consists largely of aspen, white spruce and grass. The depressions are heavily crusted in carbonate salts with sedge and grass around their borders. Depth to permafrost was greater than 1.2 m beneath these depressions.

In this same vicinity and slightly to the west, thaw or thermokarst ponds are frequent under open to closed white spruce/feathermoss cover. The ponds are relatively uniform in size, ranging from about 35 to 45 m in diameter, with the collapsing banks averaging 2.5 to 3 m above water line (Figure 6). Occasionally thaw ponds have coalesced, partially infilled and presently support willow, sedge and grass. The uniformity in size of the thaw ponds might

FIGURE 6 Thermokarst depressions in "undisturbed" ecosystem.

suggest a similar time frame for initiation. Depth to permafrost is relatively uniform under the undisturbed vegetation, being in the vicinity of 0.7 m. Examination of the exposed banks indicated a relatively uniform ice form and content to depths of 1.7 to 2 m. No major lens or massive ice forms were encountered in the thaw ponds examined.

The collapse process proceeds relatively slowly, with sloughing material ravelling rather than collapsing. This material forms debris covered lower surfaces which insulate the underlying permafrost and slow the thaw process. The shading and insulating potential of the surrounding vegetation cannot be underestimated.

In the northwestern part of the basin, in a 25 year old burn, thaw collapse processes are extremely active. The terrain surface is slightly more mounded than the area previously discussed. Vegetation consists largely of willow, aspen, grass and sedge with minor white spruce regeneration. Massive ice, of a planoconvex form containing scattered air bubbles, underlies 1-1.2 m of windworked lacustrine sediments (Figure 7). The thaw

FIGURE 7 Wind-worked glaciolacustrine sediments overlying planoconvex ice.

layer extends to the upper contact with the massive ice. Though the exact extent of this condition was not determined, nearly identical collapse profiles extend over 3-4 km².

There appears to be a very close resemblance to "pingo" ice form, however the pronounced mounded nature attributed to pingos is absent. What is probably being viewed here is a pingo cluster, some of which is in the latter stages of collapse. Stabilized collapse depressions surrounding these actively collapsing features are likely scars of former pingos. The collapse feature depicted, extends over 2-3 ha and has coalesced with adjacent smaller actively collaps-

ing features. Bank collapse is abrupt, the banks being nearly vertical and 2-3 m in height. Surface debris occasionally collapses in large blocks leaving the vegetation relatively intact.

Probing outward from the slumping bank indicated a dished or concave nature to the debris covered ice surface extending towards the centre of collapse. Moist mineral soil at the ice contact indicates that a general downwasting of the ice is occurring. Water is being removed from the system through drainage developed by the coalescing of collapse features. The collapsed debris is water saturated and appears to flow towards the initial collapse centre. Ponds are present in all collapse depressions.

The ice contains entrapped air bubbles though they are not so abundant as to lend a milky appearance to the ice. The convex bands of ice are clearly visible though there does not appear to be a discontinuity or cleavage plane along these bands when pieces of ice are broken loose.

Organic Soils

In the southeast, wetlands are considerably more abundant than in the preceding region. In this part of the Yukon Territory, permafrost occurs in most organic deposits and imperfectly drained mineral soils.

The following example is taken from an area approximately 45 km north of Watson Lake (Lat. 60° 07'N, Long. 128° 49'W). First identified on 1:70,000 scale air photographs, largely through the abundance of collapse features and leaning trees, the wetland was later examined on the ground. The uplands surrounding the depression are comprised of morainal deposits, sandy loam to loam in texture, with a nearly closed stand of white spruce, lodgepole pine and feathermoss ground cover. The wetland located in an abandoned river channel is an extensive peat plateau (palsa) with its upper surface elevated 2.5 to 3.5 m above the collapsed surface. The collapse (thaw) processes appear to have been initiated at the upland-wetland interface and have been proceeding inward towards the centre of the depression. Scalloped or circular collapse features occur within and around the perimeter of the plateau (Figure 8). Most were the result of thawing of massive ice lenses during the progressive thaw of the perimeter. The presence of these "bulges" of massive ice would indicate that considerable differences in ice conditions exist within the plateau.

Probable cause of thaw acceleration is fire that swept through the area 60-70 years ago. Though the burn may not have been intense, it was sufficient to remove or kill part of the insulating moss layer and remove much of the shade-producing tree overstory. Vegetation on the plateau surface consisted of two distinct

FIGURE 8 Collapsing edge of peat plateau.

age classes of black spruce with a uniform understory of Labrador tea, sphagnum, cloudberry and lichens.

The collapsing edges of this particular plateau revealed no evidence of mineral soils to depths of 2.5 m. A massive ice lens (pure ice) was examined along a collapse wall in one of the circular collapse areas. Its upper surface was within 1.3 m of the plateau surface. The ice was clear, containing only a few air bubbles. No other lenses of even comparable size were located elsewhere. The thaw layer was generally dry in the upper 7-10 cm of the surface with increasing moisture down to the contact with the frost table. The peat consisted of sphagnacious and woody material in the upper tier 0.4-0.6 m, poorly decomposed or fibric in nature. Underlying this deposit the clearly visible remains of sedge (fibric) continued to depths of 1.5 m, where the remains become less easily identifiable (mesic).

Open water generally occurs in the immediate vicinity of active collapse. At the outer fringes of these small thaw ponds, Sphagnum spp is usually the primary invader, while still further removed, sedges and woody plants are common. Often tree stems from the plateau surface stick above the area of collapse (Figure 9). Collapse and regrowth of these ecosystems appear to be cyclic, though it may take centuries to complete a single cycle, barring any disturbance. In a number of instances, permanently frozen, slightly elevated nodules have been encountered within the area of collapse some distance from the actively collapsing face.

Patterned Ground

Perhaps the most interesting forms in this area are those that result from intense frost action resulting in a great variety of relatively symmetrical surface ground features that

FIGURE 9 Collapse scar of peat plateau with dead black spruce protruding from the surface.

are clearly visible, unhampered by high vegetation, in alpine environments. Slope orientation, soil types, precipitation patterns, etc. all strongly influence the occurrence and distribution of perennially frozen soils at higher elevations and hence the development of a variety of surface forms.

Attempts at relating specific forms and/or degree of development of patterned ground to broad environmental parameters, have met with little success. Increasing latitude results in a lowering of the altitudinal limits where these forms occur, but specific patterns appear to be tied more closely to local site conditions (i.e. soils, moisture regime, bedrock type, etc.), than to distinct changes in climate. Most of these patterned ground features have been well documented (i.e. Washburn 1973).

Of particular interest are the symmetrical, sorted features formed under water in ponds and lakes, most clearly visible and best developed at high elevations, (Figure 10) though not specific to these environments.

The narrow, stony beaches on the northwest side of Kusawa Lake (elevation 671 m, Lat. 60°30'N Long. 136°09'W) have regular "saw tooth" indentations, 2-2.5 m in length (Figure 11). Though the above water beach displays little or no easily identifiable frost-induced features (sorting, shattering), the underwater beach extension to a maximum depth of about 1.5 m has poorly developed stone bordered net features indicative of underlying permafrost and fairly intense frost activity. The regularity of the "saw tooth" features may indicate a direct relationship to these underlying permafrost conditions. Their appearance suggests that their formation is due to more than wave action and/or wind driven ice, though these may influence their genesis to some extent.

FIGURE 11 "Saw-tooth" beaches, associated with underwater, poorly sorted nets. Elevation 671 m

SUMMARY

Patterned ground and stable and collapse features resulting from the growth and/or degradation of permafrost can often be easily seen on various forms of remotely sensed imagery. Identification and examination of

these features, during exploratory or reconnaissance level Ecological Land Surveys, has led to characterization of surface forms, their distribution, abundance and extent within a broad geographic framework. When coupled with other biological and physical components, the presence of these various forms aids substantially in ecosystem differentiation and characterization.

SEASONAL THAWING OF PALSAS IN FINNISH LAPLAND

Matti Seppälä

Department of Geography, University of Helsinki, Hallituskatu 11-13
SF-00100 Helsinki 10, Finland

This study investigates the thickness of the active layer and its temporal, local, and regional differences in palsas - permafrost-cored peat mounds - in the bogs of northernmost Finland. Regional differences in the rate and amount of thawing are not found. The normal thawing depth per year is 55-70 cm. The minimum thickness of the insulating peat layer on palsas in Finland appears to be about 50 cm.

INTRODUCTION

It is characteristic of regions of discontinuous permafrost that only in places can the cold penetrate into the earth deep enough for it not to thaw completely during the summer. Not only low air temperature but also the thickness of the snow cover is a critical factor (Seppälä 1982). Snow is a good insulator. The quality of the soil and especially the thermal conductivity of the surface soil have a decisive effect on thawing. Gravel and sand have a high thermal conductivity. They freeze to considerable depth during the winter, but they also thaw fast during the summer. For example, in Finnish Lapland at the Kevo Subarctic Research Station more than 3 m of frost have been recorded, but in the summer it thaws completely (Seppälä 1976a). Frost develops much more slowly in peat (Seppälä 1982) than in mineral soil, but because the thermal conductivity of unfrozen dry peat is also much lower, the frost is much better preserved in peat than in mineral soil. This is the reason for the preservation of permafrost in palsas in northern peat bogs.

The first measurements of the summer position of the frost table were made on the Kola Peninsula by Kihlman in 1887 (from Kihlman's diary as cited by Rikkinen 1980). The thickness of the active layer was found to be 30-50 cm in August. In the Abisko region, Swedish Lapland, it was observed that the frost table on the July 10, 1911, was at the depth of 15 cm (Helaakoski 1912). In the Karesuando region, Sweden, it was observed that the frost table in July 1965 was some 40 cm deep and at the end of October about 60 cm deep (Forsgren 1966). According to Vorren (1967) the frost-free layer in palsas in northern Norway is 50-100 cm thick, while according to Ahman (1977) it varies from 65 to 100 cm. The present author has earlier described the thawing season 1974 of a palsa at Nunnanen (Seppälä 1976b); the results obtained are included in this study.

Interesting issues from the point of view of palsa development are, for example, (1) how deep the frost needs to penetrate

into the peat bog for the formation of a palsa to start and (2) how thick the insulating layer of peat needs to be to preserve the frost over the summer.

This study investigates the thickness of the active layer of palsas in northernmost Finland and temporal, local, and regional differences in the thawing of palsas there.

METHODS OF INVESTIGATION

Observations were made during 9 years, 1972-1982 (Figure 4), by measuring the position of the frost table in palsas. An iron pole was forced into the ground through the thawed peat layer. Altogether 185 measurements were made on the top of palsas in 17 palsa bogs (Figure 1).

The pattern of thawing in different parts of the same palsa was studied at Nunnanen (1974) and at Utsjoki, Skallovvarri (1975-1977). Several measurements were made at different points at intervals during the thawing seasons.

Thermal gradients in different parts of a palsa were also measured with a Wallac thermoprobe meter (see Seppälä 1976b).

If only one or a few measurements were taken in the same palsa bog, they were carried out on a horizontal surface on the top of palsas to eliminate the effect of solar exposition.

In this study no comparison was made of weather conditions with degree of thawing. We made our own weather observations on the Nunnanen (Seppälä 1976b) and Skallovvarri palsa bogs, but the results of these will be published later and compared with the official weather recordings made at the closest observation points.

THAWING OF THE FROST IN DIFFERENT PARTS OF PALSAS

I do not think it is necessary to repeat the observations made on the Nunnanen palsa bog in 1974 (Seppälä 1976b), but we shall look in detail at a similar thawing development on Skallovvarri palsa bog in 1975 (Figure 2)(Seppälä, in press).

Thawing starts in May on the top of the

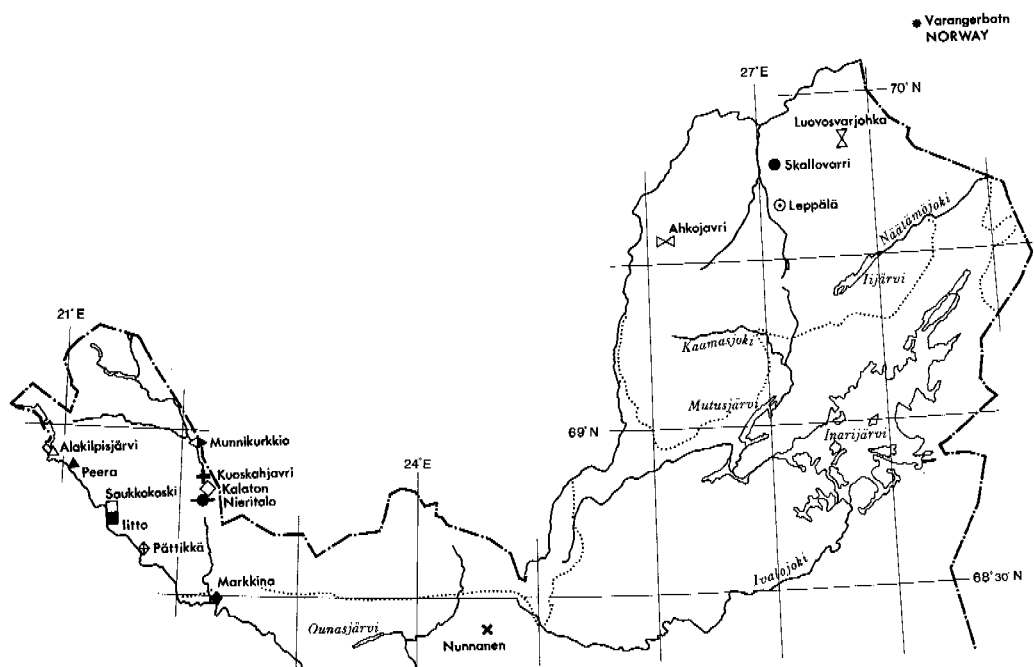

FIGURE 1 Location of the studied palsa bogs in Finnish Lapland. The dotted line indicates the northern limit of pine forest according to the Motoring road map of Finland 1978.

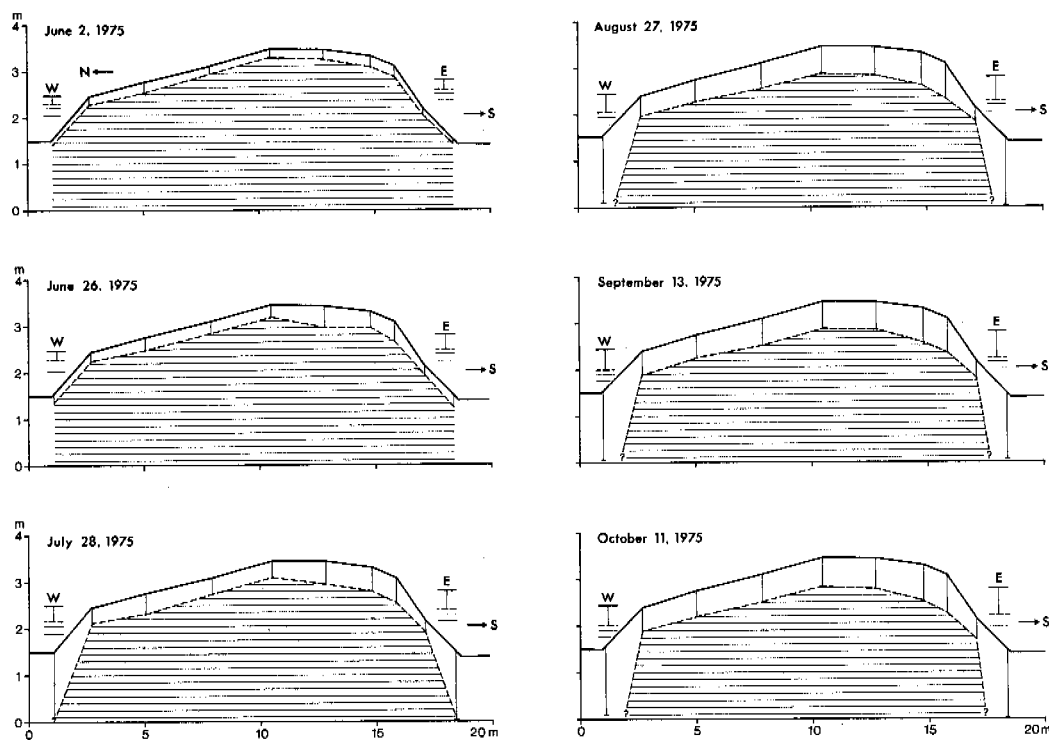

FIGURE 2 The position of frost table during the thawing season 1975 in Skallovarri. The hatched area indicates frozen parts. Vertical lines show the measurement points. W and E are the measurement points on the western and eastern parts of the palsa.

palsa when it becomes free of snow. In June and July, thawing is rapid, but in 1975 the rate of thawing decreased in August. Thawing penetrated deeper on the southern side of the palsa than on the northern side, although the differences are not great every year. Between east and west slopes the differences were slight. The east side thawed approximately as deeply as the top, while the western slope thawed least. Those slopes which are wet because of standing water at the foot of the palsa melt more quickly than drier slopes.

Local differences in the rate of thawing can be surprisingly great. At Skallovarri in 1975, for example, at two observation points, on two neighboring palsas separated by only 20 m, the frost table dropped by 28 cm at the first point and by only 7 cm at the second point during a period of 24 days in June (Figure 3). During the following month the table fell another 3 and 18 cm, respectively, so that by the end of July the difference in level between the two points was only 6 cm (Figure 3). A similar large difference in level between the two points was also noted at the beginning of the thawing season in 1976 and in 1977.

In some cases, during very hot weather, it was observed that the frost table moved upward somewhat. This may be explained by strong evaporation, which cools the lower wet layers.

Thermal gradients in different parts of a 4-m-high palsa at Pättikkä (68°37'30" N latitude, 21°45'E longitude) were measured on a warm summer day (June 23, 1973) (Figure 4). The frost table was much higher on the north side than on the south side. Differences between the top and the north side were not marked.

The lowest temperature at a depth of 10 cm (7.3°C) was found on the north side. On the south side, where there was vertical cracking of the surface and no vegetation,

Pättikkä palsabog
23 th June 1973

FIGURE 4 Temperature gradients of surface peat in a palsa in Pättikkä. Measurement points on the top, north edge (N), and south edge (S) of the palsa. The air temperature were recorded 20 cm above the surface at each point.

the temperature reached 13.0°C. At a depth of 20 cm on the top and on the north side the temperature were approximately the same. When measuring deeper layers from the top, the temperature dropped more steeply than in the other parts. The frost table on the top of the palsa lay at a depth of 50 cm, on the north side at 55 cm and on the south side at 120 cm. On the southern slope the

FIGURE 3 Observations made of the position of frost table in palsas. Lines join observations of same points. Dashed lines join those observations made at longer intervals and do not imply a linear thawing. Symbols indicate the observation points (see Figure 1).

temperature gradient from 40 to 60 cm depth was only 1°C.

Air temperature during the measurements ranges from 17.1° to 22.0°C 20 cm above the palsa surface (Figure 4).

On the same day (June 23, 1973) in this same palsa bog at Pättikkä the frost table in one palsa, 0.5 m high, lay at a depth of only 10 cm.

High day temperatures cause the asymmetrical shape of the core surface to become substantially more regular. Rain increases melting because the thermal conductivity of wet peat is much higher than that of dry peat.

Cracks on the palsa surface do not appear to have any great effect on the depth of thawing. Instead, they increase the possibility of peat blocks slumping; the palsa then loses its insulating cover of peat and a thermokarst depression is activated (Sepälä 1976b).

SEASONAL DIFFERENCES IN THAWING

In some years, thawing starts very fast, reaching great depths even by the end of June, as took place at Nunnanen in 1974 and at Skallovvarri in 1976 (Figure 5). In 1977, thawing started especially slowly, but it reached almost the same level as in 1975 and 1976.

At the end of August 1975 and 1976 (Figure 6) the differences in thawing depths were very small at most measurement points. Only at Peera was the difference 14 cm at one point and at Markkina 31 cm, neither of which could be explained.

The greatest range between frost table

FIGURE 5 Summary diagram of the observations of the position of frost table in palsas in different years (Figure 4). Symbols indicate the recording points (Figure 1). Arrows show observations at the same site in diagram. Vb Varangerbotn.

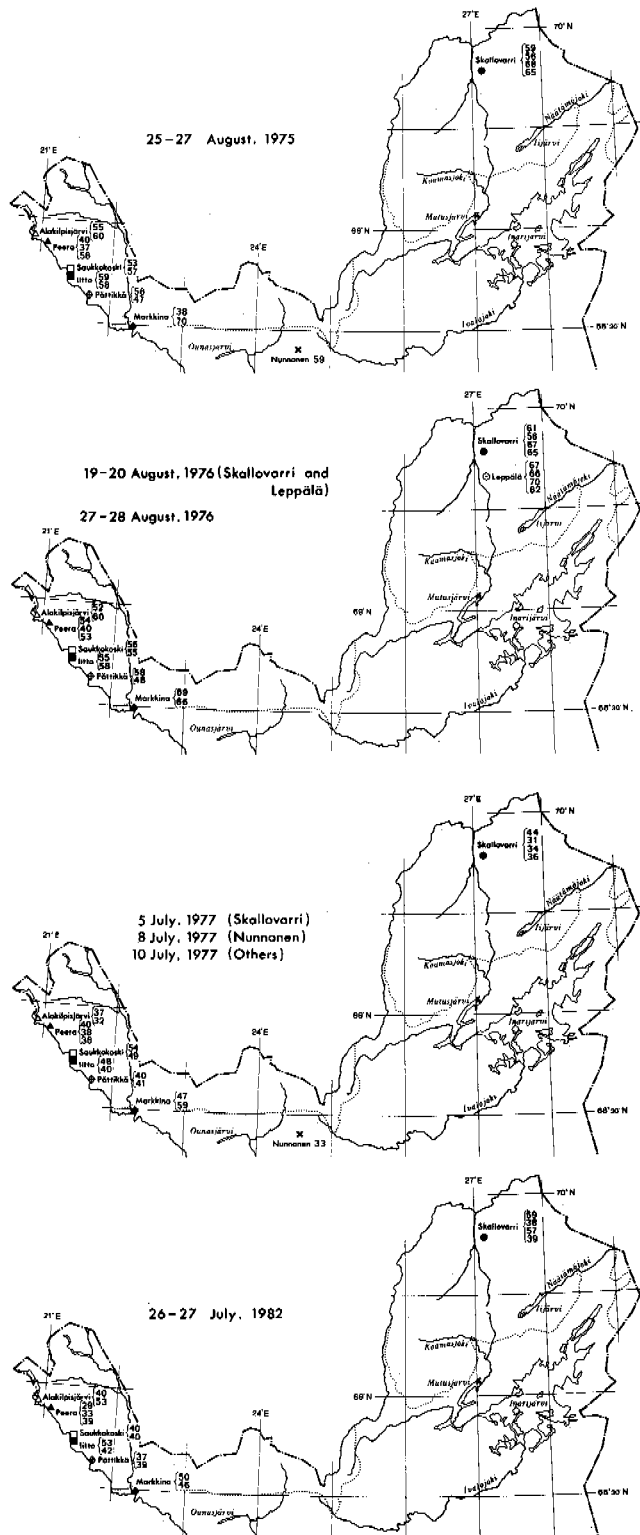

FIGURE 6 Observations made at short intervals on different palsa bogs. Numbers indicate the position of frost table in centimeters measured from the peat surface.

levels at the same points occurs in July. These differences in level were reduced by August, when in most years the differences were only a few centimeters.

REGIONAL DIFFERENCES IN ACTIVE LAYER

Regional differences in the rate and degree of thawing are not found. The differences between the various palsas were greater than the differences between palsa bogs (Figure 6). In general, low palsas melt less than higher ones in the same palsa bog. The normal thawing depth per year is 55-70 cm. This is the maximum thickness of the active layer on the top of most palsas in Finnish Lapland and is usually reached by the beginning of October (Figure 5).

In July only surprisingly small differences could be found in the thawing depth at different heights above the sea level. At Alakilpisjärvi and Skallovarri (Figure 1) the palsas had melted to very much the same depth (even less at Skallovarri in 1982)(Figure 6), although the altitude difference is almost 200 m (Table 1). Morphological differences in palsas, such as height, may explain the ranges in thawing rates better than, for example, altitude above sea level, which naturally affects the air temperature.

Vegetation on the palsa surface reduces thawing. Eroded old palsas thaw deeper than younger palsas with a covering vegetation.

The greatest difference in thawing depth was found between the Finnish and Norwegian (Varangerbotn, Vb, Figures 1, 4, and 5) palsas. In Varangerbotn one 3-m-high palsa had already thawed to a depth of 65 cm on July 6. This might be caused by its location only 50 m above sea level and close to the Arctic Ocean.

DISCUSSION

In northern Finland the frost in a flat-topped peat bog should penetrate to a depth of at least 50 cm before the frost is preserved through the summer to the next winter (Seppälä 1982). This happens only in places where the snow cover is thinner than normal. When a palsa rises above the peat bog surface, thawing starts earlier in spring and reaches deeper levels. The maximum thickness of the active layer on the top of most palsas in Finnish Lapland is 55-70 cm. If thawing goes deeper than 70 cm, as happens in some wind-eroded palsas, then the frost may fail to penetrate to the permafrost table. An unfrozen suprapermafrost layer then exists which may eventually destroy the frozen core of the palsa (cf. Salmi 1970, fig. 4).

The depths to which palsas thawed changed surprisingly little in different parts of Lapland and also remained very constant year after year. The summits of palsas covered with vegetation and located in different regions provide the best localities for comparing thawing measurements.

TABLE 1 Palsa bogs studied. See also Figure 1.

Palsa Bog Name	Approximate Location	Altitude a.s.l.(m)	Height (m)
Alakilpisjärvi	68°56'N 20°55'E	490	2-3
Peera	68°53'N 21°03'E	460	3-7
Saukkokoski	68°45'N 21°25'E	410	3
Iitto	68°44'N 21°25'E	405	5-6
Pättikkäkoski	68°38'N 21°43'E	395	1-2
Markkina	68°29'N 22°18'E	335	1-2
Munnikurkkio	68°55'N 22°10'E	440	6
Kuoskahjavri	68°51'N 22°14'E	440	1
Kalaton	68°50'N 22°15'E	440	1-3
Nieritalo	68°48'N 22°12'E	440	5-6
Nunnanen	68°25'N 24°35'E	320	2-4
Skallovarri	69°49'N 27°10'E	295	1-3
Leppälä	69°40'N 27°08'E	225	1-3
Luovosvarjohka	69°51'N 27°46'E	300	3
Ahkojavri	69°35'N 26°11'E	365	3
Varangerbotn (N)	70°15'N 28°30'E	50	3

The maximum depth of the frost table should be measured as late as possible in October-November, because heat penetrates very slowly into the peat.

The minimum thickness of the insulating peat layer on palsas in Finland appears to be about 50 cm. If the peat layer is thinner, palsas do not exist. Instead, there are small peat hummocks called *pounu*(s), characterized by a seasonally frozen core (cf. Salmi 1972, Seppälä 1979). Wind and rain erode the surface of the palsa, and as the peat layer gets thinner and vegetation disappears, then the insulation provided is no longer sufficient to preserve the frozen core of the palsa. This results in the "death" of the palsa and it forms a thermokarst hollow or pond in the peat bog.

ACKNOWLEDGEMENTS

In the field work I was assisted by J. Vainio, K. Lundén, V. Säntti, J. Rastas, A. Sujala, H. Nurminen, M. Sulkinoja, J. Heino, L. Koutaniemi, R. Ahman, and M. J. Clark. The figures were drawn in their final form by K. Lehto and copied by P. Mölsä, and the English of the text was checked by Ch. Grapes. The study was supported with travel grants from the National Research Council for Natural Sciences in Finland, Seth Sohlberg's Delegation (Societas Scientiarum Fennica), and the Rector of the University of Helsinki. To all these individuals and institutions I would like to express my sincere gratitude.

REVEGETATION OF ARCTIC DISTURBED SITES BY NATIVE TUNDRA PLANTS

G. R. Shaver,¹ B. L. Gartner,² F. S. Chapin III,² and A. E. Linkins³

² Institute of Arctic Biology, University of Alaska, Fairbanks, Alaska 99701 USA

³ Department of Biology, Virginia Polytechnic Institute and State University, Blacksburg, Virginia 24061 USA

The aim of this research was to develop new methods by which the recovery of native vegetation might be promoted on development-related disturbances in northern Alaska. Current methods depend on an expensive and heavily supported introduction of nonnative grasses, often with detrimental effects on native plant recovery. The research included studies of both native plant population dynamics and the regulation of tundra nutrient cycles. The results showed that the single most important factor in native vegetation recovery is preservation or replacement of the upper organic layer of soil. The organic layer is important because (1) it contains a large, readily germinable native seed pool (2) native seed germination rates are higher in organic than in mineral soils (3) it reduces soil thaw and thermokarst erosion and (4) it reduces nutrient losses and nutrient movement in the soil, resulting in more normal patterns of nutrient availability. Future management practices should include conservation of soil organic matter as a top priority, with heavy fertilization and seeding only where erosion potential is great or the organic mat is lost.

INTRODUCTION

In the Arctic, large areas of native tundra vegetation are inevitably disturbed or eliminated by development. Proper management requires that those areas be revegetated and ultimately restored to a state as close to the original as is economically and logistically feasible. Current revegetation methods depend strongly on the use of plants that are not native to the disturbed regions, and often require expensive and labor intensive fertilization and planting procedures (Johnson 1981). The use of these non-native plants is usually effective in ameliorating problems such as rapid soil erosion, but it may actually reduce the restoration of native plant populations either directly through competition or secondarily through fertilization and other environmental modifications (Hernandez 1973, Chapin and Chapin 1980). Thus community restoration should incorporate native plants whenever possible, particularly if it can be done at a lower cost.

Current revegetation practices were developed when little was known about the reproductive biology and growth of native tundra plants. Methods are changing rapidly as new knowledge becomes available. The aim of this paper is to summarize recent research on ecological aspects of native tundra plants that are particularly relevant to revegetation management using native plants.

Two approaches were used in this research. The first involved a series of studies of native plant population dynamics, especially seed sources and seedling establishment on both natural and artificial disturbances. These studies established the basic patterns of seed production, seed germination, and growth in native tundra plants, and some of the major controlling factors. The second line of research dealt with controls on total primary production, nutrient cycling, and the regulation of species and growth form composition in whole tundra vegetation. Underlying this research was the assumption that natural revegetation and recovery from disturbance are largely mediated by changes in nutrient cycling. Detailed descriptions of the methods have been published in the original papers.

POPULATION DYNAMICS AND GROWTH

The establishment of native plants on disturbed sites depends on survival through all stages of the plant life cycle. For the purpose of this research these stages were divided into separate studies of seed production, seed storage, seed germination, seedling demography, and seedling growth. The species of particular interest was arctic cottongrass, *Eriophorum vaginatum* L., a tussock-forming sedge that is the

dominant plant over much of the north slope of Alaska. *Eriophorum* species in general are also conspicuously successful as invaders of unmanaged disturbances.

An initial hypothesis was that revegetation by native plants might be promoted by fertilizing undisturbed areas adjacent to disturbances, to increase seed production and presumably also seed input to the disturbance. Primary production of tussock tundra is strongly nutrient limited (Shaver and Chapin 1980), and flowering of *E. vaginatum* is highly responsive to fertilization. For example, at Eagle Creek, Alaska, fertilization with NPK (Shaver and Chapin 1980) increased flowering from 11.3 ± 4.4 to 59.2 ± 12.6 inflorescences m^{-2} in 1978, 2 years after the fertilizer was applied. The number of seeds inflorescence $^{-1}$ increased from 15.3 ± 2.3 to 33.0 ± 2.4 , for a total seed production of 173 seeds $m^{-2} yr^{-1}$ in control plots and 1,954 seeds $m^{-2} yr^{-1}$ in NPK fertilized plots.

The high seed production in fertilized plots in 1978 should be sufficient to increase significantly the seed rain onto adjacent disturbances. *Eriophorum vaginatum* seed are easily wind dispersed. However, flowering varies greatly from year to year; in control plots at Eagle Creek it ranged over 3 orders of magnitude, from 0.04 ± 0.02 to 19.0 ± 3.9 inflorescences m^{-2} between 1976 and 1982. Although fertilization increased flowering, the effect was greatest in high flowering years such as 1978. In years of low flowering fertilization had little or no significant effect. Because of this annual variation the effects of fertilization are unpredictable, and one cannot depend on fertilization of undisturbed tundra to supply seed to adjacent disturbances. Fertilization of adjacent areas may be useful as a supplementary technique.

A second potential seed source for use in revegetation is the pool of ungerminated seeds that may accumulate in the soil of undisturbed tundra ecosystems. Large buried seed pools have been found in many other ecosystems (Grubb 1977, Grime 1979), but their size and significance in tundra were unknown before this work began. At both Eagle Creek (McGraw 1980) and at Kuparuk Ridge, Alaska (Gartner 1982, Gartner et al. 1983), significant numbers of *Carex* spp. and *Eriophorum* spp. seed were found in the upper 10-15 cm of organic soil of undisturbed tussock tundra. These seed germinate readily when the soil is exposed and warmed by removal of vegetation.

In experimental disturbances at Eagle Creek and Kuparuk Ridge, most of the seedlings that appeared on the plots came from buried seed (Chester and Shaver 1982, Gartner et al. 1983). The seedlings could not have come from external seed rain because most of them appeared on the plots in June or early July, before any seed were produced or shed by plants in the surrounding undisturbed tundra. The seedlings appeared without any manipulation other than vegetation removal, suggesting that buried seed in the upper layers of soil are potentially an important

source of seed in the restoration of disturbed sites using native plants.

The germination characteristics of native tundra seeds are typical of many disturbance-adapted species (Bliss 1971). In studies of *Eriophorum vaginatum* germination, in particular (Wein and MacLean 1973, Gartner 1982), the seeds generally have no strong constitutive dormancy mechanisms. Instead, *Eriophorum* seed germinate most readily under the conditions likely to occur only on disturbed sites, i.e., at soil temperatures of 20°C or higher. Germination is increased in the light, in accord with the higher light intensities at the soil surface that prevail on disturbances. These studies support the conclusion that periodic disturbance represents an important opportunity for seed reproduction in natural tundra, that native plants have been selected to respond to disturbance by maintenance of a large pool of seeds that germinate readily, and that this adaptation is of potential use in developing management schemes (Gartner 1982).

The native seedlings that appear in experimental disturbances are not evenly distributed. *Eriophorum* and *Carex* seedlings are much more abundant on organic substrates, whereas native grass species are more evenly divided between mineral and organic areas (Gartner 1982, Gartner et al. 1983). This pattern has two principal causes. Initially the most important is the distribution of seeds in the seed bank. Few or no seeds are stored in the deeper mineral layers of soil. Thus the deeper the removal of vegetation and soil, the fewer the remaining seedlings. Grasses are rare or absent from the buried seed pool (McGraw 1980, Gartner 1982), and their low seedling densities and even distribution may result from a dependence on external seed input. A second reason for the greater total abundance of seedlings on organic substrates is that seedling germination rates are higher and mortality rates lower there. When seeds of *E. vaginatum* and *Calamagrostis canadensis* were sown artificially on organic and mineral soils, the germination percentages were 3-5 times higher on the organic areas (Gartner 1982). Mortality rates were higher on mineral soils in part due to much greater needle ice action, which heaves seedlings out of the soil. Using toothpicks as model seedlings, Gartner (1982) found over 80% heaved out of the mineral soil after 2 years, but less than 20% heaved in the organic soil. Actual seedling mortality rates were lower but followed the same pattern.

Growth rates of the native grass and sedge seedlings are not significantly different on organic vs. mineral soils in the field. Thus the major differences in native plant cover after 4 years' growth on organic vs. mineral soils were due to seedling density differences rather than differences in growth rates (Gartner 1982).

The general conclusion from this portion of the research is that maintenance or replacement of the original organic mat is vital to the recovery of native graminoid species following disturbance, both because the organic mat already

contains a major potential source of native plant seed and because it is the most favorable substrate for germination of seeds derived from external sources. This is in contrast to the normal practice of removing the organic mat and preparing a mineral seed bed, which is more favorable for both germination and growth of introduced nonnative grasses (Mitchell 1979).

NUTRIENTS, GROWTH, AND COMMUNITY REGULATION

Productivity of tundra vegetation is in general nutrient limited (Haag 1974, McKendrick et al. 1978, Shaver and Chapin 1980), and nutrient availability has major consequences for the distribution and abundance of native tundra plants. As in virtually all terrestrial ecosystems, physical disturbance to tundra disrupts the normal patterns of nutrient availability (Gersper and Challinor 1975). To study the effects of disturbance-related changes in nutrient availability in tundra, we combined descriptive comparisons of disturbed and undisturbed sites with controlled manipulation of nutrient availability in fertilization experiments. The research was organized around two basic questions: First, how might an increase in nutrient availability by fertilization improve the recovery of native plant populations following disturbance? Second, in the later stages of recovery how might manipulation of nutrient availability affect the composition of the native plant community?

Fertilization has various effects on native plant growth, depending on species, time since disturbance, and type of vegetation. On recently disturbed sites (less than 5 years old), fertilization increased growth of native *Carex* and grass seedlings but not of *Eriophorum* seedlings (Gartner et al. 1983). There was no difference in responsiveness between mineral and organic substrates. However, after 10 years' recovery on a bulldozed organic site at Eagle Creek, Chapin and Chapin (1980) found no long-term fertilization effect. Cover by native species, primarily *E. vaginatum*, was nearly 100% in both fertilized and unfertilized plots, whether or not seed of various nonnative grass species had been sown following the disturbance.

The lack of a long-term fertilization effect on native plant recovery on disturbed sites is consistent with the long-term vegetation responses on unmanaged disturbances such as vehicle tracks. Production and biomass of native plants on 7-10 year old vehicle tracks is as much as 2-5 times that of undisturbed tundra (Chapin and Shaver 1981). The high productivity of old disturbed sites is accompanied by an even greater increase in annual uptake of N and P (Wein and Bliss 1974, Chapin and Shaver 1981). The native vegetation of these sites is dominated by rapidly growing graminoids and occasionally some deciduous shrubs, all characteristic indicators of high nutrient availability.

Both the fertilization experiments and the descriptive studies of older disturbances suggest that nutrient availability is relatively

non-limiting after about 5 years on a disturbance if the site is relatively moist and covered with an organic soil. Fertilization thus may improve native plant recovery in the first year or two but there is no need to continue the application except perhaps on dry mineral soils.

In fact, fertilization may cause a shift away from normal patterns of plant nutrient uptake. In *Eriophorum vaginatum*, acid phosphatase activity at the root surface is positively correlated with soil organic matter (Table 1), suggesting a well-developed ability to use organic phosphorus as a source of inorganic phosphates. In potted plants, *E. vaginatum* growth rates were twice as high on organic than on mineral soils, despite nonsignificant differences in the field (Gartner 1982). The acid phosphate enzyme system is suppressed by the presence of inorganic phosphate. Addition of inorganic fertilizers or removal of organic soil horizons may reduce success of native plants by suppressing an efficient nutrient uptake mechanism and altering competitive interactions in phosphorus uptake.

Activity is expressed as nM PNP released hr^{-1} mm^{-2} root surface ($n = 10$). Methods are described in Antibus et al. (1981).

Once an adequate cover of native species is established, restoration of a natural community must involve manipulation of the relative abundances of species and growth forms. Nutrient availability is a key variable in this process, the major problem being that nutrient cycling rates are very rapid on old disturbances. Fertilization experiments have shown that when N and P are added to undisturbed tundra, the vegetation becomes more like that on old disturbances (Figure 1) (Shaver and Chapin 1980 and unpublished). Thus management of older disturbances should be focused on slowing down nutrient movement and decreasing nutrient availability.

Nutrient cycling on disturbed sites differs from undisturbed tundra in several aspects. Potentially one of the most important of these is soil temperature, which averaged about 2°C higher at 10 cm depth in old vehicle tracks than in undisturbed tundra (Chapin and Shaver 1981).

Figure 1 Primary production (g m^{-2}) of the major plant growth forms in control and fertilized areas of tussock tundra at Sagwon, Alaska, 4 years after the fertilizer was applied. Methods and rates of application followed Shaver and Chapin (1980).

Chapin and Shaver (1981) estimated the effects of a 2°C temperature change on individual nutrient cycling processes and concluded that although the soil temperature difference was significant it could not alone explain the higher productivity in vehicle tracks. Other factors such as differences in the rate of soil water and nutrient movement are now under investigation as explanations for the differences between disturbed and undisturbed sites.

Evidence for greater nutrient movement in vehicle tracks comes from a litter bag experiment (G. R. Shaver, F. S. Chapin, A. E. Linkins, and J. M. Melillo, unpublished) in which both N and P immobilization by *Eriophorum* litter was greater by a factor of 4-8 in wet vehicle tracks than in mesic undisturbed tundra (Figure 2). This greater immobilization is accompanied by much lower phosphatase and cellulase enzyme activity and higher soil respiration rates (Table 2; Herbein 1981). Furthermore, there is a more complete decomposition of cellulose in the vehicle track, as indicated by the lower ratios of exocellulase:endocellulase activity and the higher proportion of cellulose-derived CO_2 evolved from track soils (Table 2).

These results suggest that nutrient availability to plants might be reduced by management attempts to (1) lower soil temperature and depth of soil thaw, (2) increase nutrient immobilization in litter, (3) decrease soil oxygen, and (4) decrease both surface and subsurface soil water movement. All of these objectives might be achieved at least in part by increasing the thickness of the upper soil organic mat, and providing carbon-rich and nutrient-poor organic litter to the soil. This could be accomplished first by preserving as much as possible of the original organic soil and second by adding sawdust or some other heavy mulch to old disturbances. Experimental attempts

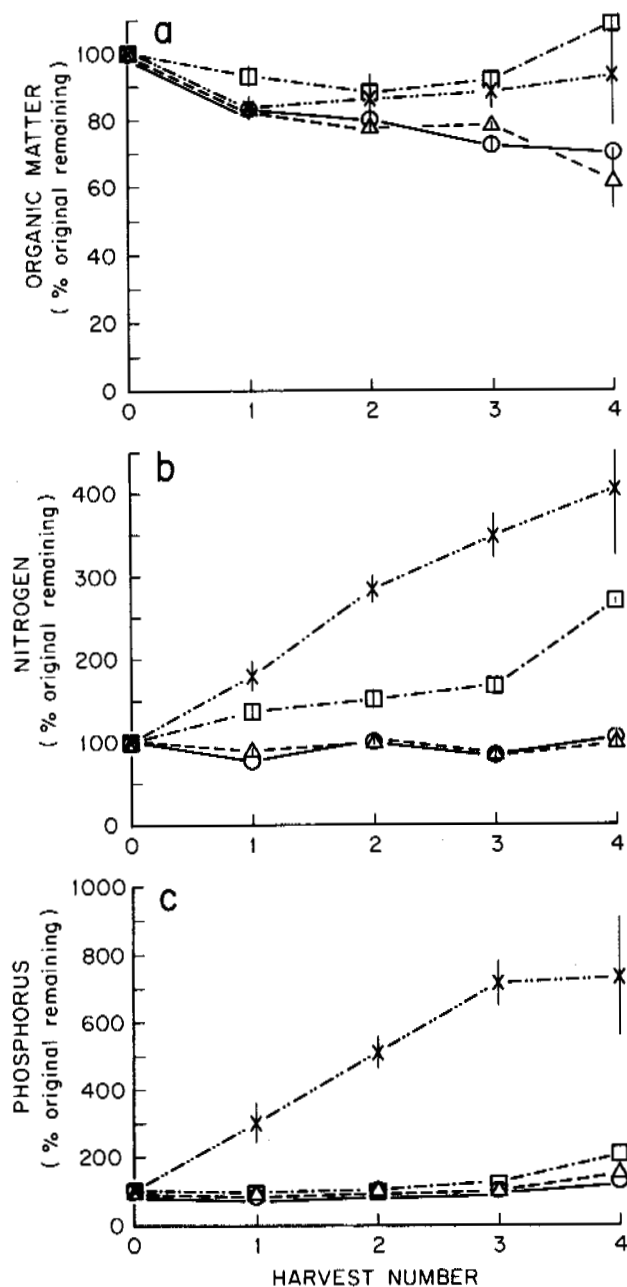

Figure 2 Changes in (a) total organic matter, (b) total N mass, and (c) total P mass in litter bags placed in and out of vehicle tracks at Slope Mountain, Alaska. Data are means \pm SE, expressed as percentages of the original mass. Circles = mesic control, triangles = mesic track, squares = wet control, crosses = wet track.

to reduce nutrient availability by adding corn starch and sugar to undisturbed tundra have suggested but not confirmed that this approach should work (Shaver and Chapin 1980, Marion et al. 1982). The long term goal is the creation of

TABLE 2 Substrate-Saturated Reaction Rates for Endocellulases, Exocellulases, and Phosphomonoesterases in the O_e-O_i Horizons of Tussock Tundra Soils at Slope Mountain, Alaska, and Associated Soil Respiration.

	Endocell- ulase	Exocell- ulase	Phospha- tase	Respir- ation	% ¹⁴ CO ₂

Mesic Track	70b	135b	15b	175b	38b

Units for endocellulase activity are hr⁻¹ gm dry wt⁻¹; for exocellulase, ug glucose equivalents hr⁻¹ gm dry wt⁻¹; for phosphatase uM PNP hr⁻¹ gm dry wt⁻¹; for respiration, ul CO₂ hr⁻¹ gm dry wt⁻¹. The last column is ¹⁴C evolution from incorporated ¹⁴C-cellulose, expressed as a percentage of total CO₂. N = 8 in all cases. Within each column, values followed by different superscript are significantly different at the 0.05 level. Methods followed Herbein (1981), Linkins and Antibus (1978), and Linkins and Neal (1982).

conditions that are more favorable for native species and more typical of the normal nutrient-limited tundra vegetation.

MANAGEMENT RECOMMENDATION

In the revegetation of arctic disturbed sites by native plants, the single most important factor is the preservation or replacement of the upper organic layer of soil. The organic layer is important because (1) It contains a large, readily germinable seed pool; (2) germination rates of native seeds are higher in organic than mineral soils; (3) it reduces soil thaw and thermokarst erosion; (4) in later stages of recovery, it may reduce nutrient movement and nutrient losses from the soil. Fertilization improves native plant recovery immediately after the disturbance but after 5-10 years it may prevent reestablishment of a normal species composition. Seeding with nonnative plants either has no effect on long-term recovery of native species, or the recovery of native species may be reduced. Nonnative species are particularly effective at reducing recovery of natives if the site is also fertilized.

Given these results, we recommend the following methods for management of development-related disturbances: (1) Replace the

natural organic soil, particularly the upper layers which contain the most seed; (2) fertilize lightly only in the first year or two; (3) do not broadcast seed except where erosion potential is great or the original organic mat is lost; (4) do not fertilize old disturbances; (5) mulching or addition of peat to the soil of old disturbances may help to create a more natural soil, with a more natural species composition in the vegetation.

A CLASSIFICATION OF GROUND WATER IN THE CRYOLITHOZONE

V. V. Shepelev

Permafrost Institute, Siberian Branch,
Academy of Sciences, Yakutsk, USSR

A subdivision is presented of the major types of groundwater in the cryolithozone, based on conditions of deposition and on the dynamics of development of the cryogenic aquicludes confining them. Among suprapermafrost waters (type 1) one may distinguish suprapermafrost vadose waters (subtype 1a) and suprapermafrost groundwater (subtype 1b). Intrapermafrost water (type 2) may also be subdivided into two subtypes. The first involves intrapermafrost water confined by horizontal cryogenic aquicludes (2a) and the second intrapermafrost water capable of vertical movements between frozen materials (2b). Subpermafrost waters (type 3) are subdivided into those in contact with the bottom of the permafrost (subtype 3a) and those not in contact with it (3b). The groundwater subtypes thus identified may be further subdivided into different categories and subcategories.

Much attention has generally been given to classification of gravitational ground waters in the permafrost region. This indicates the importance and significance of ground water in a variety of scientific and practical problems concerning the study of the conditions of distribution, formation, and discharge of ground waters of the permafrost zone, clarification of the aspects of their utilization and protection, as well as peculiarities of permafrost-hydrogeological mapping, zoning and accomplishment of water search and prospecting operations.

In 1939 N. I. Tolstikhin was the first to develop and formulate in his fundamental monograph a scientifically substantiated and, in its way, classical hydrogeological classification of ground waters in the permafrost region (Tolstikhin 1941). That classification is based on the principle of a spatial ratio of ground waters to the permafrost zone of rocks, according to which the ground waters are categorized into the three main classes: suprapermafrost, intrapermafrost and subpermafrost waters. The advances of the USSR in hydrogeological research on permafrost are quite justifiably being attributed to the emergence of this classification. Despite some criticism raised later (Meister 1955, Zelenkevich 1960, et al.) and new schemes of permafrost ground water classification (Baranov 1940, Ovchinnikov 1954) N. I. Tolstikhin's classification has been generally recognized and employed in hydrogeological exploration for nearly three decades.

However, the accumulation of new observational data acquired from hydrogeological and geocryological exploration efforts in the intensively developing northern regions of the country has contributed to a substantial improvement in our understanding of the conditions of formation, occurrence, and propagation of permafrost ground waters, as well as of the nature of their interaction with permafrost. This all demanded refinement and recomplement of the available classification. A number of new classification schemes have appeared, proposed by various

researchers, most of which use as a basis N. I. Tolstikhin's classification (Obidin 1959, Kalabin 1960, Ponomarev 1960, Sukhodolsky 1964, Shvartsev 1964, Romanovsky 1966, Velmina 1970, Tolstikhin and Tolstikhin 1974, et al.).

Of all subsequent classifications general recognition received the scheme of permafrost ground waters, advanced by N. N. Romanovsky in 1966, somewhat refined by him later (Romanovsky 1967, 1978). Following N. I. Tolstikhin, N. N. Romanovsky retains the same basic principle of ground water classification according to the spatial position with respect to permafrost, by distinguishing supra-, sub-, and intrapermafrost waters and adding to these main types open talik and inpermafrost waters. This classification has found application in hydrogeological exploration and has been included in textbooks, manuals and methodical literature. Nonetheless, this classification fails to fully reflect the present understanding of permafrost development and the conditions of its interrelationship with ground waters. The main disadvantage is that it almost completely lacks consideration of the dynamic behavior of the permafrost zone.

The main hydrogeological features of the permafrost zone are associated with the appearance in rocks of a solid phase of ground waters and with its exceedingly dynamic occurrence in the annual and perennial cycles. Every year in the active layer ground ice changes into a liquid phase and vice versa in huge amounts which has crucial influence upon behavior not only of ground waters but also of surface waters of the permafrost zone, thereby determining the distinctive features of the conditions of their interrelation and regime.

In the lower parts of the permafrost layer the magnitude of such abrupt changes in the state of freezing of ground waters is considerably smaller. A steadier perennial change of the solid phase of ground waters into a liquid phase takes place in some regions or vice versa in others which, basically, depends on general climatic, paleoclimatic or hydrogeological conditions of particular regions

of the permafrost zone. In this case also, however, seasonal changes of phase composition of ground waters are possible, being due to convective transfer of the free air through cracks and pores of frozen rock materials as well as to diffusion processes, various chemical reactions, etc.

Thus, the dynamic state of the permafrost zone is a key factor, determining hydrodynamic, hydrochemical and gas properties of ground waters, their regime and resources, contributing thus to the exceptional diversity of hydrogeological situations within even individual, not very large structures.

This, all taken together, indicates that the factor of dynamic behavior of the permafrost zone has to be taken into account in a hydrogeological classification of gravitational ground waters because otherwise it will not completely reflect the actual natural conditions and will not fulfill the requirements imposed on it.

I have elaborated a hydrogeological classification of permafrost zone ground waters, taking into account the factor of dynamic development of permafrost (Shepelev 1982). The subdivision of ground waters in this classification into the main types rests also on the principle of their position in a geocryological layering, according to which supra-, intra-, and subpermafrost waters are distinguished. As is apparent, the terminology for the main types of ground waters, except for the "open talik waters" type, remain the same as in N. N. Romanovsky's classification scheme. However, we attach to them a somewhat different meaning.

The classification we offer adopts the following definitions of the main types of ground waters:

Suprapermafrost waters have positive or negative temperatures and occur either above the top of a seasonally frozen rock layer (suprapermafrost vadose water) or above the top of permafrost (suprapermafrost ground water).

Intrapermafrost waters have positive or negative temperatures and occur within permafrost in lenses, layers, and unfrozen zones; they move either vertically or horizontally within the frozen ground or exist in a stagnant regime.

Subpermafrost waters have positive or negative temperatures and occur below the base of permafrost, either in contact with it or separated from it by water-resisting or permeable rocks (without contact).

Gravitational ground waters of the permafrost zone that have a subzero temperature are commonly termed "cryopegs" (bodies of liquid saline water below 0°C associated with permafrost, may also imply ice-free permafrost with saline pore water) (Tolstikhin 1971). Because subzero temperature can occur with all the main types of ground waters selected, one should distinguish among supra-, intra-, and subpermafrost cryopegs.

Each of the main types of ground waters are divided into subtypes, categories and subcategories, with respect to permafrost water-confining strata, their dynamic behavior, and conditions of occurrence.

Suprapermafrost waters (type 1) are divided into two subtypes. The first (1a) includes suprapermafrost waters occurring within the upper part of a seasonally frozen layer that is for them a temporal permafrost water-confining stratum. These waters exhibit the following typical features, they:

- (1) occur only during a warm period of the year;
- (2) are of small thickness and of irregular area;
- (3) are fed through infiltration of atmospheric precipitation as well as thawing of ice occurring within a seasonally frozen layer and pore air condensation processes;
- (4) are notable for an abruptly changing time boundary of the lower permafrost water-confining stratum, due to the summertime thawing of the seasonally active layer;
- (5) are characterized by a complete lack of head.

These features indicate that suprapermafrost waters of this subtype are a peculiar variety of vadose water which, admittedly, includes waters that form in the zone of aeration on relative water-confining strata (Principles of Hydrology, 1980). The relativity and temporary occurrence of the water-confining stratum, represented by earth materials of the seasonally frozen layer, thawing during the summer, are obvious and, therefore, we have good cause to term the waters of the subtype under consideration the suprapermafrost vadose water, thereby emphasizing the high changeability of the uppermost part of the permafrost zone layering.

Subdividing these waters into categories is needed because their different lifetime depends on the interrelation of permafrost with the layer of seasonal thawing. Suprapermafrost vadose water in continuous permafrost (1a₁) can persist during the greater part of the warm period. In cases where the seasonally frozen layer has a substratum of unfrozen water-bearing earth materials, there takes place its rapid failure in view of the convective and productive thermal impact of the underlying suprapermafrost water. In this connection, the suprapermafrost vadose water in discontinuous permafrost (1a₂) lasts for a shorter period of time (from several days to one or two months) and because of a rapid break in continuity of the seasonally frozen layer it frequently occurs on frozen ground lenses.

Suprapermafrost ground waters generally have above-zero temperatures and, therefore, they exert a warming influence upon the underlying seasonally frozen ground, thereby contributing to its rapid thawing.

The second subtype (1b) includes suprapermafrost water, occurring within the upper part of permafrost which represents for the former a permafrost water-confining stratum, being uniform as to time and area. Ground water occurring on the uppermost steady-state water-confining stratum is commonly referred to ground waters. However, the suprapermafrost waters of the subtype in question are defined by some distinctive features and primarily by the possibility that they are able to acquire a temporary permafrost water-confining stratum (head) as well as to partially or completely freeze up in the winter. Consequently, they can be referred only to the suprapermafrost variety of ground waters.

According to the degree of interrelation with seasonally frozen ground, the suprapermafrost ground waters in the classification we offer are divided into three kinds: seasonally freezing (1b₁), partially freezing (1b₂), and seasonally non-freezing (1b₃).

Depending on conditions of occurrence of taliks

which accumulate seasonally non-freezing supra-permafrost waters, these are subdivided into two subtypes: subaerial ($1b_1^1$) and subaquatic ($1b_2^2$). Seasonally non-freezing suprapermafrost ground waters of the subaerial saturation zone generally occur in the regions where water well confining ground is developed from the surface. Seasonally non-freezing suprapermafrost waters of the subaquatic saturation zone are widely spread within permafrost. They occur within taliks below a lake or below a river bed as well as in the shelf zone of Arctic seas where they exhibit a subzero temperature and high mineralization. In areas with man-made pollution and salinization a subzero temperature and high mineralization can be acquired by seasonally non-freezing suprapermafrost waters of the subaerial saturation zone and by partially freezing suprapermafrost ground waters.

All the above identified categories and subcategories of suprapermafrost ground waters seldom occur in isolation but most frequently they persist in conjunction in a close hydraulic interplay, producing complex permafrost-hydraulic structured suprapermafrost ground water basins or flows.

Intrapermafrost waters (type 2) with respect to frozen water-confining strata and occurrence properties are divided into two subtypes. The first (2a) includes intrapermafrost waters with horizontal boundaries of permafrost water-confining strata. The formation of these waters is associated with a variation of climatic, geomorphological, soil-vegetation, and other natural conditions, which initiate a partial perennial freezing of water-bearing taliks. The intrapermafrost waters of this subtype exhibit the following features:

- (1) presence of cryogenic head, the magnitude of which is defined by the degree of freezing of water-bearing taliks;
- (2) horizontal movement of ground waters or stagnant regime of filtration;
- (3) predominant occurrence in between the strata.

Intrapermafrost waters of the subtype under consideration are subdivided into three kinds, depending on direction and rate of variation in the boundaries of permafrost water-confining strata. The first kind ($2a_1$) includes pressure intrapermafrost waters in the stage of stable perennial freezing; the second kind ($2a_2$) includes pressure-pressureless waters with departing boundaries of permafrost water-confining strata, and pressure waters with a relatively stable position of permafrost confining them are of the third kind ($2a_3$). Each of the categories selected is in turn divided into two subcategories: hydraulically non-isolated and isolated. Hydraulically non-isolated intrapermafrost waters generally exhibit horizontal filtration and a predominant above-zero temperature. Hydraulically isolated intrapermafrost waters of this subcategory have a stagnant regime and may exhibit both an above-zero and subzero temperature. In this regard they are similar to the concept of intrapermafrost waters in N. N. Romanovsky's (1966) classification scheme.

The second subtype (2b) of the suggested classification includes intrapermafrost waters with predominantly vertical boundaries of frozen water-confining strata. These waters in N. N. Romanovsky's classification scheme are referred to an

independent type, "open talik waters" which is not fully justified. Indeed, like intrapermafrost waters of the first subtype, these waters also occur in between permafrost ground strata. The only distinctive feature for them is the fact that the permafrost confines water-bearing zones on sides rather than from above and below, thus contributing to vertical direction of filtration of these waters. However, this property cannot justify their being separated into an independent single type of permafrost ground water because, of the adopted principle of their typification.

The second subtype of intrapermafrost waters is subdivided into three categories, depending on the character of their vertical filtration. The first category ($2b_1$) includes pressureless intrapermafrost waters with a downward filtration through open taliks; the second category ($2b_2$) comprises pressure waters with an upward filtration; and the third category ($2b_3$) incorporates pressure-pressureless waters with a mixed regime of vertical filtration. The last category of intrapermafrost waters of the subtype under consideration is the most widely spread and occurs both within taliks below river beds and in water shed areas.

Depending on the conditions of occurrence of water-bearing open taliks all the selected categories of intrapermafrost waters of this second subtype are divided into two subcategories: subaerial and subaquatic. The latter are widespread because below river beds and below lakes and reservoirs are the most favorable geothermal conditions for the development of intrapermafrost taliks and for preventing them from freezing. Intrapermafrost waters of the subtype in question predominantly have above-zero temperatures.

Subpermafrost waters (type 3) in the classification we offer, as in N. N. Romanovsky's classification scheme, are divided into those in contact with the base of permafrost (subtype 3a) and those without contact (subtype 3b).

A typical feature of subpermafrost waters of the first subtype is that the permafrost for them acts as an upper permafrost water-confining layer, existence and dynamic position of which determine the peculiarity of their properties, composition and regime.

According to the dynamic state of the upper permafrost water-confining layer these waters are divided into three kinds: those with a degrading ($3a_1$) and an aggrading ($3a_2$) lower boundary of permafrost and those with a comparatively stable lower boundary of the upper frozen water-confining layer ($3a_3$).

As to the temperature, each selected category of subpermafrost waters of this subtype are divided into those with an above-zero and a below-zero temperature. Subpermafrost "cryopegs" are widespread on the Arctic coast of the USSR as well as in mainland regions where the fresh water zone has been completely frozen.

Subpermafrost waters of the second subtype make no direct contact with permafrost and therefore they normally have an above-zero temperature. According to their interrelation with permafrost these waters are divided into three categories. The first category ($3b_1$) includes pressure subpermafrost waters, separated from permafrost by a stable unfrozen lithological water-confining layer.

The piezometric level of these waters generally occurs above the base of permafrost and therefore there certainly is an interplay between them, if the relativity of water-confining strata is taken into account.

The second category (3b₂) comprises pressureless subpermafrost waters, separated from the permafrost base by water-bearing ground. Subpermafrost contact-free waters of this kind have substantial influence on the position of the lower boundary of permafrost, giving rise to its periodical oscillation due to a continual thermal convection of moisture-laden pore air and evaporation and condensation processes. The periodic variation of the lower boundary of permafrost can induce formation of a subpermafrost zone of highly jointed rocks.

Some cases of the occurrence of contact-free subpermafrost waters of this kind are reported, where the permafrost zone is represented by frozen rocks, in which ice only partially fills the porous space (Romanovsky, 1978). Such rocks are a good conductor of air and air moisture; therefore under such conditions subpermafrost waters exhibit high changeability of the water level and chemical composition.

The third category (3b₃) includes pressure subpermafrost waters, piezometric level of which is established below the base of permafrost. These normally are ground waters of deep water-bearing levels, and permafrost does not exert substantial impact on their regime, composition and properties.

Each of the selected main types of permafrost ground waters in a specific area under investigation may further be divided according to the character of water-holding rocks and their age. The need for such a subdivision is brought about by the specificity of hydrogeological work, its purpose and details.

In conclusion it must be emphasized that the ground water classification we have proposed in this study has a particular character because of only gravitational waters taken into account. To provide answers to some scientific and practical problems requires development of a general classification of permafrost ground waters that would comprise all phases of aggregation of water in rocks, occurring in different stages of cryogenesis.

A BRIEF INTRODUCTION TO PERMAFROST RESEARCH IN CHINA

Shi Yafeng and Cheng Guodong

Lanzhou Institute of Glaciology and Cryopedology, Academia Sinica
Lanzhou, People's Republic of China

The study of permafrost in China has progressed since the initial work in 1949, and is now at the stage of all-out development. The distribution and characteristics of permafrost in China have been analyzed, and taliks and other periglacial phenomena have been classified. Several kinds of permafrost maps have been compiled, including a comprehensive map showing the distribution of glaciers and frozen ground in China. A repeated segregation theory has been suggested to explain the formation of the massive ice layer beneath the permafrost table. Fossil periglacial phenomena are used to reconstruct the distribution of ancient permafrost. A series of applied parameters, including the thermal, physical, and mechanical parameters of typical soils, have been provided. An engineering classification system for frozen soils has been suggested. Some theories on frost-heaving, thaw settlement, heat transport, moisture migration, and attenuation creep of frozen soils and on the similarity criteria in model tests are recommended. Studies in road engineering, water conservation engineering, industrial and civil construction, and artificial freezing techniques for mining have been conducted. More than 2000 km of railways have been built in permafrost regions, and an oil pipeline over 1000 km long has been built from Golmud, Qinghai, to Lhasa, Xizang (Tibet).

The permafrost regions in China cover an area of about 2,150,000 km², second only to the USSR and Canada. If one includes ground that is seasonally frozen to depths greater than 0.5 m, the total frozen area occupies 68.6% of the entire territory of China. Such a vast area of frozen soil exerts a great influence on China's economy, but it will also expedite the study of permafrost in this country.

HISTORY

As early as 1633, the outstanding Chinese geographer Xu Xiake clearly described the lifting action of frost heaving; he called the block field on Wutai Mountain in northern China the "dragon-turned rock." Before 1949, however, only a few Japanese had made fragmentary observations of frozen ground in northeast China. The substantive and conscientious study of permafrost in China began only after the founding of the People's Republic in 1949.

The study of permafrost in China can be divided into four periods.

The Period of Initial Work (1949-1959)

After the founding of new China, various capital constructions in cold regions contributed much to our study of permafrost. In particular, the exploitation of forest resources in the Da Hinggan Ling in the Northeast and the construction of water conservation projects and highways on the Qinghai-Xizang Plateau and between Urumqi and Ku'erle helped amass a large amount of information and experience with permafrost.

In 1954, a permafrost research group was established under the Department of Water Conservancy and Power Construction to develop techniques for measuring and testing permafrost, to study the freezing

and thawing properties of soil, and to develop techniques for constructing compact embankments in winter. In 1956, Xin Kuide and Ren Qijia systematically reported the distribution of permafrost in Northeast China. In 1958, the Third Institute of Railway Design published "Engineering Geology and Railway Construction in Permafrost Regions," and in 1959, the Department of Water Conservancy and Power Construction published "Construction of Compact Embankments in Winter."

The Period of Growth (1960-1972)

The practical experience of the previous 10 years led to a deeper understanding of the importance of the study of permafrost. In 1960, a Research Department of Glaciology and Cryopedology was established under the Research Institute of Geography of the Chinese Academy (Academia Sinica). Special units were established for permafrost research in several governmental departments, including railways, building construction, coal mining, communication, and oil exploitation. Similar research units were also instituted in several colleges and universities.

During this period, the permafrost areas in the Qinghai-Xizang Plateau, Da Hingan Ling, and Qilian Shan and the seasonally frozen ground in the Northeast were systematically and scientifically investigated. Fixed observation stations were established and some substantial engineering experiments were made in such places as Tumen in Xizang; Muli, Reshui, and Jiangcang in Qinghai; and Da Hinggan Ling, Yakeshi, Genhe, and Daqing in the Northwest. The first low-temperature laboratories were built and various indoor tests were conducted. Several engineering problems that occur in frozen soil areas were initially solved by the voluntary application of the theory of cryopedology, including the

utilization of frozen soil in laying seepage-prevention covering for earth embankments during the construction of several reservoirs, railway construction in Da Hinggan Ling and the Tian Shan, the construction of mining shafts in Qilian Shan, and the fundamental solution of the problem of foundation stability for industrial and civil construction in northern districts.

Artificial freezing was extensively applied in drilling engineering, and frost boils on highways and frost heave were successfully prevented by using lime earth.

"Investigation of Permafrost Along the Qinghai-Xizang Highway," published by the Research Department of Glaciology and Cryopedology of the Research Institute of Geography, Academia Sinica, is a representative work of this period.

The Period of Maturity (1973-1978)

During this period, a section of railway was successfully built in Qilian Shan near the lower permafrost limit with thick ground ice by applying the principle of protecting the permafrost; 8 years later, the road bed of this section of the railway is still stable. An oil pipeline from Golmud to Lhasa was also built in this period. The reconstruction of the Qinghai-Xizang Highway by covering the road surface with asphalt began.

A group of cryopedologists started to work all along the Qinghai-Xizang Highway, undertaking geological engineering prospecting and conducting extensive physical and thermological tests to obtain enough data to allow the definition of effective principles for the design and construction of the Qinghai-Xizang Railway. At the same time, a scientific and technological cooperative group was organized for the study of frost prevention in hydraulic architecture, with more than 30 units from water conservation and scientific research departments participating as well as colleges and universities in the north.

In 1975, a group researching road construction in the permafrost regions in China visited Canada, and in 1977, a Canadian permafrost investigation group headed by the late Dr. R.J.E. Brown paid a return visit to China. China's isolated study of permafrost had come to an end.

In 1975, the Lanzhou Institute of Glaciology, Cryopedology, and Desert Research of the Chinese Academy published "Permafrost," a compilation of the special knowledge of cryopedology. "Annals of the Lanzhou Institute" first published in 1976, and "Annals of Lanzhou Institute of Glaciology and Cryopedology, Academia Sinica (Permafrost)," published in 1981, made available to the world a part of our research results before 1978.

During this period, the first specialized curriculum in glaciology and cryopedology was offered by the Department of Geography at Lanzhou University. This was the starting point for training the younger generation in the special knowledge of glaciology and cryopedology.

In this period, a complete and systematic study of cryopedology took shape, including general cryopedology, permafrost mechanics and thermology, and engineering cryopedology.

The Period of All-Out Development (1978-Present)

After the 10 years of the Great Cultural Revolution, permafrost research in China entered a period of all-out development. 1978 is a year worth remembering in the history of permafrost study in China, for the Lanzhou Institute of Glaciology and Cryopedology was separated from the Lanzhou Institute of Glaciology, Cryopedology, and Desert Research of the Chinese Academy, and reorganized. The First National Academic Conference on Glaciology and Cryopedology was held in Lanzhou, and 68 articles and abstracts on cryopedology were presented. It was also in 1978 that China for the first time sent a delegation to attend the Third International Conference on Permafrost in Canada; China presented four articles.

In 1979, the first issue of the academic journal "Glaciology and Cryopedology" was published, greatly accelerating the study of cryopedology in China. In 1980, 62 papers and abstracts on cryopedology were presented at a seminar on testing and measuring techniques for glaciology and cryopedology, and the Society of Glaciology and Cryopedology was established under the Chinese Geographical Society. In 1981, when the Second National Conference on Cryopedology was held in Lanzhou, 185 papers and abstracts were presented, reflecting the progress in the study in all fields of cryopedology in China. Drs. J. Brown and Yin-Chao Yen from United States and Dr. Daisuke Kuroiwa from Japan attended this conference.

Since 1978, cryopedological investigations have been conducted in the Altai Shan, Tian Shan, Qilian Shan, and Hengduan Shan. Such activities as the paving of the Qinghai-Xizang Highway, drilling of shafts by artificial freezing, and prevention of frost damage in hydraulic constructions have led to greater achievements in both theoretical study and engineering practice. At the same time, studies of agricultural cryopedology and the ecology of frozen regions began. The movement of the study of cryopedology in China from qualitative to quantitative, from investigative to experimental, and from macrocosmic to microcosmic marked the beginning of China's all-out development of her permafrost regions.

PRESENT CONDITION OF STUDY

The study of cryopedology in China enters the 1980's with a record of success. I will now discuss our major achievements in permafrost research with emphasis on those attained since 1978.

General Cryopedology

Through investigation and study, the distribution and characteristics of permafrost in China have been defined, patterns of temperature dispersion and permafrost thickness have been analyzed, the genesis of taliks and frost-heaving topography has been described, permafrost maps have been compiled according to regional indexes, a classification system for frozen soil has been suggested, and the concept of the regularity of alpine permafrost zonation has been presented.

On the basis of these achievements, several kinds of permafrost maps have been compiled, among them a map showing the glacier and permafrost distribution in China (1:4,000,000), a map of permafrost regionalism in northeast China (1:3,000,000), and a map of permafrost along the Qinghai-Xizang Highway (1:600,000), as well as specialized maps of particular regions. The study of the history of permafrost formation on the Qinghai-Xizang Plateau and in northeast China has been initiated. Comprehensive hydrological surveys have been carried out in some permafrost regions, such as Qilian Shan, along the Qinghai-Xizang Highway, and in Da-Xiao Hinggan Ling, and several regional maps on comprehensive hydrogeology have been compiled. Progress has also been made in compiling geological maps for engineering use.

At present, the emphasis is on the study of periglacial phenomena. The theory of repeated segregation is offered to explain the formation of thick layer ground ice near the permafrost table. The idea of a "subperiglacial stage" has been suggested on the basis of the relation between glacial and periglacial phenomena. The viewpoint that the periglacial landscape on the plateau could be divided into maritime, subcontinental, and continental types has already been publicly recognized. Large amounts of ancient periglacial remains have been discovered in north China and have been widely used to reconstruct the paleoclimate and the boundaries of paleopermafrost in the Quaternary Age in China.

Physicomechanical and Thermological Properties and Processes of Frozen Ground

The physicomechanical properties and processes of frozen ground have been studied systematically. Through a wide range of laboratory and field tests, parameters have been compiled for the bearing capacity of frozen soil, coefficient of thawing settlement, coefficient of compression, frost-heaving amount, and frost-heaving force, as well as the classification of frozen ground for engineering purposes. Most of these have been included in the detailed design regulations. Relative equations have been suggested for the relationship between the normal frost-heave force, area, and the burial depth of foundations, as well as the distribution pattern and calculating diagrams for the horizontal frost-heave thrusting force along vertical space. Equations for the process of attenuation creep and for calculating creep deformation and the time-to-stable-state have been ascertained. A semi-empirical formula for the variation of the relaxation of frost-heave stress and of the modulus with the change of time has been obtained. Several properties of sandy gravel saturated with water during freezing, such as pore water pressure and frost heave amount, have been made clear. Model experiments on a single pile under vertical and horizontal loading have been carried out. The construction technology of driven, inserted, and filled piles and the bearing capacity of a single pile have been tested on the Qinghai-Xizang Plateau; and we have started to study the properties of moisture migration during freezing from the viewpoint of energy.

In the field of thermology, the specific heat, thermal conductivity, and diffusivity values of

typical freezing and thawing soils were determined for several regions, problems of similarity criteria in model tests of frozen soil were solved, methods for calculating temperature fields and moisture migration under natural and artificial conditions were developed, the application of mathematical methods was expanded, and the application of thermological methods to calculate frost heave have begun.

Engineering Construction in Frozen Districts

Road engineering. In permafrost regions, 2000 km of railway have already been built. Railroad lines through permafrost regions have been successfully selected, and improved solutions have been found for such technical problems as the design and construction of the road bed in sectors with thick ground ice. Engineering experiments in the application of heat-preserving materials, both by model and actual construction, have been carried out. In the Hinggan Ling of northeast China and on the Plateau, methods have been developed to solve bridge and culvert foundation problems. Drilled and filled concrete piles have been used extensively and successfully. In tunnels in cold regions, where water seepage poses a serious problem, methods such as forced ventilation are used to melt ice, preserve heat, and drain water so that traffic is not interrupted.

Water conservation engineering. Throughout 13 provinces, municipalities, and autonomous regions in north China, damage to and destruction of canal systems through frost-heave deformation and thawing settlement pose a serious problem. Laboratory and field studies of protective measures for engineering construction have yielded positive results. In lining canal beds, the technique of laying sand layers under the concrete slab effectively prevents frost damage. Using soft materials and thin membranes as seepage linings improves protection against the destructive action of frost heaving. The construction of simple beam structures and the technique of sinking slabs by steam-melting permafrost are effective ways to protect medium- and small-sized dams from frost damage. Using the frost-heave reaction to anchor foundations effectively prevents the uplifting of pilings. It is also effective to use non-frost-heaving sand-gravel as fill material in foundations while ensuring appropriate water drainage during freezing.

Industrial and civil construction. It has been recognized that, based on an understanding of the regularity of the main frost-heaving zone and the characteristics of restriction of frost-heaving under overload, a residual frozen layer could be preserved under foundations. The formula for determining the minimum burial depth for foundations was developed and has been included in the relevant specifications. In addition, filling sand-gravel at the lateral sides of foundations, preserving heat on the ground surface, and explosive extension of short-pile foundations are also successful in preventing frost heaving. In permafrost regions, the use of high-filled foundations, raised-ground foundations with ventilating pipes in the bedding layer, and foundations with suspended ventilation pipes are all useful techniques. Suspended ventilated foundations are generally used for heated buildings on ice-rich frozen ground. There are several effective methods to prevent the freezing of

water pipelines, such as insulating suspended pipes or pipes on the ground surface, heating the well water, or putting the pipeline close to a hot pipeline. The problems of ensuring concrete strength and of construction technology under negative temperatures have already been solved.

Artificial freezing technique for mining. The maximum sinking depth by artificial freezing has already exceeded 400 m, reaching 358 m in loose layers. Comparatively systematic data have been obtained on thermal regime, freezing pressure, and so forth, in the shaft wall. Experiences have been gained in drilling techniques and artificial freezing. Methods to prevent the destruction of shaft walls and rupture of freezing pipes in medium-depth and deep shafts have been summarized. At present, a model is being prepared to test the creep of frozen soil under three-dimensional conditions.

Oil pipeline. The oil pipeline from Golmud to Lhasa, which transports refined oil across permafrost areas of the Qinghai-Xizang Plateau, has been operating safely for 9 years, proving that the construction designs of shallowly buried pipe, pile foundations, and hanging ventilated foundations at pumping stations are feasible and successful.

Prospecting and Testing Techniques

Geophysical prospecting techniques have been used extensively in the investigation of permafrost. The most commonly used is direct current prospecting. Direct current profiling, shallow seismic methods, and excited polarization are used to determine the permafrost table. The measurement of gas emissions for locating the talik is also being tested, and the use of radar equipment in investigation is planned. Photographs are widely used to study periglacial phenomena, and the trial use of satellite images for the interpretation of certain permafrost information is also in progress.

Measurements and testing techniques have been standardized for 14 fundamental physicommechanical and thermological parameters for the study of permafrost. A multipoint quartz crystal thermometer with an accuracy of 0.01°C has been developed. Neutron equipment is used to determine water content of permafrost. Ultrasonic techniques have been used to measure the modulus of elasticity, Parson's ratio, and unfrozen water content of frozen soil. The application of an electronic cryogenic cooling apparatus facilitates the experimentation.

Future Studies

A great amount of work has been done in the field of permafrost study in China, yet many problems remain to be solved. To raise the study of permafrost in China to a higher level, the following work has to be done:

1. Intensify the study of permafrost engineering. Solve the following problems in the near future:
 - calculation of the critical height and the design height of the subgrade of an asphalted highway and of railways in permafrost regions,
 - the design axiom of subgrade in zero-filling and cutting sections,
 - the calculating theory of the temperature field and the strength of frozen walls in drilling with artificial freezing,

- principles and method for preventing frost heave in canals.

2. Concentrate on fundamental and theoretical study, to guarantee the steady development of research into the formation and distribution of high-altitude permafrost, the theory of ice formation, moisture migration, and rheologic principles.

3. Enlarge the scope of the research by the systematic development of engineering geological forecasts, environmental protection, and agricultural cryopedology in cold regions.

4. Improve prospecting methods, measurement, and testing techniques in permafrost study. Further enhance accuracy in measuring temperature, heat, water, force, and deformation; establish self-recording and telemetry; improve telemetry and remote sensing techniques; improve low-temperature laboratory equipment; and continue to establish fixed-point observation stations.

5. Increase national and international academic exchanges and accelerate the training of young cadres who specialize in permafrost.

A COMPREHENSIVE MAP OF SNOW, ICE, AND FROZEN GROUND IN CHINA (1:4,000,000)

Shi Yafeng and Mi Desheng

Lanzhou Institute of Glaciology and Cryopedology, Academia Sinica
People's Republic of China

On the basis of recent progress on the study of glaciers, frozen ground, and seasonal snow and ice, a preliminary and comprehensive map of snow, ice, and frozen ground in China has been compiled by the Lanzhou Institute of Glaciology and Cryopedology, Academia Sinica, to express the general distribution of these phenomena in our country. The map shows the following items: (1) mountain glaciers, including the continental and monsoon maritime types of glaciers as well as the current isopleth of the snow line and the hazardous places of glacial debris flows and flood from burst of glacial lakes, (2) seasonal snow, containing the stable and unstable snow cover regions, (3) seasonal ice, involving sea ice and river-lake ice, (4) permafrost, including continuous, discontinuous, and insular permafrost, (5) seasonally and instantaneously frozen ground, and (6) periglacial phenomena and Quaternary glaciation, such as the isopleth of the past snow line, blockfields, stone stripes, polygons, frost-heave hummocks, and involutions.

Since the 1950's, studies on glaciology and cryopedology have been carried out continuously by Chinese scientists. In the past 20 years or more, progress at different degrees has been achieved on mountain glaciers, permafrost, seasonal snow, seasonal ice, and seasonal frozen ground, as well as other related hazards including glacial debris flow, avalanche and snow drift, and also of periglacial phenomena and the action of Quaternary glaciation. In the past 2 years, a Comprehensive Map of Snow, Ice, and Frozen Ground in China has been preliminarily compiled by the Lanzhou Institute of Glaciology and Cryopedology to show the general distribution of these phenomena. Nearly 20 scientists participated in its compilation, examination, and verification. Mi Desheng is responsible for its design. The preliminary draft of the map was completed in 1983.

MOUNTAIN GLACIERS

The mountain glaciers in China are distributed in the high mountains west of 104°E , covering an area of about $56,500 \text{ km}^2$ with a water storage of about 5000 km^3 and a mean annual amount of melt water of $55 \times 10^9 \text{ m}^3$ (Shi Yafeng and Yang Zhenniang, 1982), an invaluable water resource for the arid regions in Central Asia. The existing glaciers in China are distributed in the 12 mountain systems: i.e. Altay Shan, Tian Shan, Qilian Shan, Kunlun Shan, Pamirs, Karakoram, Qiangtang Plateau (northwestern part of Xizang), Tanggula Shan, Nianqing Tanggula Shan, Gangdise Shan (i.e. Transhimalaya Mts), Himalayas, and Hengduan Mountains. Main areas of

glaciers appear in the middle part of Tian Shan, west Kunlun Shan, Karakoram, the middle part of Great Himalaya, and Eastern Nianqing Tanggula, in which some long valley glaciers exceed 20, 30, or even 40 km in length. Glaciological investigations have been concentrated in the areas of Qilian Shan, Tian Shan, Hengduan Shan, and Altay Shan, as well as on the northern slope of middle Himalayas and the southeastern part of Xizang. According to their physical properties and geographical conditions, glaciers are divided into two main categories, namely the continental type and the monsoon maritime type.

From the Altay Shan to the northern slope of the Himalayas, nearly 80% of the glaciers in China belong to the continental type. Under the continental climatic conditions of Central Asia, this type of glacier has only a level of mass budget at $300\text{-}1000 \text{ mm/yr}$, and its formation of ice is mainly through the process of cold infiltration and congelation. The temperature in its active layer at the ice tongue has the characteristic of a cold glacier.

Monsoon maritime glaciers are mainly distributed in the southeastern part of Xizang (Eastern Nianqing Tanggula Shan and the eastern extremity of Himalaya) and Hengduan Mountains. Some of them have a level of mass budget at $2000\text{-}2500 \text{ mm/yr}$, and the formation of ice of this type is mainly due to the action of temperate infiltration (Shi Yafeng et al. 1980). Based on the study of Li Jijun (1982), the general demarcation line of these two types of glaciers is shown on the map from 29°N , 92°E extending northeastward to 31°N , 90°E and still eastward along the latitude through the Hengduan Mountains.

Data of glacier distribution and present snow line are taken mainly from the aerial topographic maps of 1960s and the Landsat images of 1970s, as well as from glaciological literatures. As to the regional variations of the present snow line shown on the map, except for some specific glaciers having observed data for some specific glaciers having observed data for ELA, generally the height of snow line is plotted on the aerial topographic map by using the method of H. Hess, simplifying the 2500 points totally selected for the height of snow line. Then the isopleth of snow line is drawn, the lowest is in the Altay Shan (2700-3200 m) while the highest on the northern slope of Mt. Qomolangma, the highest peak in the world (6000-6200 m) to the east of which on the same latitude in monsoon maritime climatic area the snow line descends again to 4600 m.

Correlated with some present glacial areas are the hazardous places of glacial debris flow and flood from burst of glacial lakes. Glacial debris flow concentrates densely in the southeastern part of Xizang and in the Congge'er Shan of the Pamirs, greatly damaging highway traffic, while flooding from burst of glacial lakes appears mainly in the southern part of Xizang and the Karakoram Mountains, catastrophically influencing villages and cities in the piedmont area.

SEASONAL SNOW

The study of seasonal snow in China has only developed in the past several years. Based on the snow records of 1600 meteorologic stations throughout the country, Li Peiji (1983) plotted the isopleth of annual average snow-covered days. Taking 60 days as the demarcation between a stable snow area and unstable snow area in winter, he found that the former accounts for 43% of the total area of China with an annual variation of C_v below 0.4, covering all parts of Northeast China and Inner Mongolia, northern part of Xingjiang, most part of Xizang Plateau, as well as some high mountains in the middle and southern parts of China. For example, the period of snow deposit in the Central Range in Taiwan also exceeds 2 months, that in the Altay of Xingjiang and in Da Hinggan Ling and the Changbai Shan of Northeast China all exceeds 150 days, having an annual variation within 0.1. In all these regions, the melt water of seasonal snow is an important source of surface runoff, greatly beneficial to crops and animal husbandry.

The unstable snow area with an average annual snow cover from 10-60 days is distributed in the extensive region between the Liaohe River in Northeast China and the latitudinal range of Qingling to Dabie Shan in Central China, where the

winter snow keeps a certain period of days with an annual variation between 0.4-1.0. The very unstable snow cover area with an average period from 1-10 days has its southern boundary at the latitude of 25° to 27° (from Kunming, Guilin to Wenzhou) with an average annual variation above 1, where the snow deposit of certain years is particularly influential to the life of the people. As expressed by the old Chinese saying, "Fortune-giving snow foretells a bumper harvest of a fortunate year". In a country like China with low precipitation in the winter and spring, snow deposits are favourable to agricultural production.

However, in the Tian Shan and the Altay Shan of Xingjiang, in the southeastern part of Xizang, and in several other high mountains, avalanches and snow drifts caused by seasonal snow seriously interrupt highway traffic, while snow storms and blizzards on the steppes of Inner Mongolia are very detrimental to animal husbandry.

Snowfall in China is often parallel with the advent of low temperatures, i.e. snow is thickest in January. But on the Qinghai-Xizang Plateau, snow falls more in the spring and autumn, and the snow deposit is less in severe winters.

SEASONAL ICE

Seasonal ice includes sea ice and river-lake ice. Based on the observed data from National Bureau of Oceanography, Li Peiji plotted on the map the limits of fixed and floating ice, the thickness of fixed ice, and the average annual frozen days. From the map we can see that sea ice is limited to the northern part of the East China Sea, i.e. along the coast of the Bohai and the Huanghai, and the duration of frozen period is generally 3-4 months. The extent of fixed ice is very small, limited to a few harbours with a maximum average thickness of 80 cm and a width of from several hundred metres to 3 km. Floating ice is the main form of sea ice in China, generally 10-40 km offshore, the farthest reaching 100 km with a thickness within 30 cm and a maximum floating speed at 0.6-1.8 m/s. In the years of 1936, 1947, and 1969, Bohai Bay was frozen along its coast, navigation was interrupted, and some constructions on the sea were destroyed.

River and lake ice appears in the vast area north of 30°N . Based on data from 56 hydrologic stations, the average frozen period of rivers in North China and the maximum thickness of ice are also indicated on the map. In Altay Shan of Xingjiang and the Heilongjiang (Amour) River of Northeast China, the frozen period is over 150 days every year with maximum thickness of ice over 1.0 m, in the Haihe River of North China 40-80 days, maximum thickness

of 0.6 m, for the Huanghe (Yellow River) most of the years 20-100 days, maximum thickness of 0.4-1.0 m, not frozen in particular years, and in the Huaihe River (lat. 32°-34°N) generally 10-40 days. Because the strength of cold air current in winter changes greatly year by year, the yearly variations of frozen time, frozen period, and thickness of ice in these rivers are also very great.

The frozen period of lakes in the interior of Qinghai-Xizang Plateau generally reaches about 6 months, while in Northeast China about 5 months. For example, the annual frozen period of the famous Qinghai Lake (Kokonor) at the Northeast corner of Qinghai-Xizang Plateau reaches 125 days and maximum depth of ice 0.44 cm.

PERMAFROST

Chinese permafrost researchers have investigated the permafrost in Da Hinggan Ling in Northeast China, along the Qinghai-Xizang Highway, in Qilian Shan, Tian Shan, and part of Altai Shan and Hengduan Mountains, and have compiled medium and small-scale maps of permafrost distribution, on the basis of which the important characteristics of permafrost have been primarily summarized (Zhou Youwu et al. 1982).

The present map, taking the data from actual investigations in the Altai Shan, Tian Shan, Qilian Shan, and along the Qinghai-Xizang Highway as basis, shows the result of analysis of the relation between permafrost and factors of the natural environment, and gives out the distributive boundary of permafrost. According to the study of Tong Boliang (1983 manuscript), the lower limit of insular permafrost in the Altai Shan, corresponds to the 2200 m contour, while that of the large stretch of continuous permafrost coincides with the 2800 m contour, where the snow cover on the ground surface is quite thick, elevating the lower limit of permafrost.

The snow deposit in the Tian Shan is comparatively less. According to the analysis of Qiu Guoqing and Huang Yizhi (1983 manuscript), the lower limit of the large stretch of continuous permafrost in the Tian Shan is about 2700 m on shady slope and about 3100 m on sunny slope. However, the lower limit of insular permafrost is still lowered 200-400 m.

In the Qilian Shan, the lower limits of the large stretch of continuous permafrost and insular permafrost in Reshui district at 37°25' are 3780 m and 3480 m respectively (Reshui Permafrost Study Group, 1976). According to the study of Luo Xiangrui (1983 manuscript) on the relationship between permafrost and the vegetation zone, the lower limit of permafrost is located in the zone of alpine meadow,

and by using the Landsat images the localities of insular permafrost and continuous permafrost are plotted on the map.

Qinghai-Xizang Plateau is a major district of high-altitude permafrost in China. Along the Qinghai-Xizang Highway actual surveyed data were used, but for other areas the relation between permafrost and mean annual temperature were taken as the basis for mapping. According to the analysis of Xu and Guo (1982), in Xizang the mean annual ground temperature is 2.0-5.0°C higher than the mean annual air temperature. Thus, generally the isopleths of mean annual air temperature, -4 to -5°C and -2.0°C, could be taken as boundary exponents between the large stretch of continuous permafrost and insular permafrost and between insular permafrost and seasonal permafrost. In this way, the distribution of permafrost on the Qinghai-Xizang Plateau was plotted on the map. The height of the lower limit of permafrost in the Himalayas near the 28°N already reaches about 4900 m.

The climatic conditions of permafrost regions in Northeast China are wetter than in the plateaus of West China. Under the frequent attack of Siberian cold air currents, the lower limit of permafrost in the mountain regions of Northeast China is about 800-1000 m lower than that at the same latitude in west Tian Shan and Altai Shan. According to the map of permafrost distribution in Hinggan Ling in Northeast China (1:2,000,000) compiled by Guo Dongxin (1983), large stretch of continuous permafrost (north of -5°C isopleth, mean annual air temperature), insular thawing permafrost (between -5°C and -3°C isopleth, mean annual air temperature) and insular permafrost (between -3°C and 0°C isopleth, mean annual air temperature) are discernible on the map.

SEASONAL FROZEN GROUND

Actual investigative data are lacking on seasonal frozen ground, but inference is made from ground temperature records or from difference between ground temperature and air temperature records of the meteorologic stations. Xu and Guo (1982) took the lowest mean monthly ground temperature lower than 0°C with a duration over 1 month as an index for the existence of seasonal frozen ground. This value of ground surface temperature corresponds to the mean annual temperature of 8°C in Xizang with dry climate and small annual range in temperature, but may reach as high as 10° to 14°C in the southeastern part of China with its humid climate. This southern boundary of seasonal frozen ground generally runs from southwest to northeast, situated between 25°N-35°N, mainly covering large areas of Northwest, North, and Northeast China; over 3/4 of which has a seasonal frozen layer more

than 0.5 m thick, greatly influencing highway, railway, channels, tunnels, agriculture, and engineering constructions in winter. To the south of the seasonal frozen ground zone, Xu and Guo (1982) sketched out another transient frozen ground zone with the extreme lowest ground temperature lower than 0°C and less than 1 month in year as its index generally corresponding to the mean annual air temperature 18.5° to 22.0°C.

PERIGLACIAL PHENOMENA AND QUATERNARY GLACIATION

Based on actually investigated data at more than 50 localities, Shi Yafeng and Ren Binghui (1980) carved out on the map the isopleth of the ancient snow line in the last glaciation of Late Pleistocene, which was only 2400-2600 m in the Altay Shan and rose to 5600-5800 m on the northern slope of Middle Himalaya (Mt. Qomolangma). Several famous cirques and terminal moraines used for calculation of the height of ancient snow line were also indicated on the map. According to the distributive regularity of snow line of last glaciation the possibility of the existence of Quaternary glaciers in the eastern part of China with an elevation lower than 3000 m has been expelled.

Periglacial phenomena from frost action, heaving and thawing, etc. such as block-fields, rock streams, polygons, frost heaving hummocks, involutions etc. spread extensively in China, of which a few places with typical patterns are indicated on the map by Cui Zhijiu (1980).

DESIGN AND CONSTRUCTION OF CUTTING AT SECTIONS OF THICK-LAYER GROUND ICE

Shu Daode and Huang Xiaoming

Northwest Institute of the Chinese Academy of Railway Sciences
Lanzhou, People's Republic of China

Cutting at sections of thick layer ground ice upsets the original ground layer's natural state of thermal equilibrium. To keep a new system stable, its thermal state, within a certain scope, must be restored to the original state or adapted to the conditions caused by the change of thermal state. Using this as the starting point for determining protective measures, the authors summarize the practical experience and experimental and research findings accumulated in China since 1960, especially recent ones made at sections with thick layers of ground ice on the Qinghai-Xizang Plateau, and present two major proposals for protecting permafrost in situ--the refilling and heat preservation method, based on the principle of similarity of heat power, and the method of supporting (sustaining) a structure that is based on the principle of local thawing self-burial stability. The design essentials of these techniques are described, and representative patterns of cross-sections are given. The influence of the harsh weather conditions on the Plateau on construction quality, technology, and machinery is discussed, and the main points of links in construction are emphasized.

Thick layers of ground ice in the region of the Qinghai-Xizang Plateau are one of the most serious barriers to constructing cuts in the area. The ice layer exposed in cut slopes and foundations after excavating will cause engineering hazards. Land-slides and foundation subsidence, and even slide after thawing, may force the abandonment of the project. To provide a stable and durable foundation, it is necessary to solve a series of problems that exist in design and construction. For cuts designed in the light of the first principle, that of keeping the permafrost in its frozen state, the problems to be addressed are the type of section, constructing season, as well as constructing technology.

THE EVIDENCE FOR THE MEASURES OF CONDUCTING A PROJECT AND THE PRINCIPAL DESIGNING PLAN

An appropriate approach to conducting an engineering project is bound to relate to the comprehensive consideration of the weather conditions and permafrost nature and take the deformation characteristics in foundation for road cause by natural force as the major evidence.

Regardless of the cause of formation of ground ice, the ice layer with the seasonally thawing layer over it has, under the effect of the natural environment over a long period, attained a relatively stable equilibrium. The temperature field, physical and thermal physical properties, storing, transmitting, and cycling of heat, and force system are in equilibrium. Excavating of cuts, however, will inevitably interrupt the equilibrium. To make a new system stable, i.e. to have engineering defor-

mations controlled within permitted ranges of stability and durability, it is imperative that the thermal and mechanical state of the new system be restored, to some extent, to the original state or be adaptable to the changes brought about. This is the essential starting point for determining the measures to be taken in a new project, and the two principles of designing, either protecting the permafrost from thawing by refilling and preserving the thermal regime based on the principle of thermal similarity or the protecting the construction by using retaining structures, which is based on the principle of stabilizing through self-burial and drainage.

DESIGN OF REFILLING AND HEAT PRESERVATION METHOD

Types of Section and Processing Measures

Logical types of section and processing measures are necessary to meet the following requirements: reducing to the fullest disturbance and damage to the permafrost, reducing soaking and permeation of rainfall and harm caused by suprapermafrost water as far as possible, and reducing as far as possible the amount of work to facilitate construction and maintenance. Therefore, several matters are needed in excavating.

When an ordinary section is adopted, it should be excavated to the refilling depth and leave certain amount of extra excavation so that the maximum seasonally thawing depth can be kept above the boundary surface of refill (Figure 1).

bank at the top of cut and the drainage ditch beyond the bank is built to prevent the slope from damage by suprapermafrost water flowing down from the upper part of slope (Figure 2).

A shallow and wide cross sectional side ditch is used with its bottom paved with pliable and tough water insulation material or clayey soil for convenient maintenance and unobstructed flow.

The slope of cut can be made stable by two feasible means---building a platform of side ditch or building a platform with a stone retaining pile, laid without using mortar, at the bottom of slope (Figure 2).

Pay special attention to the vertical transition and joint between refilled sector of cut, zero-section, and low embankment (Figure 3).

The following factors are considered about the measure of processing a project.

1. The refilling material is mainly taken from local materials, such as broken stones, pebble gravel, clayey soil, or turf. The protective measure of refilling with clayey soil, with a layer of turf paved over it, is advantageous to prevent the surface from sliding and reducing thawing depth.

2. To lessen the amount of refill for excavation, consideration should be given to pave industrial heat-preserving material alternately and in the course of construction lay a layer of coarse sand of certain thickness as isolating layer beneath the bottom of heat insulation plate. If heat insulation layer is placed over the surface of slope, water-discharge openings have to be provided (Figure 4).

3. To prevent the foundation from being damaged by water soaking in, it is necessary to construct a water-tight layer over proper parts of slope and foundation. The water content and density of filling material must be controlled.

4. If retaining bank is not set at the top of cut, the thawing depth there will be greater than in the middle of the slope by 6% to 10%, for the top of the cut is under the influence of heat sources from two sides. It is, therefore, essential to increase the thickness of the heat-preserving layer on the upper parts of the slope.

Determination of the Thickness of Heat-Preserving Layer to Be Refilled

The technique of heat preservation by means of refilling is based on the theory of thermal similarity. The various calculations and testing methods to determine the thickness of the refilling layer have to be connected to some extent with the equilibrium of local natural stratum in many respects, as boundary conditions, medium characteristics, etc. and should reflect the specific features of the cut section. This is the essential base for formulating the required calculations.

Equations are available which based on local natural permafrost table and revised in terms of orientation of slope, surface conditions, and the nature of filling material, etc. are used to calculate the refilling thickness of slope and foundation¹⁾; this also can be done by a statistical formula based on local average monthly air temperature in August²⁾. In case industrial heat insulation material is used to pave over slope or foundation, a conversion equation that takes the theory of attenuation of amplitude as its basis is used instead³⁾.

Computation of Slope and Foundation Stability

The strength of foundation of cut in permafrost area can be computed with respect to the requirements in ordinary areas. As long as the thermal calculations are reliable, the maximum seasonally thawing depth will not exceed refilling thickness, and the foundation itself is effective enough to prevent the permafrost beneath it from being soaked by rain as well as suprapermafrost water of slope.

The stability of slope of cut constructed in warm seasons should be calculated by taking filling or excavating boundary surface as sliding surface. To avoid local instability, as surface slide, etc. caused by sudden increase of water content of slope which is brought about by rapid thawing of accumulated snow in warm season or rainstorm, it is necessary to pay attention to the choice of filling material and method of protection as well. The gradient of slope of cut located at region of thick layer of ground ice should be less than 1:1.5.

Design of Protection with Retaining Structure

This method is based on the principle of stabilizing by self-burial, hence the requirements needed to be satisfied include the stability of the structure itself and favorable conditions of the construction site. The merits of this method are reduction in cut section and reduction of the earthwork of cut and refilling. It is, in general, only adequate for shallow cut or deep cut with heat preservation (Figure 5 and 6). The main points considered in designing are: first, the method should normally be used in

places where the horizontal slope of ground surface is gentle; second, the foundation of the retaining wall should be buried deeper than the permafrost table by 0.3-0.5 m or founded on bedrock; third, estimate the area of collapse of slope and the accumulated height of soil mass behind the wall, and design the section of retaining wall taking the pressure yielded by the soil accumulated behind the wall as the main evidence; fourth, discharge openings should be arranged at different heights of the wall and the verticle drainage capability of cut is required to be enhanced.

For deep cuts, the adoption of such sections that are capable of retaining at the lower part and protecting the upper part can lessen the amount of excavation and refill, only the material refilled behind the wall is required to have sufficient thickness. In designing, the factors to be considered include the stability under the action of horizontal frost heaving pressure and the thickness of heat-preserving layer.

CONSTRUCTION OF CUT

The most serious threat encountered in building cuts in regions of thick ground ice has been the thawing-freezing mud flow, which seriously delays the planned speed of construction and even makes the section can not shaped. There had been such an example on the Qinghai-Xizang Plateau where a test cut had to be abandoned because of damage to over 60% of its length by thawing. This was due to neglect of heat preservation in the course of construction (Figure 7). It is, therefore, an important principle to get rid of or reduce to the fullest extent the disturbance of heat-thawing while constructing in the region of thick ground ice.

Construction Season

In permafrost areas it is favorable for excavating and shaping in cold seasons, for refilling in warm season. Thus construction seasons

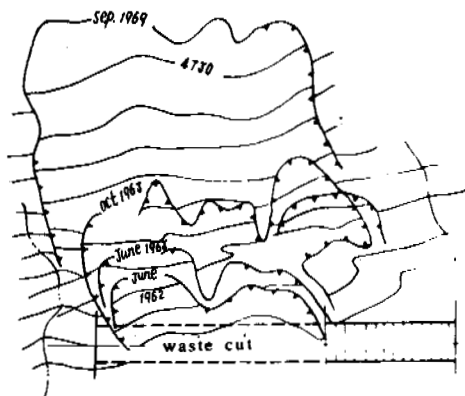

FIGURE 7 Deformation of cut caused by heat-thawing landslide in 1960.

are relevant to rationally solving the relation between excavating and shaping and the source of filling material, which are contradictory with each other.

If coarse granular soil is taken as refilling material and concentrate borrow is adopted, it is suggested to carry on construction in cold seasons so as to improve construction quality and avoid possible harm.

If construction has to be carried out in warm seasons, it is imperative not to do it in August or September, when rainfall is most frequent and heat-thawing effect is most active. The proper time under such conditions is likely summer and late autumn, and heat preservation is still worth to be noticed even then.

Construction going beyond the year, i.e. excavating and shaping in Autumn and refilling in warm seasons of next year, is beneficial to the stability of cut, which can meet the different requirements of both excavating.

Construction Technology

Construction technology is the key problem connected with the success or failure of building cuts. The working procedure should be planned and linked up as a whole, and carried out successively. It consists of the following four steps: planning---excavating---refilling---leveling.

Planning before construction includes construction organization design, setting construction schedules, building construction roads, delineating borrow areas and transport routes, and preparing construction facilities and materials, and establishing construction team, etc.

Prior to completion of planning, it is imperative to protect construction site and the surrounding natural vegetation. Rashly breaking ground is not allowed.

Pay attention to the natural drainage of the construction site. Built permanent drainage device is permitted before construction.

It is necessary to adopt high-speed mechanized construction in excavation to achieve quick completion.

Loosening soil with machinery or boring demolition are the efficient ways of excavating cuts. Deep hole demolition is feasible. Several points are to be noticed:

Borings are arranged according to the principle of excavating section to achieve shaping by demolition in once so as to shorten the working time to the fullest, thus lowering the effect of heat-thawing.

Parallel operation of drilling and cleaning up earth work is recommended. Sector-by-sector construction is effective for long cuts (50-100 m for each sector). Cleaning up after demoli-

tion and drilling the last sector are carried out simultaneously.

Great attention must be paid to waterproof and freezing-protecting of explosive. Explosive of good waterproof and freezing-protecting quality, e.g. J-2 pulp-like explosive, is satisfactory.

Damage of vegetation before drilling is strictly prohibited.

Procedure of excavating: excavate foundation first then slope for shallow cuts, and vice versa for deep ones. A drainage trough of certain width must be left over foundation surface for both cases to prevent mud flow from being accumulated in cuts.

The earthwork loosened by demolition or the loosener is cleaned up by bulldozer or loaded or transported by other means.

The loosened earthwork lying at the top of cuts, which can be reused, should be transported 30 m beyond the excavating limit; the ice layer containing soil and frozen soil of rich ice beneath permafrost table should be, according to the length of cut, bulldozed vertically at once or through horizontal passages sector-by-sector and piled up at certain place beyond the cut. While discarding waste soil, notice not to leave unfavorable effect on draining up silt during refilling and hidden trouble.

The building of horizontal passage should be done at the same time with loosening soil, the adequate interval between them being round 100 m. For cuts shorter than 200 m, excavation is carried out on both ends and horizontal passages are set up at the lower part of them; for long cuts over 200 m excavation is carried out sector by sector and an additional horizontal passage is equipped in the mid of the cut. Bulldozing is done from top to bottom.

When excavating comes to the stage of refilling, protection measure, covering in the day time and removing the cover in the night, should be adopted to exposed ice layer to reduce the effect of heat-thawing.

After the completion and cleaning up of cuts excavated in warm seasons, entire refilling must be done immediately to prevent the cut surface from being exposed too long. The points for attention are:

The necessity of sufficient refilling material supply. Refilling material should first be paved over both side slopes along the cut

and then get downward up to the bottom step by step to provide good heat preservation. Compaction is needed immediately after paving of refilling material, especially at the time when it is likely to rain.

The sequence of refilling is from inner to outer and from top to bottom, thereby allowing the clean up of the thawed mud of the sector followed.

Attention should be paid to refilling and compaction side slopes. When compaction equipment is not available, by hand compaction must be resorted to layer by layer. The gradient of slope is adjusted by means of paving the slope.

Levelling includes the following steps: cleaning up the soil left after paving slope, cleaning up the side ditches, levelling off the platforms of side ditches and foundation surface, and the shaping of cuts, etc.

SUMMARY

In regions of ground ice, which is considered as the specially harmful geological area, the design as well as construction of cuts are most complicated and arduous and need a comprehensive consideration of local weather and permafrost conditions, topography, vegetation, the run of the cuts, and the nature of stratum, etc., and it is, therefore, impossible to have a unique method for designing section and construction. The article only presents an essential discussion on several main points, and many other problems, such as measures of water-insulation and drainage, construction technology, choice of machine, and commentary on work efficiency, etc. are left for further discussion so as to obtain a plan more applicable.

AN EXPERIMENTAL STUDY OF CRYOGENIC FACTORS AFFECTING
GEOLOGICAL PROCESSES IN PLÁÇER FORMATION

Yu. V. Shumilov

Permafrost Institute, Siberian Branch,
Academy of Sciences, Yakutsk, USSR

It was determined that rocks subjected to stress for long periods at negative temperatures experience a reduction in stability. This process accelerates the disintegration of the rocks in the hypergenesis zone due to pressure release unloading, weathering, and erosion. This effect should be taken into account in mining, construction, and geological investigations. It was demonstrated that weathering of rocks in the cryolithozone is accompanied by the simultaneous formation of unconsolidated materials of varying particle size. Cryogenesis results in intense removal of ions of some elements in water and thus increases the mineral content of the ground water. Migration of matter in the cryolithozone is clearly demonstrated both in ice and in water. Elements differ greatly with regard to their mobility, a factor which distinguishes the cryolithozone from other climatic zones.

INTRODUCTION

Advances of our country in developing the theory of permafrost rocks, including their structure, morphology, and evolution in space and time, make it possible to employ observed geocryological relationships in a broad range of scientific, technological, engineering, and agrobiological activities. One such application is the prospecting for mineral deposits in the permafrost zone. Presently available detailed investigations of cryogenic mechanisms and processes, and of properties of syngenetic and epigenetic residue, refer only to the formation of unproductive deposits. The formation, structure, and occurrence in the permafrost zone of mineral deposits such as placers represent a virtually unexplored field from the point of view of the cryology and geology of mineral deposits. Progress in this direction (Shilo, 1981) so far includes only general statements about the interrelation of the placer formation with cryolithogenesis. To render these insights effective in search and prospecting operations requires more detailed knowledge of cryogenic factors and their role in placer formation and other geological processes.

During the last decade we have been conducting an experimental study of the primary factors of placer formation including the cryogenic (Shumilov, 1981). A study was made of three groups of cryogenic phenomena and mechanisms: physical breakdown of monolithic homogeneous frozen rock and minerals; frost weathering of rock materials associated with gold, platinum, tin, and diamond deposits; and the formation of secondary haloes of gold and attendant element dispersion in conditions of the permafrost zone.

PHYSICAL BREAKDOWN OF FROZEN ROCKS

Experiments were aimed at modeling physico-chemical weathering in the Arctic, using temperature controlled chambers of "Synthesis" type and

"Nema" type. The determining factor was chosen to be a cyclic alteration of phase states of water in its transition from 25°C to -25°C and vice versa. Techniques were also employed to break samples through uniaxial compression, hydromechanical fragmentation, and impact. In these experiments variations of rock strength, porosity, mass loss, granulometric composition (once collapse was initiated), escape of material in the liquid phase, and related data were taken. Experimental results were compared with geological field observations.

The experiments have provided a detailed definition of the mechanism for cryogenic failure of rock, a process that originates within a rock long before it is subjected to temperature fluctuations, phase transitions of water, and the influence of other weathering factors (Shilo and Shumilov, 1981). It is known that when rock and ores crystallize and solidify, a large number of crystal dislocations, inhomogeneities, and other defects of the structure form within them. This primary condition is defined by a certain initial strength which is less than that of an ideal crystalline structure with no defects. The reason is that a portion of the atoms on the lattice sites are in a non-equilibrium (overstressed or understressed) state and tend to occupy a position of stability having the lowest energy level of thermal oscillation. The decrease of rock temperature in the case of permafrost formation leads to a greater degree of instability of non-equilibrium bonds in the crystalline lattices of minerals. Under mechanical influences present in upper levels of the Earth's crust (such as tectonic, seismic, tidal, etc.) frozen rock develops sites of micro-failure within mineral crystals in the form of incipient micro-cracks and the growth of existing cracks.

Thus, the process of rock breakdown should be considered as proceeding continuously in the region of subzero temperatures. The frozen state of rock under conditions of long stress with changing magnitude and sign enhances the fatigue of the material and leads to its destruction without any

mass exchange. Micro-destruction in mineral crystals is particularly intensive with temperature fluctuations in the subzero temperature domain and when freezing and thawing occurs cyclically. These processes accompanied by phase transitions of water, if any, introduce additional energy which produces a kinetic fluctuation of unstable atoms and ions (Regal and Slutsker, 1973), destabilizing the atom-ion links within the material.

Experiments have confirmed that cryogenic destruction of rock is analogous to the brittle rupture of solid bodies as documented in technical physics. Destruction under the action of cryogenic factors proceeds discontinuously. During a time interval an accumulation of critical stresses occurs accompanied by the growth of micro-cracks which bring about a rupture along the most overstressed directions. The process then repeats itself. Sample mass loss and an increase of sample porosity also proceed discontinuously and simultaneously with the destruction.

It is important to note that cryogenic destruction evolves in two stages: precritical and post-critical. In the first stage the rock, despite previous cryogenic destruction, retains its external homogeneity and some residual strength as a consequence of purely mechanical engagement of grains, crystals, and aggregates. However, when such rock is subjected to weathering conditions on the ground it immediately enters the stage of post-critical destruction and rapidly changes to a dis-aggregated state under increases of stress, especially if there is a slight impact stress.

A similar situation arises when various structures (tunnels or various chambers) are built within ledge rock. If the rock is cryogenically altered, i.e. had been subject to a long stressed state at low temperatures or to periodical freezing and thawing, then the rock exhibits abruptly weakened mechanical and atom-molecular links within its structure. The rock structure approaches a critical point of internal stress where a minor increase of stress is sufficient for the rock to disintegrate, in the manner of brittle solids subjected to postcritical stress.

The influence of the degree of rock weathering upon rock strength is well known (Yarg, 1974). A typical feature of the phenomenon of cryogenic pre-destruction is the possibility that cryogenic effects may be present "behind the scenes" in rock that lacks external signatures of weathering decay, and that may appear monolithic and even possess considerable mechanical strength when tested in the domain of above zero temperatures. However, when such rock begins to bear a stress, there occurs an unforeseeable destabilization of its elements; its load-carrying capacity is abruptly decreased, with grave implications for the facilities under construction. There have been cases also of a considerable reduction in longevity of concrete structures built in areas with severe cold climate. One cause of these effects is the use of crushed stone for concrete aggregate which has been prepared from cryogenically modified rock. A further cause is an experimentally demonstrated increase of water corrosivity as it freezes, leading to a rapid physical and chemical weathering of unstable carbonate inclusions in rock.

In principle, the results of the experimental

study of cryogenic destruction corroborate previous results. Similar data had been obtained from omnilateral compression of quartz samples beyond the stress at which the sample would be pulverized without deformation (Bridgeman, 1955). Latent processes of destruction of monolithic rock are suggested by the flaking of mining working walls exposed to mining pressure, and by other observations. The results show that in order to identify the field of application of the observed phenomena for technological and geological purposes, further investigations are pertinent. In particular, even in dedicated papers (Chistotinov and Shur, 1980; Tsytoovich, 1979), cryogenic physical and geological processes in ledge rock have not previously been considered.

CRYOGENIC WEATHERING OF ORE MINERALS

The aim of another set of experiments was to study physical and chemical weathering of gold, tin, platinum, and diamond ores in conditions of the permafrost zone (Shumilov, 1981; Shilo, Shumilov, and Sporykhina, 1981; Prokopchuk, Shumilov, and Vazhenin, 1981). It has become apparent that dispersion of ore material in the permafrost zone proceeds from the earliest stages of weathering simultaneously at three levels: crude dispersion into particulates of crushed stone of gravel size and larger fragments, fine dispersion up to the size of pellet fractions, and chemical extraction of elements and their compounds from ore material. Within the layer of secular and seasonal temperature fluctuations, a weathering crust forms of the cryogenic type with inhibited development of chemical transformations but with a pronounced physical dispersion of ore material. Dispersion proceeds most strongly within the layer of seasonal thawing and initiates the liberation of valuable (placer-forming) minerals from the primary minerals of particulates. The latter are entrained into the movement of fragmented material downslope and produce haloes of secondary dispersion.

In contrast to lithogenetic situations where liquid water is available, the permafrost zone exhibits a sharp increase of exchange processes between eluvium and original substrate, between slope deposits and underlying rock, and between the river bed and its solid bed. The high velocity of material on the slope in the permafrost zone creates favorable conditions for feeding river beds with productive material. Cryogenic weathering contributes crucially to hydromechanical fragmentation of ore debris within the bed, resulting in the conversion of minerals to a free state and their subsequent concentration into a crudely inhomogeneous water-debris medium (a placer deposit). After the formation of a placer, syngenetic freezing of the productive layer contributes to subsidence of minerals into cracks of bedrock while epigenic freezing causes deformations and discontinuities of the productive layer.

The experimental results were used to evaluate the stability of different formative types of ore against cryogenic weathering (according to an index of formation of a fraction smaller than 1 mm in the weathering products). Comparison was made of seven formations: gold-quartz with low sulphide content,

gold-quartz with moderate sulphide content, cassiterite-quartz, cassiterite-silicate, cassiterite-sulphide, dumite, and kimberlite. Assuming the stability of the first (most stable) formation to be 100, we obtain the following series of cryogenic stability: 100:9:62:29:3:14:2. This series indicates that within the permafrost zone the formative conditions of placers from different sources are sharply different and the search criteria for each mineral type of placer will differ substantially. The permafrost zone, as a whole, is found to be a site of intense production of disperse material that contributes to the formation of placers of a comparatively narrow mineral series.

CRYOGENIC CONCENTRATION OF FINE PARTICULATES OF MINERALS

The third group of laboratory experiments was aimed at a study of the chemical component of cryogenic weathering and of the behavior of finely divided mineral particulates. This work was carried out together with V. M. Pitulko and V. L. Sukhoroslov.

The mineralization of solutions produced during cryogenic weathering varied between 10 and 3000 mg/l. These solutions contained the following elements (in decreasing order of concentration): chlorine, sulphur, magnesium, calcium, zinc, manganese, barium, nickel, copper, and sodium. Phase transitions of water led to an increase of mobility of arsenic, silver, manganese, nickel, titanium, antimony, molybdenum, and chromium.

The properties of cryogenic weathering were most pronounced in processes that form secondary haloes of dispersion within ore fields of gold and silver deposits (Pitulko, Shumilov, and Sukhoroslov, 1979). Detailed surveys (1:5000 and larger) reveal a zonal structure of secondary haloes that can be used as the criterion for evaluating the productivity of an ore outcrop. In this case we distinguish between secondary residual and secondary translated haloes, whose relative positions can be used to reveal the presence of a bedrock and its dimensions. In a single zone of anomalies the combination of ore complex elements (Au, Ag, As, Pb, Zn, Sb) and of antagonist-elements (Ti, Ni, Co, Ba, Mn, B, Sn and partly Mo) is indicative of the productivity of the source outcrop.

The experimental results have confirmed that up to 30-50 percent of ore components in the form of free primary minerals are concentrated in a small fraction of eluvium and deluvium of the cryogenic type. The predominance of a mineral form is particularly well-defined for gold. Fractions of 50-100 mkm size and of less than 50 mkm include up to 60 percent of extracted bullion gold. Up to 30 percent of gold particulates occur in aggregations with quartz and other minerals. Residual haloes of mineral forms in stripping are concentrated near the base of a seasonally thawing layer and also occur at the base of a suffosion level. Secondary accumulations of translated haloes, on the other hand, more frequently occur near the upper part of stripping.

The comparison of experimental laboratory and in situ measurements leads us to conclude that migration of material in the permafrost zone is actively

manifested in the chemical composition of solid and liquid phases of cryogenic weathering. In this case we distinguish: salt migrators of rather mobile components (Zn, Mo, Ag, Ni, As, Mg, Sb, Ca); mechanical migrators of weakly mobile elements (Au, Sn, Ti, Al, and partially Pb); and mixed migrators (Fe, Cu, Bi, Ba) involved in migration both in a salt and mineral form. On the whole, analysis of the data shows that the behavior of material in the permafrost zone is defined by the following factors: permafrost conditions within watershed and slope deposits, the character of the surface and the micro-relief; individual signatures of the micro-landscape situation (degree of turfing, the character of vegetation, exposure, inclination, etc.); composition of the ore source and its configuration and orientation with respect to relief elements.

The distribution of sorption-salt and mineral forms in ore haloes of the permafrost zone permits a diagnosis of residual and migrated haloes and anomalies. Cryogenic dispersion attributes to a high input rate of components into the deposit and to an effective development of lithochemical and hydrochemical anomalies.

Thus, there is a wide range of geological processes whose adequate interpretation in handling specific geological problems requires proper allowance for cryogenic factors and their further laboratory and in situ investigation.

EXPLOSIVE EXCAVATION OF FROZEN SOILS

James K. Simpson¹ and Peter M. Jarrett²

¹Mobile Command Headquarters, St. Hubert, Quebec, J3Y 5T5, Canada

²Department of Civil Engineering, Royal Military College,
Kingston, Ontario, K7L 2W3, Canada

Explosive cratering trials were carried out at four distinct sites in the vicinity of Inuvik, NWT. The primary aim was to correlate measured properties of the frozen soils with the cratering results. Two of the sites were underlain by coarse grained, sandy soils and two by fine grained silty soils. At each site ground temperatures and seismic properties were measured and core samples taken to allow laboratory measurement of moisture content, density, strength, and seismic properties. At each site seven craters were formed using 5 kg charges of ANFO explosive detonated at various depths. From crater measurements the optimum depths of charge burial and the maximum dimensions of the apparent and true craters were found. It was concluded that no single property is sufficient to characterize the soil with respect to its cratering behavior. Parameters derived from the seismic velocities appear to offer the best hope for possible characterization.

INTRODUCTION

Many previous studies concerning the explosive excavation or disintegration of frozen soils have been limited in scope to specific individual sites or mines. A search of the available literature reveals that in most instances the soil conditions have not been described in sufficient detail to allow behavioral correlations between the cratering results and the soil properties. One attempt at such a general correlation by Morgenstern et al. (1978) concluded that whether a soil was frozen or not appeared to make little difference to the relation between charge weight and optimum crater dimensions. Only the broadest differentiation was possible between soils, and this showed that in general larger craters are produced in fine grained soils than in coarse grained soils for a given weight of charge. A recent study by Smith (1980) points to the complex nature of the problem. Significant variations were observed in crater dimensions produced in a frozen silt compared to an unfrozen silt (moisture content about 30%). Only minor variations were observed between a frozen and a thawed gravel (moisture content 2-8%) and between the frozen gravel and the frozen silt. The problem therefore is that simple differentiation between soils as coarse or fine grained is insufficient to reflect the changes in probable cratering behavior.

With the uncertainty surrounding the descriptions of the soils in previous studies, it was decided that it would be of value to conduct basic cratering trials on different types of frozen soils and to attempt to correlate the cratering results with more extensive geotechnical properties. To this end cratering trials and geotechnical evaluations were carried out at four sites near Inuvik, NWT in February 1981. Limited results are presented in this paper but a detailed report was given by Simpson (1981).

CRATERING VARIABLES

There are three basic variables that determine the dimensions of the surficial crater produced by an explosive event. These are the energy and form of the explosive charge, the depth of burial of the charge beneath the surface, and the type of soil.

The energy released by a specific explosive may be represented as a function of the weight used (W). To maximize a particular crater property, such as its depth or volume, there is for a specific explosive charge an optimum depth of burial (d_c). This optimum depth of burial has been shown within reasonable limits of practical accuracy to vary linearly with the cube root of the weight of explosive used:

$$d_c = \text{Constant} \cdot W^{\frac{1}{3}} = C \cdot W^{\frac{1}{3}}$$

The constant C is known as the scaled depth of burial. The use of this constant in "cube root scaling" of explosive events is reasonably valid over a wide range of explosive weights. However, the optimum depth of burial may well be different for such individual factors as the diameter, the depth, or the volume of both the apparent and the true craters. Thus a series of constants, C , need to be defined for any specific situation.

In addition the dimensions of the crater produced by a specific weight of charge also respond to "cube root scaling," such that:

$$\text{Crater depth or diameter} = \text{Constant} \times W^{\frac{1}{3}}$$

and

$$\text{Crater volume} = \text{Constant} \times W$$

Thus another series of constants is required and these represent the scaled depth, scaled diameter, or scaled volume of the apparent or the true craters. It is the aim of most cratering trials to find experimentally the scaling constants for the crater dimensions and for the optimum depths of burial for particular soil conditions and explosives.

When considering the effects of the soil conditions on cratering, it is desirable to define some characteristic properties or behavior to which the scaling constants can be referenced. On a simple intuitive level one would expect cratering to be a combined function of the dynamic strength of the soil, the constitutive relationship between stress and strain and the soil density. Defining these properties, except for the density, is virtually impossible when consideration is given to the dynamic nature of the event. For a frozen soil the problem is more difficult than in an unfrozen soil.

Recognizing the difficulty of a "proper" solution, one may start at the other end of the spectrum and seek empirical groupings of soils that may have similar strength properties. This leads initially to simple differentiation or classification based on perhaps grain size and moisture content. For frozen soil the temperature should also be considered as an integral factor. Beyond this first empirical stage, "static" strength measurements may be made either on samples or using penetrometers in the hope that dynamic strengths will be relatively similar. These may be combined with seismic velocity and density measurements to attempt a more rational

albeit still empirical approach. Support for some aspects of such an approach was given by Westine (1970) and Garg (1982), who both considered the seismic velocity to be a useful indicator of cratering behavior.

In this study attempts have been made to characterize the four sites studied using both the simple empirical approach and the somewhat more rational approach.

SITES STUDIED

Four sites south of Inuvik were selected for the trials. Two were composed of primarily fine grained soils (Sites FG1 and FG2) and two of coarse grained soils (Sites CG1 and CG2). Site FG1 was a natural undisturbed site, whereas the other three had all served as borrow pits. Basic soil classification information for the four sites is presented in Table 1.

Site FG1 was underlain by a fine grained, silty till with a thin surficial layer of peat. The moisture content for this soil was rather difficult to characterize with a single average value. The main reason for this was that limited zones existed with very noticeable ice stratification and yet the bulk of the soil was dense with a relatively low moisture content. In addition, where the surface peat layer was saturated it possessed a very high moisture content. The moisture content presented in Table 1 is an average for the basic soil without the ice stratification. The range of values measured including the stratified material was 18-55%.

Site FG2 was formed by the base of a deeply excavated quarry. The "soil" appeared to be a brittle stratified shale or siltstone. Good fragmentation was observed at this site, which is believed to be a function of the brittleness and stratification.

Site CG1 was a sand pit used in the construction of the Dempster Highway. The water table was very close to the surface, giving a well bonded, ice-rich, medium sand.

Site CG2, also a sand pit, was better drained and the moisture content was considerably lower, giving a poorly bonded, unsaturated, medium sand. Sampling at this site proved difficult because of the poor bonding and the presence of a significant network of roots through the upper soil layers. The roots also appeared to affect the cratering, as a number of large slabs of soil were observed to be held together by the roots after the explosion.

In addition to the classification of the soils the following geotechnical program was carried out at each site:

1. Core samples of the soils at each site were obtained using a CRREL pattern sampler. These samples were shipped in the frozen condition to the University of Alberta in Edmonton, where unconfined compression tests were made on them in a cold room maintained at -8°C . The average results from these tests are presented in Table 2. The soil from site FG1 was notably more plastic than that from the other three sites as may be seen from the strain at failure of 13.4%

2. Seismic velocities were measured both in the laboratory and in the field. In the laboratory each unconfined compression sample was tested using Terrametrics ultrasonic equipment prior to the actual compression test. In the field, standard seismic equipment using a small primer charge as a source of disturbance was employed. The basic results together with certain derived parameters are presented in Table 3.

3. Ground temperatures were measured using strings of six thermistors placed at depths between 0 and 3 m. Typical results obtained midway through the trials, on a day when the air

temperature was -32°C , are presented in Figure 1. Site FG2 is significantly colder than the other three. This is representative of the conditions as measured.

CRATERING TRIALS

Snow was cleared from each site in December and again at the end of January immediately prior to the cratering trials. Seven craters were formed at each site with a sufficient variation in depth of charge burial to enable the optimum depths of charge burial for both apparent and true crater dimensions to be found. Because of the limited extent of certain of the sites, charges were formed using only 5 kg of AMEX II (Ammonium Nitrate Fuel Oil) explosive detonated with 0.45 kg Procure III primers and EB electric blasting caps. The explosives were charged in 16.5 cm holes at a free pour density of 890 kg/m^3 . Such charges may be considered spherical in action.

Prior to and after cratering, surveys were made of the ground surface along set cross sections to allow determination of the apparent crater dimensions. Unfortunately during the operation the only two back-hoes within a few hundred miles broke down. Measurements of the true crater dimensions were still obtained but by hand excavation of the debris. It is felt that this led to lower estimates of the true crater volumes than would have been obtained by machine excavation.

The results for the apparent crater volumes are presented in scaled form in Figure 2. From these graphs the optimal conditions indicated in Table 4 are obtained.

The results for the true crater volumes are presented in scaled form in Figure 3. These results produce the optimal values given in Table 5.

FIGURE 2 Scaled results from apparent craters.

TABLE 4 Optimum Results for Apparent Craters.

Site	Scaled Apparent Volume m^3/kg	Optimum Scaled Depth of Burial $\text{m}/\text{kg}^{1/2}$
FG1	0.46	0.68
FG2	0.33	0.58
CG1	0.34	0.49
CG2	0.43	0.69

CORRELATIONS AND DISCUSSION

The relative behavior of the scaled diameters and depths followed very similar trends to those of the scaled crater volumes indicated in Tables 4 and 5. In general, sites CG2 and FG1 produced similar results with CG2 tending to be slightly higher. Except for the apparent depth and apparent volume, site CG1 always produced the smallest craters, although the results were reasonably similar to site FG2.

FIGURE 3 Scaled results from true craters.

TABLE 5 Optimum Results for True Craters.

Site	Scaled True Volume m ³ /kg	Optimum Scaled Depth of Burial m/kg ^{1/3}
FG1	1.42	0.73
FG2	1.14	0.73
CG1	1.06	0.78
CG2	1.70	0.83

No single soil property sufficiently characterizes the soils' behavior to give a usable correlation with basic cratering results. Looking initially at simple factors:

1. At CG1, the site with the lowest density, the smallest craters were produced. This is the opposite of what might be expected.

2. For the coarse grained soils the higher moisture content site, CG1, produced the smallest crater, whereas for the fine grained sites the

higher moisture contents at FG1 produced larger craters. Qualitatively the anomaly may be explained for the coarse grained soils in terms of the better bonding and strength of the saturated soils at CG1 compared to the poor bonding in the unsaturated soil at CG2. This leads one to expect that a correlation may be developed with the soil strength!

3. This, however, did not show up, as the soil at FG2 was apparently weaker than that at CG2 even though the craters at FG2 were much smaller. Two factors may be affecting this correlation. At site CG2, sampling was very difficult, with many attempts producing little more than broken pieces. The samples obtained must by "natural selection" have been from areas of better bonded, stronger material and may therefore be unrepresentative of the in situ average strength. The second factor was the colder ground temperature measured at site FG2. All laboratory strength tests were carried out at a constant temperature of -8°C. Relatively, therefore, the in situ strength at FG2 may be expected to be greater. However, even accepting such rationalization, one cannot explain the closeness of the cratering results between FG2 and CG1 in view of the considerable strength difference between the soils.

4. The seismic velocities are also confusing. The two coarse grained sites had very similar values, which were larger than those at the fine grained sites. The fine grained sites also produced similar results.

Thus if an all-encompassing explanation is to be obtained, it will have to be in terms of some combination of properties. Westine (1970) suggested the term (ρc^2) as an indicator of the soil's "compressibility" or "constitutive effect," where ρ was the soil density and c the seismic dilation wave velocity. Once again CG2 appears the most serious anomaly, as its value of ρc^2 is the highest. At least the other three sites show a logical progression for this combined value. Another similarly based term would be the dynamic Young's modulus derived from the soil density and seismic velocities. Values are given in Table 3, and again, if CG2 could be ignored, then some limited consistency of pattern emerges between the moduli and the cratering volumes in Tables 4 and 5. One further possibility, which seems logical and arises as a grouping from a dimensional analysis, is to divide a strength term for the soil by the dynamic modulus value. This produces what might be thought of as an "elastic failure strain."

King and Garg (1982) suggested that correlation existed between the compressive strength and either the dynamic Young's modulus or dilation wave velocity. The results for the unconfined compressive strengths and dilation wave velocities obtained in the laboratory tests for this study are presented in Figure 4. A measure of agreement is observed. Certainly this type of agreement gives further credence to the concept that seismic velocities may be a possible general indicator of constitutive behavior as suggested by Westine (1970). From a practical point of view this certainly would be a desirable outcome.

FIGURE 4 Strength vs dilation wave velocity from laboratory samples.

As a summation one can only consider the situation qualitatively. The four sites tested were certainly very different. In terms of many of the factors the fine grained soils were consistent when viewed alone and similarly the coarse grained soils could also be explained. Therefore, as in most other soil problems, it appears useful to divide the soils by grain size and treat coarse and fine grained separately. The next factor seems to be the degree of bonding or perhaps saturation. If the soils are well bonded, then they will be more resistant to cratering. Having grouped the soils in terms of grain size and bonding, it may then be more reasonable to expect factors such as strength or seismic properties to provide a correlation.

CONCLUSIONS

1. No single geotechnical property of the frozen soils correlated well enough with cratering behavior to allow for explosive designs to be made based on variation in that property.
2. Variation in the frozen soil properties does make a significant difference in cratering behavior. Maximum variations of 55% in true crater volume and 22% in its optimum scaled depth of burial and 31% in apparent crater volume and

42% in its optimum scaled depth of burial were observed in this series of trials.

3. Derived parameters based on the seismic velocities of the frozen soil are considered to provide the best possibilities for correlation, especially if soils are dealt with in more limited groupings.

ACKNOWLEDGMENTS

Many people and agencies assisted this study with logistical support and the loan of equipment. The authors particularly wish to thank those persons who assisted on site, Messrs. Hogg, Withers, Mast, and Nolan from DRE Suffield and especially Messrs. J. Dipietrantonio and L. Harvey from the Royal Military College, who bore the brunt of the arduous work involved. The University of Alberta through Dr. D. Sego provided facilities to perform the laboratory testing, and the Inuvik Research Laboratories through Dr. P. Lewis provided everything from a soil laboratory to a shovel.

Financial support for the study was provided through a grant from the Chief of Research and Development of the Department of National Defence.

**DEEP ELECTROMAGNETIC SOUNDING OVER THE PERMAFROST TERRAIN
IN THE MACKENZIE DELTA, N.W.T., CANADA**

Ajit K. Sinha and L. E. Stephens
Geological Survey of Canada, 601 Booth Street, Ottawa, Ontario, Canada K1A 0E8

A number of deep electromagnetic (EM) soundings using a multifrequency and a transient system were carried out over several locations near Tuktoyaktuk, N.W.T., during the spring of 1982. The locations were near drill holes that had already been surveyed with various geophysical logs. The multifrequency EM system used a vertical magnetic dipole as the transmitter with 128 frequencies from 1 Hz to 60 kHz for the detection of conductive horizons to a depth of 700 m from the surface. The transmitter for the transient soundings was a large Turam-type loop that can transmit square wave pulses with two base frequencies of 3 and 30 Hz.

The motivation for the experiments was to test a relatively inexpensive and environmentally acceptable geophysical technique for detecting horizontal layers at large depths, especially the contact between ice-bonded permafrost and the underlying unfrozen sediments, which varies in depth from 250 m to 650 m in the Mackenzie Delta area. The multifrequency EM sounding interpretations generally agreed well with well-log information at most sites. The time-domain results, on the other hand, detected major interfaces but could not resolve minor discontinuities. This could be attributed to the fact that the resolving capability of the time-domain system was somewhat less than that for the multifrequency system. The experiments demonstrated the viability and usefulness of conducting routine electromagnetic soundings for detecting and delineating horizons within areas of thick continuous permafrost.

INTRODUCTION

In the past few years, several electrical and electromagnetic (EM) methods have become available for routine mapping and delineation of continuous and discontinuous permafrost zones in the arctic regions of Canada and Alaska (Annan and Davis 1976, Arcone et al. 1978, Rossiter et al. 1978). These methods generally yield good estimates of the permafrost thickness and conductivity when the permafrost is relatively thin, i.e., less than 50 m thick. However, in areas of thick and continuous permafrost, other methods with greater depth penetration must be used. This study deals with the use of two deep electromagnetic sounding methods, one frequency-domain and the other time-domain, for mapping permafrost to depths of 700 m in the Mackenzie Delta, N.W.T., Canada.

The motivation for the study was to test and evaluate a relatively inexpensive and environmentally acceptable geophysical technique for detecting interfaces at large depths, especially the contact between the ice-bonded permafrost and the underlying unfrozen sediments. This interface is at depths varying from 250 m to 650 m in the Mackenzie Delta area. All test areas were chosen to be within 75 km from Tuktoyaktuk, N.W.T., where the facilities of the Polar Continental Shelf Project are available. The tests were carried out near deep oil and gas exploration wells that had already been surveyed by thermal and other geophysical logs for detecting various geological horizons, including the permafrost/thawed-zone contact, and were carried out during the spring of 1982 when the ground was frozen. Hence the active layer did not pose a problem in our study.

DESCRIPTION OF SURVEY TECHNIQUES

Multifrequency EM System

The multifrequency deep EM sounding system (Maxi-Probe) used for the test surveys consists of a vertical magnetic dipole transmitter of large moment and a receiver to record simultaneously the vertical and the radial components of the total magnetic fields at a distance. The transmitter loop placed on the ground behaves like a vertical dipole when the receiver is placed at a distance of at least 5 times its diameter. The transmitter is powered by a 2.5 kW gasoline-driven generator. The transmitter operator may select up to 128 discrete frequencies from 1 Hz to 60 kHz from the transmitter console. The receiver system consists of a horizontal and a vertical coil enclosed in a fiberglass, spherical shell to reduce wind noise. The shell is normally placed on a fiberglass tripod for stability. By using a built-in bubble-level and a directional arrow on the antenna, it is possible to ensure that the measured fields are true vertical and radial components of the magnetic field.

The transmitter and the receiver consoles are usually synchronized with the help of two crystal clocks at the beginning of the survey. This eliminates the need for a connecting cable between them for phase reference. The receiver operator normally records the ratios of the vertical field component H_z to the horizontal field component H_x and their phase differences at each frequency. Since absolute values of field components are not required, it is not necessary to keep the current constant or the geometry of the transmitter loop in any particular configuration. This simplifies field operation over rugged terrain.

The depth of investigation with this system is a function of frequency, electrical parameters of the ground, transmitter-receiver separation, and the strength of the transmitter dipole. The lower limit of usable frequency is normally dictated by the extent of atmospheric and cultural noise. Since the frozen ground was quite resistive, it was possible to sound to depths about 1-1.5 times the transmitter-receiver separation. The field results were initially interpreted by graphical means (Sinha 1979) and finally by comparing the field plots of $|H_z/H_x|$ versus frequency with computer generated responses of multilayered earth sections to obtain a good match. The plotting point is taken to be the middle point between the transmitter and the receiver. The system has been described by Sinha (1979, 1980, 1983).

Transient EM System

The deep sounding transient EM system (EM-37) consisted of a large square loop transmitter 450 m by 450 m lying flat on the ground. A steady current, most commonly 15 to 20 amperes is passed through the loop long enough to allow turn-on transients to dissipate. The steady current is then abruptly terminated in a controlled fashion. The rapid reduction of the transmitter current in a very short time causes the magnetic flux to change rapidly, thereby inducing an electromotive force (e.m.f.) in the ground conductors. This causes eddy currents to flow in the ground, and these currents decay in characteristic fashion depending on the conductivity, size, and shape of the conductor. The time rate of change of the decay field may be measured by a mobile receiver loop that may be oriented in three orthogonal directions to record the decay in three directions.

The decay of the field is measured at 20 preset time intervals or channels after the current is turned off. In practice, the fields are measured over many cycles and stacked to increase the signal/noise ratio. The system operates with two base frequencies of 3 and 30 Hz. Thus, if both frequencies are used, data over a total of 30 channels (from 0.089 msec to 72 msec) are recorded, since the last 10 channels of 30 Hz are identical with the first 10 channels of 3 Hz.

A 5-HP gasoline generator powers the transmitter loop. There are four possible ways of synchronizing the primary and secondary pulses, the most stable of which involves the use of an oven-warmed crystal oscillator. McNeill (1980) has described the system in detail. In late times, i.e., when the decay current pattern has stabilized, the decay voltage components are related to the apparent resistivity of the ground by a simple relation. Hence the decay values over 30 channels yield 30 apparent resistivity values of the ground at different time intervals. The field results are interpreted by comparing field plots of apparent resistivity versus $(\text{time})^{1/2}$ with a set of precomputed master curves for two- and three-layer media or by direct comparison with sets of computer generated responses over multilayered earth sections. Kaufman (1977) has adequately described the procedure.

GEOLOGY OF THE AREA

Field tests with the two EM systems were carried out at seven sites in the Mackenzie Delta, as shown in Figure 1. The Tertiary and Quaternary sediments of the Mackenzie Delta consist of fluviodeltaic clastic sediments eroded and transported from bordering, uplifted highlands to the west and south of Mackenzie basin (Young et al. 1976). The reworking and sorting of sediments by basinward progradation of delta formations and the meandering channels of the Mackenzie river and episodic marine transgressions create a very diversified sequence of sediments in the area. The sediments are more uniform east of Tuktoyaktuk than those west of it, possibly because of their offshore prodeltaic origin. In this paper results will be presented from one site west of Tuktoyaktuk (#1) and two sites east of it (#6 and #7).

FIELD RESULTS

Multifrequency EM Survey

Figure 2 illustrates a plot of the raw field data from site #1 (YA-YA P-53) obtained with the multifrequency system using a transmitter-receiver

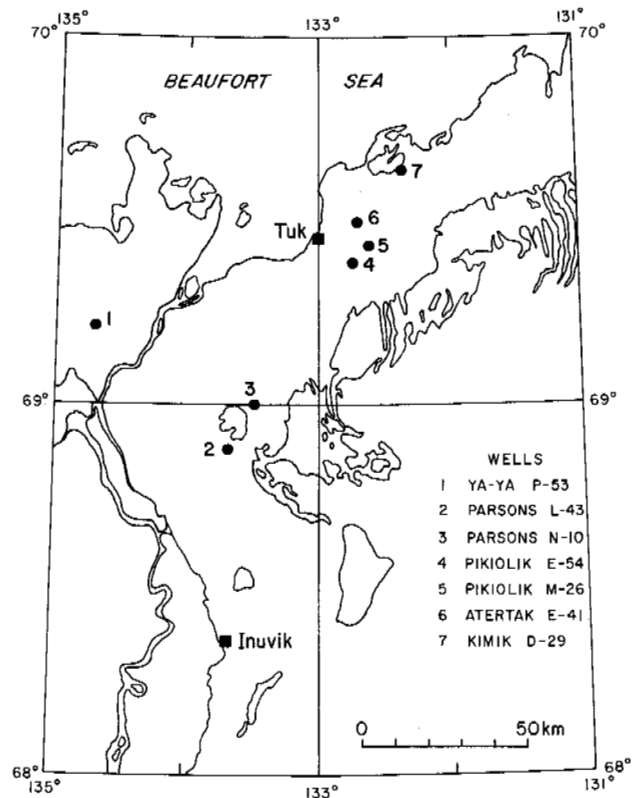

FIGURE 1 Locations of the test sites in the Mackenzie Delta.

FIGURE 2 Raw field data with the multifrequency EM system at YA-YA P-53.

separation of 500 m. The amplitudes of H_z/H_x are plotted on the ordinate against frequency in the abscissa. The dashed line represents the response of a homogeneous half-space. As the frequency is decreased, greater depths are probed by the system. Any divergence of the field plot from the half-space curve represents a departure of the medium from this half-space model. By comparing such field plots with precomputed half-space and multilayered curves plotted with a nondimensional parameter proportional to frequency along the abscissa, it is possible to obtain the depth and resistivity parameters of a multilayered medium (Sinha 1979).

Figure 3 illustrates a plot of the same data (N-S direction) after correcting for the effects of altitude differences between the transmitter T_x and the receiver R_x (Sinha 1980). The data were inverted in terms of resistivity and thickness parameters of a multilayer earth after comparison with responses from several computer generated models. The results indicate the presence of a conductive layer at a depth of 444 m from the surface. Borehole geothermal surveys (Taylor and Judge 1977) have indicated the depth of the permafrost in the hole to be 433 m. Figure 4 illustrates the corrected field response over the same location with the transmitter and the receiver in a E-W direction, keeping their separation constant. The conductive horizon is now interpreted to be at a depth of 435 m. The good agreement between the two depth values when the transmitter-receiver system is rotated by 90° indicates that the layers are more or less horizontal and attests to the repeatability of the survey technique. The upward hump in the field values in Figure 3 could not be exactly modelled on the computer, thereby indicating the presence of a two- or three-dimensional resistive body in the area.

FIGURE 3 Interpretation of multifrequency EM data over YA-YA P-53 for T_x and R_x in a N-S line.

Figure 5 shows a section of a deep induction log at the same drill hole. The log shows a decrease in resistivity from a range of 10-30 ohm m at depths of 325-400 m to about 7 ohm m at a depth of about 405 m presumably where thawing begins. The resistivity of the permafrost however exhibits wide fluctuations possibly due to the presence of conducting materials like clay lenses at various depths. Thus the multifrequency interpretations differ from those from thermal and induction logs by less than 10 per cent.

Figures 6 and 7 show the field ratio versus frequency plots at two other sites, Atertak E-41 and Kimik D-29 (see Figure 1), respectively, with transmitter-receiver spreads of 600 m. In Figure 6, the depth sounding indicates a conductive layer at 565 m with another possible conductor at 750 m. Thermal measurements have indicated the permafrost/thawed-zone interface to be at a depth of 535 m at this site. At Kimik D-29 site (Figure 7) conductive features have been mapped at depths of 265 m, 330 m, and 635 m. Apparently there are several conductive horizons other than the unfrozen layer at this site, consisting possibly of clay and mudstone horizons. Geothermal data indicate the permafrost to be 663 m deep at this site, which differs from the interpreted value from multifrequency interpretation by about 4 per cent.

Transient EM Survey

Figures 8 and 9 show the corrected field plots for two transient EM soundings in the near zone at Atertak E-41 and YA-YA P-53 respectively. The transmitter consisted of square loops with sides of 450 m, and the receiver was located near the centre of the loop. Using both frequencies of 3 and 30 Hz,

FIGURE 4 Interpretation of multifrequency EM data over YA-YA P-53 for T_x and R_x in a E-W line.

it was possible to obtain the decay voltages and hence apparent resistivities over 30 channels. For plotting purposes, apparent resistivities were plotted along the ordinate and $(time)^2$ along the abscissa. The field data were interpreted in terms of resistivity and thickness of a layered earth by comparing them with a set of computer generated response curves. The models with the best match are indicated in Figures 8 and 9.

At Atertak E-41 (Figure 8) the depths to the conductive layers are at 370 m and 530 m, respectively. The bottom layer with an interpreted resistivity of 2 ohm m is close to the permafrost depth of 535 m from thermal logs and 565 m from the multifrequency sounding results. Figure 9, showing the depth sounding curve at YA-YA P-53 yields a three-layer medium with depths at 315 m and 440 m from the surface. This agrees well with thermal logs and multifrequency interpretation at this site. Table 1 indicates a comparison of interpreted results from the three sites with multifrequency and transient soundings with the thermal logs.

DEEP INDUCTION LOG

YA-YA P-53

YA-YA P-53	435-444	440	433
Atertak E-41	565	530	535
Kimik D-29	635	625	663

FIGURE 6 Interpretation of multifrequency EM data over Atertak E-41.

FIGURE 8 Interpretation of transient EM data over Atertak E-41.

FIGURE 7 Interpretation of multifrequency EM data over Kimik D-29.

FIGURE 9 Interpretation of transient EM data over YA-YA P-53.

It was observed at a few sites that interpreted permafrost depths obtained by EM depth soundings tended to be somewhat less than those obtained from thermal logs. This may normally be explained by the relationship between the temperature and resistivity of various geological materials (Hoekstra and McNeill 1973). Another possible

reason may be that ice-bonded permafrost thaws at a shallower depth than that predicted from thermal logs because of the presence of electrolytes but their temperatures still remain below 0°C. Therefore, the material below that depth may still be called permafrost but electrically speaking, that will be a more conductive medium.

SUMMARY AND CONCLUSIONS

Experimental results with deep EM sounding indicate that both frequency and time-domain systems may be used over the permafrost terrain of the Mackenzie Delta with a fair degree of reliability. The multifrequency system has somewhat higher vertical resolving power to identify thin beds of contrasting resistivity. The use of large Turam-type loops for the transient EM systems lowers the resolving power for that system. On the other hand, the use of large loops as transmitters makes the transient system less susceptible to terrain effects, which may be substantial in the multifrequency system.

The agreement between the interpreted depths of the permafrost/thaw-zone interface from EM sounding results and thermal logs were usually within 5% in almost all sites. It is obvious, however, the interpreted model parameters are one of several possible models that would satisfy the field data because of the phenomenon of equivalence. Multifrequency EM systems seem to be more susceptible to lateral inhomogeneities since T_x - R_x separation has to be larger than the loop size for transient systems for similar depth penetration. This is obvious at YA-YA P-53 where the interpreted highly resistive layer in Figure 3 was missing in Figure 4 when the T_x - R_x set up was rotated by 90° presumably because the hump in the field plot in Figure 3 was caused by a resistive body of limited extent. In terms of cost and productivity, the two systems are comparable. The field equipment is heavy for both systems requiring helicopter transport. On a good day, it was possible to carry out 3-4 soundings with either system with a three-man crew.

The success of the two relatively inexpensive and environmentally acceptable geophysical techniques to predict the depth of permafrost to depths up to 700 m may lead to their use in connection with exploration for oil and gas in the Mackenzie Delta. Such surveys may be carried out on a routine basis for siting of drill holes, and the results may be used by seismic exploration crews in making corrections to seismic time sections and for interpolating permafrost thicknesses between drill holes.

ACKNOWLEDGMENTS

We wish to acknowledge the logistical help rendered by the Polar Continental Shelf Project. We also thank Canada Oil and Gas Lands Administration for allowing us to use information regarding the logs for one of the drill holes. We are also grateful to Geoprobe Ltd., Toronto for lending us one of their Mark III receivers during the field tests.

SUMMER STREAMFLOW AND SEDIMENT YIELD
FROM DISCONTINUOUS-PERMAFROST HEADWATERS CATCHMENTS

C. W. Slaughter, J. W. Hilgert, and E. H. Culp

Institute of Northern Forestry, USDA Forest Service,
Fairbanks, Alaska 99701

The presence of permafrost in a catchment system affects the hydrology and water quality of streamflow. Summer streamflow and concentration of suspended sediment in streamflow from first-order catchments in the discontinuous-permafrost taiga of central Alaska (latitude 65°10'N) have been analyzed. In terms of resultant streamflow, permafrost-underlain terrain is much more responsive to precipitation inputs than is permafrost-free terrain, and proportion of permafrost, with concomitant cold, thick organic layers overlying mineral soil, is a primary determinant of differing streamflow characteristics in headwaters catchments. A permafrost-free first-order stream consistently has higher (summer) baseflow than does an adjacent permafrost-dominated first-order stream. A small permafrost-dominated catchment has consistently lower suspended sediment concentrations than does a similar-size virtually permafrost-free catchment. During storm-free periods, suspended and dissolved loads are consistently less than 5 mg·l⁻¹ in both basins. Concentrations are commonly an order of magnitude higher during storm events. Sediment and streamflow relationships are highly variable in this stream system.

INTRODUCTION

Less than two decades ago, virtually no published information existed concerning hydrology of headwaters, first-order streams in Alaska's discontinuous-permafrost regions. Covert and Ellsworth (1909) published hydrologic reconnaissance measurements of some small streams, but most historical (and present day) continuous streamflow measurements are of larger rivers.

Dingman (1966, 1971) provided the first modern, quantitative analysis of hydrologic conditions in a North American discontinuous-permafrost catchment. Dingman (1971) showed that a small (1.8 km² basin) stream had quite prolonged storm-flow recessions when compared to similar-sized basins in more temperate settings, and suggested that the concept of variable-source-area runoff production (Hewlett and Hibbert 1966, Dunne 1978) is applicable to subarctic watersheds. Kane et al. (1978b) stated that "...permafrost areas are responsible for contributing a large percentage of the peak flow for both snowmelt and rainfall runoff events" in subarctic Alaska. Streamflow measurements in upland basins with differing proportions of permafrost provided further evidence that permafrost presence strongly affects headwaters runoff patterns (Slaughter and Hilgert 1978).

Hydrology of small catchments in the subarctic and Arctic has received increased attention in recent years, particularly in Canada. Anderson (1974) showed that streamflow from a 31-km² basin in the Mackenzie Delta, N.W.T., had hydrograph recessions and precipitation/runoff patterns similar to those reported by Dingman (1971), and suggested that stream response was strongly influenced by permafrost and "widespread occurrences of peaty topsoil and mosses." Ambler (1974), Jasper (1974), Newbury et al. (1979), Vincent and Russell (1979), and Marsh and Woo (1979), among others, have reported on

high-latitude catchment studies in recent years.

Possible effects of frozen ground are considered in detail by Dingman (1975). Permafrost (perennially frozen ground) can act effectively as an aquiclude, confining groundwater and restricting aquifer recharge; in the discontinuous-permafrost zone this effect is localized and water is yielded to the surface through unfrozen zones (Kane and Slaughter 1973, Nelson 1978). Infiltration is severely restricted by fine-grained frozen soils (Dingman 1975, Kane et al. 1978a). Permafrost-underlain slopes would be expected to yield water more rapidly to streamflow than would non-permafrost slopes, other factors held equal, because of restricted water infiltration. Taiga permafrost-underlain sites are commonly mantled with a thick (0.1-0.5+ m), virtually continuous living and dead organic layer which has strong influences on hydrologic response (Dingman 1971). This permafrost/surficial organic mat condition must contribute to the "flashy, responsive storm hydrographs" observed in Glenn Creek (Dingman 1971) and in catchment C-3 in this study. Dingman (1971) also attributed prolonged storm-flow recessions (compared with more temperate basins) to storage and subsequent slow drainage of water in the surficial organic layer.

Stream ecology and quality are affected by the land-water interface (Cummins 1974, Hynes 1975), and by sediment introduction to streams. Analysis of undisturbed streams draining catchments of varying area, permafrost, aspect, slope, and vegetative cover should provide better understanding of hydrologic-sediment relationships within subarctic stream/catchment systems.

This study was undertaken to determine hydrologic and stream system quality characteristics of first-order subarctic catchments encompassing permafrost-dominated and permafrost-free landscapes. Results are being utilized in research concerning the consequences of land and resource management practices for taiga watershed systems.

Table 1. Catchment characteristics (adapted from Bredthauer and Hoch (1979) and Lotspeich and Slaughter (1981))

Catchment	Drainage area, km ²	Elevation range, m	Dominant aspect	Area distribution (%) by elevation range (m)				Dominant vegetation	Drainage density, km/km ²	Proportion of permafrost, %
				<305 m	305-487 m	488 m-639 m	>640			
C-2	5.18	329-738	S	0	29.0	38.0	33.0	Deciduous	0.70	3.5
C-3	4.55	305-770	NE	0.1	39.5	51.4	9.1	Coniferous	0.73	53.2
C-4	8.34	240-773	SSE*	5.9	27.3	50.9	15.9	Mixed**/	0.70	18.8

* / Extreme headwaters of catchment C-4 are northeast-facing.

** / Mixed: Deciduous forest on south, southwest slopes, coniferous forest on north, northeast slopes.

METHODS

Study Area

Field work was conducted in the Caribou-Poker Creeks Research Watershed (CPCRW), a 110-km² Experimental Ecological Reserve located at 65°10'N latitude, 35 km north of Fairbanks, Alaska. The study area is in the "Interior" climatic zone of Alaska, characterized by large diurnal and annual temperature extremes and low precipitation. The long-term mean annual precipitation at Fairbanks (elevation 132 m) is 285 mm; mean January and July temperatures are -24.4°C and +17.1°C, respectively. Mean annual precipitation at CPCRW is estimated at 500 mm; the average ratio of summer (May-September) precipitation at CPCRW to precipitation at Fairbanks is 1.47:1 (Haugen et al. 1982), consistent with precipitation/elevation gradients observed elsewhere in central Alaska (Santeford 1976). The estimated mean annual temperature at CPCRW varies from -4.9°C in the Caribou Creek valley (elevation 240 m), to as warm as -1.2°C at mid-elevation (480 m) on south-facing slopes (Haugen et al. 1982).

CPCRW lies in the Yukon-Tanana Uplands (Wahrhaftig 1965). Bedrock metamorphic Precambrian schists are mantled with Quaternary aeolian silts of varying thickness, commonly less than 1 m, and rock outcrops are encountered on ridges at higher elevations. Periglacial activity is evidenced by solifluction lobes and slumps on north-facing permafrost-underlain slopes. Soils of south-facing (permafrost-free) slopes are silt loams or gravelly silt loams, free from permafrost; north-facing slopes and valleys include extensive areas of permafrost-underlain silt loams (Rieger et al. 1972). The vegetation of the basin is heterogeneous, reflecting soils, aspect, elevation and fire history. Permafrost-underlain, north-facing and valley sites are generally occupied by black spruce (*Picea mariana* (Mill.) B.S.P.) forest stands, with riparian (valley) settings dominated by willow (*Salix* sp.), dwarf birch (*Betula nana* L.), and stunted stands of black spruce and tamarack (*Larix laricina* (DuRoi) K. Koch). Warmer, better-drained south slopes support extensive stands of aspen (*Populus tremuloides* Michx.), birch (*Betula papyrifera* Marsh.), lesser areas of white spruce (*Picea glauca* (Moench) Voss), and commonly a major understory component of alder (*Alnus crispa* (Ait.) Pursh.) (Troth et al. 1975).

Hydrologic data

The catchments studied are designated C-2, C-3 and C-4; pertinent characteristics are summarized in Table 1. Summer precipitation was recorded in the lower Caribou Creek valley (240 m elevation). Summer streamflow data were obtained from fiberglass Parshall flumes (23-cm throat in C-2 and C-3, installed in summer 1977; 45.7-cm throat in C-4, installed in fall 1979) equipped with waterstage recorders (Slaughter 1981a). Data analyzed in this report were obtained during the summer (ice-free) streamflow season, after breakup and snowmelt runoff. Acquisition of streamflow data during breakup has been hindered in these headwaters streams by extensive auffs accumulation at the gaging sites (Slaughter 1982), and flows during breakup are often estimated using time-lapse photography (Slaughter 1981b).

Summer streamflow data continuity was good during the three years reported here (1978, 1980, 1981). The 1979 hydrographs had poor data continuity, and were not included in this analysis.

Non-filterable Residue (Suspended Sediment) Data

Non-filterable residue (suspended sediment) was sampled using pre-washed 500-ml widemouth Nalgene bottles. Weekly grab samples were taken at the center of each Parshall flume throat, and were not depth and width-integrated because of extremely shallow water depths at most sampling times. Storm-flow samples were obtained using automated water samplers, with the sampler intake nozzle suspended in the flume throat. A liquid-level actuator was placed in each flume, with the timer set to sample at 6-hour intervals following exceedance of a pre-determined flow level. The samplers were also manually activated weekly, at the time of grab sampling, to obtain a simultaneous collection for technique comparison.

The non-filterable residue (NFR) samples were returned to the lab and analyzed for turbidity and specific conductance, then filtered through tared, pre-ignited 0.45 micron Gelman micro-quartz fiber filters. The filter with residue (>0.45 micron) was dried to a constant weight at 105°C, and weighed again to determine NFR. If residue concentration exceeded 25 mg·l⁻¹, the filter was ashed at 550°C, wetted, dried, and weighed to determine the amount of volatile material (American Public Health Association 1975).

Estimates of sediment production were calculated using mean daily flow and the mean of the residue samples taken in that day, because the NFR collections represented such a small sample both in terms of volume and time. Total estimated sediment production in each stream was then calculated as residue per unit area and residue per unit volume of stream discharge.

RESULTS AND DISCUSSION

Haugen et al. (1982) showed that 1978 and 1980 were summers of below-average precipitation, based on long-term Fairbanks climatic records, and thus reflect relatively dry conditions. June and July 1981 were quite wet and cumulative summer 1981 precipitation was 70% higher than the previous years.

Streamflow records of 1978, 1980 and 1981 were examined to determine whether previously reported (Slaughter and Hilgert 1978) hydrologic patterns are consistent over the more recent study period. Qualitative inspection of seasonal hydrographs and storm unit-area hydrographs ($l \cdot sec^{-1} km^{-2}$) (Figure 1) immediately shows the disparity in behavior between catchments C-2 and C-3. The storm of late June 1978 (Figure 1a), observed in both Caribou and Poker Creeks (Haugen et al. 1982, Figs. 9 and 10), was prominent in the C-3 hydrograph. Peak mean daily flow (24 June) was $61.5 l \cdot sec^{-1} km^{-2}$; the instantaneous C-3 peak for that storm was $69.3 l \cdot sec^{-1} km^{-2}$. Response to the same storm event in the south-facing C-2 catchment was later and relatively subdued, with the peak mean daily flow (27 June) being $8.0 l \cdot sec^{-1} km^{-2}$; instantaneous C-2 peak flow was $11.9 l \cdot sec^{-1} km^{-2}$. Basin-averaged total storm yields (22 to 30 June 1978) were 4.6 mm and 22.9 mm for C-2 and C-3, respectively.

Similar patterns are seen in storm hydrographs from 1980 and 1981. The modest storm of August 1980 (Figure 1b) produced virtually no streamflow increase in C-2, slight increase in C-4, and a prominent hydrograph rise in C-3. Storm period (120 hours) yields were 4.3 mm, 12.5 mm and 5.9 mm for C-2, C-3, and C-4, respectively. The larger July 1981 storm (Figure 1c) resulted in pronounced and synchronous flow peaks in the three streams; unit-area C-2 flows exceeded those of C-4. As in previous years and other storms, catchment C-3 yielded much higher unit-area peak flows than C-2 or C-4: storm period (312 hours) yields were 22.6 mm, 29.5 mm, and 16.2 mm for C-2, C-3, and C-4, respectively.

Flow-duration curves provide another method for comparing streamflow patterns (Dunne and Leopold 1978). Figure 2 presents flow-duration curves based on mean daily unit-area streamflow, for the years 1978, 1980 and 1981 (C-4 in 1980 and 1981 only). Any point on a curve indicates, for the time period used in its construction, the percent of time (X-axis) during which that flow (Y-axis value) was equalled or exceeded. The 1978 plot (Figure 2a) shows that at flows in the range of 3 to $5 l \cdot sec^{-1} km^{-2}$, the C-2 and C-3 catchments are in fair agreement; the curves are approximately coincident in the 40-50% time equalled or exceeded range (in the following discussion, "time equalled or exceeded" is simply termed "duration"). At low-

Figure 1 Storm hydrographs for (a) 1978, (b) 1980, and (c) 1981.

er flows, the C-3 curve dropped relative to the C-2 curve, indicating that C-3 experienced relatively more low-flow days, in 1978 than did C-2. For flows above $5 l \cdot sec^{-1} km^{-2}$ the C-2 curve shows moderate responses, while the C-3 curve indicates a high proportion of flows equaling or exceeding the

highest levels of C-2. The flow at the 20% duration was about $5 \text{ l}\cdot\text{sec}^{-1}\text{km}^{-2}$ for C-2, compared to $10 \text{ l}\cdot\text{sec}^{-1}\text{km}^{-2}$ for C-3; flow at the 10% duration was about $6 \text{ l}\cdot\text{sec}^{-1}\text{km}^{-2}$ and $17 \text{ l}\cdot\text{sec}^{-1}\text{km}^{-2}$ for C-2 and C-3, respectively.

1980 was a summer of generally lower flows than 1978, as reflected in Figure 2b. The flow-duration curves for C-2 and C-3 again differ

markedly at high flows (low duration). At 20% duration, the C-2 flow was less than half that of C-3; at 10% duration, the C-2 flow was approximately 25% that of C-3. At low flows (high durations) the flow-duration curves for C-2 and C-3 were quite similar in 1980.

The 1981 summer was markedly wetter (Table 2), a condition reflected in the curves of Figure 2c. The 50% duration point, nearly coincident for C-2 and C-3, is approximately $13 \text{ l}\cdot\text{sec}^{-1}\text{km}^{-2}$. Little difference between C-2 and C-3 is evident at lower flows, except that C-3 shows appreciably lower flows above 80% duration. At higher flows, the relative position of the curves is similar to that in 1978 and 1980, although C-2 evidenced higher unit-area flows than in the earlier years. At 20% duration there was little difference between C-2 and C-3, but at 10% duration the C-2 value was only 50% that of C-3.

It is evident that the streamflow pattern of contrasting catchments initially suggested, that the north-facing, permafrost-dominated C-3 basin has higher peak flows and lower low flows than the south-facing C-2 basin, is consistent during both dry (1978, 1980) and relatively wet (1981) summers.

Despite its larger size, the C-4 catchment is intermediate between C-2 and C-3 in terms of permafrost and aspect (Table 1). The northeast-flowing headwaters of C-4 presumably are strongly influenced by permafrost terrain, while major downstream slope areas are south-facing and permafrost-free. The hydrographs and the flow-duration curves suggest that streamflow patterns of C-4 may be considered "intermediate" between those of C-2 and C-3. In both 1980 and 1981, the flow of C-4 closely paralleled that of the permafrost-free C-2 basin. In the drier 1980 summer, the C-2 and C-4 unit-area flows were virtually coincident through the entire measurement period. In 1981 the patterns were again similar, although C-2 maintained a higher unit-area base flow than did C-4 (which in turn had higher unit-area base flow than C-3). The 1980 C-4 flow-duration curve closely follows that for C-2, but is displaced upward on the Y-axis. This indicates that streamflow response to precipitation was similar to that of C-2, but for any given duration the C-4 stream had a higher unit-area flow. During the wetter 1981 summer, the pattern was less consistent (Figure 2c). At durations above 70% the C-4 flows exceeded those of C-2, but at low durations the unit-area flows of C-4 were less than those of C-2. In both 1980 and 1981, the flow-duration curves indicated that the behavior of C-4 is more like that of C-2 than that of permafrost-dominated C-3.

The years 1980 and 1981 saw increased emphasis on NFR storm response monitoring. On a unit area/unit streamflow basis, NFR yields (Table 2) in the relatively dry 1980 season were highest in C-4 and lowest in C-3 (1.00 and $0.25 \text{ g}\cdot\text{m}^{-3}\text{km}^{-2}\text{day}^{-1}$, respectively) with C-2 having $0.34 \text{ g}\cdot\text{m}^{-3}\text{km}^{-2}\text{day}^{-1}$. The wetter 1981 season showed increased residue yields, with C-3 having the highest mean yield and C-2 the lowest (12.04 and $2.80 \text{ g}\cdot\text{m}^{-3}\text{km}^{-2}\text{day}^{-1}$, respectively), and C-4 having an intermediate yield of $7.71 \text{ g}\cdot\text{m}^{-3}\text{km}^{-2}\text{day}^{-1}$. The much higher NFR yields in the C-3 stream are an apparent result of more pronounced hydrologic response to storm events (Jasper (1974) reported that

*NFR=non-filterable residue.

about 80% of total summer sediment yield occurred during storm runoff events in a catchment at 65°23'N in the Mackenzie Mountains, N.W.T.). When total residue yields for the 1981 season are compared (Table 2), C-3 and C-4 have high values (5862 and 6882 kg, respectively), while C-2 had only 1553 kg. The drastic dissimilarity of residue yields from the similar-sized C-2 and C-3 basins emphasizes the difference in catchment response.

Analysis of data from the 1978, 1980 and 1981 ice-free seasons suggests that in high-discharge water years NFR (suspended sediment) is yielded at a much greater rate in watersheds with relatively higher proportions of permafrost. Assuming that this observation is consistent with other watersheds within the discontinuous-permafrost zone, the effects of land management practices on sediment yield must be evaluated in the context of differing "natural" sediment production rates of watersheds. This "natural" sediment yield is affected by both permafrost and by precipitation, with major storm events and higher baseflows producing markedly higher yields of sediment.

CONCLUSIONS

Summer streamflow and sediment yield in subarctic Alaska are affected by presence of permafrost in headwaters catchments. A permafrost-dominated first-order stream has higher peak streamflow, higher storm-flow suspended sediment concentrations, lower base (non-storm) streamflow, and lower base-flow suspended sediment concentrations than does a nearby, virtually permafrost-free first-order stream. Such consistent differences in streamflow and sediment yield in undisturbed, close-proximity catchments suggest that (1) detailed understanding of streamflow and sediment production from upland watersheds throughout the discontinuous-permafrost taiga is needed; (2) regulation of land and

resource management practices on the basis of possible consequences for streamflow and water quality must be accompanied by knowledge of the "natural", pre-management behavior of taiga watersheds, paying specific attention to effects of permafrost-underlain landscapes on catchment/stream systems; (3) extrapolation of hydrologic and water quality data from existing records, which are largely for major rivers, to lower-order (upstream) basins must include awareness of natural variation in hydrologic regimen of subarctic headwaters catchments as demonstrated in this study.

PERMAFROST SENSITIVITY TO CLIMATIC CHANGE

M. W. Smith and D. W. Riseborough

Geotechnical Science Laboratories, Geography Department,
Carleton University, Ottawa, Ontario, Canada K1S 5B6

Possible large-scale climatic warming, due to the so-called greenhouse effect, has obvious implications for the stability of permafrost conditions. This paper presents a preliminary examination of the possible effects of climate change on the ground thermal regime in the zone of discontinuous permafrost. Caution must be exercised in extrapolating a warming trend in the atmosphere to the ground. The significance of atmospheric warming for permafrost depends on the accompanying increase in the ground surface temperature and the proximity of ground temperatures to 0°C. The characteristics of natural surfaces determine the interaction between climate, microclimate, and ground thermal conditions. A numerical microclimatic model based on the surface energy balance, has been used to investigate the range of ground temperature response under a uniform climate, due to variation in site conditions. Site factors included slope, albedo, wetness, roughness, snow cover, and soil thermal properties. Site wetness and snow cover were the most sensitive factors. The potential for permafrost degradation during 25 years of climatic warming was then simulated for various sites using climatic data for Whitehorse, Yukon Territory. In one part of the analysis, three different patterns of warming were analysed at a single site. The distribution of warming during the year had relatively little effect on long term permafrost degradation. Much greater differences in degradation resulted from variation in site conditions, for the case of uniform warming.

INTRODUCTION

This paper discusses the possible effects of climate change on the ground thermal regime in the zone of discontinuous permafrost. The possibility of large-scale climatic warming, due to the so-called greenhouse effect, has obvious implications for the stability of permafrost conditions, although this has been generally ignored in northern geotechnical considerations. A warming trend could be significant in areas of discontinuous permafrost, for, as the mean annual air temperature rises, some permafrost at the southern limit could thaw and ground ice would melt (e.g., see Thie 1974, Mackay 1975, Chatwin 1981). Judge (1973) suggests that permafrost up to 30 m thick in the Mackenzie Valley thawed completely during the warming period from approximately 1850 to 1950. Recent results from Alaska show that permafrost is beginning to warm up, in response to higher winter temperatures, and that active layer thicknesses are increasing (University of Alaska 1982, p. 16). It is important, therefore, to attempt some determination of the nature, rate, and magnitude of ground temperature changes that might occur as a result of climate change over the next 30-50 years.

As a result of human activity, carbon dioxide concentration is increasing in the atmosphere, and could double by the middle of the next century. There is, as yet, no definitive answer to what climatic structure would exist in a 2 X CO₂ world. However, the basic effects of a global warming, concentrated in the Arctic, and increased precipitation seem to be generally accepted (e.g., see Harvey 1982). Such changes will have significant and profound effects on the arctic environment.

However, the nature and extent of these effects have yet to be determined; in fact, some may be indeterminable until they actually occur. For example, whilst thermal boundaries would move northward, increased precipitation could mean deeper snow cover, which would act to complicate the effects on ground thermal conditions. In addition, whilst winter temperatures could rise by as much as 15°K, summer increases could be much less.

Caution must be exercised, then, in extrapolating a warming trend in the atmosphere to the ground. The specific effects on permafrost conditions of any large-scale climate change will be modulated, perhaps strongly, by local microclimatic and lithologic conditions. The significance of any climate change depends on the magnitude of any accompanying increase in the ground surface temperature, and on the proximity of ground temperatures to 0°C. The change in surface temperature will depend upon the way in which energy is dissipated at a site. For example, at a wet site, additional energy would result largely in increased evaporation and have little effect on sensible heating. At a very dry site, however, additional energy input would be mostly utilized in sensible heating. The characteristics of natural surfaces determine the interaction between climate, microclimate, and ground thermal conditions, and between climate change and ground thermal response.

Because of the complex relationship between permafrost and climate, prediction of the rate and magnitude of ground temperature change is not simple. This paper discusses the use of a numerical microclimatic/ground temperature model based on the

surface energy balance (Outcalt 1972, Outcalt et al. 1975, Smith 1977) to (1) illustrate the range of ground temperature response under a homogeneous climate, due to variation in site conditions, (2) analyse the susceptibility of permafrost to degradation due to various climate changes, and (3) analyse the role of site conditions in modulating permafrost degradation under climatic warming. A flow diagram of the model is shown in Figure 1; it identifies that changes in the ground thermal regime, and hence in the thickness and extent of permafrost, can result from changes in climate and/or local conditions. Before proceeding with the results of an analysis, various field data are first presented to demonstrate these interrelationships.

MICROCLIMATIC INFLUENCES ON GROUND TEMPERATURE CONDITIONS

Wide variations in ground thermal conditions are known to occur within a small area of uniform climate. In areas where mean annual ground temperatures are close to 0°C, local factors can determine whether permafrost is present or not. Ground temperature data from Smith (1973, 1975) show that substantial differences exist between various sites in the Mackenzie Delta. Whilst the mean annual air temperature there is -9° to -10°C, mean annual surface temperatures range from about -4.2° to above 0°C over a small area. In fact, permafrost is over 60 m thick at some sites, but absent at others, due to local factors. Figure 2 shows the annual regimes at 50 cm depth for five sites, the details of which can be found in Smith (1975). The following points are noteworthy.

1. Site 1 (no vegetation) is warmest in summer but cools the most in winter (virtually no snow cover).
2. Site 4 (open vegetation canopy) is warmer than site 5 (dense canopy) all year round.
3. The regimes at sites 2 and 3 are distinctly different from the others, there being a virtual absence of the winter cooling wave because of deep snow cover.
4. Ground temperatures during the second winter were everywhere higher than in the previous year, even though monthly air temperatures were 2° - 9°C lower. This is because at all sites snow depths were greater and, moreover, snow was on the ground by the end of September.

Such data show that, although certain temperature differences arise because of vegetation effects, the most significant factor to the ground thermal regime in permafrost regions is snow cover (see Goodrich 1982), which can determine whether permafrost is present or not.

Table 1 presents 2-m ground temperatures at 10 closely spaced sites in the Takhini Valley, near Whitehorse, Yukon Territory, in the zone of discontinuous permafrost. The data (taken for approximately the warmest time of year) show a range of 3.5°C; permafrost is present at five sites, but at most of these it is very close to 0°C. The warmest sites include those where snow accumulates in winter. Permafrost in this area would presumably be very susceptible to a climatic

warming, and therefore ground temperature observations here will be continued in the future.

TABLE 1 2-m Temperatures (September 1982), Takhini Valley, Yukon Territory.

Site	Temp. (°C)	Site description
1	-0.1	High ground, well drained (Snow free?)
2	1.3	Low, well drained, small poplar
3	2.3	Low, with bushes up to 1 m (Snow trap?)
4	-0.1	Poplar forest

The data in Figure 2 show the variation in ground temperatures over less than a 2-year period. In Figure 3 are shown 1.06 m (3.5 foot) temperatures at four closely spaced sites at Churchill, Manitoba, for almost a 4-year period (data adapted from Brown 1978). It is interesting to note that

1. Permafrost is present at sites 2 and 3 but absent at 1 and 4.
2. Intra-annual variation is large at site 1 (high thermal diffusivity), moderate at 2 and 3, and small at 4 (high heat capacity).
3. Interannual variation is greater for winter than for summer, except at site 4. Variation is large at site 1, small at site 4, and intermediate at 2 and 3 (see note 2 above).
4. The summer of 1975 was the coolest at site 1, the warmest at site 2, and intermediate at 3 and 4 (little variation).
5. For sites 1 and 3, the summer of 1976 was warmer than 1975; for sites 2 and 4, 1975 was warmer than 1976.
6. Site 2 was cooler than 3 in summers 1973, 1974, and 1976, but warmer in 1975.
7. At site 2, the winter of 1975 was colder than 1974; at 4, 1975 was warmer; at 1 and 3 they were about the same.
8. At sites 1, 2, and 3 the winter of 1976 was colder than 1975; at 4 they were about the same.

These data illustrate the variability of ground thermal response to climatic conditions, and to climate variation. They demonstrate the difficulty of assessing the sensitivity of permafrost to climate change, and the need to unravel, first, the interactions of climate, microclimate, and ground thermal conditions.

SIMULATION RESULTS

This part of the paper discusses the application of a numerical climate/microclimate/ground temper-

ature model to analyze the variability in ground thermal conditions and the magnitude and rate of response to climate change. The strategy for this is outlined in Figure 1. The local surface energy regime (microclimate) is modeled as the interaction between atmospheric (climate), surface, and subsurface conditions. This, in turn, provides the boundary condition governing the ground thermal regime. Hence, ground temperatures are explicitly linked to the microclimate, which is itself linked to the climate.

Soil moisture is modeled as a simple reservoir, the level of which serves to limit evaporation, via the equilibrium model. Soil thermal properties are fully temperature dependent, and moisture dependent in the surface layer. Except for snowfall, monthly normal climate data for Whitehorse, Yukon Territory, were used in the analysis. Snow accumulation was specified on a daily basis.

In part one a sensitivity analysis was conducted, the results of which serve as an indication of the range of possible ground thermal conditions created by variations in local (site-specific) factors under a uniform climate. These factors included albedo, slope and aspect, surface wetness, aerodynamic roughness, snow cover, and lithologic conditions, which were varied in turn in the model. The effect on the mean annual surface temperature is summarized in Table 2.

TABLE 2 Simulation of Changes to Mean Annual Surface Temperature by Changing Various Site Factors.

Site Factors		Mean Annual Surface Temp.	
		Normal	ΔT
SFC LAYER	PEAT	+1.4	1.6
	SILT	0.0	1.4
SURFACE ROUGHNESS .01 (Cm)	0.1	+0.5	1.5
	1.0	0.0	1.5
	10.0	-0.2	1.3
ALBEDO	.1	+0.2	1.4
	.2	0.0	1.4
	.3	-0.2	1.4
	.4	-0.5	1.4
	.5	-0.7	1.4
WETNESS	0.0	+7.2	2.8
	0.2	+3.3	2.4
	0.4	+1.0	2.1
	0.6	0.0	1.4
	0.8	-1.6	1.1
	1.0	-3.0	1.8

	10°N	-0.4	1.4
	0°	0.0	1.4
	10°S	0.0	1.9
	30°S	+0.9	2.0
SNOW COVER	½ NORMAL	-2.2	1.8
	NORMAL	0.0	1.1
	2XNORMAL	+0.5	0.2

Note: Values in column 1 are referred to 0°C at the standard site (underlined) for the normal climate

In addition, the surface temperature change for the same site conditions, but for a uniformly 2°K warmer climate, is also shown (ΔT). The authors recognize the limitations of varying site-specific factors independently, since they are actually cross-correlated in nature. The same holds true for varying air temperature alone, since climatic variables are also cross-correlated. To some extent, therefore, the results discussed in this section are a sensitivity test of the model, rather than of nature per se.

The main results of the sensitivity analysis are as follows.

1. Variations in every microclimatic parameter result in some variation in surface temperature. The variation is smallest for aerodynamic roughness (0.7°K for three orders of magnitude) and albedo (0.9°K for a five-fold change). However, such variations could be significant enough in the discontinuous permafrost zone to determine whether permafrost was present or not. The most sensitive factor is the surface wetness, since evaporation is such an important term in the energy balance. Snow cover is also important.
2. The difference in surface temperature due to the variation within a single microclimatic factor is, in some cases, greater than the change caused by air temperature warming. For example, variations in surface wetness, snow cover, wind speed, and slope angle result in differences in surface temperature greater than that due to air temperature warming.
3. The range in response to the 2°K warming among all sites simulated was 0.2° to 2.8°K (column ΔT , Table 2). Thus a simple correlation between air temperature changes and ground temperature changes is not likely to occur in nature.

In the second part of the analysis, three climatic warming patterns were investigated (based on Harvey 1982): (1) all months increased by 0.2°K/year, (2) an annual warming concentrated in the winter months (0.6°K/year), and (3) same as (2) but with double winter precipitation. The effect of each of these on mean annual surface temperature and active layer development at the standard site was simulated for 25 years. The results of these simulations are summarized in Figures 4 and 5.

1. Permafrost degradation proceeds more rapidly under a climatic change which is uniform in all months. Where the warming is concentrated in the winter months, the snow cover insulates the ground from the warming trend. The maximum difference at any time between active layer depths for the uniform trend and the winter trend is about 50 cm.
2. After 25 years, permafrost degradation associated with a winter warming trend alone does not appear to be significantly different from that associated with a winter warming trend accompanied by increased winter precipitation. Comparison of surface temperature trends shows that mean annual surface temperature of the site with increased snow cover is initially higher, but as the simulation proceeds, increasing amounts of winter precipitation fall as rain, thereby both reducing

the insulation effect and increasing evaporation, and thus lowering surface temperatures. Longer term simulations should produce greater degradation at sites without increased precipitation, where the effect of evaporation will not dominate.

In the last part of the analysis, four different model sites were subjected to a 25-year warming of 0.2°K per year in each month. Naturally, it is important to establish an equilibrium profile as the initial condition. Because of the thermal offset effect in ground temperature profiles (see Goodrich 1978), which is a function of soil thermal properties, the relationship between surface and subsurface temperatures is somewhat complicated. Equilibrium profiles for the four model sites (Figure 6) were established by repetitively running an annual simulation using normal Whitehorse climatic data. Whilst the profiles may not be precise replications of actual conditions, the marginal nature of permafrost they portray would seem to be quite representative for the region.

Figure 7 shows the lowering of the permafrost table at the four sites over a 25-year uniform climatic warming.

1. Variations in site characteristics produce larger changes to the rate of permafrost degradation than variations in the details of the climatic trend (compare Figures 4 and 7).
2. Where the subsurface material is changed to pure ice, active layer depths and the rate of degradation are greatly reduced, although the mean annual surface temperature is higher than for the standard site.
3. At the sites without ice rich lithology, degradation proceeds rapidly due to the lower heat required for melting in the ground materials. Degradation accelerates in the middle years, presumably because the whole profile has been warmed.

The authors have alluded to the limitation of using arbitrary changes in individual variables to represent climate change. In subsequent analyses, it is planned to synthesise future climatic data via stochastic simulation.

CONCLUSIONS

The implications of climatic warming to permafrost conditions must be viewed in the context of the complex interactions of climate, microclimate, and ground temperature conditions. This paper has presented a strategy for analyzing these interactions and for incorporating them into an assessment of the impact of climate change on permafrost. Climatic warming would be undeniably serious for permafrost conditions; however, the results presented here indicate that site effects can be as important as climatic factors in determining ground temperature response to environmental change.

ACKNOWLEDGMENTS

Some of the work reported here has been supported by a research contract with the Department of Energy, Mines and Resources, and a

research grant from the Natural Sciences and Engineering Research Council, Ottawa. The authors also wish to thank G.H. Johnston, National Research Council, for supplying some of the field data presented. The assistance of Margo Burgess in various refinements to the computer model is gratefully acknowledged.

ENGINEERING DESIGNS FOR LAYING PIPELINES IN PERMAFROST
AREAS AND BOGGY TERRAIN IN THE NORTH

V. V. Spiridonov

All-Union Scientific Research Institute on Construction of
Pipeline Mains (VNIIST), Moscow, USSR

On the basis of extensive research and prototype construction the USSR has accumulated considerable experience in the area of northern pipeline construction; engineering designs have been developed and standard documents produced to solve the problems of building large-diameter pipelines in northern regions. Systems for laying pipelines that are new in principle have been developed for various conditions. These include an above-ground system with slightly curved sections; an above-ground system with partial compensation for longitudinal strains for anchoring the pipeline on heaving or waterlogged sections; an underground system on supports for floodplain sections with permafrost conditions; a system where the exposed pipeline is laid on the surface with compensating sections; and finally, various modifications to all of these. Methods of analyzing the various systems and recommendations as to engineering design have been developed.

The urgent need for more and more energy resources for the successful development of all economic areas makes the development of the gas and oil industry of great priority. Major gas and oil deposits have been found in the northern regions, with most of the deposits far beyond the Arctic Circle. The main consumers of gas and oil, however, are in the temperate and southern climates. The construction of high-capacity pipeline systems has become a major challenge to the USSR, the USA, Canada, and other countries. The range of constructed pipelines that are 1220-1420 mm in diameter increases steadily with each passing year. At the same time the ratio of the lines laid in the northern regions also increases.

CONSTRUCTION IN NORTHERN REGIONS

Pipeline construction in the northern regions depends on climatic, hydrogeological, geocryological, technological, and economic factors. The northern regions of the USSR are characterized by long winters with low temperatures (down to -65°C), frequent snowstorms and winds up to 40 m/s, prevalence of permafrost, an appreciable number of bogs and water bodies, territories, the long-lasting polar night, a poorly developed infrastructure, and the lack of a permanent road network.

Pipeline mains as engineering constructions are unique in the nature and intensity of their interaction with the environment due to their length, surface area, the mass of the transported product, and its heat content, as well as the volume of the ground with disturbed natural structure. During their lifetime, in all their parts, pipelines are subjected to very high tensions approaching the standard characteristics of metal strength. Even moderate deviation of the operating conditions from the initial design parameters bring the system into a state of extreme tension.

Pipeline construction significantly changes the

environment, and there appears to be a specific problem of long-term prognosis and control of the interaction between the pipeline and the environment. The existing dynamic balance of the biosphere of the northern regions is unsteady, so it is easily upset by any intervention.

Prognosis for the northern regions is highly complicated due to the many factors involved and the many interconnections of the processes and phenomena of natural development.

Therefore, the following considerations must be taken into account when constructing pipelines in all northern regions, including areas with permafrost:

- (1) the thermal and mechanical interaction of the pipeline with freezing-thawing ground, with water (in passing), and with the surrounding atmosphere;
- (2) the change in the physicomachanical properties of the ground during processing, freezing, and thawing;
- (3) the change in the ground water content along the route of the pipeline;
- (4) the impact of territorial development on geocryological processes and the change in the perennial frozen ground condition due to changes in vegetation, redistribution of the snow cover, formation of new foci for the waters over the permafrost, and so forth.

Permafrost presents a number of phenomena that make the construction and maintenance of pipelines difficult, such as ground subsidence, heaving, landslides, thermoerosion, the formation and development of ice coating, and frost fissures in the ground.

Therefore, a specific feature of such projects in permafrost regions is the formulation of a quantitative long-term prognosis of geocryological changes due to the pipeline construction and maintenance that affirms technological design, construction techniques, and transport regulations for gas and oil. This prognosis should not be passive, but

must provide for future changes to the system.

Engineering and geological studies for pipeline construction in permafrost regions are the basis for design, and require, apart from routine operations, intensive geocryological research along the entire pipeline route, using the full range of photography and geophysical methods.

PIPELINE CONSTRUCTION IN NORTHERN REGIONS

The length of large-diameter (1220-1420 mm) gas and oil pipelines with compressors and pumping stations is considerable. They are laid in permafrost regions, wet and boggy territories with a large number of rivers and streams and their floodplains, without roads, and under unfavorable climatic conditions. Their construction is a complex scientific and engineering problem that must be solved with due regard for the most recent experience in preliminary studies, design, implementation, and maintenance of similar constructions both in the Soviet Union and abroad.

Most gas pipelines from northern deposits to the central regions have to cross permafrost (a complex, multicomponent ecosystem) and boggy and wet areas. In many cases, the permafrost may be classified as unsteady, and there are sites where violation of its temperature and humidity modes may turn it into a liquified mass. There may be an increase in or the appearance of landslides or thermokarst phenomena at these sites, as well as washouts, heavings, and the formation of permafrost belts, depending on the changes introduced into the 'natural life' of the region in the course of pipeline construction and maintenance. Those phenomena must be foreseen in the prognostic studies and must be taken into account in engineering design, construction management, and maintenance requirements.

The route may also have sites with relatively satisfactory characteristics from the viewpoint of the requirements for laying pipelines. Along the route, considerable diversity of geocryological conditions, landscape relief, water content, and other factors necessitate the use of different systems of pipeline construction at different sites, based on the requirement for high reliability at minimal cost and labor. Any solution should be justified, above all, from the point of view of equal reliability along the entire pipeline system, and both cost-effectiveness and technological reliability.

There are two principles to be applied in the construction of pipelines on permafrost. The first principle is maintaining the frozen state of foundations during construction and maintenance. The second allows thawing of the permafrost during construction and maintenance. Accordingly, underground, surface, and aboveground systems for laying pipelines are depending on the conditions along the route and the product transport method. Laying pipelines in complex geocryological conditions should take into account the possibility that the restraining capability of the ground may change, destabilization, changes in ground temperature during construction and maintenance, and the processes and phenomena in the ground surrounding the pipeline, as well as the dynamic wind load on aboveground pipelines. These and other features

required principally new engineering designs of pipelines for various construction conditions.

The Soviet Union has constructed and is maintaining pipelines in the extreme North and in permafrost regions. We have accumulated considerable experience based on a large volume of scientific research and prototype construction of a number of complexes, which allows for the reliable design and construction of large-diameter (1220-1420 mm) pipelines.

At present, about 600 km of gas pipelines 529 mm in diameter have been built and are maintained in the permafrost region near Yakutsk, out of which 250 km is aboveground. More than 600 km of aboveground 720 mm gas pipeline and 300 km of lesser diameter, and 40 km of underground 429-529 mm diameter gas pipelines have been built in the floodplains of the rivers near the city of Norilsk. The fourth leg of this gas pipeline system is currently being designed and built. Gas pipelines 1220-1420 mm in diameter were built and are maintained on the Medvezhie-Nadim-Punga, Urengoi-Chelyabinsk, and Urengoi-Nadim routes. There is a total of more than 12,000 km of large-diameter pipelines in the complex engineering and geocryological conditions of northwest Siberia.

The eleventh five-year plan (1981-1985) includes construction of six pipeline mains from the Urengoi gas deposit, a total of more than 22,000 km. A 1220-mm-diameter pipeline 1285 km long was built in Alaska. Of this length, 640 km are aboveground on steel supports and 630 km are underground. US and Canadian experts have designed an underground large-diameter gas pipeline with refrigerated gas especially for laying in permafrost.

To substantiate engineering designs for the northern parts of Canada and for Alaska, experimental stations and testing grounds were built with pipeline legs of 1220 mm pipes, and a large complex of studies has been conducted concerning pipeline/environment interaction, pipe resistance to cold, techniques for pipeline construction and maintenance, as well as the development of construction technology.

Research and analysis of the results of these studies, as well as the design, construction, and maintenance of pipeline systems in the northern parts of Canada and in Alaska show that although these regions are climatically similar to the northern regions of west Siberia, many differences have been observed in geographical, geological, geocryological, and hydrogeological conditions. The US and Canadian engineering designs are highly labor-intensive and costly.

Traditional methods cannot be used to lay pipelines in boggy regions and in perennially frozen ground. Perennially frozen ground may change its characteristics in the area of construction due to disturbance of the thermal and hydrogeological regimes. When the frozen ground thaws, there may be considerable subsidence, formation of thermokarst sinks, solifluction phenomena, landslides, cave-ins, mud flows, and avalanches. Most such regions are characterized by ground heaving when the seasonally thawed layer is freezing.

The engineering methods, technology, and maintenance techniques have an essential bearing on the stability and durability of the pipeline and other constructions located in its vicinity. In this

connection, the prognosis of the interaction of the pipeline with the permafrost and problems of geocryological control are of great significance in solving problems of pipeline design, selection of pipeline structures, construction technology, and maintenance techniques.

ENGINEERING DESIGNS APPLIED IN PIPELINE CONSTRUCTION IN THE SOVIET UNION

There are no precedents for constructing a long (3000 km) pipeline 1420 mm in diameter during a single construction season under the complex engineering and geological conditions found in western Siberia. Unlike Alaska and Canada, western Siberia lacks the large-aggregate and gravel ground required for road construction, ground replacement in pipeline trenches, and banking under surface constructions, as well as for producing construction structures. It also lacks a network of permanent roads for freight hauling and temporary construction roads.

In the USSR, the study of the problems of pipeline construction in northern regions involved a large number of scientific research and industrial organizations. Many years of research have produced technical solutions and standardized documents allowing construction of large-capacity pipeline systems in those regions.

In the Scientific Research Institute on Construction of Pipeline Mains (VNIIST), studies on pipeline construction in regions with perennially frozen ground were started in 1959. Experimental studies on the construction and operational parts of the Messoyakha-Norilsk gas pipeline have been carried out since 1968.

Research is currently underway at the 8-km looping experimental site in the Ukhta area, where 1220 mm pipes are buried underground, banked up on the surface, and aboveground on roller and sliding supports. There are also special testing grounds.

Concurrent with the studies on operational and experimental parts of gas pipelines, research is being carried out at test rigs, with special devices, on models using analog and digital computers, and there is a wide spectrum of theoretical studies.

The primary directions of research are engineering designs and calculation methods, prognosis of thermal and mechanical interaction of pipelines with the environment, the technology of gas transport, construction technology, and machinery design.

Experimental and theoretical studies have investigated the aboveground laying of 529 and 720 mm gas pipelines on suspended and sliding supports and of 1220 mm pipes on roller and sliding supports, underground and surface laying of pipelines of various diameters, and surface pipelines without embankments. Also designed and studied are diverse support structures (wooden, reinforced concrete, metal, slab, pile, thermopiles, with prestressed tension members, suspending, sliding, roller, etc.), as well as the loads on the supports, coefficients of pipeline displacement resistance, stress resistance of supports, and ground foundations.

The dynamic stability of aboveground pipelines under various effects including wind, stress

resistance, and resilience of curved elements and pipelines of different contours with bent and welded laterals that have small and great curvature radii were studied, as well as stability and strength for all types of pipeline-laying, restraining and ballasting capacity of grounds, and reinforced concrete weights.

The design and construction of various devices have been developed and studied, including devices for preventing pipeline oscillations for anchoring and ballasting underground pipelines in areas of frost heave and subsidence, and new types of anticorrosive insulation for pipelines, improved methods for construction of supports, anchoring stabilizers, and other constructions for permafrost regions.

The thermal and mechanical interaction of pipelines with the surrounding ground has been studied, including temperature fields in the ground, aureoles of freezing and thawing, gas temperature changes along pipelines of various engineering designs, the dynamics of thermal and mechanical interaction processes under various conditions of long-term pipeline maintenance, the processes of foundation heaving and settling, as well as the stresses to the pipelines brought about by these processes.

Geocryological processes along the routes of the pipelines in the North, such as thermoerosion, thermokarst, solifluction, ice crust formation, have also been studied.

Many years of complex studies resulted in the development of new systems for laying pipelines in the regions of the extreme North and permafrost grounds, including an aboveground system with slightly curved sites, surface and underground systems with partial compensation of longitudinal strains and special anchoring devices for heaving and wet sites, an underground system on supports for floodplain sites with permafrost, an open ground system without banking-up with compensating portions, laying on float supports, and their various modifications applied to concrete conditions.

It should be noted that aboveground and surface systems of laying with slightly curved aboveground sites have been comprehensively studied and checked in the course of industrial operation. The open aboveground system of laying is the most economical of all systems applied to date.

The aboveground laying without embankments may be applied widely in permafrost regions, as well as over bogs where placing the pipeline below the surface leads to appreciable construction and technological difficulties.

Methods of analysis were worked out for various systems of pipeline-laying, as well as recommendations for engineering design. In particular, the construction of roller supports that convey minimal loads to the foundations was studied, making it possible to use light foundations for the supports, such as slabs or piles, and avoiding transfer of dynamic loads to the pipeline. Constructions were designed for thermopiles and high supports with tension members to pass over narrow gullies and ravines.

To prevent oscillations in aboveground pipelines, special devices have been designed and studied that allow greater distance between supports, thereby lowering the cost of the whole construction.

In a number of cases it has been necessary to lay pipelines underground in unstable heaving ground (e.g., in wide river floodplains where ice drift is possible. In these cases the pipeline is fixed by means of patented anchoring devices (USA p.3903704 and Canadian p.988927). Also developed and patented was a construction of reinforced concrete ballasts that increase the restraint on buried pipelines that has been quite cost-effective and allows the development of new systems of pipeline laying with partial compensation of strains (USA p. 4166710 and Canadian p. 1076373).

Methods have been developed to analyze the thermal and mechanical interaction of pipelines with the surrounding ground, to predict and control the geocryological processes brought about by pipeline construction and maintenance, as well as methods of technological design for large-diameter

gas pipelines of various constructions and in diverse climatic conditions.

These studies have led to the solution of problems of pipeline construction in the extreme North. However, they must be continued at the research stations with experimental sites of 1220-1420 mm pipes and on operational large-diameter gas and oil pipelines under various natural and climatic conditions, engineering designs, and technology of gas, oil, and oil products transport. These studies are necessary since advances in other fields of science and technology make it possible to steadily improve designs in the field of pipeline construction, increasing their reliability and lowering costs.

All the developed methods of analysis and design were thoroughly studied under laboratory conditions, as well as on operating pipelines and are now incorporated in practical pipeline design and construction in the USSR.

INVESTIGATIONS AND IMPLICATIONS OF SUBSURFACE CONDITIONS
BENEATH THE TRANS ALASKA PIPELINE IN ATIGUN PASS

J. Michael Stanley¹ and John E. Cronin²

¹Alyeska Pipeline Service Co., Anchorage, Alaska USA

²Shannon & Wilson, Inc., Fairbanks, Alaska USA

In June 1979, a leak was detected in the Trans Alaska Pipeline in Atigun Pass, located in the east central Brooks Range. A major subsurface investigation was performed for the purpose of providing detailed subsurface information as input to the design of remedial measures to repair the leak and to detect any other problem areas. Another area of pipe settlement was found on the south side of the pass in an insulated section of the pipeline. Subsurface exploration revealed thawing of the foundation materials, apparently as a result of subsurface water flow. Large-diameter diamond coring with refrigerated fluids was found to be the only exploration method capable of providing samples of adequate quality for thaw strain testing. Thaw strain test data, in conjunction with information on subsurface conditions obtained by refrigerated coring, allowed estimation of the settlement that might occur if the pipeline foundation materials were to continue to thaw. Data from test holes and other investigations during 1980 and 1981 have allowed determination of the need for additional repair work and a rational prediction of future pipeline performance.

INTRODUCTION

The completion of the Trans Alaska Pipeline in 1977 was a major achievement in arctic engineering and construction. Almost 1,290 km in length, the pipeline delivers crude oil from the oil fields of Prudhoe Bay to a tanker loading facility at the Port of Valdez (see Figure 1). Luscher (1977) and Liguori et al. (1978) provide a summary of the design and construction of the pipeline.

Engineering problems associated with permafrost were a major concern during pipeline design and construction. The 122 cm diameter pipeline was generally buried only in areas where permafrost was absent or was judged to be thaw-stable. In areas of non-thaw-stable permafrost, the pipeline was elevated on vertical support members. Because of the greater difficulty and expense involved in aboveground construction, initial route selection attempted to optimize the amount of belowground pipe.

At a few locations, subsurface conditions required special construction techniques. Atigun Pass was one of these locations.

MONITORING THE PERFORMANCE OF THE PIPELINE

Where burial of the pipeline prevents direct observation, data collected using a number of techniques are available to Alyeska engineers. Level surveys of monitoring rods attached to the top of the pipe, when compared with as-built surveys, allow determination of pipe settlement. Surveys of the pipe interior with a corrosion/deformation pig can detect pipe shape changes, which may indicate unsatisfactory pipe movement. (A pig is a device that fits inside the pipeline and is moved through the line by the force of the fluid flowing through the

line.) Aerial reconnaissance of the pipeline right-of-way can reveal ground surface disturbances related to pipe settlement. In addition, where thermistor strings have been installed, future thermal performance may be predicted using computer techniques.

In the latter situation, where the thermal regime beneath the pipe is changing, accurate information on subsurface soil and rock conditions is critical to determination of possible future performance of the pipeline. Qualitative information from test hole logs is essential, and quantitative information from laboratory testing of samples is also an aid.

HISTORY OF THE PIPELINE IN ATIGUN PASS

Background

Atigun Pass, with a crest elevation of nearly 1,450 m, is the highest point on the Trans Alaska Pipeline. Located in the east central Brooks Range 265 km south of Prudhoe Bay and 160 km north of the Arctic Circle (see Figure 1), the pass is underlain by permafrost to great depth.

Construction of the pipeline in the pass took place in late 1976. Preconstruction subsurface investigations revealed large amounts of segregated ice, both in unconsolidated colluvial and glacial deposits and in weathered and fractured zones in the underlying bedrock.

Were it not for the hazards of avalanches, slush flows, and rock slides, the pipeline would have been constructed aboveground through these two ice-rich areas on the north and south sides of the pass. Instead the pipe was buried in an insulated box designed to thermally isolate the warm pipeline from

the underlying ice-rich soil and rock. This box surrounded the pipe with over 50 cm of rigid foam insulation, designed to limit thawing to 0.3 m beneath the pipeline. About 0.5 km of pipe on the north side of Atigun Pass and 1.3 km on the south side were buried using this insulated box design (Figure 2).

Geology and Subsurface Conditions

Atigun Pass is typified by unconsolidated deposits of various origins overlying a bedrock sequence of quartzites and argillites. The unconsolidated deposits consist of varying thicknesses of talus, rock glacier, avalanche, and landslide deposits in addition to glacial till. The colluvial material is typically quite angular and contains material of all fractions from clay size to boulders, the coarser fractions predominating. These deposits are generally perennially frozen in their undisturbed state and inclusions of clear ice are common.

Pipeline Performance

In June 1979, a leak developed in the pipeline on the north side of Atigun Pass. The leak was found to be due to buckling of the pipe at a location about 40 m outside the southern end of the north insulated box (Figure 3). An extensive subsurface investigation carried out at that time to determine remedial measures revealed that the buckling had been caused by thawing of a limited zone of ice in the colluvial soils and fractured bedrock.

Since 1979, detailed monitoring of pipeline performance, in conjunction with gathering of additional subsurface information, has allowed Alyeska engineers to assess the condition of the pipe and predict its future performance. While conditions have necessitated extensive remedial measures in some instances, no further leaks have occurred. The largest remedial effort was required at the northern end of the south insulated box; it is described in detail in a later section.

SUBSURFACE INVESTIGATIONS IN ATIGUN PASS

Preconstruction

During the design and construction phases of the pipeline project, a total of about 200 exploratory test holes were drilled in Atigun Pass for purposes of route selection, design, and design verification. Almost all of these were drilled using some version of air rotary techniques, in which the test hole is logged primarily on the basis of drilling action and classification of cuttings ejected with the air. None of these exploratory holes indicated that potential problems existed in the areas later experiencing settlement nor did any of them indicate a need for further exploration.

South Repair Area-1979

Following the investigation of the leak area on the north side of Atigun Pass in June 1979, additional test holes were drilled in other areas, including 13 test holes near the northern end of the south insulated box. These 13 test holes were all drilled by logging cuttings from an air track. After

drilling was completed, the holes were equipped with thermistor strings to measure ground temperatures.

This investigation revealed subsurface conditions as depicted in cross-section in Figure 4, with thaw extending much deeper than design criteria allowed. In addition, abundant groundwater was encountered in the test holes, which penetrated thawed materials beneath the south insulated box. Groundwater was also encountered in holes drilled adjacent to the uninsulated pipe above the box.

South Repair Area-1980

To provide detailed information for analysis and remedial action as necessary, Alyeska authorized a subsurface exploration program in the spring of 1980. Conventional auger drilling and drive sampling techniques were not capable of penetrating the bouldery overburden and indurated bedrock in the pass. Differentiation between bouldery overburden and the abundant soil-filled fractures in the bedrock was difficult with air rotary drilling techniques. For these reasons, diamond core drilling was used in the 1980 drilling program.

Almost 310 m of exploratory test holes were drilled in the repair area in 1980. Half of the holes were drilled using diamond core drilling techniques. Half of these utilized refrigerated drilling fluids to maintain the original thermal state of the core samples.

The diamond coring employed a triple-tube, PQ-size, wireline core barrel. The relatively large diameter PQ core (82.6 mm core diameter) was chosen to minimize the effect of thermal disturbance and fluid erosion on the core. The wireline system allowed relatively trouble-free advancing of the test hole through fractured rock or other caving materials, while the triple-tube core barrel design facilitated recovery of highly fractured or colluvial material in a relatively undisturbed state.

For refrigerated coring, a solution of propylene glycol and water was cooled to temperatures in the range of -2° to -6°C by an electrically-powered refrigeration compressor coupled to a heat exchanger system. In general, frozen core recovery was excellent, including recovery of ice lenses in the colluvial soils (see Figure 5). Some erosion of ice lenses in hard bedrock was found to be unavoidable.

Since loss of freezing-point-depressing drilling fluids in the soils adjacent to the pipeline might prevent later refreezing, coring in these areas used fresh water at about 15°C . Ice and some fines were washed away in this process, but core recovery was sufficient to differentiate between colluvial soils and bedrock.

When the primary purpose of a test hole was the installation of temperature or groundwater measuring instrumentation, air rotary drilling techniques were used. Both conventional and casing-advancing, down-hole-hammer drilling allowed rapid penetration of both frozen colluvium and bedrock. Limited geotechnical information was obtained by logging drill penetration and cuttings from these test holes.

The use of refrigerated and fresh water diamond coring techniques greatly improved the state of knowledge concerning subsurface conditions in the repair area. The thickness of colluvial soils was found to be somewhat greater than had been revealed by the 1979 air drilling program. In addition, refrigerated coring provided the first accurate assessment of the extent of ice in both the colluvium and the bedrock.

Ground temperature and groundwater monitoring instrumentation was installed in most test holes, depending on whether the ground was frozen or thawed. Thermistor strings were installed in 2.5 cm (nominal) plastic pipe filled with a propylene glycol/water mix. Slotted plastic pipe of the same size served as standpipe piezometers for observation of groundwater levels.

Laboratory testing of samples from the pass consisted primarily of standard index property tests. Because of the wide variation of grain sizes and the abundance of coarse gravels and cobbles, it was difficult to predict thaw settlement using parameters such as moisture content, density, and grain size. For this reason, specially fabricated cells that matched the core diameter were used to test representative samples for thaw strain (see Figure 6). After trimming with a diamond saw, the samples were subjected to a uniaxial load provided by dead weight, and strain upon thawing was measured with a dial indicator. Thaw strains as high as 55% were measured.

DATA ANALYSIS AND DETERMINATION OF REMEDIAL MEASURES

Abundant data were available from the test hole program, including test hole logs, thermal data from thermistor strings placed in the test holes, and water levels measured in piezometers. On the basis of these data, it was clear that thawing had exceeded design criteria for a significant distance along the insulated box. The presence of still-frozen, potentially ice-rich colluvial deposits below the existing thaw depth caused concern for the future stability of the pipeline.

Investigation of the area indicated that runoff water from snowmelt and rainfall was entering the backfilled pipe ditch near the top of the pass. Flowing through the ditch along the uninsulated pipe, it was being heated by the warm (about 55°C) oil. This heated groundwater then apparently flowed under and around the insulated box and appeared responsible for the observed thawing.

Alyeska engineers developed a repair program that was implemented in the summer of 1980. The program consisted of surface drainage to minimize water influx to the area and grouting to cut off the water flow beneath the insulated box followed by mechanical refrigeration and installation of self-refrigerating heat pipes to refreeze the ground. This program is described by Thomas et al. (1982). Figures 3 and 4 show the area of the pass where this work was undertaken, and Figure 7 shows this work being implemented in the summer of 1980.

For this repair program it was necessary to analyze a variety of data including pipe and soil movement monitoring, ground temperature measurements, groundwater levels, and groundwater movement information. By analyzing the data from this array of instrumentation, it was possible to (1) develop a repair program, (2) monitor the effectiveness of the program as the various components were implemented and judge their interaction, and (3) monitor the effectiveness of the repairs in subsequent years.

Pipe and Soil Movement

Pipe and soil movement data were obtained from several sources: (1) the elevation of the top of pipe exposed for repairs or monitoring rod installation, (2) the elevation of the top of a monitoring rod of known length attached to the buried pipe, and (3) inclinometer/extensometers founded in bedrock, some of which were also attached to the side of the pipe. Pipe movement data (the difference in elevation between the as-built top of pipe elevation and the present top of pipe elevation) determined from monitoring rods were used in the initial determination that there was a problem that required remedial action. Later, data collected from the rods showed that there was continuing movement and allowed estimation of the magnitude of the movement and the rate. After installation of the inclinometer/extensometer instrumentation, it was possible to very precisely measure pipe and soil movement in three dimensions. This allowed determination of movement vectors and enabled the engineers to analyze the stability of the pipe and soil independently.

Surface Water

The influence of surface water, as noted above, was evident from observations that water disappeared into the ground near the top of the pass except in times of very high runoff. In addition, rainfall events in the pass caused increases in the groundwater elevations observed in the standpipe piezometers in the repair area within a few hours of the onset of the rain. The amount of surface water that could enter the pipe ditch was reduced by channeling the surface water into control ditches.

Groundwater

Analysis of the data from the standpipe piezometers installed in the test holes and the pumping tests performed on test wells installed in the project area led to the conclusions that (1) the groundwater flow along the pipe uphill (north) of the repair area was causing the ground thawing and subsequent pipe settlement, (2) groundwater velocities through the area were too high for passive ground freezing to be effective, and (3) active ground freezing efforts would be severely effected by the flow through the site. On the basis of these conclusions, it was determined that it would be necessary to grout the area prior to any refreezing efforts.

A grouting program was designed with three components. An upper grout curtain would cut off groundwater flow above the insulated box. Grouting of the soils around the box would reduce porosity and allow artificial freezeback. Finally, a lower grout cur-

tain would confine slurry grout within the limits of the repair area. The grout curtain locations are shown in Figures 3 and 4.

During the grouting and ground freezing programs, extensive monitoring of the piezometers and test wells was performed. The data were used to determine when sufficient grout had been injected to immobilize the groundwater or to reduce the velocities sufficiently to allow ground freezing to be effective. Later, groundwater data were used in the determination of the long-term effectiveness of the grouting and ground freezing programs.

Ground Temperature

Initially, data from the thermistor strings installed in the test holes was used in the determination of the cause of the pipe settlement in this area. Temperature measurements north of the insulated box section indicated that ground water temperatures were as high as 21°C near the pipeline. This led to the conclusion that flowing groundwater was the agent of thaw and subsequent settlement of the pipeline immediately to the south. Secondly, thermal data were used in determining the limits of thawed ground that could be grouted. Thermal data revealed that it was not feasible to install the upper grout curtain because of the extreme size of the thaw bulb at that location (greater than 15 m wide by 20 m deep). Third, the thermal data were used during the ground freezing program to determine the effects of the freezing efforts and to determine when the shutdown criteria for the freezing operation had been met. Finally, long-term thermal data are being gathered to provide information on the performance of the repairs.

EFFECTIVENESS OF REMEDIAL WORK

General

Analysis of data collected during 1981 and 1982 indicates that the repairs and remedial measures effected during 1980 and enhanced by additional work during 1981 (primarily surface drainage control) stabilized the northern end of the south insulated box. The maximum depth of thaw in the repair area was above the bottom of the insulated box during 1981 and 1982. In 1980 it had extended to depths greater than 10 m below the box. No significant degradation of the artificially refrozen zone occurred during the summer months, although it had been anticipated that the northernmost portion of the site would experience some thawing. Contingency plans were prepared for installation of a series of dewatering wells across the valley north of the insulated portion of the pipeline and for installation of a grout curtain at the northern end of the insulated box. The wells were installed during 1981 but were only test-pumped. Because of the excellent performance of the repairs accomplished during 1980 and 1981, there was no need to operate the wells after the test pumping was completed. The wells were not operated at all during 1982 and the upper grout curtain was not installed.

Verification by Subsurface Investigation

Subsurface conditions adjacent to the south insulated box south of the 1980 repair area were investigated by a drilling program in the summer of 1981 consisting of 270 m of diamond coring. Over half this amount was cored using refrigerated fluids. One purpose of this program was to assess the effectiveness of the remedial work in reducing the flow of heated groundwater (and consequent thaw settlement) beneath the insulated box. The investigation showed that groundwater flow was reduced, improving conditions downstream of the repair area.

CONCLUSION

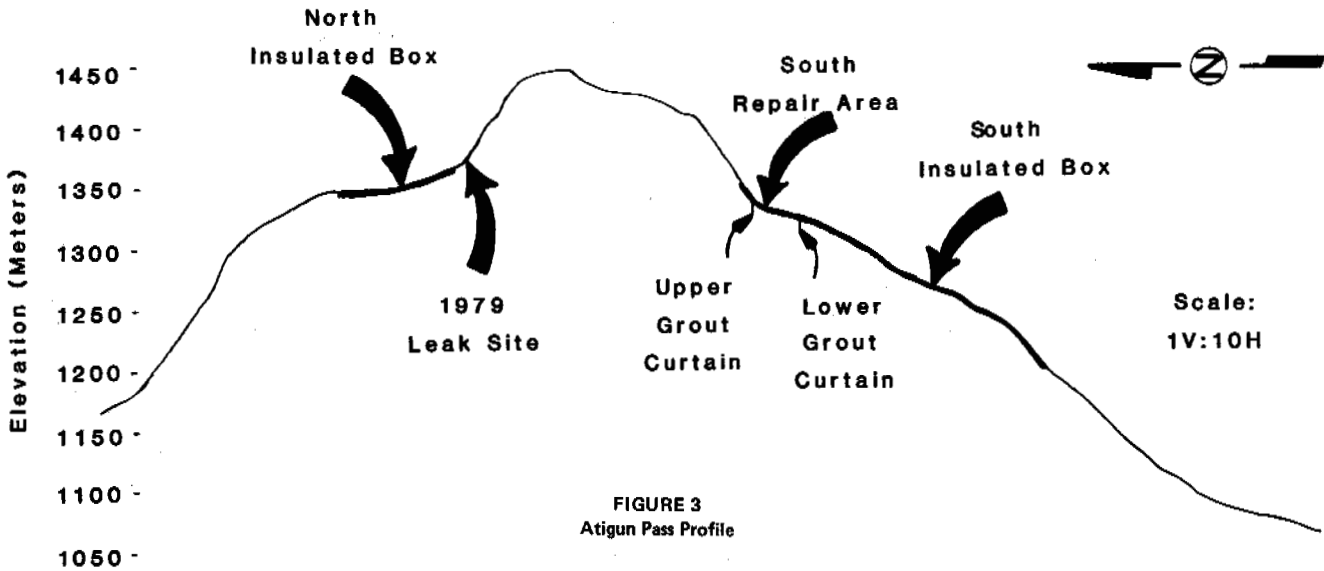

Experience with the Trans Alaska Pipeline in Atigun Pass has proven the necessity for reliable subsurface geotechnical information in predicting the performance of structures in permafrost terrain. In coarse-grained colluvial deposits and frozen bedrock such as are found in the pass, diamond core drilling with refrigerated fluids was found to be the only practical method to obtain both this information and samples of suitable quality for laboratory thaw strain testing. Subsurface soils information in conjunction with data from instrumentation has allowed assessment of conditions, development of a repair program, and prediction of future performance of the pipeline.

MOISTURE AND TEMPERATURE CHANGES IN THE ACTIVE LAYER OF ARCTIC ALASKA

M. G. Stoner, F. C. Ugolini and D. J. Marrett
College of Forest Resources, University of Washington
Seattle, Washington 98195 USA

Occasional deep percolation of meteoric water in the foothills of the Brooks Range is critical to the genesis and physical behavior of well-drained Spodosols. In situ measurements of soil water tension and temperature were made during three consecutive summers at two sites in northern Alaska, one in the boreal forest and one in the arctic tundra. Soil climate responses to changes in weather conditions are explained with additional data on soil physical properties measured in the laboratory. Important factors controlling depth of wetting front penetration include: precipitation, vegetation cover, soil texture and antecedent soil moisture content. Coarse textured soils in the arctic tundra show leaching of the profile with only 5-7 mm of precipitation. Medium textured soils in the boreal forest require in excess of 25 mm of rain to overcome high evapotranspirative demands. Stable soil temperature profiles develop by July, exhibiting a sharp decrease in temperature with depth. These conditions are abruptly altered by a significant pulse of heat transmitted through the active layer during summer storms. This study shows that deep percolation is an important mechanism of transport for soil water, solutes, and heat at well-drained sites in permafrost affected regions.

INTRODUCTION

Accurate interpretation of observed changes in the active layer is especially important in permafrost affected regions. Many workers have studied the environmental factors controlling active layer depth and behavior in relation to permafrost stability and have found that sparse vegetation, convex landscape topography, and coarse soil texture favor deep thaw penetration (Drew et al. 1958, Brown 1973, Gold and Lachenbruch 1973, Linell and Tedrow 1981). Soil development at these deeply thawed northern sites is also affected by these site-specific conditions. In terms of latitudinal distribution, Spodosols are found in well-drained areas of the boreal forest, and Inceptisols and Entisols tend to dominate upland positions in the arctic tundra (Tedrow et al. 1958). However, repeated reports of Spodosols well beyond present treeline in Alaska and other arctic regions (Brown and Tedrow 1964, Ugolini 1966, James 1970, Moore 1974, Tedrow 1977, Everett 1979) have raised questions about the relations between soil processes and environmental conditions at high latitudes. A leaching water regimen, needed for podzolization, seems unlikely in the excessively harsh and limiting arctic climate. Brown and Tedrow (1964) suggested that Podzols (Spodosols) in northern Alaska may be relict features of a warmer and wetter paleoenvironment. More recently, it has been postulated that podzolization has been a continuous process in the boreal forest, but has occurred in the past and/or sporadically in limited areas of the arctic tundra (Ugolini et al. 1981a). This hypothesis is based in part on the climatic transition across the Brooks Range from the relatively warm and wet boreal forest to the relatively cold and dry arctic tundra (Berg et al. 1978). However, the effect of this climatic and

biotic transition on active layer processes and soil development has not been adequately addressed.

Evaluation of the physical behavior of these apparently anomalous arctic Spodosols in relation to current environmental conditions is reported in this paper. The study required instrumentation of two sites, one in the boreal forest, where Spodosols normally occur, and one in the arctic tundra. Data collection included daily monitoring of soil moisture and temperature fluctuations in response to changing weather conditions during the summer. Additional data on soil physical properties determined in the laboratory are used to explain these observed soil climate variations.

SITE DESCRIPTION

Field investigations were conducted at two locations in the Brooks Range of northern Alaska which have been previously studied and extensively characterized (Brown 1966, Goldstein 1981, Ugolini et al. 1981a, Ugolini et al. 1981b). The boreal forest site is at 600 m elevation near Walker Lake (67°09'N, 154°22'W). It is near latitudinal treeline (*Picea glauca*, *P. mariana*) with a ground cover of ericaceous species and lichens. The arctic tundra site is at 610 m elevation in the Okpilak River valley (69°26'N, 144°02'W) and is 100 km north of present treeline with a lichen mixed-heath vegetation assemblage. Parent material at both sites is glacial drift approximately 13,000 years old (Hamilton and Porter 1975, Sable 1977, Hamilton 1979). The drift consists of medium textured mica schist in the boreal forest and extremely coarse textured granitic clasts in the arctic tundra. Remarkable soil morphologic similarities between sites are evident despite major lithologic, biotic and climatic differences (Ugolini et al. 1981a).

FIGURE 1 Particle size fraction, bulk density by large irregular hole (total) and small undisturbed sample (core), and moisture desorption at boreal forest and arctic tundra sites in Alaska.

METHODS

Soil climate responses to changes in weather conditions were measured daily at 1000 hrs for several weeks at each site during the summers of 1980-1982. Active layer depth was in excess of 1 m at both sites during the month of July for each of the study years. Weather data included air max/min temperatures, precipitation, relative humidity, and cloud cover. Soil temperatures were measured to 0.1°C at seven depths to a maximum of 1 m with thermocouples. Soil moisture tension was measured to 0.1 cm Hg (1.5 cm H₂O) at three depths corresponding to the A2, B2, and B3 horizons by mercury manometer tensiometers. Three soil moisture and temperature profiles were instrumented at each site.

Soil physical properties were measured by genetic horizon in the field and on samples in the laboratory. Measurements taken on site included bulk density by large irregular hole and percent particles larger than 2.0 mm. Small undisturbed cores (5.0 cm dia. x 3.0 cm) were collected for field moisture content, oven-dry bulk density, and moisture desorption. Large soil columns (11.5 cm dia. x 50.0 cm) were used for saturated hydraulic conductivity and ponded-head infiltration. The column from the boreal forest was collected intact in the field; the arctic tundra column was packed by genetic horizon to bulk density approximating that measured between large cobbles and stones. Particle size analysis was done by the hydrometer method. All laboratory experiments were run at room temperature.

RESULTS AND DISCUSSION

Soil Texture

This study has shown that climate, vegetation and soil texture are critical in controlling active layer processes. Texture, bulk density, and water holding capacity values through the profiles are summarized in Figure 1. Coarse fragments (greater than 2.0 mm) are much more prevalent in the arctic tundra soil, especially in the B3 and C horizons, but textural multi-layering is evident in both soils. Both soils have significant components of silt and clay in the A2 horizons which provide much of the similarity in their morphologies. The texture of the <2.0 mm fraction of each horizon is important in determining water holding capacity and flow rates. Although the A2 horizons retain substantial moisture at 10 kPa (23.1% in the forest and 28.0% in the tundra), large differences occur in the lower horizons. At the boreal forest the C horizon is finer than the overlying B horizons, but at the tundra the B3 and C are much coarser than the upper horizons. These textural discontinuities impede downward infiltration; however, at the tundra site the dramatic increase in pore size with depth is more significant under conditions of low soil tension (Baver et al. 1972).

Moisture Flow

The importance of texture is further illustrated by moisture flow studies of these layered soils.

The saturated conductivity and infiltration capacity of porous media are functions of several factors, but mainly pore size. In multilayered soils the conductivity is limited by the layer with the smallest pore size; in our soils this feature is found at the surface. It was observed that ponded-head infiltration into dry (<5% moisture) soil columns was slowed at the lower boundary of this surface layer. Measured hydraulic conductivities were almost identical for each column: $1.53 \times 10^{-5} \text{ m-s}^{-1}$ for the forest and $1.55 \times 10^{-5} \text{ m-s}^{-1}$ for the tundra. The curves for cumulative infiltration and wetting front penetration versus time are shown in Figure 2. Water moves rapidly into the surface layer after saturation of the organic mats, due to a combination of capillary tension and gravity. Flow characteristics are very similar for the upper 22 cm of soil for both sites. Initial wetting of the columns is rapid, then slows as the higher matric potential in the A2 must be overcome. Once sufficient pore pressure is attained, wetting proceeds into lower horizons. Deeper wetting in the tundra column is rapid as gravitational water cascades through the large pores in the B3 and C horizons. Only 2.55 cm of water is needed to wet the column to 47 cm. The boreal forest soil responds more slowly at depth, requiring 5.86 cm of water to wet the column, more than twice as much as in the tundra soil. Thus soil texture at these two sites is a critical factor controlling deep percolation of meteoric water through the profile.

Observed variation in soil climate in response to weather conditions can be explained more completely with this information on soil texture, water holding capacity, and infiltration characteristics. Representative data on air and soil conditions for the 1981 field season are graphed for each site in Figure 3. During dry periods at the arctic tundra, moisture losses are due to evapotranspiration from the A2 horizon and downward unsaturated flow from the C. Under these conditions the B2 horizon (16 cm) remains wet (50 cm H_2O) despite soil matric tension of 145 cm H_2O in the A2 (7cm) and as high as 330 cm H_2O in the B3 (30cm). Soil tension in the B2 is sufficient to prevent downward flow into the coarse B3. This textural arrest of the wetting front may be important to pedogenesis as heat and solutes associated with the moving water are conserved in the upper body of the soil. Percolation through these textural barriers does occur, however, as is evidenced after 3 days of light orographic precipitation (July 4-6) totaling only 0.9 cm of water. A subsequent rain of 1.0 cm on July 11 was then sufficient to saturate the soil to at least 30 cm and cause intense downward leaching. Thus a sequence of light rains and fogs, common during July, can lead to deep saturated flow through the profile. This moisture regimen was documented several times at the arctic tundra site during the study period.

At the boreal forest, soil tension can be as high as 200 cm H_2O at 8 cm depth while only 80 cm H_2O at 35 cm depth, indicating that hydraulic gradients may at times be upward in the active layer. This is due to the relative humidity, often as low as 40%, the high transpirative demands of

FIGURE 2 Cumulative infiltration and wetting front penetration on dry soil columns from the arctic tundra and boreal forest, Alaska.

the forest and the capillary continuity of the medium textured soil. Wet periods in the boreal forest are initiated in the summer by intense convective precipitation events. For example, on July 27 the profile was saturated after 4.0 cm of rain, but drying of the surface is shown over the next several days despite interception of an additional 2.3 cm of rain. Frequent showers of smaller magnitude often result in partial wetting of the profile. Limited penetration of the wetting front may also have pedogenic consequences in the boreal forest as solutes are repeatedly leached through just the upper portion of the soil.

Deep percolation through the active layer is clearly shown to be a normal hydrologic event in both of these northern Spodosols. Antecedent soil moisture content in the upper horizons is more critical in the arctic tundra where precipitation during the summer is much less than in the boreal forest. Coarse textured soils in barren convex positions of the tundra site allow repeated leaching of the profile. In the boreal

FIGURE 3 Soil moisture and temperature changes in response to weather conditions in northern Alaska. Measurements were taken daily at 1000 hrs during the summer of 1981.

forest, intense thunderstorms can regularly overcome vegetational demands and cause deep percolation even in these medium textured soils.

Soil Temperature

Soil temperatures are controlled by various factors including climate, organic layer insulation and thermal conductivity of the soil. Organic layer insulation is most effective at our sites during dry periods, particularly at the boreal forest where the surficial debris is thicker and continuous. Daily soil temperature fluctuations in the active layer are relatively small below the soil surface and a short-term steady state condition is attained by midsummer (Figure 3). These intervals of relatively uniform temperatures are abruptly broken by percolative events when temperature sensors indicate the rapid transmission of heat downward through the soil. Measured soil temperature increases during these episodes were as high as 5°C in the boreal forest and 1°C in the arctic tundra even at 100 cm

depth. Heat inputs from 6 cm of precipitation in the boreal forest and 2 cm in the arctic tundra with air-soil temperature differences of 3°C total 0.75 MJ-m⁻² and 0.25 MJ-m⁻², respectively. These caloric inputs are not enough to cause temperature changes of this magnitude (Linell and Tedrow 1981). Nor is this occasional small heat input from precipitation significant in relation to total heat absorbed by the soil on a daily basis from global radiation in July, which can be conservatively estimated at 2.3 MJ-m⁻² at the boreal forest and 3.5 MJ-m⁻² at the arctic tundra (Carlson and Kane 1973, Ng and Miller 1977, Ryden 1978, Goldstein 1981). Since there is no decrease in surface temperature associated with the increase at depth, redistribution of heat in the soil mass must also be discounted (Gavrili'yev et al. 1973). Consequently, these measured temperature increases must be localized to a portion of the soil which is dramatically affected by percolating water, as are the thermocouple sensors. During wet episodes rapid flow prevents temperature equilibrium between relatively warm

meteoric water and the bulk soil mass, however, surfaces of particles respond quickly to this pulse of heat. As moisture flow slows, pore water and particle surfaces equilibrate with the thermal mass of the bulk soil, and measured temperatures return to normal steady state values. Although precipitation does not add appreciable heat to the soil body per se, the temporarily elevated temperatures of the liquid phase and particle surfaces can be significant not only for soil weathering reactions, but also for transpiration and net photosynthetic activity of treeline and tundra plant species (Billings et al. 1977, Tranquilini 1979, Goldstein 1981).

CONCLUSIONS

This study gives direct evidence that percolation of meteoric water through the solum and active layer is a contemporary hydrologic event, both in the northernmost boreal forest and arctic tundra of Alaska. There is no reason to question podzolization as a present phenomenon in arctic environments due to moisture limitations. In well-drained northern locations downward pulses of heat associated with summer storms may also create temporary conditions in the soil more conducive to biotic and mineral reactions.

Data also confirm that climate, vegetation, and soil texture control soil moisture and temperature changes in the active layer. Climatic conditions in the southern foothills of the Brooks Range are capable of overcoming the high moisture demands of the boreal forest in midsummer. Although the measured precipitation during the study was much less in the arctic tundra, losses from evapotranspiration were low due to sparse vegetation and persistent low clouds and fog. In coarse textured soil with a moist surface, precipitation of 5-7 mm can induce a percolative event through the profile. It is not, therefore, a coincidence that Spodosols in the tundra are limited to convex landscape positions, coarse textured parent material, and thin vegetation where repeated leaching can occur.

Further research of this type along more detailed transects and with more complete data collection is required for mathematical modeling and prediction of active layer responses to climate at well-drained locations in the arctic.

PLEISTOCENE DIAPYRIC UPTURNINGS OF LIGNITES AND CLAYEY SEDIMENTS
AS PERIGLACIAL PHENOMENA IN CENTRAL EUROPE

Horst Strunk

University of Saarbruecken, Department of Geography
6600 Saarbruecken, Federal Republic of Germany

Diapirlike intrusions of lignite into gritty or sandy topsoil, several meters thick, are widespread in the central European lignite fields and wherever clayey sediments lying near the surface. These structures occur outside the limits of the Scandinavian ice sheet. This eliminates the assumption that their formation was primarily caused by the weight of the ice. Rather, the upturnings were caused by density inversions during the degradation of permafrost. The light lignite, water-saturated by the freezing process, rose up--much the same as saline domes--into the overlying layers having greater specific weight. Previously-frozen lignite has an agglomerate structure, resembling "coffee grounds". Disturbed layers thus provide information about the minimum depth of permafrost penetration. If it did not penetrate as far as the lignite, then the latter did not become upturned. The boundary between agglomerate and undisturbed lignite appears to mark the limit of maximum frost penetration and thus the lower limit of the permafrost. The maximum thickness of Pleistocene permafrost in central Europe decreases rapidly from several dozen meters in the northeast to less than 10 m in the west and southwest.

INTRODUCTION

In central and western Europe, permafrost aggradation and degradation took place several times during the Pleistocene. A number of phenomena are known to occur only in the presence of permafrost (cf. Washburn 1979) and are found today as they leave definite traces behind even after the ice has melted. In many other cases unfortunately no signs can be found in the subsoil to indicate whether or not permafrost had formed. It is harder still to obtain reliable evidence on the thickness of the permafrost.

PROBLEMS

Because the Scandinavian ice sheet advanced to Europe several times during the Pleistocene (cf. Liedtke 1981), a southerly movement of the peripheral periglacial area must be assumed synchronous to the advance of the ice. There was a reverse direction, when the ice sheet retreated. It remains unclear, however, whether degradation of the permafrost came about beneath the ice. In any case, a different southerly and southwesterly limit to the extent of the permafrost must be assumed for each ice age. Only a small number of paleoclimatic or paleogeographic studies have been made so far for the Pleistocene of central and western Europe. These exist only for the "Weichselian" (i.e., late Devensian) ice age, approximately 30,000-13,000 B.P. for Britain (Williams 1975, Watson 1977). For the western parts of central Europe there is a synthesis by Karte (1981), who points out that diverging opinions still exist about the "Weichselian" permafrost extent in this area. Intrusions of lignite into the topsoil provide evidence to substantiate the occurrence and maximum depth of permafrost in each region, and, depending on the soil profile formation, infer the age of the intrusion

phases.

DISTRIBUTION AND APPEARANCE

Intrusions of lignite into overlying sediments occur in all the lignite fields in central Europe, provided the upper limit of the lignite is not more than a few dozen meters below the recent surface. A small number of similar clay intrusions also exist. Because their occurrence has an extremely detrimental effect on the quality of the lignite and its exploitation, and also makes draining the pits a problem, attempts to describe and explain the intrusions go back nearly 150 years. The literature covers more than 120 titles: more recent summaries include Viete (1960a, b), Ruchholz (1977), and Eissmann (1978, 1981). The intrusions may be wide dome shaped, pointed cones, pillar shaped, and moundlike or walllike (Eissmann 1978). Enclosed depressions set within a moundlike surrounding frame with either round or oval outlines are also widespread (Strunk 1982). The base of the upturnings in central Germany lies at a depth of up to 150 m beneath Quaternary topsoil (Fries 1933). Intrusion heights are more than 50 m (Viete 1960a), but not greater than 10 m in the southeast (Heim 1971) and extreme west of Germany (Kaiser 1958, Quitzow 1958). They occur a long way outside the maximum extent of the Scandinavian ice sheet.

DEVELOPMENT

The deformations are partly "load casts" (Kuenen 1953), brought about by gravitational compensatory movement caused by the instability of lighter hydroplastic layers being affected by overlying strata with a greater specific weight (Dzulynski 1966, Anketell et al. 1969). Load casts up to a

few decimeters height are known from all eras of earth history, starting with the Precambrian up to the present day (e.g., Allen 1982, Pettijohn and Potter 1964). Frequently, the lignites have penetrated the topsoil and become diapirs. These differ from the small forms described here only in their dimensions, and not in their origin of formation, i.e., density inversion (Heim 1958). They constitute a worldwide phenomenon (Ramberg 1972). The most spectacular examples of compensatory movement due to density inversion must surely be the saline domes (Lotze 1938, Balk 1949, Trusheim 1957).

Lignite from mining has a water content of 55-65%, as was established by Potonié (1930), Haase and Pflug (1958), and Spelter (1968). It should be kept in mind however, that the mining areas are given deep-drainage treatment before mining is begun and the water content of the lignite will thus be considerably higher below the groundwater level. Despite the fact that the Tertiary lignite deposits with high water content are covered by more than 300 m of gravelly sediments which may be old as Tertiary in age, no indication are found in the literature that the lignite intrusions in central Europe are older than the Pleistocene. Eissmann (1978) came in the same conclusion.

Bajor (1958) and Berger (1958) are exceptions since they describe intrusions of fine sand into lignite in the soft coal region of the German Rhineland. However, these were caused presumably by the transgression of the North Sea in the Miocene period and are not genetically linked to the lignite intrusions.

The considerable difference in density between lignite at $1.2-1.4 \text{ kg dm}^{-3}$ and gravel at $2.0-2.4 \text{ kg dm}^{-3}$ (Ruchholz 1977) was not enough to trigger density inversions between the lighter lignite and the heavier topsoil. However, these density inversions occurred several times in the Quaternary period. This is why it was conjectured that autoplasmic lignite movement (Lehmann 1922, Weigelt 1928, Wölk 1937) and the permafrost of the Pleistocene period caused the upturnings (Grahmann 1934, Pruskowski 1954, Kaiser 1958, Schenk 1964). Ruchholz (1977), Eissmann (1978, 1981), and the author hold that the autoplasmic intrusions of lignite are density inversions occurring in watersaturated, thawing permafrost (e.g., French 1979, Vandenberghe and Van

den Broek 1982). Much the same conditions occur in peat deposits (Czudek and Demek 1973), where extensive lenses of segregational ice form during the freezing process. If the lower frost limit does not reach the base of the lignite deposit, already containing a good deal of water at the outset, (this being the general rule in the western parts of central Europe), the freezing of lignite takes place in an "open system" (Beskow 1935, Dücker 1939, Peltier 1953). Unlimited amounts of water keep reaching the freezing front. Horizontal crevices filled with sand from the topsoil, 8 cm thick and up to 17 m long (Keilhack 1921, Magalowski 1963), together with the fine flaky structure of the lignite (Keilhack 1921, Fliegel 1937, Kaiser 1958) indicate the former presence of lenticular segregational ice in the permafrost. Due to the formation of ice in the freezing lignite, the latter takes on an agglomerate structure. In extreme cases, this produces a "coffee grounds" type disintegration (Hübner 1979). Corresponding observations can be found in almost all descriptions of lignite upturnings. The degradation of the permafrost produces diapirlike compensatory movements of the water-saturated hydroplastic lignite into the heavier overlying sediments, which sink at the same time. They must also have been hydroplastic, because, as the author has observed, rocks accumulate in the gravel-filled depressions between the diapirs in the bottom of the hollows. Hunger and Seichter (1955) observe the same. This compensation of density inversions is referred to as "mollisol diapirism" by Eissmann (1978).

The idea of pure gravitational density inversions did not win wide acclaim until recently, and conflicted with the concept of upturnings occurring due to the load pressure of the ice sheets (e.g., Eissmann 1978). But, even for areas within the maximum extent of glaciation, Eissmann (1981) provides evidence of the autoplasmic ascent of the lignite in several places, without being affected in any way by the ice sheet. Here, diapirism occurs--and this is clearly substantiated by stratigraphic observations--temporally independent of glaciation, with diapirs still forming in the last (i.e., Weichsel) ice age, when ice stagnated 100 km to the north. Lehmann (1922) made similar observations.

Figure 1 Deformation of lignite and thin, light layers of clay, caused by density inversion, Zievel claypit, German Rhineland. Scale is given in meters.

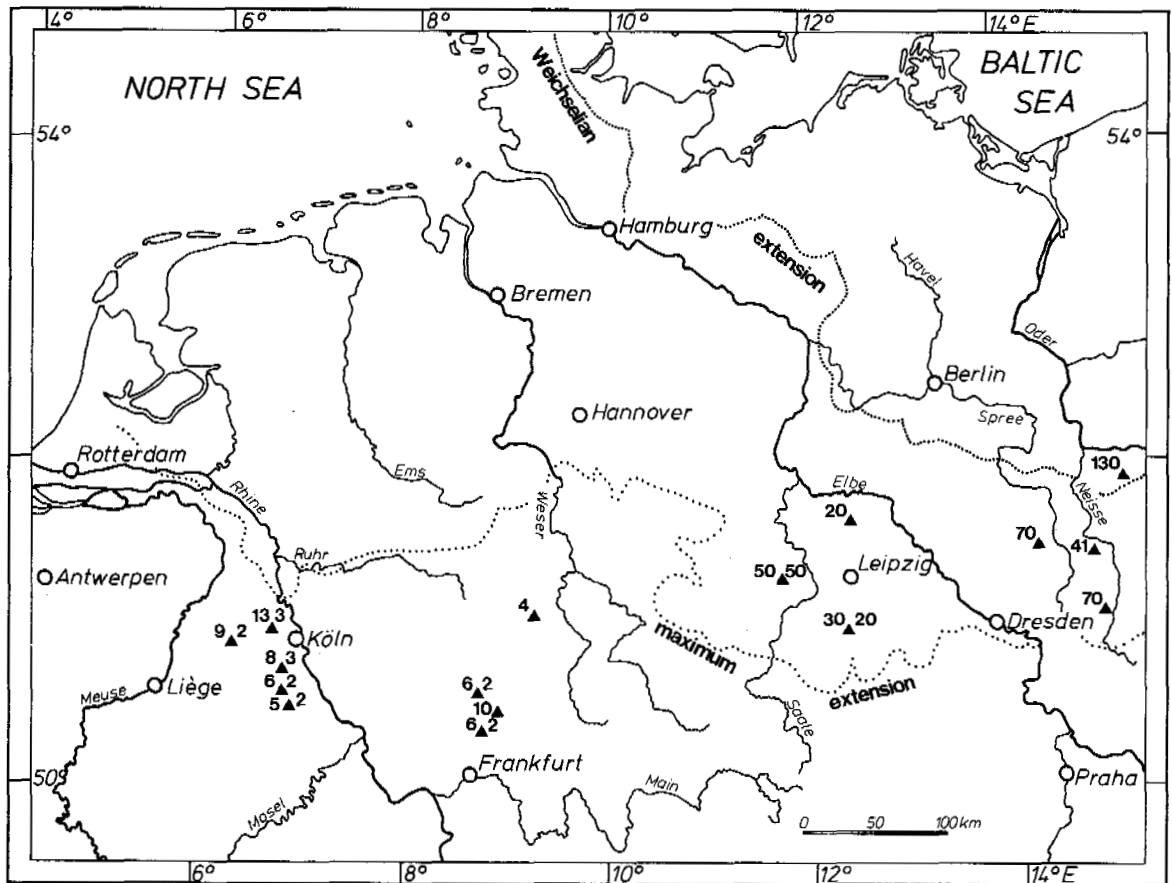

Figure 2 Depth in meters of permafrost in central Europe, with the left-hand value indicating the maximum Pleistocene thickness and the right-hand value the thickness during the last (i.e., Weichsel) glaciation. Pointed lines mark maximum extension of the ice sheets and the extent of the Weichselian ice sheet.

PERMAFROST DEPTH

As described above, previously frozen lignite is, to a greater or lesser extent, agglomerate. In areas of diapiric structures, it has a flow structure. The thin, light layers of clay, normally deposited undisturbed in lignite layers, are also affected by these upturnings, as can be observed in any mine (see Figure 1). The lowest limit of these upturnings runs through the deposits evenly or in slightly discordant waves. According to Eissmann (1981) and Maarleveld (1976) this lowest limit of deformations is the lowest limit of the active layer. With degradation of the permafrost, this limit moves down and must have caused upturnings there. It is striking that the lowest limit in the northern part of central Europe is 2-4 times deeper than in the south and west. This signifies, according to Eissmann (1981), that the ground thawed to a greater depth close to the ice sheet than further to the south and west. That is thought unlikely. If, however, the lowest limit of deformations and upturnings in the lignite is considered to be the maximum depth of the permafrost, then this interpretation better fits the observations made thus far. The thickness of the permafrost would have de-

creased as distance from the ice sheet increased, and with it, of course, the depth of the upturnings caused by permafrost-degradation.

PALEOGEOGRAPHIC ASPECTS

If the observations made of the lowest limit of the upturnings caused by permafrost and the depth of the lignite deposits below the surface are put into spatial order, the following results:

1. As the distance from the ice sheet increases, the thickness of the permafrost decreases.
2. If lignite does not possess upturnings, the maximum permafrost depth must have been less than the thickness of the overlying sediments.
3. Without further stratigraphic evidence, the lowest limit of disturbed lignite provides only the maximum depth of the permafrost attained at some point in time during the Pleistocene age.
4. By considering the overlying layers that can be dated (e.g., gravel or interglacial soils)--pos-

sibly in a discordant manner--the minimum age of the permafrost degradation can be determined. If the intrusions are syngenetic, the age of the permafrost degradation corresponds to the age of the covering sediment.

The permafrost thicknesses for central Europe, obtained in the way described above, are shown in Figure 2 (in part according to Eissmann (1981)), with the left-hand value indicating the maximum Pleistocene thickness and the right-hand value the thickness during the last (i.e., Weichsel) glaciation. The data are given in meters.

ACKNOWLEDGMENTS

The author thanks E. Bibus, K. Heine, H. D. Lang, W. Schirmer and G. Seidenschwann for helpful discussions and unpublished observations. He also thanks H. M. French for revising the English text.

LARGE-SCALE DIRECT SHEAR TEST SYSTEM FOR TESTING PARTIALLY FROZEN SOILS

Brian J. A. Stuckert and Larry J. Mahar

Ertec Western, Inc.
Long Beach, California 90807 USA

The design and construction of offshore earth-fill structures in the arctic environment requires the determination of mechanical properties of the construction material under appropriate thermal conditions. Salt-water saturated materials exhibit a zone of partially frozen soil at the frozen/unfrozen soil interface. To define the critical failure surface and governing shear strength in this zone, the effects of partial freezing on the mechanical behavior, as a freezing front advances, must be well understood.

A large-scale direct shear apparatus was developed to test the shear strength of a soil sample through an undisturbed partially frozen inter-facial zone. The apparatus has the capability of shearing a 30 cm square, frozen specimen using a wide range of shear displacement rates. The specimen is instrumented with thermistors to provide the capability to monitor the thermal regime as the partially frozen zone progresses toward a predetermined shear plane in a 30 cm deep sample. The shear box is constructed from transparent plexiglas material which minimizes thermal disturbance and permits visual inspection of the sample during shearing. A sample preparation system was designed to provide a specimen having a reproducible thermal condition while thermal and mechanical disturbance during handling is minimized.

The paper presents details of the design of the large-scale direct shear apparatus and testing procedures. Typical results from tests conducted on freshwater and seawater-saturated gravels are shown, demonstrating the usefulness of system and procedures for determining the strength of partially frozen soils.

INTRODUCTION

The design of offshore earth-fill structures constructed in arctic waters requires knowledge of the mechanical response of the construction material to anticipated loading conditions. Lateral ice loading can result in three potential failure modes: (1) localized edge failure, (2) foundation failure at or below the mudline, (3) shear failure in the fill material. The latter mode will likely occur as a gross horizontal shear failure at or near the frozen/unfrozen interface (Prodanovich 1979). Due to the presence of saline pore fluid, a significant zone of poorly bonded ice exists at this interface in typical granular fill material (Mahar et al. 1982). It is of interest to understand the mechanical behavior within this zone when subjected to vertical overburden and subsequent horizontal shear. Development of appropriate design strength parameters requires that anticipated loading and thermal conditions be modeled.

An ideally suited laboratory test to characterize horizontal shear strength in a soil sample is the direct shear test. Roggensack and Morgenstern (1978) performed direct shear tests on natural fine-grained permafrost, and Thomson and Lobacz (1973) performed direct shear tests at the thaw interface in freshwater saturated silt; however, the results are not applicable to the design of artificial arctic islands because of the coarse-grained nature of the construction

material and the effect of a saline pore fluid on strength behavior. The only data available on the strength of saline-saturated granular materials is in the form of triaxial test results (Ogata et al. 1982, Sejo et al. 1982); however, these studies do not investigate the strengths under the relatively warm conditions that exist within the freeze-front zone. The present study represents an effort aimed at investigating the strength within this zone.

The direct shear test simulates anticipated field loading conditions; however, conventional direct shear equipment is not suitable for testing the coarse-grained material of interest because of the small shear box size. Large samples must be tested to minimize particle size effects on test results. A large-scale direct shear machine and sample preparation system has been developed, allowing a large sample to be subjected to a wide range of repeatable thermal and loading conditions.

The equipment and procedures developed to test frozen and partially frozen coarse-grained material within and near the frozen/unfrozen interface zone are described below. Typical test results from a preliminary testing program are provided.

TEST APPARATUS

The large-scale direct shear system described

here was designed to permit inducing shear failure at a controlled plane within the partially frozen freeze-front zone. The system was designed to incorporate the following capabilities:

1. ability to induce shear failure at a prescribed plane in a sample at a controlled rate of displacement
2. sample size large enough to eliminate particle size effects associated with testing gravel material
3. adjustable shear gap to accommodate maximum particle size of material being tested
4. ability to maintain desired thermal conditions during direct shear setup and testing
5. ability to simultaneously freeze multiple samples uniaxially under well-controlled environmental conditions
6. remote monitoring of freeze-front progression and shear testing to minimize operator time inside cold room
7. ability to apply vertical load during shear testing to simulate in situ stress conditions

The large-scale direct shear test apparatus comprises a sample preparation system and a direct shear test system in which large samples (30 cm x 30 cm x 30 cm) are frozen uniaxially in a controlled-environment chamber and tested to failure under direct shear loading. Temperature monitoring of the sample allows direct shear testing when the desired thermal condition exists at the shear plane. The sample is then placed in the shear apparatus, subjected to an overburden pressure and sheared at a constant rate of displacement. Horizontal load, vertical load, horizontal deformation, vertical deformation, and temperatures are monitored during the shear test. All data from the freezing and shearing portions of the test are gathered and stored on tape, and selected data are plotted using a computer-based data acquisition system.

Sample Preparation System

The sample preparation system is shown schematically in Figure 1. The purpose of this system is to induce uniaxial freezing by application of a surface air step temperature. A wide range of step air temperatures (0 to -25°C) can be controlled to provide sample temperature distributions and freezing rates so that tests can be run for specific, repeatable thermal conditions at the shear plane.

The system is situated in a cold room in which air temperatures can be controlled to within $\pm 1^\circ\text{C}$. Up to three samples can be prepared simultaneously inside a second environmental chamber in which temperatures are controlled to within $\pm 2^\circ\text{C}$. The cold-room and preparation-chamber temperature can be varied to provide air temperatures from -25°C to +20°C.

Figure 1 Sample Preparation System

The preparation chamber consists of a polystyrene foam insulation base, with cubical receptacles to house specially designed sample preparation and testing containers, covered by a plexiglas environmental chamber. The air temperature is controlled using a proportional temperature controller that supplies a current to a heating wire running the perimeter of the chamber. Four fans provide adequate circulation to maintain constant thermal conditions throughout the chamber. Samples are surrounded by a minimum of 30 cm of styrofoam, which ensures predominantly vertical heat flow and hence uniaxial freezing. Heated drain lines from the sample box allow expulsion of pore water to eliminate sample expansion during freezing.

The sample preparation and testing containers, shown in Figure 2, are made of two halves of a cubical plexiglas box joined by a membrane that prevents water leakage through the shear gap and allows relative displacement of the box halves during shear. Spacers are inserted in the shear gap and the upper and lower halves of the box are clamped against the spacers to minimize physical disturbance during transport prior to testing.

Direct Shear Test Machine

The shear testing system was designed to induce a horizontal shear failure using a controlled rate of displacement in a frozen or partially frozen soil sample while minimizing thermal disturbance during setup and testing. The apparatus, shown schematically in Figure 3 and pictured in Figure 4, is composed of four components: (1) horizontal reaction frame, (2) vertical load system, (3) shear box assembly, and (4) power train. Together, this system is

capable of shearing a 30 cm square, completely frozen gravel sample over a wide range of displacement rates under vertical loads up to 2,270 kg, while maintaining desired thermal conditions established during sample preparation. The components of the apparatus are discussed below.

Figure 2 Sample Container

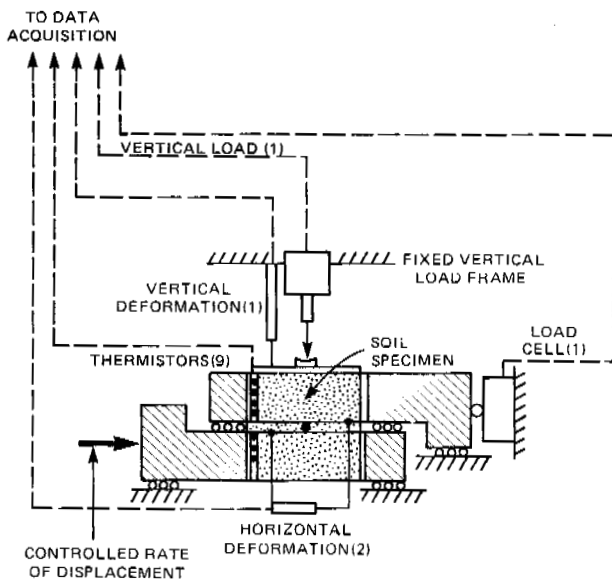

Figure 3 Schematic of Large Scale Direct Shear Apparatus

1. Horizontal reaction frame—The reaction frame is made of two structural-steel end sections tied together by four 3.8-cm diameter, high-strength steel tension rods 300 cm in

length. It is capable of providing a 90-tonne horizontal reaction. The reaction frame is mounted on a base frame that distributes concentrated vertical loads to the cold room floor.

Figure 4 Large Scale Direct Shear Test Machine

2. Shear box assembly—The shear box assembly (Figure 5) is designed to withstand a horizontal compressive loading of 90 tonnes and allow shear displacements up to 5 cm. The shear box is constructed of transparent plexiglas, providing the required structural strength and insulating the sample to minimize thermal disturbance during setup and testing. The material also allows visual observation of the sample during shear. Tolerance between the sample box and shear box was minimized to eliminate sample rotation during shear. A slide bearing system provides axial alignment of both halves of the shear box, while maintaining static stability of the system. The shear box halves are separated by an adjustable bearing mount to allow a shear plane gap from 0 to 2.5 cm to accommodate testing of variety of maximum soil particle sizes. The ends of the shear box are fitted with steel plates to distribute

Figure 5 Shear Box Assembly

forces from the load cell and loading ram over the plexiglas face. A spherical interface between the plates and the ram and load cell ensures transmittal of a horizontal load.

3. Vertical load system--Vertical loads up to 2,270 kg are provided by a pneumatic ram cylinder fixed to a reaction beam. The system is mounted on the horizontal tension rods, and vertical tension rods tied to the base frame provide the necessary reaction. The vertical frame is mounted on linear slide bearings to maintain a vertical load centered on the sample throughout the test. Although the bottom half of the shear box is tied to the drive system to provide the relative shear displacements, small horizontal displacements of the upper half of the sample do occur due to system compliance.

4. Power train-- The power train is composed of a variable-speed electric motor, speed reducer, shaft assembly, and high capacity-screw jack. The motor and speed reducer are located outside the cold room, being connected by a drive shaft assembly to the screw jack mounted on the horizontal load frame inside the cold room. Once set at the desired speed (range: 30-1,800 rpm), the motor transmits torque as required directly to the speed reducer, which reduces at a constant ratio of 2,537:1. The shaft assembly drives the worm gear (6.4 turns/cm) of the screw jack. The entire system is designed to provide a 90-tonne horizontal thrust at a displacement rate in the range of .112 cm/min to .0019 cm/min.

Instrumentation and Data Acquisition System

A microcomputer-based data acquisition system is capable of monitoring temperatures of three samples during freezing and load-displacement during shearing. All raw data are stored on tape, reduced data are printed out, and selected data are plotted for quick reference.

All samples are instrumented with 10 thermistors, 9 at set 1.2- to 2.5-cm spacing providing internal soil temperatures and 1 monitoring the chamber air temperature 2 cm above the sample. The rapid-response thermistors are waterproofed and have certified accuracies to within $\pm 0.1^\circ\text{C}$. During freezing, thermistor data are monitored at selected time intervals (typically 1 hr), stored on tape, printed out, and temperature versus depth plots are generated to observe progression of the freezing front or zone. Vertical deformation of the sample during freezing is monitored using a dial gauge (± 0.0002 cm).

During shear testing the shear test sample is monitored at selected time intervals (typically a 10-s scan rate). Sample temperatures are recorded to quantify thermal disturbance, if any, during testing. In addition, vertical load, vertical deformation, horizontal load, and horizontal shear deformation are recorded and printed. Relative shear displacements are measured between the top and bottom halves of

the sample box at the shear plane, on both sides of the sample. Average shear displacement is plotted against horizontal load throughout the test.

TEST PROCEDURE

The test procedure consists of three separate stages: (1) sample preparation, (2) freezing phase, (3) shear test phase. The procedures are summarized as follows:

1. A membrane is installed in the 1.3-cm shear gap. Sample box halves are separated by 1.3-cm spacers that are removed prior to testing. Hoisting rods are inserted on the outside of the sample, and are used to clamp against the spacers, thereby reducing disturbance during subsequent transport. A string of thermistors is placed at the desired spacing on the inside of the sample box wall. A pea gravel drain, overlain by filter paper, is placed in the bottom of the box, and the air-dried test soil is placed in 5-cm lifts at the desired density. Two interior thermistors are placed down the middle of the sample, one an inch above and one directly at the shear plane. Saline fluid, prepared at the desired salinity (ASTM Standardized Sea Salt) and checked with a conductivity meter (± 1 ppt), is used to saturate the sample slowly from the base under approximately 30 cm of head. Saturation levels are typically 95% $\pm 5\%$. A top bearing plate is then placed, and the sample is put into a cooler and brought to an isothermal condition of approximately -5°C . The sample is then transported to the cold room testing facility, while great care is taken to ensure minimal physical disturbance during transport.

2. The sample is then placed in the freezing preparation chamber. A heated drain line is hooked up to the base of the sample and the desired air temperature is established and maintained to within $\pm 0.2^\circ\text{C}$ throughout the freezing phase. The top perimeter of the sample is sealed against the surrounding insulation using insulation tape to minimize horizontal heat loss and thus achieve uniaxial freezing.

The test time is then selected based on the sample temperature profile. For the testing of distilled-water-saturated samples a distinct freeze front exists and is clearly identified from the temperature profile. Tests can be performed when the freeze front is at the desired location relative to the shear plane. Because a distinct freeze front does not exist in a saline-saturated soil, the progression of a desired test temperature, rather than depth of freeze front, is monitored to define testing conditions.

Typical thermal data during preparation are shown in Figure 6 for a saline-saturated sample. For the particular saline test shown the desired test temperature was -2.3°C . Also shown is a typical temperature profile generated during freezing of a distilled-water-saturated sample.

The distilled-water sample was tested when the freeze front coincided with the shear plane. The temperature profiles generated allow testing precisely when the temperature in the middle of the sample is at the desired test temperature. The outside thermistor string provides the progression of the temperature profile, while the interior thermistor 5 cm above the middle of the shear plane is used to assess uniaxial freezing close to the shear plane, as depicted in Figure 7. The interior thermistor at the shear plane is used to provide an exact testing time. This thermistor is removed at the end of the freezing to avoid thermistor failure during shear testing, and thermal disturbance during sample transport and testing is assessed with the remaining eight thermistors. At the end of the freezing phase, the sample is hoisted to the direct shear machine.

Figure 6 Temperature Profiles During Freezing

3. When the sample is ready for testing, it is removed from the preparation chamber and placed in the shear box. The hoisting rods and spacers are removed, and the LVDT mounts are attached to the sample box. The vertical load frame is centered over the top of the sample, and the desired vertical load is applied. The sample is then subjected to a constant shear displacement rate to obtain peak and residual strengths. Upon completion of the test, a portion of the frozen sample is removed for salinity and moisture-content determinations.

TYPICAL TEST RESULTS

Typical test results are presented for three well-graded sandy-gravel samples (maximum grain

size diameter of 1.3 cm), similar to arctic gravel island construction material. The first sample was completely unfrozen and was performed as a reference test. A second test was performed on a distilled-water-saturated sample, with the freezing front coincident with the shear plane. The results for these two tests were essentially identical, implying that the unfrozen strength is appropriate for the strength at the freeze front for distilled-water-saturated material. A third test was performed on seawater (30 ppt) saturated material, with a sample temperature at the shear plane of -2.3°C . This is assumed to correspond to the cold portion of the poorly bonded ice zone.

Figure 7 Assessment of Uniaxial Freezing

The results of distilled-water versus-seawater-saturated material are shown in Figure 8 for comparison. Note that a 15% gain in peak strength over the unfrozen state is obtained for the partially frozen saline sample, and the residual strength is essentially that for unfrozen material.

The test system described herein is currently being used in a major, joint industry/proprietary research study to investigate the shear strength of saline-saturated sands and gravels for use in arctic exploration and production islands. Although the detailed results and conclusions of this study are not yet available for publication, the large-scale direct shear test has proven to be a very effective method for determining the shear strength of soils in the region close to the frozen/unfrozen interface.

SUMMARY

It has been shown that the need exists to characterize the mechanical behavior, near and within the freeze-front zone that is present in saline-saturated granular material, for design of earth-fill structures constructed in arctic marine environments. To do so, in situ stress, thermal, and loading conditions must be modeled using typical construction soil.

Figure 8 Typical Load-Displacement Results

The large-scale direct shear testing system described allows uniaxial freezing of large soil samples and subsequent direct shear testing when desired thermal conditions have been obtained at the shear plane. It has the capability to induce horizontal shear failure, a principal design failure mode, allowing simultaneous application of a vertical load to simulate overburden pressures present in situ. This testing system can be used to characterize the mechanical behavior within the freeze-front zone of saline-saturated granular material.

Typical test results are presented for three well-graded sandy-gravel samples. Two distilled-water-saturated samples, one completely unfrozen and the other with the freeze front coincident with the shear-plane, were found to exhibit very similar mechanical behavior. A saline-saturated (30 ppt) sample tested with a temperature of -2.3°C at the shear plane exhibited at 15% increase in peak strength and no increase in residual strength over the unfrozen material.

DEFORMABILITY OF CANALS DUE TO FREEZING AND THAWING

Sun Yuliang

Water Power Research Institute, Northeast Design Institute,
Ministry of Water Conservancy and Electric Power
Changchun, People's Republic of China

The destruction of canals by frost heave and thaw settlement is a serious problem in the northern regions of China. To lay down effective measures for preventing frost damage, the author has investigated the deformation characteristics of canals during freezing and thawing periods in situ. The results show that frost heave differs along the cross section of a canal: it is greatest at the bottom, smaller on the slope, and least on the top. The length of the slope is shortened during freezing and extended during thawing, and depends mainly on the amount of frost heave at the foot of the slope. Freezing and thawing will cause the collapse of canals and destroy the lined pavement, due to the distortion of concrete slabs, soil erosion, and thawing collapse. Based on the data, the authors have worked out formulas for estimating both the amount of slope shortening and the displacement of concrete slabs, and propose measures to protect canals from frost damage.

To study the reasons of the canal's frost damage for the lay down methods for preventing it, we went into field observations at 1979-1982 in some irrigation districts of Jilin province. Observed canals included soil canals, cement lining canals, plastic film lining canals, etc. This paper is the summation of these observations.

DEFORMATION IN CANALS DURING PERIODS OF THAWING AND FREEZING

Distribution of Frost Heave Along the Cross-Section on a Canal

Frost heave along the cross-section of a canal is unequal due to the effects of the shape of the canal, differing temperature conditions due to differences in height, and, most importantly, the diversity of moisture conditions. The drainage at the top of a canal is better than at the bottom, the moisture content at the top is less than at the bottom, and the distance to the level of ground water is greater at the top of the canal than at the bottom. Thus the conditions of moisture replenishment during freezing periods is different. The result is that the largest frost heave is at the bottom, less heave occurs in the middle part and the least heave occurs at the top of canal.

Investigations and observed data show that such deformation characteristics are abundant and universal and are the principal form of cross-sectional deformation in canals.

In some deeply excavated canals the distribution of frost heave along the cross-section is greater in the middle or at the upper part and smaller at the lower part. This behavior has been observed when the level of ground water is higher than or approaching the canal bottom, and at the same time the soil beneath the canal has a greater density and smaller permeability than soil

beneath the sides. For example, at a certain section on the Xiangyang reservoir east main canal in Yushu county of province Jilin, the moisture content in the soil is over 30%, the maximum frost heave actually measured is 43 cm, the corresponding frozen depth is 149 cm, frost heave ratio is as large as 40.5%, and the distribution of frost heave takes the form of larger at the upper part and smaller at the lower. Figures 1, 2, and 3 show the distribution of maximum frost heave along the cross-sections of Songqian No. 1 main canal, Xiangyang west main canal and Xiangyang east main canal, respectively. TABLE 1 gives characteristics of the three observed canals.

In engineering practice, canals with cross-sectional frost heave amount larger at the lower

part and smaller at the upper are more common, therefore this article will lay emphasis on discussing the regularity of this kind of deformation.

Regularity of Deformation Along Canal Cross-section During Freezing and Thawing.

Frost Heave Deformation at the Bottom of the Canal: During freezing, the locus line of frost heave deformation at the toe of the slope is a straight line perpendicular to the canal bottom, as shown in Figure 4. Such frost heave deformation at the toe of the slope indicates that during the period of freezing the width of the canal bottom basically remains unchanged or changes only little. These observations also illustrate that the connecting point of the canal bottom and the slope on the whole has no lateral displacement. As seen from the distribution of frost heave amount, it appears that there is a little more frost heave in the middle of the bottom than at both ends. Frost heaving at the toe of the slope is restrained by the slope, while the restraint action in the middle part of the bottom of the canal is relatively small.

Frost Heave Deformation and Displacement Direction on the Slope Surface: As mentioned above, when the distribution of frost heave amount on the slope surface is larger at the lower part and smaller at the upper, i.e. the frost heave amount at the base of the slope is larger than on the slope and on the top of slope, the frost heave ratio on the lower part is all along larger than that on the upper part. As the frozen layer thickens and its strength increases, frost heaving at the canal bottom affects the deformation of each point on the slope. As seen from Figure 5. for point 5 at the toe of the slope, because of its nearness to the canal bottom, at only 18.3 cm, its frost heave condition is actually just the same as that at the bottom, therefore its orientation is vertical to the bottom of the

FIGURE 4 Process curve of freezing and thawing at the base of slope, Xiangyang east main canal. 1 Frost heave, 2 Thawing process.

FIGURE 5 Locus of the displacement of observed points on the face of right side slope on the Xiangyang west main canal. 1,2,3,4,5...number of observing points, 6...observed points on 6 Jan. 1981.

FIGURE 6 Observed points.

canal. The orientation of displacement of other points on the slope surface retains an including angle with the slope surface smaller than 90° , and the value of θ smaller while nearing the top of the slope. At point 2 near the top before Jan. 6, $\theta=0$ ie the displacement orientation is mainly along the direction of slope. The deformation value of each point on the slope surface, in addition to its own frost heave, also includes part of the deformation from the upward thrust caused by frost heaving at the canal bottom.

Shortening of Slope During Freezing: Although there is a difference between the frost heaving at the upper and lower parts of the canal slope, there may be no lateral displacement at the toe of the slope during the period of freezing. Therefore, as the cross-sectional line at the canal bottom is lifted during freezing, the length of the canal slope surface line is shortened. The amount of the shortening is related to the difference between the frost heave amount at the toe of the slope and at the top. The larger the difference, the greater the amount of shortening, and vice versa. TABLE 2 gives a practical example showing the amount of displacement and the shortening amount along the slope direction of all the measured points on the right slope throughout the freezing period at the Xiangyang west main canal.

TABLE 3 shows the shortening amount of distances between measured points on the same cross-section from 1 Dec. 1981 to 11 March 1982. This could further prove that in the course of freezing, the canal slope shortens while the width of the canal bottom basically stays unchanged.

Though the line of the slope deformation during freezing is slightly curved, it could be taken as linear with only little effect on the length of the slope surface. In this way, the shortened amount could be expressed approximately by the

FIGURE 7 Diagram of contracted amount on the side slope. 1 Line of cross-section of the canal after freezing, and 2 Line of cross-section of the canal in original state.

TABLE 2 Displacement and Contraction Between the Observed Points on the Side Slope of Xiangyang West Main Canal.

	7 - 8	0.9	
	8 - 9	1.9	

following formula:

$$AB = B - \sqrt{B^2 - 2Bh \cdot \text{Sin} \alpha} \quad (1)$$

Where ΔB is the shortened amount of slope, in cm
 B is the distance between two calculated points, in cm,
 α is the original slope angle of the canal, in degrees. (See Figure 7),
 when $\frac{h}{B} \leq 0.1$, eq 1 could be approximately expressed by:

$$\Delta B = h \cdot \text{Sin} \alpha \quad (2)$$

For example, on 20 March 1981, the frost heave amount measured at the foot of the right slope of the canal is 14.8 cm, and the frost heave amount at the top of the canal is 0.5 cm, giving a value of difference of frost heave amount $h=14.3$ cm. The calculation gives

$\Delta B = h \cdot \text{Sin} \alpha = 14.3 \cdot \frac{1}{13} = 7.9$ cm while the value from actual measurement is 7.0 cm (see Table 2).

Deformation of Canal Cross-Section During Thawing: The side slope of a canal shortens during the period of freezing, but in the process of thawing it generally resumes its shape. Following the thawing and settlement of the toe of the slope, the canal bottom with the down-slide of the thawed layer and the thawed layer at the canal bottom is compressed and narrowed. TABLE 4 shows the actual measured data at the Xiangyang west main canal. Under the condition of a frost heave amount difference value at 16.3 cm, the right slope surface with a length of 314 cm and

the left slope surface with a length of 238 cm have a downward slide of 6.7 cm and 7.1 cm, respectively. During the same period, the width of the canal bottom contracts 6.8 cm.

Under the condition of a very large frost heave amount and a very high moisture content in frozen soil, as in Figure 8, downward slide or slope slipping of the embankment of the canal often occurs.

During thawing, the moisture in the upper part of the soil drains away through the pores in the surface layer of the thawing soil, and the upper part of the soil settles under its own weight and is compacted, reducing its permeability. The drainage condition of the thawing soil in the deep layer is due to heaving of a frozen layer below

FIGURE 8 Variation of water content before and after freezing, Xiangyang east main canal.

it and a thawing layer with small permeability over it. Consequently, this thawing soil layer with high moisture content slides down along the surface of its underlying frozen layer, simultaneously creating slope slipping with the thawed soil above it. Such a hazardous freezing-thawing phenomenon frequently occurs at the sections of deep excavation at pumping stations and canals, giving great trouble to the management of engineering works. Every year large amounts of silt deposits must be removed before irrigation to facilitate channelling water into the fields.

FROST HEAVE DEFORMATION OF CANAL AND LINING PAVEMENT

To reduce the canal seepage loss, resist erosion, and ensure the stability of the canal, various types of lining pavement should be provided for canal. However, in cold regions, since the lining usually is not adaptable to frost heave deformation, frost damage problem is generally present in engineering works. There are a lot of different kinds of materials and different types of lining for canal, here we will lay emphasis on discussing concrete plate lining for trapezoid canal, which is a representative canal type widely used in engineering practice and has more frost damage problems.

The Main Cause of Destruction

The difference of frost heave amount between two certain points at the foot of and on the top of slope or on the slope surface arouses the contraction of the slope and causes the bottom face of the lining plate to receive a contracting pressure resulting from the freezing force between the lining plate and soil of the slope surface. These are the main reasons for the destruction of lining plates. Under such condition of reception of force, the lining plate would be subjected to different forms of destruction of different types.

When the lining plate bends and force is received at a deviated centre, the lining plate will be broken at point O as Figure 9, furthermore, it will heave up and hollow out in the process of slope shortening as Figure 10. When there is longitudinal expansion joint between

FIGURE 9 Deformation of lining plate in the process of freezing. 1 Line of cross-section of the canal in original state, 2 Line of cross-section of the canal after freezing, 3 Lining plate of slope after bending, 4 Lining plate hollowed out down below, 5 Sealed top with cement sand grout, 6 Lining plate and soil bed frozen together, 7 Direction of frost heave at the base of freezing soil bed, 8 Frozen soil bed.

FIGURE 10 Lining plate bulging and hollowed out down below, in cm. 1 Lining plate in 50X50X8, 2 Lining plate swelling and caving, 3 Line of cross-section of the canal after freezing, 4 Line of cross-section of the canal in original state.

FIGURE 12 Bulging of lining plate at top of the embankment, in cm. 1 Lining plate, 2 Line of cross-section of the canal after freezing, 3 Line of cross-section of canal in original state.

lining plates on the slope surface, and if the plate above the joint remains unmoved while that below it heaves up gradually following the frost heaving of the slope surface, then the plates on the opposite sides of the joint will be staggered as (FIGURE 11). When the plate on the upper part does not stick very strong with the base soil by freezing or plastic thin film or sand gravel underlying layer is provided, then comparatively thick surface plate will move upward along the slope surface in a whole piece and protrude (Figure 12). When the inequality of frost heave amount along the slope surface is comparatively great, the middle and upper part of the lining plate on the slope surface would often hollow out as shown in Figure 9. If the plate is rather thin and the section hollowed out is rather long, then the plate will fail and break under its own weight. If prefabricated plates are used for protecting the surface, several terraces may take place.

The destruction location of the lining plate from bending is related to the deformation state

of the slope surface during freezing and the restrictive condition of the frozen layer to the plate body, and generally it is at a place about 40-60 cm above the bottom of the canal. After the appearance of crack, the heaving up and hollowing out of the lining plate will occur in the process of continuous frost heave displacement at the bottom. The frost heave hollow-out amount can be calculated by the following formula:

$$H = \frac{1}{2} \sqrt{2B \cdot \Delta B - B^2} \quad (3)$$

Where H is the frost heave hollow-out amount in cm, B and ΔB share the same symbols in eq (1).

The frost heave hollow-out amount H is related to B and ΔB . When B=100, 200, and 400 cm, and if $\Delta B=5.5$ cm, the amount of frost heave deformation aroused would be 16.3, 23.0, and 33.0 cm respectively. It could be seen that a small frost heave amount might bring about a big heave deformation. In the investigation of frost damage, it could often be seen that the concrete plate near the foot of the slope heaves up outwards and vertically to the slope surface and the height of the upheaving is about 10-20 cm, a result of such frost heaving action. Therefore, in the design of canal lining, measures should be taken to prevent the heaving-up and hollowing out of the plate as far as possible.

Types of Lining

To alleviate the damage of frost heaving to the lining, it is necessary to raise the seepage prevention property of the lining so as to lower the moisture content and the frost heave amount in the base soil on the one hand and to select the lining materials that are adaptable to the frost heave deformation in the base soil on the other hand. In cold regions, soft lining is preferable. Engineering practice shows that using thin membrane, plastic thin film, asphalt felt, etc. to prevent permeation and prefabricated concrete plate as protective layer is a better way for lining. Its adaptability to deformation depends on the length of the prefabricated plate and the material used to fill the seams. Previous calculation indicates that under the same conditions of frost heaving, the amount of upheaving and hollowing out of prefabricated plate is directly proportional to the length of plate (along the direction of slope). With the smaller length of plate, the up-heaving and hollowing out amount is smaller and subsequently its adaptability to the frost heave deformation is higher. We are of the opinion: the length of the prefabricated plate running in the same direction of the slope should be 50 cm for the canal with greater frost heaving amount, while 100 cm for the canal with smaller frost heaving amount. The seam between the prefabricated plates should be at about 1.5 cm which is to be filled with stiff asphalt sand mortar, a mortar won't be squeezed out at high temperature, serves as a buffer between plates during frost heaving and restores the prefabricated plates to their original position under their own weight during thawing in the base soil. If the plates are directly connected and cement mortar is used for filling the seams, they are easily breakable, and once up-heaved

and hollowed out, for the great friction between plates, restoration to their original position following thawing is impossible, thus reducing their protective ability to the thin film.

Lining of canal, besides as a means to prevent seepage, is also used to guard against erosion and wash out from freezing and thawing. If a layer for antifiltration and drainage is added under the antiseepage thin film, under certain condition, the action of slope slipping during freezing and thawing could also be resisted. If a layer for antifiltration and drainage at 15-20 cm thick is added to the canal lining for small size side slope, the consolidation by drainage in the surface soil layer could be accelerated during thawing. It would together with the lining resist slopeslipping during thawing in the deep layer. For the stability of side

slope, the degree of slanting of the slope may be reduced. For the canal with deep excavation, especially when the level of ground water is much higher than the bottom of the canal, for the sliding force is too great and lining is ineffective to prevent sliding of the slope, then ground pipe should be considered for use.

VENTIFACTS AS PALEOWIND INDICATORS IN A FORMER PERIGLACIAL AREA OF
SOUTHERN SCANDINAVIA

Harald Svensson

Geographical Institute, University of Copenhagen, Copenhagen, Denmark

Studies of ancient wind activity have been performed in a coastal area of southern Sweden, situated below the highest shoreline of Late Weichselian time. The area is composed of fluvioglacial and eolian deposits. Cultivated fields show very distinct patterns (crop marks) of cast ice-wedge polygons. Pavements of intensely blasted stones are found below an eolian sand cover. Many ventifacts are sculptured with two facets. Larger, well-anchored ventifacts have been studied in detail (fluting and grooving) to determine the active wind direction. The main directions of wind-blasting are from the ENE-ESE and W-SW sectors. The east-facing facets are the most numerous and generally also represent the greatest re-shaping of the stones. According to shoreline chronology, the area was deglaciated about 13,000 B.P. and constituted a periglacial environment. During this period the area was constantly influenced by steady, easterly winds from the nearby ice cap, shaping the east-facing facets. The west-facing facets are considered to have been formed during the Allerød period (11,800 to 10,900 B.P.).

LOCATION AND EMPIRICAL FINDINGS OF THE PERIGLACIAL
ENVIRONMENT INVESTIGATED

The research area (Figure 1) constitutes a plain at the Laholm Bay, southern Sweden ($N56^{\circ}30'$, $13^{\circ}E$), situated below the highest shoreline (55-60 m a.s.l.) of Late Weichselian time and composed of fluvioglacial sand and gravel, which was reworked by the sea during the isostatic upheaval of the land. Formerly having been a heath, the area is now intensely cultivated.

FIGURE 1 Index map. The location of the area investigated is shown by the black rectangle.

Indications of large-scale polygon patterns were first observed as faint lines on aerial photographs (Svensson 1962). Later the presence of polygons was demonstrated as crop marks (Figure 2) outlining patterns of higher-growing cereals (barley and oats). In vertical sections cut through the lines, funnel-formed casts show up (Figure 3), so the observations clearly confirm the existence of a fossil pattern of ice-wedge polygons. In some parts of the area, dry valleys occur whose existence can

clearly be associated with the polygon pattern that indicates a thermokarst origin of the valley

FIGURE 2 Oblique aerial view of fossil ice-wedge polygons in cultivated fields.

FIGURE 3 Pseudomorph of ice wedge. Due to higher moisture content the infilling contrasts clearly with the coarser side soil.

trains. In total, the geomorphologic evidence proves the area to have been underlain with permafrost during a period after the withdrawal of the Weichselian ice sheet.

PRESENT-DAY WIND ACTIVITY

The top soil of the cultivated area is mostly made up of sand, and sections indicate the origin to be wind accumulated. At the Laholm Bay, coastal dunes are active, and by means of aerial photographs, contours of fossil dunes can be observed also in some fields located at a greater distance from the sea. Stones are not frequent in the cultivated fields, but some stones found show wind-blasted surfaces.

During dry seasons, especially in early spring, sand drift normally occurs for some days. The blasting may thus be a present-day phenomenon, but it may also be of an older date. Anyhow, these blasted stones cannot be used for a determination of active wind directions, as they have been turned again and again during cultivation.

PAVEMENTS OF OLD WIND-BLASTING

During the research of the fossil periglacial features of the Laholm area, gravel pits have regularly been observed for studies of sections since 1962. During these inspections a pavement of wind-blown stones was found at the village of Våxtorp, 14 km from the present coast, and later also at the village of Veinge, 12 km farther to the north and at a distance of 8 km from the coast. The altitudes are 54 and 55 m a.s.l. respectively, which means a few meters below the highest shore level of Late Weichselian time.

At both localities the pavements are composed of well-rounded, 5-20 cm blocks of granite and gneiss. Geomorphologically they belong to a fluvio-glacial delta complex accumulated at the highest shoreline during the deglaciation. The blocks are well anchored in the underlying gravelly material and have for a period of time constituted a sea-washed zone during the isostatic upheaval of the area. Later the stone pavement was exposed to deflation and thereafter preserved under a cover of wind-blown sand. In the sometimes more than 1 m thick sand cover, fossil frost structures occur (Svensson 1973a), a fact that proves the wind-blasting not to be recent or subrecent but belonging to an early period of an arctic climate.

The wind-blasting of the pavement is evidenced by a smooth polish with furrows, or elongated hollows starting from rock structures or mineral aggregates in the stone surface. The intensity of the blasting is, however, most conspicuous in the resulting facets which, because of the well-rounded form of the stones, constitute a distinctly outlined new element of the surface (Figure 4).

PREPARATION AND SELECTION OF STONES FOR ANALYSIS OF ACTIVE WIND DIRECTION

From the first inspection of the pavements it was obvious that many of the wind-worn stones show-

FIGURE 4 Ventifacts from the Våxtorp gravel pit.

ed facets. In order to determine whether any significant directions of wind erosion could be established, 325 blocks were collected at the Våxtorp locality and 400 at the Veinge locality. At Våxtorp the blocks were dug out in a vertical section, the strike and dip of the block surface were marked and noted, and the blocks brought for analysis in a laboratory with adequate light conditions. Out of the 325 blocks, 100 were chosen for detailed analysis. Criteria of the choice were (besides marked wind-blasting) that the blocks were larger than 10 x 10 x 5 cm and had an almost plane bottom surface. Taking into consideration that the pavement is anchored in a gravel surface, it is supposed that the two characteristics are a fair guarantee that the blocks were hardly moved, turned, or dipped during deflation. At the Veinge locality the pavement was uncovered and the study thus made in a horizontal section (Figure 5). The selection and analysis of 100 stones were made in situ in the pavement, as adequate light conditions were provided on the sunlit ground surface. Otherwise the same criteria for selection of specimens were used as at the Våxtorp locality.

FIGURE 5 Part of uncovered pavement at Veinge. Most of the larger stones are modeled with facets.

It is worth noting that among the large number of blocks observed, no "Dreikanter" were found. The formation of "Dreikanter" is usually explained by the assumption that a stone was turned more times, facing new sides toward the eroding wind. Ventifacts with two facets have been found, one facing eastward and one westward, the east-facet always

being the larger one.

DIRECTIONS OF ERODING WIND

The wind-worn microforms, wind furrows and elongated hollows (Figure 6), make possible a determination of active wind direction(s) on each stone. The directions are measured with a compass within 2° , and the values placed in sectors of 22.5° . From Table 1 it is evident that there exist two maxima for each locality, one main and one secondary maximum. At Våxtorp the main maximum is centered in the E-sector and at Veinge in the ENE-sector. Because of fewer observations the secondary maxima have not the same degree of significance. It is, however, worth noting that they are found in westerly sectors: at Veinge in the WSW-sector and at Våxtorp in the SW-sector.

TABLE 1 Initial Directions for Wind-Blasting

	N	NNE	NE	ENE	E	ESE	SE	SSE	S	SSW	SW	WSW	W	WNW	NW	NNW
Veinge	1	3	18	33	27	12	3	0	1	0	4	7	4	5	1	0
Våxtorp	0	3	8	10	34	20	17	3	1	1	13	8	7	4	4	0

Number of investigated blocks is 100 at each site. Several blocks show wind-blasting from more than one direction.

Based on the frequent occurrences and the intense reshaping of the blocks, it can be stated that the blasting from the east has been far more active than the abrasion by westerly winds. A few ventifacts have been found on which an east-facing facet meets a westward facet in an intervening edge. On such stones the westward facet was developed over the eastward facet, which thus gives their relative age, namely the westward facet was last formed.

CHECK OF THE DETERMINATIONS OF ACTIVE WIND DIRECTIONS

After detailed studies of ventifacts at Våxtorp and Veinge had been performed, two new observations were made that can be used to test the reliability of the measurements of active wind direction on the ventifacts.

The first observation was made in the gravel pit at Våxtorp, where a huge ventifact (side lengths, 4.4, 3.2, 3.1, and 2.1 m; height, 2.0 m) is exposed. The upper part of the block was embedded in wind-blown sand, whereas the basal part lay enclosed in the original beds of fluvioglacial gravel. Because of its dimensions and stable foundation this block must be considered stationary under the deflation phase and its records of wind direction consequently of greater reliability than those of the smaller ventifacts. The block is intensely blasted and contains a lot of facets, the largest being 1.7 m wide (Figure 7). On the eastern, upper side of the block a very distinct direction of wind erosion is found all over the surface, namely from S76E. This is in good agreement with the result of the measured directions on ventifacts in the same

FIGURE 6 Close-up view of block in situ abraded by easterly wind (from the left).

gravel pit, where the most frequent observations were from E-ESE (Table 1). Furthermore, the good agreement between the wind direction observed on the block and in the sample of wind-blown stones justifies the methods used of measuring the direction of eolian abrasion in a great number of ventifacts, well anchored in the ground, to get a fairly good reconstruction of a main wind direction.

On the western side of the huge block the main direction of wind-blasting is found to be from N57W. This direction does not coincide with the secondary maximum of Table 1. The disagreement is probably due to the fact that the total number of observations of westerly wind-worn stones is too small.

Also, for the Veinge locality a chance of testing the measured wind direction appeared. Two

FIGURE 7 Part of large wind-eroded facet on the huge ventifact at Våxtorp.

kilometers from the pavement investigated an out-cropping gneiss surface was found facing southeast and showing intense wind-blasting with strictly parallel wind furrows from N86E. As the main maximum of the measurements in the wind-worn pavement at Veinge is centered in the sectors E-ENE (Table 1), it again confirms the possibility of reconstructing a main wind direction from measurements on a large number of wind-blasted specimens. No check of the western wind-blasting found in the Veinge pavement could be performed in the out-cropping gneiss surface, as it had no slope exposed to the west. The existence of blasting from the west in rocks of the Veinge area is, however, documented in a paper by Mattsson (1957), but without giving a more precise direction (number of degrees) of the active wind. Mattsson also observed an easterly, possibly periglacial wind activity, and from the coastal area further to the north, Hillefors (1969), besides frequent observations of easterly wind-blasting, mentions wind erosion from the west at lower levels.

CONCLUDING REMARKS CONCERNING PALEO-ENVIRONMENT AND AGE OF WIND EROSION

To decide the character of the environment in which the wind-blasting acted, it is at first important to state that the ventifacts are situated just below the highest shoreline of the area developed by wave erosion in Late Weichselian time. It means that the pavements once constituted a beach area. The fluvioglacial material below the pavement contains casts of ice wedges, which demonstrates that the area was underlain with permafrost. Furthermore, the cover of wind-blown sand shows thin infillings of the character of sand wedges, which indicates that the area was affected by frost fissuring also after the deposition of the eolian sand. From these facts it is quite clear that the wind-blasting took place in an arctic environment shortly after the isostatic upheaval of the innermost parts of the coastal plain.

From marginal deposits accumulated during the deglaciation of the area, it can be stated that the front of the receding ice cap had a NNW-SSE direction in the coastal area (Mohrén and Larsson 1968, Mörner 1969), indicating that the Våxtorp and Veinge localities had been subject to periglacial conditions outside the ice cap during its retreat eastward.

The steady easterly winds responsible for the intense wind-blasting of the pavements were caused by the ice cap, either as an element in the general circulation from a high-pressure cell, or simply as a catabatic effect just outside the ice margin. During this first period of wind-blasting the abrasive material may largely have been snow (ice crystals) at very low temperatures.

The younger westerly wind-blasting corresponds to a later period of deglaciation, when the glacial high pressure had moved northward, and west-wind systems could penetrate into the area. At that time, vast areas of sand deposits were set free from the sea due to the isostatic upheaval of the land and could supply material for the blasting as well as for the burying of the pavements.

Chronologically the eastern wind-blasting be-

longs to an early period of Late Weichselian time. According to a shoreline diagram of the Swedish west coast constructed by Mörner (1969), the Våxtorp and Veinge areas were raised above sea level 12,900 and 12,700 years B.P., respectively, which may thus be considered the earliest starting time of the intense eastern wind activity.

A chronological determination of the western wind-blasting is more difficult. As the covering sand shows frost fissures, the blasting must have been followed by a period of arctic climate. This fact points to the Allerød chronozone (11,800 to 10,900 B.P.), a period in which a west-wind regime is considered to have started. Furthermore, the Allerød period was followed by a period of cold climate, the Younger Dryas chronozone. That the area was really affected by frost-fissuring during this period is also documented by the existence of fossil ice-wedge polygons in the western, lower parts of the coastal plain (Svensson 1973b). To reach a more than hypothetical dating of the western wind-blasting, however, more observations of wind-worn blocks or outcrops, especially in lower levels of the area, are needed.

HEAT AND SALT TRANSPORT PROCESSES IN THAWING SUBSEA PERMAFROST AT PRUDHOE BAY, ALASKA

D. W. Swift, W. D. Harrison and T. E. Osterkamp
Geophysical Institute, University of Alaska, Fairbanks, Alaska 99701

The thickness of the subsea thawed layer near the West Dock, Prudhoe Bay, Alaska, and its temperature, pore water salinity and pore water pressure are described. The pressure data are the first of their kind and provide good evidence for non-hydrostatic behavior that is probably due to pore water motion. Present knowledge of heat and mass transport mechanisms controlling the thawed layer development is summarized. Heat transport is conductive, but salt transport (necessary because temperatures are negative) is by pore water motion, probably on the order of a few tenths of a meter per year. What drives the motion is still uncertain. Driving by the release of relatively fresh, buoyant water by thawing must occur, but it may not provide enough energy to explain the observations. Driving by surface wave action seems unimportant, at least at West Dock.

INTRODUCTION

During the past decade or so of high interest in subsea permafrost, it has become increasingly obvious that subsea permafrost is a different material from its subaerial analogue. The most obvious reasons are the transient nature of subsea permafrost, and the important and complex role of salt in its evolution. The importance of salt is particularly obvious when ice-bearing subaerial permafrost is inundated by shoreline retreat, and a thawed layer develops beneath the sea bed even though mean annual sea bed temperatures are negative, over most of the Beaufort Sea shelf of Alaska. Much of the salt necessary for thawing in this negative temperature regime probably enters the sediments after inundation, although the transport of salt obviously would not be necessary in sediments that were sufficiently salty initially. Since lithology can influence the thaw rate by several orders of magnitude, it is clear that physical and chemical controls on the salt transport process must exist. In near shore regions where new subsea permafrost formation is rapid because of rapid shoreline retreat, its evolution in response to the salty, relatively warm sea water is correspondingly rapid. Prediction of the response of subsea permafrost to natural or man-made changes in sea bed boundary conditions given the lithology, is a task that cannot yet be accomplished because of an inadequate understanding of salt transport mechanisms.

This paper focuses on the observations and interpretations from the West Dock area, Prudhoe Bay, Alaska, that have a more or less direct implication for the heat and salt transport mechanisms operating in the thawed layer there. The data are described in greater detail in a series of reports, the most relevant of which are Osterkamp and Harrison 1976, 1980, 1982a; Harrison and Osterkamp 1977, 1981a. Additional data reduction has led to some small differences

between the reports and this paper. Additional research has been carried out by several other investigators in this area (Sellman, 1980; Harrison and Osterkamp, 1982; Smith et al. and Morack and Rogers, in press). Data were obtained along a single line bearing N 31.5° E from North Prudhoe Bay State Number One well (Figure 1). The sediments are thick in this area, exceeding the permafrost thickness on shore of 560 m at the well. They consist mainly of alluvial material overlain by several meters of recent silty marine sediments. The shoreline retreat rate is roughly 1 m per year. The water is shallow, reaching 3 m depth about 3 km from shore. At the sites from which the data in this paper were obtained, the spring sea ice thickness usually equals or exceeds the water depth, although several hundred meters or more from shore it may occasionally be lifted by tide.

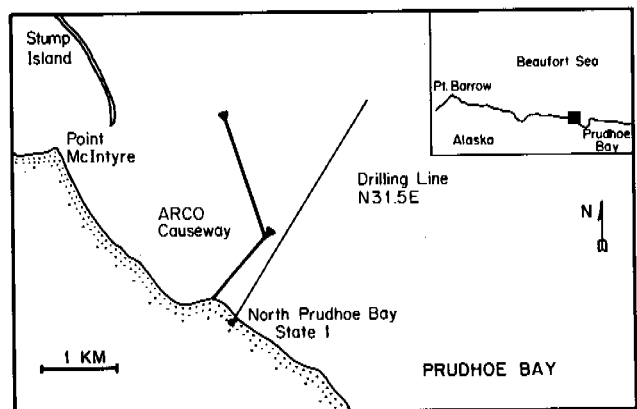

FIGURE 1 Location map of study area.

RESULTS

We begin with a summary of the results which give the most obviously direct information about heat and salt transport processes in the thawed layer at the West Dock. Old results are briefly summarized; new ones are described in more detail.

Theory

It has been shown (Harrison and Osterkamp 1978) that convection of the pore water in the thawed layer should occur at the West Dock, basically because relatively fresh and therefore buoyant water is generated by thawing of ice at the bottom of the thawed layer. This will be referred to here as gravity driven convection. To be effective the hydraulic conductivity of the sediments must not be too small.

Phase Boundary Definition

Present drilling and probing data indicate that the transition between ice-free and ice-bearing sediments at the bottom of the thawed layer, which we refer to as the phase boundary, is sharp at the West Dock. This implies that thawing is occurring in response to salt transport through the thawed layer, and not predominantly in response to salt that was present before the permafrost was submerged by changing shoreline position (Harrison and Osterkamp 1982).

Phase Boundary Shape, Shoreline Retreat Rate, and Mean Annual Temperature

Although there is an uncertainty of a factor of 2 or more, the shoreline retreat rate at the West Dock is on the order of 1 m yr^{-1} . To the extent that conditions have not changed in the last few thousand years or so, the offshore distribution of the thawed layer thickness, the phase boundary shape, can be interpreted to give the thaw rate over past time. The shape is shown in Figure 2. Little thawing seems to have taken place within 400 m of shore, but in the next 40 meters there is a "ramp" area where the phase boundary drops rapidly and more or less linearly. Beyond this the phase boundary is almost parabolic out to several kilometers from shore (Harrison and Osterkamp 1982, Osterkamp and Harrison, 1982b). The behavior of the ramp area is not yet understood, because its steep slope implies a thaw rate too rapid to be understood with any reasonable sea bed temperature model. However, beyond the ramp the parabolic shape must be due to the expected approximate $\sqrt{\text{time}}$ thickness dependence, and it seems fairly safe in this region to estimate thaw rate from phase boundary shape and shoreline retreat rate. The result (typically several hundredths of a meter per year) is much too fast for the necessary salt transport to be by molecular diffusion, given the typical mean annual sea bed temperature of -1°C (Harrison and Osterkamp 1978).

FIGURE 2 Depth to the base of the thawed layer.

Hydraulic Conductivity and Porosity

Hydraulic conductivity probably controls the transport regime through the thawed layer. Several profiles of it have been measured through the thawed layer in the course of pore water sampling, by determining the rate at which water enters the pore water sampling probe (Harrison and Osterkamp 1981b). These measurements tend to indicate a fairly constant distribution of hydraulic conductivity with depth, typically from 1 to 10 m yr^{-1} , which implies a scatter of perhaps a factor of 3 about some mean value. In the formulation of the simplest theory for heat and mass transport through the thawed layer based on Darcy's law (Harrison 1982), the porosity enters as well, but when it can be considered constant, only the combination, hydraulic conductivity to porosity ratio, enters. Unfortunately, probing does not determine porosity, and a value of 0.4 characteristic of deep samples on shore (Lachenbruch et al. 1982) is taken as representative. A typical hydraulic conductivity to porosity ratio is then 10 m yr^{-1} .

The uncertainty in porosity, the possible importance of anisotropy in hydraulic conductivity, and the method of measurement of hydraulic conductivity all leave something to be desired. The measurement problem is due to the possibility of clogging of the probe filter and filter guard through which the pore water is collected, and the fact that the incoming flow rarely obeys Darcy's law. The possibility of significant systematic errors in hydraulic conductivity to porosity ratio therefore still seems open.

Temperature

The linearity of temperature profiles below the depth of seasonal fluctuations suggests that heat transport, unlike salt transport, is essentially diffusive, or conductive; that is, it is not influenced appreciably by pore water motion. This means that the Peclet number for heat, a rough measure of the ratio of convective to diffusive transport, is significantly less than one, which translates into a typical vertical component of pore water velocity significantly less than 1 meter per year (Harrison and Osterkamp 1982, Osterkamp and Harrison 1982). Although not

completely convincing, because of complications due to seasonal temperature variations and other factors, there is some evidence for curvature in some temperature profiles that could possibly be due to pore water motion on the order of several tenths of a meter per year (Figure 3).

FIGURE 3 Temperature profile through the entire thawed layer thickness in hole 435-1981, June 2, 1981. The leading digits in the hole number represent the distance in meters off-shore from a fixed mark near the tundra edge; it is the same reference mark used in the 1980 holes. Except for the point at about 4.5 m depth the temperatures are probably within a few hundredths of a degree of equilibrium.

Pore Water Chemistry

Although there are detectable differences, the pore water chemical composition resembles that of sea water (Iskandar et al. 1978, Page and Iskandar 1978). This may be evidence for a fairly efficient pore water flushing mechanism.

Pore Water Salinity

Pore water samples were collected through the thawed layer using lightweight driving equipment and specially designed sampling probes (Harrison and Osterkamp 1981b), and the electrical conductivity was measured in the lab to precision and accuracy of 0.5% or better. Since, as noted previously, the chemical composition is similar to that of sea water, salinity can be estimated from conductivity by standard methods. Recently measured pore water conductivity profiles exhibit most of the characteristics of those determined previously, notably the small gradients expected in a strongly convecting system. The large gradient observed in a very thin layer above the phase boundary, at the bottom of the thawed layer,

is interpreted as a boundary layer over which the transport regime changes from convective to diffusive. The lower parts of two profiles from holes about 421 and 441 m from shore are shown in Figures 4a and 4b, along with probe driving information.

FIGURE 4a Pore water electric conductivity (right profile) and blows required to drive the sampling probe 0.15 m (left profile) at hole 421-1981, May 31/June 1, 1981. Length of sampler was 0.1 m. The point labelled F.P. is the conductivity at the phase boundary as estimated from temperature data in hole 420-1981, 1 m closer to shore

The boundary layer feature is not so obvious as Figure 4 would indicate, because once the probe tip encounters ice, there is enough probe driving energy available to melt some of it, possibly diluting the samples and giving an erroneously low conductivity at the deepest point. Nevertheless, the conductivity has already begun to decrease at the second greatest depth, which is a consistent feature. However, the magnitude of the conductivity jump across the boundary layer cannot be estimated very accurately from these data. The result of an attempt to improve the estimate by determining the conductivity exactly at the boundary from measured temperature and freezing point data is labelled F.P. in Figure 4. The error bars are for a temperature uncertainty of 0.03 K, which may be optimistic, because while the agreement in Figure 4b is satisfactory, that in Figure 4a is not. It is concluded, however, that the conductivity (or salinity) jump across the boundary layer is typically very small, not much more than a few percent,

which is similar to previous estimates at different sites (Harrison and Osterkamp 1982).

FIGURE 4b Pore water electrical conductivity (right profile) and blows (left profile) at hole 441-1981, May 28-30, 1981. The point labelled F.P. was estimated from temperature data in the same hole.

If convection of the pore water is the dominant salt transport mechanism, it is likely that the typical vertical component of velocity considerably exceeds the thaw rate ($\approx 0.03 \text{ m yr}^{-1}$ 700 m from shore). Otherwise a convecting parcel of water would have to give up most of its salt as it approaches the phase boundary, a condition that seems unlikely because of the small salinity variation in the thawed layer.

Pore Water Pressure

The most direct evidence so far for pore water motion comes from a pore water pressure profile measured through the thawed layer at one site. It was obtained with a commercial pneumatic piezometer connected to the filter assembly of a pore water sampling probe. The result from a hole about 441 m from shore is presented in Figure 5 as the difference between pressure and hydrostatic pressure. The latter was calculated from the density profile implied by the known electrical conductivity (salinity) of the pore water; density is almost independent of temperature under the prevailing conditions. The result shows a small deviation from hydrostatic pressure, which appears to be a real effect, but with two qualifications. First, the pressure

gauge used was calibrated before and after use to standards traceable to National Bureau of Standards, but the transducer was not. However, the nonhydrostatic effect exceeds by an order of magnitude any effect of system nonlinearity as specified by the manufacturer (Sinco, Seattle, WA). Second, the effect could be caused by a deviation of the probe from the vertical of 10° , which seems extremely unlikely but not impossible. The nonhydrostatic effect, amounting to about 0.23 m head over a depth of about 14 m, appears to be real.

FIGURE 5 Pore water pressure minus hydrostatic pressure in hole 440-1981, May 27-30, 1981.

Certain other observations are also important. First, tide was measured by observing the level of water in a nearby hole through the sea ice, referenced to a probe driven securely into the sea bed; typical peak-to-peak amplitude was about 0.15 m. It is interesting that pore water pressure variations of approximately the same amplitude and phase occurred at least below the 5 m depth, although the ice did not float at the hole, and there was probably some seasonal ice formation in the sea bed above 1.45 m depth. The tide data used to correct the piezometer pressure data, which were obtained at different times and therefore at different tides. Second, failure to obtain expected system resolution (7 mm head) at depths less than 4 m may have been instrumental or operator related, or may have been due to the time varying in situ conditions. Third, an exponentially decaying pressure transient after driving the probe was observed at depths up to 3.3 m. Fourth, the point marked "freezing" in Figure 5 was obtained after the piezometer had been at the phase boundary for 34 minutes and could be due to freezing in or around the piezometer. Fifth, the high pressure at 0.54 m depth is probably related to the seasonal freezing in

the shallow sediments indicated by temperature and conductivity data.

The solid line is a least squares fit to the data below 5.72 m. Its slope indicates an average head gradient of -0.016 , which would indicate a downward vertical component of pore water velocity, the opposite direction to what would be caused by thaw consolidation, for example. Given a representative value of 10 m yr^{-1} for the hydraulic conductivity to porosity ratio discussed earlier, the implied velocity component would be 0.16 m yr^{-1} , which is of the expected order of magnitude in the light of previous discussion, and therefore suggests that the error in hydraulic conductivity to porosity ratio is not large.

Summary

The general conclusion is the following: Salt transport is rapid relative to molecular diffusion. The mechanism is probably convection of the pore water, with a typical vertical component of velocity on the order of a few tenths of a meter per year.

GRAVITY DRIVEN CONVECTION

Pore water motion can provide the necessary rapid salt transport, and good evidence for its occurrence now exists. However, to predict anything from first principles such as lithology and sea bed boundary conditions, we must understand what drives that motion. For example, is the energy source "external", driven by motion of the overlying sea water, or is it "internal", with the energy source below the sea bed? In the latter case the likely energy source would be the gravitational energy of the relatively fresh, and therefore buoyant, water released by thawing at the bottom of the thawed layer. This process will be called gravity driving, and we can investigate whether the energy it can supply is sufficient to explain the observations. A two-dimensional model is used.

If the pore water motion is governed by Darcy's law, it is straightforward to show that the frictional power (F) dissipated in the pore volume of the thawed layer is given by

$$F = \int \int \frac{\rho_r g}{k} v^2 dx dy \quad (1)$$

where g is the gravitational acceleration, k is the ratio of hydraulic conductivity and porosity, ρ_r is a reference density used in defining the head unit, v is the pore water velocity, and x and y are the horizontal and vertical coordinates. The power (E) available from gravitational potential energy release is given by

$$E = \int \beta \Delta \rho g Y \frac{dY}{dt} dx \quad (2)$$

where $\beta < 1$ is the fraction of H_2O in the solid state just below the phase boundary ($\beta < 1$ if

the salt content is unequal to zero there), $\Delta \rho$ is the density difference between the water at the sea bed and that at the phase boundary, Y is the thawed layer thickness, and dY/dt is the thaw rate. The maximum energy would be available if $\beta = 1$, and if $\Delta \rho$ had its maximum value ($\Delta \rho_{\text{max}}$) corresponding to fresh water at the phase boundary. In fact, the available mechanical energy will usually be considerably less, because of its transformation to chemical energy by diffusion. When spatial variations of Y and dY/dt are ignored, Equations (1) and (2) give the following constraint on the rms velocity ($\sqrt{v^2}$):

$$\sqrt{v^2} < \left[\frac{\Delta \rho_{\text{max}}}{\rho_r} \frac{dY}{dt} k \right]^{1/2}$$

For an apparently typical sea bed salinity of 43 ‰ $dY/dt \approx 0.03 \text{ m yr}^{-1}$ (700 m from shore), and $k \approx 10 \text{ m yr}^{-1}$ (Harrison and Osterkamp 1982) this gives

$$\sqrt{v^2} < 0.1 \text{ m yr}^{-1}$$

Since any convecting pore water velocity field is probably highly non-uniform, v could be considerably less than $\sqrt{v^2}$.

The net result of all of these factors is that conservation of energy applied to gravity driving seems to imply mean velocities considerably less than 0.1 m yr^{-1} . This seems too low in the light of the conclusion at the end of the previous section.

DISCUSSION

Although this calculation raises serious doubt that the gravity driving mechanism by itself will be able to explain the observations, we do not feel that it is entirely ruled out at the present stage of field observation and interpretation. A more complete interpretation, which includes the possible effect of convective driving from the sea bed by salinity variations there, awaits our completion of a numerical calculation of the pore water velocity field. In the meantime, it is clear that other driving mechanisms should be considered.

This has been done already for the most obvious of the possible "external" mechanisms, the driving of pore water motion by sea surface wave action, and its effect on salt transport into the sea bed. Harrison et al. (1983) have shown that this process, via a mechanism known in ground water hydrology as mechanical dispersion, is important where the hydraulic conductivity is characteristic of sand, but not at the West Dock where it is much smaller. This is another illustration of how the physics of the transport mechanisms through the thawed layer depends critically on hydraulic conductivity.

It should be emphasized that the brief summary in the second section does not describe all that is known about permafrost in the West Dock area, so there are probably other clues to the

processes operating there if one knew how to interpret them. Possible examples are the uniformity of the phase boundary salinity, higher salt concentration in the pore water than in normal sea water, and the presence of significant amounts of brine below the phase boundary. None of these features is understandable within the framework of present ideas. We are forced to the conclusion that despite some progress, the evolution of subsea permafrost under natural conditions is not well understood, even in the intensely studied West Dock area. It seems to follow that new ideas are needed to predict the effects on subsea permafrost of future man-made disturbances, such as hot pipelines and well bores.

ACKNOWLEDGEMENTS

We are grateful to all who have helped with the field observations, particularly to Robert Fisk, Victor Gruol and Masayuki Inone. Primary financial support was from NSF grant DPP 77-28451. Support from NSF grant DPP 81-20471, and from the NOAA-BLM Outer Continental Environmental Assessment Program, is also acknowledged.

EXCAVATION RESISTANCE OF FROZEN SOILS UNDER VIBRATING CUTTINGS

Shingi Takasugi¹ and Arvind Phukan²

¹Research Engineer, Technical Research Center, Komatsu Ltd. Kanagawa, Japan

²Professor of Civil Engineering, University of Alaska,
Anchorage, Alaska, U.S.A.

This paper presents the dynamic laboratory experimental studies of frozen sands and silts at temperatures varying from -2°C to -11°C ; using various cutting velocities from 2mm per second to 18mm per second. The 6Hz vibration mode used was varied from 1.3mm amplitude to 4mm amplitude. Theoretical analyses of the cutting resistance of frozen soils under vibration cutting are formulated to explain the failure characteristics obtained during the experimental work.

Energy ratio versus the number of contacts per inch of cutting (N_c) plots show a similar tendency for both silty and sandy frozen soil samples; that is, as the energy ratio increases, N_c increases. The contact length between the soil and the tool in a vibration cycle is inversely proportional to N_c . At high N_c , the contact length is too small to cause the soil failure and thereby increases the vibration energy. Relationships between the energy ratio and N_c at various amplitudes for both soil types, show a greater energy requirement at 4mm amplitude of vibration than at 1.3mm amplitude, in spite of the identical draft energy reduction at both vibration amplitudes. It is possible that by inducing vibration of the cutting tool, a reduction in draft energy can be obtained and thereby excavation process can be efficiently executed in frozen ground.

INTRODUCTION

Construction of foundations and installation of underground structures in the arctic and subarctic regions often require excavation in frozen ground. Various investigators (Mellor, 1977; Nishimatsu, 1972; Harrison, 1972 and Wismer et al., 1972) have reported the results of theoretical as well as experimental studies on the mechanics of cutting soils and rocks under different parameters such as width of tool, rake angle, cutting depth and speed. Smith et al. (1971), Barkan (1974), Burton et al. (1977) and Gohlieb et al. (1981) reported the results of experimental studies on coal, rock and soil cutting by vibrating tools under different test conditions of vibration amplitude, frequency, tool size and shape. Most of these reports indicated that the cutting resistance was reduced significantly with the use of the vibrating cutting mode. Since this cutting mode requires additional energy to vibrate the cutting tool, the total energy consumption per unit length of soil cut has to be compared with the energy required for static cutting to evaluate the efficiency of vibration cutting. Very little data is available regarding static as well as dynamic cutting characteristics of frozen soils. Excavation resistance of frozen soils under static loadings was studied by the authors (Phukan and Takasugi, 1982) and this work reported here is an extension of this earlier research work.

The paper summarizes the laboratory studies of dynamic cuttings of frozen sand and silt samples at temperatures varying from -2°C to -11°C . A vibration cutting mechanism was designed and used to operate at 6Hz vibration mode. The amplitude of vibration was varied from 1.3mm to 4mm to obtain the relationship between the energy ratio and the number of contacts per inch of cutting for both frozen soil types. Theoretical analyses are formulated to evaluate the failure characteristics of frozen soils under vibration cutting.

LABORATORY STUDY

Equipment

The vibrating cutting device consisting of a 3/4 H.P., DC motor with a gear reduction box, fly wheel and toggle linkage was designed and prepared as shown in Fig. 1. This device is able to produce up to 10 Hz frequency with 12.7mm amplitude vibration to the cutting tool. The vibration device was attached to the cutting tool, the sample feed device was the same one used in the static cutting test reported by Phukan and Takasugi (1982). Due to the characteristics of the toggle mechanism, the shape of the vibration was not a pure sinusoidal wave. A typical wave shape generated by this device is shown in Fig. 2.

Measurement

The horizontal force acting on the cutting tool was measured by strain gages. Two sets of four strain gages were glued on link CB (Fig. 1). Prior to the experiment, the calibration was obtained between strain and force.

A Gilmore acceleration pick-up was installed on the cutting tool and the output signal was integrated and amplified by a Gilmore Model NS04 integral amplifier. This output signal was used to activate the strain gage circuit. The output power (force x velocity) was monitored by a Hewlett-Packard plotter with respect to time. A second set of strain gages was used to monitor the force acting on the cutting tool, and the force was recorded on a Houston Instrument X-Y recorder with respect to the tranverse length.

Since the output power of Model NS04 is too small to activate the strain gage circuit, a Condyna analog computer GP6 was connected between the integral amplifier and the strain gage circuit. Details of the measurement system are given by Takasugi (1982).

Test Procedure

Initially, the samples were placed in the walk-in cold room for 24 hours to attain the required test temperature. The temperature of the soil samples were monitored until a constant desired temperature ($\pm 0.5^\circ\text{C}$) was obtained. After they remained for 8 hours at constant temperature, the prepared samples were tested.

Special attention was given to obtaining a flat surface on the sample to ensure a constant cutting depth for the entire 0.25m sample length. Each sample was cut by 6 test runs at various cutting velocities from 2.5mm to 20.3mm at a particular vibration amplitude. One of the six test runs did not employ the vibration mode.

The power and the cutting resistance were monitored as the sample was moved against the vibrating cutting tool.

Test Results and Discussion

The vibration energy was measured by means of the vibration velocity (V) and cutting resistance (F). The vibration energy (E_v) may be written as:

$$E_v = \int F \cdot V \, dt \quad (1)$$

similarly, the draft energy without vibration (E_d) is given by:

$$E_d = \int F \, ds \quad (2)$$

The energy ratio (R_e) is defined as:

$$R_e = \frac{E_v + E_d^v}{E_d} \quad (3)$$

where E_d^v is the draft energy vibration.

The number of contact per inch of cutting is calculated as:

$$N_c = \frac{f}{V'} \quad (4)$$

where

f : vibration frequency (cps)

V' : cutting velocity (cm/s)

The draft energy ratio is defined as:

$$R_d = \frac{E_d^v}{E_d} \quad (5)$$

The energy ratio and the draft ratio against N_c for frozen silt and Ottawa sand are determined at different amplitudes and freezing temperatures and the results are shown in Figs. 3 to 5, inclusive.

The reason for the reduction in cutting resistance because of vibration of the cutting tool is not well understood. There appears to be no general agreement about the fundamental cause of this resistance reduction. Some of the more common hypotheses (Barkan, 1974) are as follows:

(1) In vibration cutting, the actual contact time between the soil and cutting tool is much smaller than the overall cutting time. This reduces the friction between the soil and the cutting tool and results in reduction of cutting resistance.

(2) An interaction between the frequency of the vibrating cutting tool and the natural frequency of the soil shear plane formation results in a decrease of the cutting resistance.

(3) The pressure wave caused by the vibrating tool breaks the ice bond matrices of the frozen soil near the tool, thus reducing the soil shearing strength, and hence, reducing the resistance of the cutting tool.

No one hypothesis explains more than 60% of the reduction in resistance. A combination of the above hypotheses is required for a full explanation of the cutting resistance reduction.

The energy ratio versus N_c relationship (Fig. 3) show a similar tendency for both samples; that is, the increase of the energy ratio as the N_c increases. The contact length between the soil and the tool in a vibration cycle is inversely proportional to the N_c . At higher N_c , the contact length is too small to cause the soil failure and that increases the vibration energy.

The relationship at various amplitudes between the draft ratio and N_c is shown in Fig. 4 and Fig. 5 for frozen sand and frozen silt, respectively. These plots show a greater energy requirement at 3.81mm amplitude of vibration than at 1.27mm amplitude, in spite of the identical draft energy reduction at both vibration amplitudes.

Results at different test temperatures are also shown in Fig. 3 for sand and silt. These plots are almost identical and indicate that the temperature, within the range tested, does not have a significant effect on the results.

THEORETICAL ANALYSIS

In this analysis, the vibration is assumed to be a pure sinusoidal wave. Every time the cutting tool contacts the soil, the failure of the soil occurs.

The acceleration, velocity and displacement of the cutting tool are expressed as:

$$\text{Acceleration, } X = A \cdot W^2 \cdot \cos(W \cdot t) \quad (6)$$

$$\text{Velocity, } X = A \cdot W \cdot \sin(W \cdot t) = V \quad (7)$$

$$\text{Displacement, } X = A \cdot (1 - \cos(W \cdot t)) = V \cdot t \quad (8)$$

where

V = cutting velocity, cm/s

W = angular frequency, rad/s

A = vibration amplitude, cm

The relationship among displacement, velocity and acceleration are shown in Fig. 6.

Consider the first cycle after $t = 0$; the tool velocity is zero at both t_0 and t_r :

$$X(t_0) = A \cdot W \cdot \sin(W \cdot t_0) = V = 0 \quad (9)$$

$$X(t_r) = A \cdot W \cdot \sin(W \cdot t_r) = V = 0 \quad (10)$$

The times at which these occur are given by:

$$t = \frac{1}{W} \sin\left(\frac{V}{A \cdot W}\right)$$

or

$$t_0 = \frac{\pi}{W} + \frac{1}{W} \sin\left(\frac{V}{A \cdot W}\right) \quad (11)$$

$$t_r = \frac{2\pi}{W} - \frac{1}{W} \sin\left(\frac{V}{A \cdot W}\right) \quad (12)$$

$$t_2 = t + T \quad (13)$$

where

$$T = 2 \cdot \pi / W$$

The time t_1 when the cutting tool begins to contact is calculated from the following equation by trial and error.

$$V \cdot t_0 = A \cdot (1 - \cos(W \cdot t_0)) = V \cdot t_1 + A \cdot (1 - \cos(W \cdot t_1)) \quad (14)$$

It is assumed that the resistance acting on the cutting tool is the same as in the static condition.

Then

$$\text{Draft Energy Ratio} = \frac{t_2 - t_1}{T} \quad (15)$$

The vibration energy in a cycle may be calculated as:

$$E_v = \int_{t_1}^{t_2} F \cdot A \cdot W \cdot \sin(W \cdot t) dt \quad (16)$$

The vibration energy per inch cutting is:

$$E = E_v \cdot f / V \quad (17)$$

where f = frequency of the vibration

Then the energy ratio is:

$$E_r = \frac{E_v \cdot f}{V \cdot F} = \frac{t_2 - t_1}{T} \quad (18)$$

The equation (18) is plotted in Fig. 6 against the number of contacts per inch cutting, which may be expressed as:

$$N_c = f / V$$

Fig. 6 shows that except for small values of E_v , the energy ratio can not be less than unity. The calculated draft ratio shows a similar tendency of the test results.

CONCLUSIONS

1. In every test condition, the cutting resistance was reduced with vibration by more than 60% in both soils. The reduction of cutting increased as the number of contacts per inch cutting increased.

2. The 1.27mm amplitude vibration and 3.81 mm amplitude vibration showed the same percentage reduction of cutting resistance, but the 3.81mm amplitude vibration required more energy than the 1.27mm amplitude vibration.

3. It was found that the temperature of the samples did not affect the test results at the range tested.

4. At optimum conditions, which are 1.27mm amplitude and about 12.7mm/s cutting velocity, 50% reduction in the energy required for cutting were measured in both soils.

5. Once the vibration system fails to operate properly due to overloading, the static cutting resistance, which is about three times more than dynamic resistance, acts on the vibration system. This may produce inefficient cutting.

6. Most tractors have more than enough Horsepower to counteract the cutting resistance. In most cases, the limitation of the drawbar force of a tractor depends on the traction that its treads can develop, which is controlled by the tractor weight and soil condition. By inducing vibration of the cutting tool, a reduction in the draft can result, thus allowing smaller-sized tractors to be employed to do the same job.

7. It is recommended that further static and dynamic cutting tests should be carried out on frozen soils at additional temperatures. The geometry of the cutting tool should be investigated to arrive at a rake angle for minimum cutting resistance. The effect of ice bonding on the behavior of frozen soils under different frequencies and amplitudes of vibration needs to be investigated. Such research can lead to a major improvement in excavation techniques for frozen soils.

WINTER CONSTRUCTED GRAVEL ISLANDS

Rupert G. Tart, Jr.

Woodward-Clyde Consultants, Anchorage, Alaska 99503 USA

This paper addresses a theoretical assessment of the performance of winter constructed gravel islands with respect to settlement. The basis of the material presented is our work during the recent winters in which we have inspected several gravel islands as they were constructed in the Alaskan Beaufort Sea as well as other winter constructed gravel pads. Construction procedures used to build the islands are summarized, and the effect of technique and construction materials on the subsequent performance of the fill is addressed. Our observations indicate that total island settlement potential is primarily dependent on the in-place dry density of fill. The actual settlement and the rate of settlement were found to depend on the thermal environment. We also found that in at least one case the island fill was stratified into three distinct layers shortly after construction. This paper presents opinions developed regarding the formation of these strata and how the performance of the island relates to the layers formed. The methods used to make these observations and the methods used to estimate thaw strain are also covered.

INTRODUCTION

Designing for settlements within foundation fills has always been an important concern. This is especially true in the arctic regions when frozen borrow sources are used in fills without providing time for the materials to thaw between excavation and placement. In frozen soils, the pore water (ice) is a solid and the dry density of a fill constructed from reworked frozen deposits will decrease as the natural water content of the material increases. When these fills thaw, substantial settlements can occur. This paper addresses this phenomenon as it pertains to winter constructed gravel islands in the Beaufort Sea.

Exploration drilling offshore in the Alaskan Beaufort Sea is typically performed from man-made gravel islands built with frozen materials. Because thaw strains of close to 25% have been recorded within portions of existing man-made islands (Scher 1982), it is critical to be able to estimate settlement during design. Fairly accurate estimates of settlement within a frozen fill can be made if the as-placed densities of the material are known. All settlements in granular, fills including thaw, creep, and consolidation, are dependent on the dry density of the in-place material. However, there are many variables that control in-place density such as soil gradation, moisture content of the undisturbed soil, environmental conditions at the time of construction (temperatures, precipitation, etc.), and the medium in which the fill material is placed, air or water.

Winter constructed gravel islands are typically built between January and April. Construction generally begins as soon as the sea ice is sufficiently thick to build ice roads capable of supporting gravel hauling equipment. The procedure to build the islands is basically to: (1) construct an ice road to the site, (2) cut and remove the sea ice at the site, (3) haul gravel and dump it through the ice, and (4) once the gravel has surfaced above the water line, spread and compact the material in thin lifts until the design freeboard is reached.

The remainder of this paper will focus on the performance, in terms of settlements, of man-made islands built during the winter with frozen fill in the Alaskan Beaufort Sea. In addition, techniques are discussed for predicting settlement within man-made islands built with frozen gravels.

ABOVE WATER FILL

The above water fill is typically placed in lifts and compacted; the final dry density being a function of the materials, ice content, and the amount of compactive effort during placement.

To estimate the dry density, the following rationale has been used. The in-place fill consists of solid borrow and newly created voids which form during placement. This solid borrow would contain both mineral and ice. The fill voids would contain air in the above water zone of the fill and seawater in the below water zone of the fill. Since the gravel sources used were

almost always found to be saturated, we have assumed there were no air voids in the frozen chunks that were excavated. Thus, knowing the moisture content and specific gravity of mineral solid, we can determine the density and void ratio of the borrow material. Details of these calculations are given by Tart (1982).

Estimates of e_f , the fill void ratio considering both ice and mineral as solids, can be made by assuming the dumped frozen chunks of borrow material act as individual grains and form a mass with a void ratio similar to void ratios of dumped sands and gravels. In loose conditions, a realistic value of e_f probably falls between 0.3 and 0.6.

Using an assumed specific gravity of solids, $G_s = 2.7$, and the rationale described above, Figure 1 was developed. From Figure 1 estimates of dry density of a fill constructed of saturated frozen chunks can be made, if e_f can be estimated and the borrow moisture content are known.

FIGURE 1 Chart for estimating as-placed density

Laboratory and field data by Clark (1970) and others have reported that the dry density of a frozen fill is inversely proportional to the moisture (ice) content as indicated in Figure 1.

Further, our experience has shown that the response of frozen materials at a given moisture content to compactive effort in the field can be simulated in the laboratory using procedures similar to those used for unfrozen materials. The frozen compaction tests differ from standard laboratory compaction tests in that the samples remain frozen and the moisture content is not changed. Thus, the maximum and minimum densities determined by laboratory tests can be used to predict in situ field densities by using an approach very similar to the approach used in thawed fills.

As the above water fill is placed conventional field density tests can be made. Sand cone density tests can be relatively accurate. However, since the chunks can be large, a foot

or more in some cases where the borrow moisture content is high, caution must be exercised in using the sand cone to assure the volume filled with sand is representative of the volume of material removed and weighted. Nuclear density tests can be made as long as the instrument is not left in the cold for extended periods and care is used to prevent densification as the probe is driven into the ground.

A third method for obtaining in-place densities is the chunk density test which was described previously by Tart and Luscher (1981). In this method the zone to be tested is sprinkled with water. After the water freezes, a chunk of material is removed and a bulk density determination can be made of the frozen chunk. Moisture contents are determined from samples adjacent to but outside the flooded area.

For above water fills where borrow source moisture contents were around 10%, average as-dumped densities have been observed to be around 90 pcf. (Dry densities as low as around 70 pcf have been observed when borrow moisture contents were near 30%.) The 90 pcf density fill reached could be compacted to densities of 105-110 pcf.

Our field observations indicate that the effect of compactive forces applied decreased significantly with depth in a given lift. The density in the upper 2-5 in. was usually close to the maximum dry density as determined in the laboratory. The next 2-4 in. was usually a transition zone, and the density of the remaining bottom portion of the lift appeared to have not been affected by compaction equipment.

Further, we could not observe any significant increase in density that could be related to a specific type of compaction equipment. Equipment used included a grid roller, a vibratory roller, and a sheepfoot roller. Most of the increase in density took place when the dumped gravel was spread and leveled. Compaction tests taken immediately after spreading gave densities that were generally as high as those where compaction equipment had been used, indicating that the use of compaction equipment was not effective. From this, we believe that careful spreading of the material in thin lifts followed by rolling with the gravel hauling equipment will result in as much productive compactive effort as the use of any of the above-mentioned standard compaction equipment.

BELOW WATER FILL

Winter construction of the below water portion of the island is accomplished by simply dumping the frozen gravel through a hole in the ice. In the past there has been no effort to mechanically compact the below water fill. By the time the gravel is mined and hauled to the construction site, it has cooled to roughly the ambient temperature (-15°F in late January at Prudhoe Bay). When this gravel is dumped in the sea, which has a temperature near 29°F, it

begins to remove heat from the water with which it has contact, and some additional ice is formed.

This new ice may be only a surface coating or may fill a significant portion of the available void space. Standard thermal calculations can be used to estimate the amount of ice that would be formed by estimating the temperature of borrow (gravel/ice) mass when it stops dropping and estimating the temperature of the seawater trapped in the voids. Since convection would cause warming of the borrow material as it drops further through the water, one would expect more ice in the upper portions of the fill.

Similar to above water fill, the material underwater can be assumed to fall into a loose state with a void ratio somewhere between 0.4 and 0.6. By assuming a degree of saturation, usually 100%, an unfrozen moisture content can be estimated.

The formation of additional ice in the fill as it is dumped in the water is suggested by the steep island slopes formed below water reported by Galloway et al. (1982). Observed above water, the angle of repose of the frozen material was about 35-45° (32° thawed). However, underwater the island slopes were found to be between 60° and 80° from horizontal.

The existence of the steep underwater slopes seems to indicate the presence of additional ice and to imply that slumping will occur when the material thaws during the summer months. In addition, thaw or degrading of sea ice formed in the frozen fill could occur in the winter months at the base of the fill in deep water. The average underwater slope angle also appears to be not only a function of temperature and initial ice (freshwater) content, but also water depth. While we have not investigated this in detail, it appears as the water depth increases, the average slope angles will decrease, possibly due to warming of the gravel.

The design material volume of the island should be sufficient to allow the slumping of slopes from the initial average slope of around 0.6 horizontal to 1 vertical (0.6H:1V) to the summer average slope of around 3H:1V. This can be accomplished by making sacrificial beaches around the island perimeter which contain enough material to allow the slumping to 3H to 1V without losing required working space on the island slough. Another method of accomplishing this same goal is to groom the slopes to 3H:1V during construction.

Actual measurements of the underwater fill densities could not be obtained. For saturated fills the most definitive method of establishing the in situ density would be to obtain undisturbed samples of the fill. Until recently, the techniques used for this have been unsuccessful. Drive sampling densities and/or remolds the material. Rotary drilling with mud melts the ice and disturbs the particle structure in the samples. Even with refrigeration, there is some melting and physical alteration to the sample perimeter. In addition, the core water is frequently contaminated by drilling fluid.

Recognizing the problems with existing sampling techniques, a series of borings were made through the island fills to mudline and split spoon samples were obtained. The densities measured on the limited samples retrieved from the below water averaged about 80-85 pcf, with moisture contents about 25-30%. This suggests saturations of only about 75%. This saturation seems low, since water was observed to flow into the boreholes, which would indicate saturations closer to 100%. Assuming 100% saturation, the dry density should be expected to average about 90-95 pcf.

Additional below water sampling should be done as well as laboratory modeling to better determine the actual condition of frozen materials dumped in cold seawater. During the winter of 1982 an experimental technique was used to core the frozen and partially frozen gravel fills. Very cold air and a thin kerfed bit were used which allowed the bit to cut with minimal friction and grinding. This technique produced a frozen core which looks very much like a concrete core, with ice replacing the cement. The experiment proved the mechanics of the technique to be sound. However, because there was not enough moisture in the gravel samples to securely bond the particles when cooled, no undisturbed samples were recovered.

ISLAND ZONES

Various borings made shortly after completion of construction indicated that the fill material existed in up to three zones of individual conditions of moisture content, phase, and structure depending on the water at the island. The material above the waterline had approximately the same moisture content it had before it was excavated. Below the waterline, the moisture contents increase to near saturation. However, the percent frozen moisture appeared to decrease with depth. The two underwater zones are distinguished by the change in unfrozen moisture content. Figure 2 illustrates these three zones. The figure also presents a theoretical gravel-ice-water matrix of the material in each zone at that time.

FIGURE 2 Three zones of gravel island

One explanation of the formation of the two underwater zones is that when the gravel particle is dumped in the water, it quickly cools the surrounding water, forming additional ice. However, the longer it is moving (dropping) in water, the more it warms, approaching the seawater temperature. As this happens, the additional ice formed, plus some of the initial ice content, may melt. Thus, below a certain depth, the fill has more thawed moisture content than frozen. Near the water surface the amount of unfrozen pore water can be very low. The physical separation of these two zones is apparent when a large-diameter hole is drilled. Several feet below the water, surface water flows into the hole. We estimate that near this elevation the unfrozen moisture content approaches 50%. Below this elevation the unfrozen moisture content increases.

An advancing "freeze front" or "freeze plane" can also contribute significantly to this development of two distinct underwater zones. The construction technique used on several islands has been to develop a full diameter surface of the island to an elevation near sea level, then build to a design freeboard elevation. During this period that the island surface is near sea level, the "freeze front" has the opportunity to advance into the upper portion of the below water fill. In one case we have observed water flowing into a shallow (3-5 ft) pit made during construction when the island elevation was at elevation +2 to +3 ft. After about 3 weeks and the addition of 10-13 ft more fill, this "apparent" freeze level was observed at an elevation near -8 ft.

This seems to be a somewhat rapid advance rate, and it seems possible that water flowing into the earlier shallow pit could have come from water entrapped as the gravel was pushed over the edge of the island surface during construction. More observations are necessary to be more conclusive about the zone formation process.

The existence of the three zones has only been observed in the period immediately after the fill material is placed (1-2 months). Borings made through one island a year after construction indicated that changes had occurred in the state of the pore waters. Analyses of the data are not yet available to explain the changes.

SETTLEMENT MECHANICS

Each of the three zones should be considered separately in characterizing the total settlement in the island. Scher (1982) has presented data indicating that the unit thaw strain in remolded frozen gravel fills is a function of the in-place dry density. However, this relationship has only been tested in gravels with no unfrozen moisture content. From Scher (1982), thaw strains in Zone 1 have ranged from roughly 10-25% depending upon the fill dry density and the maximum density the thawed fill

can obtain. During the first summer, thaw may progress to depths of 6-8 ft, and maximum settlements of between 1.5 and 2.0 ft have been observed. The rate of settlement through Zone 1 would follow closely the advance of the thaw plane. After the first thaw period, additional settlements in Zone 1 would probably be minor.

Zone 2 is, for all practical purposes, insulated from summer warming by the air and the lack of a significant hydraulic gradient across the island, making it unlikely that there would be much warm water flowing through this zone. Thus, we believe it is relatively stable, thermally. However, as will be shown later, some settlement does occur in this zone. This settlement is most likely a result of creep between the ice and gravel particle contacts due to the overburden and possible warming from the above water fill.

Although the exact mechanics of the settlements in Zone 2 are not known, estimates of settlement potential can be made if the dry density can be determined. First the material around the well bore may thaw, in which case the thaw strain versus initial frozen dry density relationship (Scher 1982) can be used. For the remaining fill, it would be reasonable to assume that with time the in situ ice has filled the voids. If the ice content is known, a void ratio and dry density can be estimated. Here the settlement potential is tied to the creep rate of the pore ice. Long term settlements could approach settlements resulting from thaw, whereas, short term settlements are likely to be very small.

In Zone 3, the high unfrozen moisture content, over time, will probably react with and erode the bonding ice. As this bonding breaks down, the loose saturated fill should begin a slow settlement similar to that observed in the consolidation of fine-grained deposits. Similar to Zone 2, accurate settlement predictions in Zone 3 cannot be made unless the exact structure and mechanics of movements have been defined. Estimates can be made assuming that the fill density would approach that of a loose thawed gravel. However, the length of time for this to happen is unknown. Settlements in the fill around the well bore, if they thaw, should be predictable using the aforementioned thaw strain versus initial frozen dry density relationship.

FIELD SETTLEMENT OBSERVATIONS

Settlement information described above was based on observations we have made at several locations. The most effective method of measuring we have used is the Sondex system in which a flexible casing containing metal rings at designated spacings is placed in a large-diameter (8 in.) drill hole and then backfilled with clean pea gravel. As settlement occurs, the rings move in the zones which are moving, and the rings are detected using a sonde, which detects the relative position of each ring electronically.

To obtain the temperature profile for correlation with these movement data, thermistor strings can be installed in 1-in. PVC tubing filled with glycol.

To measure lateral movement of the islands, slope indicator casings can be installed. These casings are most easily installed in conjunction with the Sondex casings. The slope indicator casings will provide the stiffness for the flexible Sondex casing and prevent it from collapsing. It would also provide a one-location source of both lateral and vertical movement data.

In Figure 3, typical temperature curves that could be observed from a winter constructed gravel island during the first summer after construction are plotted. In Figure 4 the expected shape of the accumulated settlement versus depth curve is presented. This curve represents settlement that could be expected to occur during the summer thaw season. The rate of settlement in a stratum can be implied from the slope of the settlement curve. Our observations indicate that the seafloor sediments settle at a slower rate than any portion of the fill. In Zone 3 the rate of settlement is more than that of the natural sediments but less than that in Zone 2. In the lower portion of Zone 1, where active thaw settlement is occurring, the slope is the steepest.

FIGURE 3 Typical temperature profiles

FIGURE 4 Typical settlement profile

From this, we believe that settlement in Zone 3 is occurring as a result of the slow degradation of the frozen material in this portion of the fill as a result of the high percentage of unfrozen moisture. Much of the Zone 3 settlement probably occurred during construction, before measurements could be made. In Zone 2, the additional unfrozen moisture probably resulted in a looser structure initially which also is degrading as a result of gradual infiltration of the seawater. This results in a slightly higher rate of settlement in this zone. Above sea level in Zone 1, the high rate of settlement is a result of thaw settlement resulting from the advance of the thaw front from the surface of the island. In this zone, even though there was some compactive effort placed on the fill which increased its initial density 5-20 pcf above that of the below water fill, the influence of the warming air through this nonsaturated portion of the fill results in an accelerated rate of settlement. Near the ground surface in Zone 1 the settlement rate decreases to near zero because thaw settlement occurred in this zone prior to instrument installation.

CONCLUSIONS

The experience reported herein demonstrates that short-term, above water settlement in winter constructed islands can be reasonably predicted once the in-place density is determined, the maximum dry density is defined, and the depth of thaw is established. Further methods for estimating these densities have been presented based on in situ moisture content measurements and in-place void ratio approximations. Long-term thaw strains in the below

water portions of the fill could be large if in-place densities are found to be low. However, it is likely that some of the settlement in these lower zones occurs during construction and that the rate of subsequent settlement in these zones is relatively low.

Winter constructed gravel islands should be studied further to confirm settlement estimates and long-term stability predictions. These studies may include long-term monitoring and detailed sampling of the fills at various time intervals to relate the amount of settlement to the changes in the in-place density. In addition, because of the relatively undefined structure and condition of the below water fill, laboratory tests could be used to model the response of frozen soil fills placed in cold seawater.

SHORELINE REGRESSION: ITS EFFECT ON PERMAFROST AND THE
GEOTHERMAL REGIME, CANADIAN ARCTIC ARCHIPELAGO

In the Queen Elizabeth Islands of the Canadian Arctic Archipelago, the late Quaternary event with the most profound influence on ground temperatures is shoreline regression accompanying post-glacial isostatic uplift. The coastal margins of many islands have experienced hundreds to several thousand years of submergence since 8,000 years ago. The effect on the geothermal regime is far from subtle because of the large contrast between arctic air temperatures and sea temperatures.

Permafrost thicknesses measured today reflect this surface temperature history. Two deep wells 1 km apart on Cameron Island have measured permafrost thicknesses of 726 and 660 m; the geothermal analysis attributes the difference entirely to the first, and higher, site having emerged from the sea around 7,000 years B.P., about 2,000 years before the second. Inland sites on the Sabine Peninsula of Melville Island may have, in a similar lithology, permafrost twice as thick as at coastal sites. The geothermal analysis explains this variation in terms of a simple sea regression model derived from emergence curves published for the region.

INTRODUCTION

In a pioneer permafrost study, Misener (1955) examined a deep temperature profile at Resolute in the central part of the Canadian Arctic Archipelago and calculated a high outward flow of heat. Terrestrial heat flow originates largely from radioactive decay deeper within the crust and upper mantle, and this value for Resolute was considered anomalous for the geologic setting. This prompted Lachenbruch (1957) to undertake an extensive study of the thermal effects of the ocean on permafrost and on the geothermal regime in arctic regions. The Resolute temperature cable (site "O" in area E, Figure 1) is about 350 m inland from the modern shoreline to which the sea has regressed since the last glacial epoch. Lachenbruch showed that the enhanced heat flow could be attributed partly to the proximity of the ocean and partly to a geothermal regime still reflecting the much higher surface temperature conditions when the site was submerged following deglaciation.

For over a decade following the Resolute measurements, few other deep ground temperature data were available for studying the influence of a past surface temperature history on present subsurface temperatures. Concurrent with the accelerated petroleum exploration in the Canadian Arctic since the late 1960's, an extensive data set of subsurface temperatures has become available (Judge 1973a, Taylor et al. 1982, and preceding volumes referenced in the latter). In this paper, the data set will be surveyed for wells that reflect the shoreline regression history, and the effect on permafrost and present ground temperatures will be

calculated at a number of sites. A full palaeoclimatic reconstruction at all the sites will be left to a later paper.

THE LATE QUATERNARY HISTORY

Much interest has developed over the past decade on the extent of glacial ice cover in the Queen Elizabeth Islands during the late Wisconsin (e.g., Blake 1970, Prest 1970, Paterson 1977, Sugden 1977). Geological evidence favours a lack of continuous ice cover over the central portion of the region for the past few tens of thousands of years (England 1976, Hodgson 1982). The break-up of this ice may have begun by 11,000 BP but most of the inter-island channels were freed of glacial ice by 9,000 BP, probably all by 8,000 BP (Blake 1972). Many islands exhibit marine terraces to 100 m above present sea level and the dating of materials found in these beaches suggests emergence of such magnitudes from the sea has occurred since that time. Curves drawn for various areas using these dates demonstrate the shoreline regression history for the Archipelago (Henoeh 1964, Walcott 1972, McLaren et al. 1978; Figure 3).

The gentle topographic relief of some of the islands has resulted in land several kilometres from the present ocean having experienced this recent bimodal history (e.g. Sabine Peninsula, Figure 2). Because of the large contrast in sea temperatures, this history of inundation followed by the present subaerial conditions represents a major thermal event for the coastal margins of many of the islands.

FIGURE 1 The Canadian Arctic Archipelago showing the distribution of sites discussed in this paper. The major geologic provinces are labeled by open lettering. A and B represent the Sverdrup Basin. The stipled area is the Sabine Peninsula (Figure 2). C is the Franklinian Geosyncline, D the Arctic Platform, E the Cornwallis foldbelt, and F the Coastal Plain. The measured permafrost thicknesses are in metres and the Earth Physics Branch file numbers are in brackets (Taylor et al. 1982).

A further treatment of Holocene history and its geothermal implications is given in Desrochers (1983).

THE GEOTHERMAL ANALYSIS

Temperature changes impressed upon the earth's surface are preserved for considerable periods of time because of the low thermal diffusivity of rock and are propagated downwards with an amplitude that diminishes exponentially with depth and with a phase that lags the causative change at the surface. The geothermal temperatures measured today may be considered to

have imbedded in them the steady state thermal regime typical of the geologic environment and a superposition of transient effects arising from a time series of surface temperature variations. In traditional heat flow studies, these transient effects are stripped away to leave a residual thermal regime that reflects the underlying geology (e.g. Birch 1948); here we find particular value in the magnitude of these transient contributions themselves, as they relate to our understanding of Holocene history.

The classical theory of heat conduction is used to calculate the effects of these surface temperature variations on subsurface

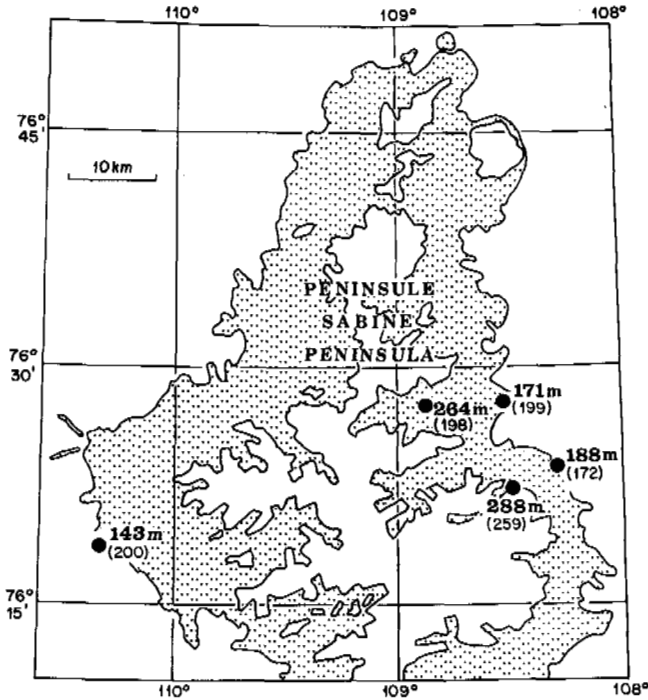

FIGURE 2 The Sabine Peninsula area, Melville Island. The stipled area is presently below 60 m ASL, and was subject to late Wisconsin marine submergence (McLaren and Barnett 1978). Five sites with deep temperatures are shown.

temperatures. The method is basically one-dimensional and the linear equations may be solved analytically for many problems. Gold and Lachenbruch (1973) suggest that other heat transfer mechanisms can be disregarded in thick permafrost because groundwater is largely immobilized either as ice or by surface forces. The latent heat of a phase change may be neglected in considering the overall thermal regime if there is not appreciable movement of an ice-rich permafrost boundary.

The theory will not be outlined here; concise summaries appear in Jaeger (1965) as it applies to traditional heat flow corrections, and in Gold and Lachenbruch (1973) for permafrost environments in particular.

THE DATA

Precise temperature profiles to depths of hundreds of metres are available for more than 40 sites in the Canadian Arctic Archipelago (Table 1 and Figures 1 and 2). Present mean surface temperatures are largely independent of elevation or geographic position throughout the region. Consequently, the wide variation in permafrost thicknesses may be attributed to the lithology (through the thermal conductivity) and the past surface temperature history at each site (Judge 1973b). For our calculations,

estimates of thermal conductivity have been made from measurements in our laboratory on rock chips recovered during drilling and from porosities calculated from well logs; the general method has been described by Sass et al. (1971).

RESULTS

The two Bent Horn wells on Cameron Island (sites 196 and 286, area C of Figure 1) have measured permafrost thicknesses of 726 m and 660 m respectively, although they are only 1 km apart. We hypothesize that the difference in permafrost thickness may be attributed to the shoreline regression in the area. Both sites would have been sub-sea from the time when the inter-island channels were freed of glacial ice until the time of emergence. We assume 8,000 years BP for the first date as a conservative estimate (Blake 1972). Emergence curves (Walcott 1972) suggest that the site at higher elevation, number 196, emerged about 7,000 years ago, and the lower site about 2,000 years later (Table 2). To test the hypothesis, we assumed surface temperatures while inundated by the cold sea were 15 K higher than when subaerial, and applied the climatic correction (Jaeger, 1965) to data from the Bent Horn wells. The analysis predicts temperature profiles that would be expected today, had the marine episode not occurred. The permafrost thicknesses extracted from these calculated temperatures are

FIGURE 3 The three principal emergence curves for Melville Island (Henoch 1964, McLaren and Barnett 1978). The inset depicts the localities where samples were collected to establish the curves and the locations of the six geothermal sites on Melville Island.

essentially identical for the two sites (Table 2), thereby confirming the hypothesis.

The thermal effects of recent shoreline regression are most pronounced at several geothermal wells in the Sabine Peninsula of Melville Island (Figure 2). The position of the present surface elevations of the geothermal sites on the East Coast curve in Figure 3 suggests a wide range of emergence dates (Table 2). The temperature profiles measured today (Figure 4) reflect this recent thermal

event through enhanced temperature gradients in the upper few hundred metres, a pronounced curvature and thinner permafrost. The effects are most pronounced in comparison with the Bent Horn wells (numbers 196 and 286) and with the Winter Harbour site (number 73); the latter may have had no marine episode in the Holocene.

The large changes in temperature, gradient and heat flow attributed to the simple shoreline regression history (Table 2) is calculated for site 172 (Figure 5). The high gradients are

FIGURE 4 Temperature profiles for sites in the Sabine Peninsula and for Cameron Island, 100 km to the east (Figures 1, 2).

reflected in an unusually high apparent heat flow, an effect similarly noted in the Resolute data (Misener, 1955). The calculated temperature profile suggests that permafrost would be considerably thicker if the site had not experienced the lengthy marine inundation; without this event, permafrost would be expected to be up to double the present thickness at the three coastal wells (numbers 172, 199, and 200; Table 2). At the site further inland close to the marine limit (number 259), the thermal regime may be considered to be in quasi-equilibrium with present surface temperatures.

The pronounced peak in temperature gradient

and heat flow is common at similar depth intervals in all the Sabine wells. It is consistent with an unusually cold climatic episode in the past century at the termination of the Little Ice Age, but has not been adequately resolved at present.

CONCLUSION

A simple geothermal analysis has demonstrated that substantial thermal effects of Arctic shoreline regression are reflected in today's deep ground temperatures and permafrost thicknesses. Arctic geothermal sites must be analyzed carefully for these and similar historical surface temperature variations if calculated values of terrestrial heat flow are representative of the geological environment. Alternatively, the geothermal analysis provides a method to confirm glacial and palaeoclimatic models.

Our limited data suggest that coastal areas of much of the central Arctic Islands will show similar thermal effects of shoreline regression accompanying glacial rebound. A two-dimensional numerical model, constrained by measured temperature profiles, would provide insight into the thermal signature of shoreline regression.

ACKNOWLEDGMENTS

This short analysis is based on data collected over the past 15 years and published in Taylor et al. (1982) and preceding volumes referenced therein. We thank the various oil exploration companies, principally Panarctic Oils Ltd., for their cooperation in that data collection, and for the logistic support to the program offered by the Polar Continental Shelf Project, EMR Canada. Assistance in fieldwork and thermal conductivity measurements was provided by V. Allen, M. Styles, D. Williams, L. Wilson, and A. Wilkinson. Assistance in manuscript and diagram preparation was given by R. Decosse, R. DeLaunais, E. Gélinas, and M. Whissell. We thank the reviewers for their helpful suggestions, especially D. Hodgson for insight into the Holocene history.

This paper is a contribution of the Earth Physics Branch, no. 1062.

THERMOKARST FEATURES ASSOCIATED WITH BURIED SECTIONS OF THE TRANS-ALASKA PIPELINE

Howard P. Thomas¹ and John E. Ferrell²

¹Woodward-Clyde Consultants, Anchorage, Alaska 99503 USA
²Alyeska Pipeline Service Company, Anchorage, Alaska 99512 USA

Following startup in 1977, thermokarst ground surface features started to appear along buried segments of the Trans-Alaska Pipeline. Features observed included longitudinal cracks and various depressions. Proper interpretation of these features became an important element of pipe settlement investigations which were initiated in 1979. Most of the features were relatively shallow and were not related to pipe thaw settlement. However, a few features provided an advance indication of developing critical pipe settlement conditions. These advance indications enabled the planning and undertaking of timely remedial actions.

INTRODUCTION

Natural and manmade thermokarst features are relatively common in Arctic and sub-Arctic regions (see Mackay 1970, French 1979, Sweet and Connor 1980). Examples of natural causes are fires, river bank undercutting and coastal retreat. Well-known manmade causes involve stripping or compression of the tundra moss mat as a result of plowing, bulldozing or vehicular movements. The potential effects of burying the Trans-Alaska Pipeline in permafrost terrain were recognized well before its actual construction (Lachenbruch 1970).

The pipeline, which carries warm crude oil, was allowed to be buried in permafrost soils only where the pipe itself could be supported on thaw-stable soils or bedrock. Following startup in 1977, thermokarst ground surface features started to appear in several segments of the buried pipeline. These features were formed by thawing of massive ice or ice-rich soils overlying the thaw-stable soils. Contributory factors included the additional disturbance to the thermal regime caused by the presence of the gravel workpad and, in some cases, thermal erosion caused by surface water.

This paper describes thermokarst features observed during pipeline surveillances in 1979 and 1980, and comments on their engineering significance. Selected photographs are presented to illustrate typical features.

FEDERAL STIPULATIONS

The operating temperature of the Trans-Alaska Oil Pipeline varies between 38 and 63°C. This elevated temperature is maintained throughout the length of the line by the effects of friction heating. To ensure adequate support for the 48-in.-diameter pipeline, the federal stipulations for its construction (U.S. Government 1974) allowed it to be buried only in initially-thawed or thaw-stable materials: "Below the level of the pipe axis, the ground shall consist of competent bedrock, soil naturally devoid of permafrost, or, if frozen, of thaw-stable sand and gravel." In a footnote,

thaw-stable sand and gravel was defined as "Material within classes GW, GP, SW and SP but with less than 6 percent by weight passing the No. 200 U.S. Standard sieve." The stipulations did not prohibit ice-rich permafrost above the level of the pipe axis.

The federal technical stipulations provided the basis for justification of the buried pipeline construction mode. Mode designations were assigned during mile-by-mile design on the basis of borings and landform analysis. These designations were continually updated as alignment adjustments and new borings were made. The buried mode was further verified during construction by continuously logging the pipe ditch by qualified geologists as soon as it was excavated (see Luscher and Thomas 1979). Application of this process included drilling over 4,000 borings resulting in about 600 km of the pipeline (half of the total alignment) being buried.

FIGURE 1 Route of the trans-Alaska pipeline

Buried sections varied in length from 150 m up to a maximum of 100 km. As shown in Figure 1, north of the Brooks Range, the line traverses continuous permafrost; from the Brooks Range south to about Pump Station 12, the line traverses discontinuous permafrost; and, south of Pump Station 12, the line traverses about 100 km of non-permafrost terrain.

THAW BULB GROWTH AND PIPE SETTLEMENT

In those segments where the pipe was buried in frozen ground, a thaw bulb started to grow around the pipe at the time of startup in June 1977. Early thermal simulations based on conductive heat flow estimated thaw bulb growth rates shown on Figure 2.

FIGURE 2 Growth of thaw bulb with time

Actual thaw bulb growth depended strongly on local conditions including initial ground temperature, soil stratification, groundwater flow, and presence of a gravel workpad. A North Slope example of the shape of the thaw bulb six years after pipeline startup is shown on Figure 3. At this location, the presence of a high water table and about 6 m of highly-pervious gravel immediately beneath the pipe has accelerated lateral growth of the thaw bulb as a result of convective heat flow. Presence of the gravel workpad on the right side of the pipe has resulted in slightly more thawing (also more winter freezeback) on that side.

By 1979, the thaw bulb had typically progressed to a depth of 3 to 6 m below the pipe, and to a similar distance laterally. In buried pipeline sections, pipeline settlements accompanied the thawing, but these were less than about 30 cm (5 to 10 percent thaw strain) over at least 95 percent of the buried pipeline.

At two widely-separated locations (Mileposts 166 and 734), large settlements (approaching 1.5 m) occurred which caused the pipe to buckle and leak in June of 1979 (see Johnson 1981). The pipe was quickly repaired and stabilized at these locations. Subsequent investigations revealed that the cause of the leaks was thaw settlement of unstable permafrost which had not been identified during construction. At Milepost 734 just north of Pump Station 12, the pipe was laid across an "island" of ice-rich silt, a near-circular remnant feature about 90 m in diameter. The gradual thaw around the warm pipeline caused the frozen silt to thaw and consolidate, resulting in loss of support for the pipe. The Milepost 166 leak at Atigun Pass was caused by melting of thick ice lenses in frozen weathered bedrock beneath the pipe and consequent loss of pipe support.

FIGURE 3 Milepost 34 thaw bulb cross-section - 1983

SPECIAL SURVEILLANCES

Concurrent with the 1979 leak investigations, intensive mile-by-mile studies were undertaken of all buried pipeline sections north of Milepost 740. These studies comprised both office reviews of design and construction documents and special field inspections of the buried pipeline sections.

Two special geotechnical surveillances of the pipeline were conducted in 1979. The first took place from June 27 to July 4 and concentrated on disturbance areas identified by Alyeska field personnel. Some of the areas were visited by helicopter, while others were reached using a four-wheel drive vehicle. Numerous photographs were taken, ground features were measured, detailed field notes were recorded, and tentative causes for the disturbances were advanced.

The Phase I studies demonstrated the usefulness of field observations and office records for evaluating buried pipeline foundation conditions. The objective of Phase II was to extend the general process developed in Phase I. Following the first field surveillance, a detailed office review was made of information available on the belowground pipeline sections.

Particular attention was paid to the continuous soil logs which had been prepared during construction of the ditch bottom and sidewalls.

Utilizing a detailed itinerary, the second special surveillance was conducted by helicopter from September 19 to 21. Each suspect area was circled in the air and on-the-ground inspections were made at most of the sites. Several unscheduled stops were also made to inspect suspicious ground disturbances. Once again, detailed field notes were recorded and numerous photographs were taken.

OBSERVATIONS

Typical ground features observed in the field inspections were cracks and depressions. The cracks were usually longitudinal (parallel to the pipe), were often 10 cm or more wide and 1 m or more deep, and sometimes ran for 100 m or more along the buried pipe (see Plates 1 and 2). The cracks occasionally ran right along pipe centerline, but were more often offset 3 to 6 m from pipe centerline. Sometimes there were parallel cracks on either side of the pipe, other times on one side only (as in Plates 1 and 2). Depressions were of the thermokarst type, sometimes abrupt (see sinkholes on Plates 3 and 4) sometimes gentle (see undulation on Plate 5), sometimes water filled (see ponding on Plates 6 through 8). Concentric cracking was sometimes evident around depressions.

MECHANISMS

Several possible mechanisms were advanced for development of the observed ground features:

- (1) Settlement of ditch backfill;
- (2) Settlement of in-situ soil outside ditch walls;
- (3) Compression of natural soils below ditch bottom.

Of these, only (3) could cause pipe settlement. (Compression of the relatively-thin pipe bedding layer was generally minor.)

Longitudinal cracking along the buried pipe is schematically depicted in Figure 4A. Cracking 1.5 to 3 m from pipe centerline usually reflected the edge of the pipeline ditch; likewise, cracking 4.5 to 6 m from pipe centerline usually reflected the edge of the thaw bulb. The asymmetric geometry associated with the presence of the workpad explains why cracking sometimes appeared on one side of the pipe but not on the other.

Wide and/or deep thaw bulbs were observed at several locations. As was the case at Milepost 34, these anomalies were generally associated with groundwater flow/convective heat flow.

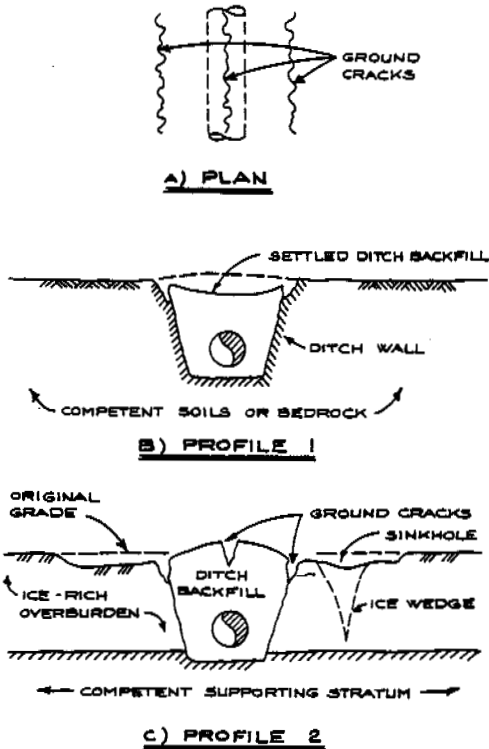

FIGURE 4 Causes of ground surface disturbance features

Causes (1) and (2) are depicted schematically in Figures 4B and 4C, respectively. As suggested by Metz et al (1982), ditch backfill settlement typically resulted from poor compaction of the backfill or thawing of backfill which was placed in a frozen state. The most frequent cause of ground disturbance was thawing of ice-rich overburden overlying either thaw-stable gravels or competent bedrock. Abrupt features such as cavities and sinkholes were generally explained by melting of ice wedges and other massive ice inclusions in or beyond the ditch walls. Other causes of disturbance features included poor backfilling of bellholes made for remedial welds and hydrotesting.

The following points emerge from the foregoing discussion:

- Pipe settlement could only be caused by thawing of ice-rich permafrost beneath the pipe.
- Severe ground disturbance, even close to pipe centerline, did not necessarily imply pipe distress.
- It was difficult to tell from surface features alone if pipe settlement had occurred.
- The deeper the pipe was buried, the more difficult it was to interpret ground surface features in terms of pipe distress.
- Regrading sometimes obliterated past ground disturbance features, but complete absence of disturbance features in a buried pipeline segment was generally taken as a favorable indication.
- Presence of thermokarst features in a segment designed for thawed soil conditions was taken as an a priori cause for concern.
- Presence of transverse cracking and/or severe undulations along pipe centerline (see Figure 5) were cause for special concern as these had a high likelihood of being related to pipe settlement.

FIGURE 5 Surface feature associated with buried pipe settlement

Ground surface features at the leak sites were quickly obliterated by priority construction activities associated with containment of spilled oil, excavation of the buried pipe, and completion of temporary repairs. However, at the MP 734 site, a prominent longitudinal crack about 4.5 m west of pipe centerline was observed and photographed (see Plate 1). Probably because of snow cover, but perhaps also because the pipe was buried under 4 m of soil cover, no ground disturbance features were reported at the MP 166 site. It was concluded that it would have been quite difficult to anticipate pipe failure at the two leak locations based solely on visual surface disturbance observations.

Subsequent special surveillances were performed along the pipeline alignment in 1980 and 1981. An important feature of these surveillances was the obtaining of photographs which could be compared from year to year to see whether site-specific conditions were worsening or stabilizing. Staking of pipe centerline in critical areas prior to these surveillances aided in interpretation of ground disturbance features.

SUMMARY AND CONCLUSIONS

Numerous thermokarst features appeared along buried sections of the Trans-Alaska Warm Oil Pipeline following startup in 1977. Typical features observed were longitudinal cracks and various depressions. The most dramatic features appeared in the first two or three years after startup, when the thaw bulb was growing rapidly and was intersecting massive ground ice inclusions. These features have since been filled with gravel as part of Alyeska's ongoing right-of-way maintenance program.

Primary causes for the ground surface disturbance features were identified as:

- Thaw settlement of ice-rich permafrost overlying thaw-stable materials on which the pipe was founded;
- Settlement of ditch backfill above the pipe (frozen, wet, or uncompacted backfill);
- Inadequate backfilling of post-construction excavations such as bellholes for welds and excavations made during hydro-testing.

Some instances of ground disturbance appeared to be, and were later confirmed to be, due to local occurrences of unstable permafrost beneath the pipe. In a parallel investigation, both the MP 166 and the MP 734 leaks were attributed to settlement of the pipeline due to thawing of unstable permafrost. An ongoing mile-by-mile review focused on identifying such occurrences by evaluating a combination of design and construction records and field disturbance observations. Questionable pipeline segments so identified were excavated so that monitoring rods could be attached to the top of the pipe. This program succeeded in locating and stabilizing eight areas where the pipe was approaching buckling curvature.

By 1983, the thaw bulb had generally progressed to a depth below the pipe where soil ice contents are reduced, and the rate of thaw penetration has slowed to a point where the pipe

settlement rate is generally quite small (less than 15 mm/yr).

Inspection and knowledgeable interpretation of thermokarst features proved to be a valuable tool in identifying potential pipe settlement areas along buried sections of the Trans-Alaska Pipeline. These observations provided important input into ongoing engineering evaluations which enabled early identification of pipeline sections requiring remedial actions (e.g., stabilization).

THE ECOLOGY OF PERMAFROST AREAS IN CENTRAL ICELAND
AND THE POTENTIAL EFFECTS OF IMPOUNDMENT

Thora Ellen Thorhallsdottir

Institute of Biology, University of Iceland, Grensasvegur 12, Reykjavik, Iceland

In the central highland of Iceland, extensive hydroelectric developments are now planned. Small areas were flooded in 1981, but there are concerns over the ecological effects of a much larger reservoir, planned at a later stage. This would involve inundation of parts of the Thjorsarver Reserve, comprising the most extensive and richest tundra vegetation in Iceland. In 1981, a long term study of the ecology of the Thjorsarver tundra was initiated, with emphasis on the vegetation and soils and the potential effects of impoundment. Permanent transects were set up in disturbed and undisturbed areas for detailed recording of vegetation and soil parameters. This paper reports the preliminary results on the distribution and thickness of permafrost, active layer development, ground water and soil characteristics, but only brief descriptions of the vegetation.

INTRODUCTION

Central Iceland is a highland plateau with glaciers and isolated mountains rising above a generally flat or gently rolling terrain. It is characterized by black basaltic sand and lava with extremely sparse vegetation. Continuous vegetation cover is limited to areas with a dependable water supply. Permafrost in Iceland is more or less confined to this central region, where, according to Priesnitz and Schunke (1978), it is found at altitudes between 460 and 720 m. The highland vegetation of Iceland has been described by Steindorsson (1945, 1964, 1966, 1967). A survey and classification of Icelandic palsas is given by Schunke (1973). Priesnitz and Schunke (1978) discuss aggradation and degradation of palsas with reference to climatic fluctuations. Other reports of palsas and periglacial phenomena in Iceland include Thorarinsson (1951), Friedman et al. (1971) and Bergmann (1972). These investigations, however, are largely limited to general descriptions or qualitative observations. There is no detailed information on the extent and thickness of permafrost, active layer development, groundwater status and soil characteristics. With plans for extensive hydroelectric developments in central Iceland, the need for a functional understanding of the ecology of these areas becomes all the more pressing.

Several major hydroelectric projects involve the Thjorsa River, the largest glacial river in Iceland. In the first instance, all its easterly tributaries will be diverted south, through a series of man-made lakes and finally into the Thorisvatn Reservoir (Figure 1). The first of these lakes, Dratthalavatn, was flooded in 1981, and partly submerged some vegetated land. At a later stage, there are plans to dam the uppermost part of the Thjorsa proper. The resulting reservoir would inundate parts of the Thjorsarver tundra. Thjorsarver is a collective name for the largely continuous vegetation immediately south of Hofsjökull Glacier and the more discrete and isolated vegetation further south and east (Figure 1). They are now a nature reserve, comprising the richest tundra

vegetation in Iceland, as well as being the world's largest breeding ground of the pink-footed goose (e.g. Kerbes et al. 1971). Recent experience from Alaska and Canada has shown how susceptible tundra ecosystems may be to physical disturbances and impoundment (e.g. Kerfoot 1974, Rickard and Brown 1974, Newbury et al. 1978, Baxter and Glaude 1980, Newbury and McCullough 1982). There is concern

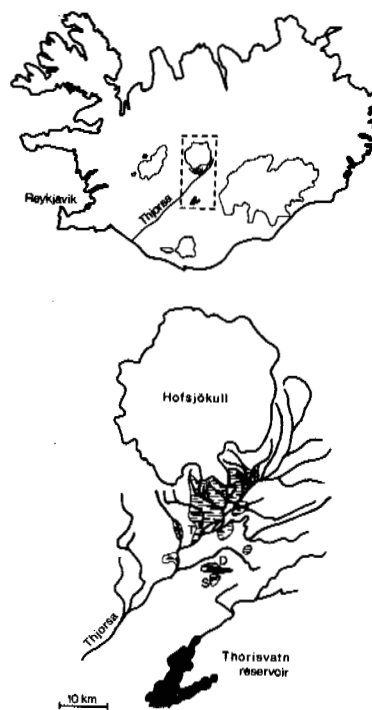

FIGURE 1 (Top) Location of Thjorsarver and the Thjorsa River in central Iceland. (Bottom) The area in detail. Vegetated land is dashed. T = Tjarnaver; D = Dratthalavatn; S = Storaver

over the potential ecological effects of a large reservoir in the Thjorsarver Reserve.

The purpose of the research described here is twofold. It is a long term investigation of the general ecology of the Thjorsarver tundra with particular emphasis on the dynamics of the palsa areas. Second, the project is intended as a pilot study to assess the ecological impact of a large reservoir in the Thjorsa River, partly through monitoring the effects of the much smaller Dratt-halavatn. Preliminary results are reported here with emphasis on the soil features.

CLIMATE AND GENERAL DESCRIPTION OF THE AREA

Thjorsarver lie at an altitude of about 600 m a.s.l. The generally flat and undulating plateau is broken by gently rolling hills. These are partly moraines and drumlins, and partly eroded bedrock, mainly basalt and sediment. Small mountains, bordering the area to the east and northeast usually have a palagonite core. Extensive esker complexes are found. Moraine covers most of the area, overlain by fine sand and in places by glacio/fluvial and lacustrine sediments (Tryggvason and Einarsson 1965, Tomasson and Thorgrimsson 1972, Kaldal 1981).

Mean monthly and annual temperatures, annual precipitation and general climatic information is given by Jonsson (1978) (Table 1).

TABLE 1 General Climate of the Thjorsarver Area for the Years 1966-1975, modified from the table of Jonsson (1978). Values are partly derived from the nearest permanent weather station at Hveravellir (approximately 50 km north west of Thjorsarver, altitude 642 m). For further information, see Jonsson (1978)

Mean monthly air temperatures (°C)	Precipitation 800 mm/yr
January -5.9	
February -6.3	<u>First total snow cover</u>
March -5.6	September/October
April -2.6	
May 1.1	<u>Last total snow cover</u>
June 5.0	late May
July 7.3	
August 6.7	<u>Earliest total ablation</u>
September 3.2	early June
October -1.0	
November -0.5	<u>Number of days of freezing</u>
December -6.2	about 220
Mean annual air temperature	-0.8

The largest part of the Thjorsarver tundra forms a rough triangle south of the Hofsjökull glacier (Figure 1). It is flanked by the main Thjorsa River to the south and two of its tributaries to the east and west. Numerous other glacial tributaries traverse the vegetation, giving rise to tall sedge (*Carex rostrata* and *C. lyngbyei*) fens in the wettest parts. Palsas are mainly found in slightly drier areas, and are more numerous and

diverse in form than elsewhere in Iceland. Mosses, (especially *Racomitrium canescens* and *Drepanocladus uncinatus*) and lichens are conspicuous on the palsas, which also carry a diverse flora of higher plants, notably willows (*Salix glauca* and *S. herbacea*), forbs such as *Armeria maritima*, *Polygonum viviparum*, *Saxifraga caespitosa*, *S. hirculus* and *Silene acaulis*, and grasses such as *Festuca* spp and *Poa* spp. *Carex rariflora*, *Eriophorum angustifolium* and *E. scheuchzeri*, as well as *Calamagrostis neglecta*, often fill the depressions between palsas. *Salix glauca*, *S. lanata* and *Racomitrium canescens* dominate the driest parts. For a complete floral list and species distribution maps, see Johannsson et al. (1974).

East of the Thjorsa River, areas of similar vegetation are found, but less extensive and occurring more as isolated patches in depressions in the Sprengisandur Desert. They are generally drier and less diverse vegetationally.

The initial stages of hydroelectric development only affect the land east of the Thjorsa, whereas the proposed Thjorsa reservoir inundates vegetation both east and west of the river.

MATERIALS AND METHODS

The project started in 1981. Seven permanent transects were constructed by Dratt-halavatn Lake and another seven in various vegetation types east of Thjorsa. In 1982, a single transect was set up in Thjorsarver proper, west of the river. The transects were usually 105 m long, and marked at either end by 1.5 m long aluminium poles.

On level terrain, each transect was further divided at 15 m intervals by 70 cm long wooden pegs. At each of these, the soil profile was examined, and the following soil variables recorded: 1) thickness of the organic layer; 2) mean and maximum rooting depth; 3) qualitative assessment of rooting density; 4) active layer thickness in early July (8 to 12), and late August (18 to 19) by five recordings with a metal auger; 5) the thickness of permafrost. This could only be done with the auger where the ice was 40 cm or thinner. Measurements were made on permafrost thickness of six palsas only, using a COBRASuper drill (BORROS AB Sweden).

Local topography was mapped by theodolite readings every 15 m. Vegetation was sampled as percentage shoot frequency in 0.5 x 0.5 m quadrats divided into 25 grid quadrats with 10 cm sides. Recordings were made along a 5 m belt transect at every 15 m interval. Mosses were collectively grouped because of difficulties in field identification. Mosses on the drier heath were probably mostly *Racomitrium canescens*.

In palsa bogs, the topography called for a different sampling procedure. Soil measurements were taken at the top and edges of all the palsas and in the depressions between them, where possible. The distribution of permafrost was mapped, and depth of active layer measured, as described above, on the top and sides of all palsas and in the depressions between them. Local topography was mapped, as above, to show the outlines and maximum height of the palsas. Vegetation was recorded, as above, except that a belt transect running the entire length of the palsa was used. Recordings

were made in the depressions, where possible.

Groundwater was measured in five transects: three by Dratthalavatn Lake, numbered 3 (gravel slope), 4 and 5 (moss/willow earth hummocks); one in a cottongrass/sedge plain (transect 7); and one in a willow/moss heath west of Thjorsa River (transect 9). Water level was measured in 60 or 100 cm long perforated plastic tubes by lowering a sealed (varnished) oak cube, attached to a string, into the tube. Water level was measured every 4 days from July 12 to August 18 by the lake, on July 12 and August 19 on transect 7, and on August 13 on transect 9.

RESULTS AND DISCUSSION

Vegetation

The most common species in six of the transects are shown in Table 2. The gravel slope with its sparse cover, had the greatest diversity of species. Mosses had very high frequency values (0.75-1.0) in all the communities. Calamagrostis neglecta was fairly ubiquitous. Salix glauca and Festuca spp, probably mostly F. rubra, but including some F. vivipara, were conspicuous in drier vegetation. Cottongrass and sedges dominated the wetter parts.

In a qualitative survey of palsas in Tjarnaver, that on photographic evidence were at least seven years old, no live plants, except Carex rariflora and Eriophorum spp., were found. They must be remnants from a wetter stage, indicating the slow successional processes. Since the majority of palsas in the area carry a diverse flora, very distinct from that of the bogs, it is likely that they are at least several decades old, but not less than about 10 years old, as claimed by Priesnitz and Schunke (1978). Further, typical palsa vegetation in Thjorsarver is not xerophilic (e.g. Priesnitz and Schunke 1978) but includes species normally associated with moist conditions, such as Salix herbacea, Calamagrostis neglecta (Table 2) and Saxifraga hirculus (see also Johannsson et al. 1974).

Soil Characteristics

The organic layer. There was no organic layer on the gravel slope. Under all continuous vegetation, decomposing organic matter was found, and this was usually sharply delimited from underlying sand. Mosses were invariably the chief constituents. The mean thickness of the organic layer on the moist heath was almost twice that of the palsas,

with the moist heath intermediate (Table 3). Very wet vegetation posed methodological problems, but in five sites examined in the cottongrass/sedge community in transect 7, the organic layer was always about 17 cm thick. These values are somewhat

TABLE 3 Mean Organic Layer Thickness in three Types of Plant Communities in Thjorsarver in July 1981. N = sample size; S.D. = standard deviation

Community	N	Mean Thickness (cm)	S.D.
Moist moss/ willow heath	12	12.2	4.8

Palsas (tops)	31	6.3	2.5

low compared with the figures of 10 to 30 cm, given by Bliss (1981) as typical for the Low Arctic. For palsas in the Northern and Southern part of the Canadian discontinuous permafrost zone, Zoltai and Tamocai (1975) recorded average peat thicknesses of 267 and 355 cm respectively. These values are not directly comparable to Thjorsarver, since the Icelandic palsas are not forested, but they are nevertheless low. This may reflect a generally young vegetation, or possibly repeated cycles of erosion and revegetation, with the palsas being gradually eroded by sand and finer aeolian deposits, rather than collapsing and leaving a thermokarst pool.

Soil and rooting patterns. The materials underlying the organic layer consisted of alternating layers of fine sand and pumice with an occasional peat layer. On two sites on the gravel slope, however, coarse gravel and pebbles were found at depths of 17 and 25 cm. This layer extended down to permafrost at about 68 cm. No gleying or horizon differentiation was evident in any of the profiles. Poor horizon development is characteristic of Icelandic soils in general (Johannesson 1960). Depth to moraine or more consolidated material underneath has not been fully assessed, but in one site examined at Dratthalavatn Lake and another in Tjarnaver west of Thjorsa River, this was at least 2 and 3 m respectively. Rooting was sparse. Most roots lay in, or just below, the organic layer. Scattered roots extended to just above the permafrost.

The distribution of permafrost. The permafrost is thin and discontinuous. It was more or less confined to densely vegetated areas, although a 10 to 20 cm thick ice layer was still present on the gravel slope (transect 3) on August 18, 1982. In early July, there was ice under all vegetation. Very wet bogs, where surface water remained through all of the growing season, and very sandy areas, especially where *Salix lanata* was conspicuous, were ice free towards the end of summer. Elsewhere, the ice measured from about 10 to 30 cm in late August, except in palsas where the ice was much thicker. The ice lenses recorded varied in

thickness from about 1.1 m in the smallest palsa to about 3.1 m in the largest. It is not possible to generalize from the small number of palsas drilled (6), but the permafrost may never be more than a few metres thick. The relatively small size of the palsas may also reflect this. Most rise 0.6-2.0 m above their surroundings, although occasionally they reach heights of about 2.5 m.

Groundwater. It is highly likely that groundwater status is the most critical single factor affecting both the occurrence and type of vegetation in Thjorsarver. True groundwater is difficult to measure in the presence of permafrost. For large scale measurements of groundwater table in the region, see Hjartarson (1981). Of interest here is simply depth to a water table accessible to plants, and the term is used in that limited context only. In the transects by Dratthalavatn Lake, monitored every three days, the water levels gradually subsided from July 12 to August 5, but changed little after that (illustrated in Figure 2 for two of the transects). The pattern was similar in all

FIGURE 2 Changes in groundwater level from July 12 to August 18 in transect 3 on the gravel slope (A), and between the earth hummocks on transect 5 (B).

three transects, although the underlying materials were appreciably coarser on the gravel slope. The decrease varied from 23-39 cm between the earth hummocks on transect 5 (which had surface water at most sites in early July), from 43-61 cm on the gravel slope, and from 17-31 cm in the cottongrass/sedge plain on transect 7. Groundwater levels at the end of the growing season are shown in Table 4. The sites on transect 5 may have been influenced by their low elevation above Dratthalavatn Lake, and the values may be higher than typical for *Salix herbacea*/*Anthelia* depressions. Mean groundwater depth was greatest on the gravel slope, followed by

TABLE 4 Depth to Groundwater on August 13 (transect 9), August 18 (transects 3 and 5) and August 19 (transect 7), 1982. All the sites included for transect 3 were elevated more than 1 m above Dratthalavatn Lake. The sites on transect 5 were 0.6-0.8 m above the lake level. N = sample size; S.D. = standard deviation.

Transect	Community	N	Mean depth (cm)	S.D.

9	Willow/moss heath	6	45.1	8.1

the willow/moss heath, and finally by the cotton-grass/sedge plain.

Active layer development. The depth of the active layer on August 18 and 19 is shown in Table 5. There was no significant difference between active layer depth on the palsas and other sites with continuous vegetation cover. On the gravel

TABLE 5 Active Layer Depth at the End of the Growing Season (August 18-19) 1982. Data are presented separately for palsas and for the gravel slope, which had very sparse vegetation cover. N = sample size; S.D. = standard deviation.

	N	Mean depth (cm)	S.D.
Sites with continuous vegetation cover	48	60.3	9.4
Palsas	13	58.8	8.0
Gravel slope	7	69.5	9.4

slope, the active layer was on average about 10 cm thicker. If, on the other hand, increases in active layer depth between early July (9-12) and late August (18-19) are compared, then this is slightly lower for the palsas than for the other closed vegetation (Table 6). Both are significantly lower than the gravel slope. The figures in Table 4 agree well with those given for active layer depth at Stordalen, Abisko, Sweden (40-80 cm), and for True-love Lowland, Devon Island (30-100 cm) (see Ryden 1981).

The depth of seasonal thaw was always greater than the organic layer thickness, hence the permafrost was confined to the underlying layers of fine sand. The presence of Dratthalavatn Lake (flooded in 1981) did not influence active layer depth, but

on the gravel slope, there were indications that backwater might affect melting of permafrost from below.

TABLE 6 Changes in Active Layer Depth from Early July (9-12) to Late August (18-19) 1982. Data are presented separately for palsas and for the gravel slope, which had very sparse vegetation cover. N = sample size; S.D. = standard deviation.

	N	Mean change (cm)	S.D.
Sites with continuous vegetation cover	48	18.5	7.4

The Potential Effects of Impoundment

The presence of permafrost may indirectly cause catastrophic shoreline erosion in inundated areas, since a stable slope is not established with ground ice being continually exposed by wave action (Newbury et al. 1978, Newbury and McCullough 1982). Here, the outlines of ground ice generally followed the shoreline of Dratthalavatn Lake. Slumping and overhanging, as described by Newbury et al. (1978) and Newbury and McCullough (1982) has only been observed on a small scale where a cluster of palsas formed the shoreline of Dratthalavatn Lake. Since the lake was only flooded in 1981, it is premature to draw conclusions about potential erosion. It seems unlikely, though, that the thin and discontinuous permafrost will significantly contribute to erosion in the manner described above. The soil properties give more cause for concern. The spongy organic layer and the sparse roots will hardly provide much resistance to erosion. The underlying fine sand layers are similarly susceptible to wind and wave erosion alike.

ACKNOWLEDGMENTS

This work is part of a larger project on various aspects of the biology of the Thjorsarver Reserve, and is carried out under contract to the National Power Company of Iceland.

The help of the following in collecting field data is acknowledged: Th. Eysteinnsson, B. Gunnlaugsson, H. Sigurjonsdottir, S. Snorrason and A. G. Thorhallsdottir. The National Energy Authority kindly lent staff and equipment for COBRA drilling of palsas.

A. Gardarsson and Th. Hafstad offered advice and constructive criticism on the preparation of the manuscript.

STRATIGRAPHIC EVIDENCE FOR VARIABLE PAST PERMAFROST CONDITIONS
AT CANYON VILLAGE BLUFF, NORTHEAST ALASKA

Robert M. Thorson

University of Alaska Museum and Geology/Geophysics Program
907 Yukon Drive, Fairbanks, AK 99701 USA

The Canyon Village Bluff, a 30 m high gravelly exposure located along the Porcupine River (northeast Alaska), contains stratigraphic evidence of four fossil ice-wedge-cast horizons within alluvial sediments. Radiocarbon dating and geomorphic features in the area indicate that all ice-wedge-cast horizons are more than 35,000 years old and may be late Quaternary in age. Each ice-wedge horizon is interpreted to represent one cold-warm oscillation of soil temperature which could have been caused by any number of factors. These features indicate that the bluff locality has been very sensitive to conditions causing soil-temperature changes for a prolonged period of time.

INTRODUCTION

Only a few localities in Alaska are known where definitive evidence for fossil permafrost has been found in controlled stratigraphic contexts older than the Wisconsinan Stage (Péwé 1975, 1966). In many cases, ancient periglacial features are well documented, but unambiguous evidence for ancient permafrost is lacking. This paper presents evidence for the development of multiple relict permafrost horizons of late Quaternary age at one locality along the Porcupine River valley in northeastern Alaska.

Between 1979 and 1981 an interdisciplinary research team from the University of Alaska Museum conducted a reconnaissance archeological survey along the Porcupine River valley between the Canadian border and Fort Yukon (Figure 1). Numerous excellent exposures of Quaternary sediments in river bluffs were mapped and described during the survey. On the higher older bluffs, which consisted largely of gravelly alluvium, several silty cryoturbated zones and horizons exhibiting ice wedge casts (IWC) were observed.

The most complete sequence of these periglacial horizons is at Canyon Village Bluff (hereafter referred to as the bluff) located approximately midway between the Canadian border and the Yukon Flats (Figure 1). In this bluff, evidence for six stratigraphically distinct intervals characterized by periglacial conditions are present, four of which contain unambiguous evidence for ancient permafrost.

The Porcupine River, one of the largest tributaries of the Yukon River, originates in central Yukon Territory and flows westward into Alaska 220 km to its mouth at Fort Yukon. Its westward course through Alaska crosses four distinct physiographic zones: (1) a narrow straight deep canyon (Upper Ramparts), (2) a broadly circular alluvial basin (Fishhook Bend), (3) a straight, narrow, shallow canyon (Lower Ramparts), and a broad alluvial plain (Yukon Flats). The bluff occurs as a high cutbank on the outside of a prominent meander near the center of Fishhook Bend basin.

The present course of the Porcupine River was established in late Quaternary time as the result of overflow from large proglacial lakes in Yukon Territory (Hughes 1969, Thorson and Dixon, in press). Prior to its capture of drainage from the Yukon Territory, the Porcupine River in the area of the bluff was only a modest-sized stream that was carving a broad erosional valley along its upper course and carrying gravels to Fishhook Bend (Thorson and Dixon, in press). During the initial overflow event, which occurred sometime prior to 31,000 years B.P., these older alluvial sediments were first buried by a thin sheet of gravel deposited by braided streams and later deeply incised, preserving the older gravels well above the level of subsequent fluvial activity.

The bluff area has a rigorous continental climate. Mean annual temperature averages about 7°C (Péwé 1975) with a mean January temperature of -30°F or less and a mean maximum July temperature of more than 70°F (Selkregg, n.d.). Vegetation on the bluff top is a dense spruce forest that occurs as part of the lowland spruce-hardwood forest ecosystem (Joint Federal-State

FIGURE 1 Map of the Porcupine River area showing localities mentioned in the text.

Land Use Planning Commission 1973). Permafrost is presently widespread throughout the area, which lies near the northern edge of the zone of discontinuous permafrost (Hopkins et al. 1955). At Fort Yukon, permafrost is at least 98 m thick (Péwé 1975). Modern ice wedges are not exposed at the bluff but are widespread in lowland alluvial plains bordering the river.

CANYON VILLAGE BLUFF

The bluff is a 1.9 km long, 30–35 m high east-facing bluff that offers nearly continuous exposure. The lower two thirds of the bluff consist of weakly indurated fluvial and lacustrine sediments of Tertiary age (Brosgé and Reiser 1969) which are well exposed and slope steeply to the river. The upper 13–15 m of the bluff exposes unconsolidated alluvial and eolian sediments of Quaternary age. The lower part of the Quaternary section is very sandy fine gravel that ravel rapidly and produces poor exposures. Prominent silty zones, which are especially common near the top, stand as nearly vertical faces. Nowhere along the bluff in 1980 was there a continuous vertical exposure. The best exposure is about 900 m from the eastern end of the bluff, where all units were exposed within a horizontal distance of 50 m. Shifting east and west of the median line of section did not introduce much error, because all prominent unit contacts within this area are horizontal. A measured stratigraphic section at the bluff, and a description of the units at this point, are presented in Figure 2 and Table 1, respectively. Particularly resistant congeliturbated zones and ice-wedge-cast (IWC) horizons occur at the same height over a horizontal distance of several hundred meters. Significant erosional discontinuities would also be horizontal as well, but none were detected.

Interpretation of Units

Unit 1 is interpreted to represent lacustrine and fluviodeltaic sediments which were built into a basin now occupied by Fishhook Bend. Following deposition the beds were weakly indurated and tilted as much as 9°. The contact between Unit 1 and the overlying gravels is horizontal and only locally scoured, suggesting that it represents a broad erosional surface formed beneath an ancient stream.

Units 2, 3, and 5 are interpreted as lateral accretion deposits laid down by a relatively low-energy meandering stream during basin aggradation. Modest discharge is suggested because (1) the stream was competent to transport sediment no coarser than fine gravel and sand, (2) large-scale trough cross-bedding and deep channeling are absent, and (3) the fine-grained interbeds are highly discontinuous and lenticular. These silty organic-stained interbeds probably represent channel margin and overbank deposits that accumulated locally during general aggradation. Some apparently represent incipient paleosol development.

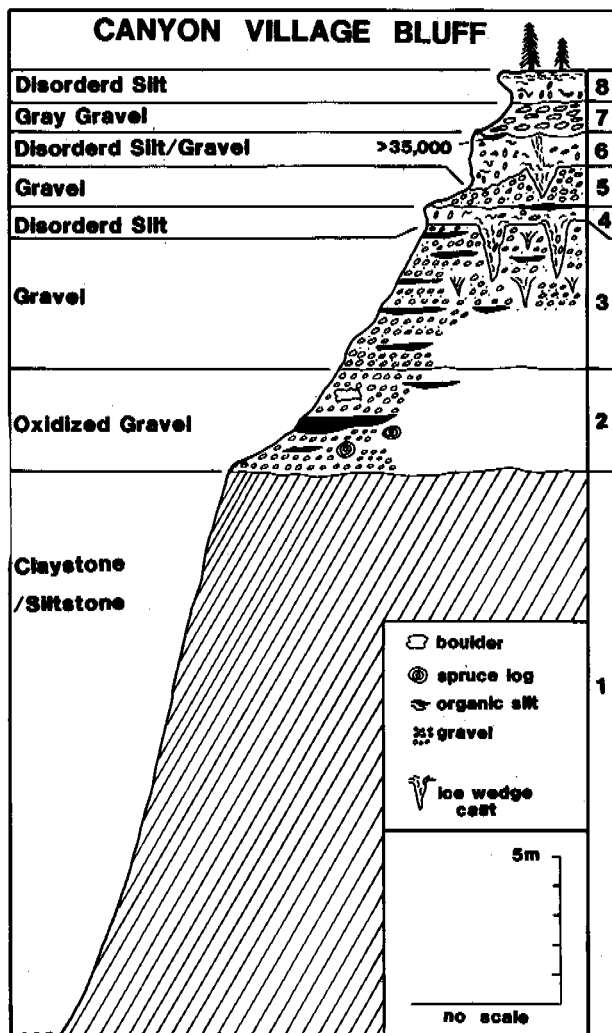

FIGURE 2 Measured stratigraphic section at Canyon Village Bluff. Refer to Table 1 for description of the units and to Figure 1 for location of section.

Well-rounded chert and quartzite pebbles identical to those from local Tertiary deposits comprise an estimated 60% of the gravel clasts in the lowest gravel (Unit 2). The decrease in abundance of these pebbles upward to an estimated 40 and 25% in Units 3 and 5, respectively, suggests that Tertiary deposits became less important as a source of sediment with time. This observation is consistent with a gradual aggradation of the Fishhook Bend Basin during Quaternary time.

Large, stained but unweathered, weakly abraded spruce logs in Unit 2 decrease in apparent abundance upward, with none being observed in younger units. Given the similar depositional environments inferred for Units 2–5, the absence of spruce in higher units may indicate a local extinction of spruce from this vicinity. The

TABLE 1 Description of Units at Measured Stratigraphic Section at Canyon Village Bluff.

Unit	Thick- ness (m)	Description
1	19	Claystone and siltstone: Laminated to massive gray siltstone and claystone interbedded with sand and well-rounded fine gravel. Weakly indurated. Unit dips 9° to northwest.
2	3.5	Oxidized gravel: Rounded to subrounded pebble- to small cobble-sized polymictic clasts in a subangular-rounded mixed sand matrix. Mean maximum clast diameter 2-4 cm. Commonly weakly bedded as subhorizontal slightly imbricate zones, with occasional cross-bedded lenses where sandy. Smaller pebbles are clasts of exceptionally well rounded chert and quartzite. Several large basalt boulders to 35 cm diameter occur within fine gravel matrix and exhibit percussion scars and occasional scratches. Unit contains common large spruce (<i>Picea</i>) logs to 15 cm diameter which have roots intact, slightly abraded appearance, and are stripped of bark. Logs diminish in abundance upward. Black organic silty lenses with flat tops and rounded lenses are present in channeled zones. Entire unit stained strong brown, with matrix less oxidized than clasts. Sharply defined horizontal slightly channeled lower contact.
3	4.5	Lower brown gravel: Rounded to subrounded pebble- to small cobble-sized polymictic clasts in a loose subangular to rounded sand matrix. Mean maximum diameter is 4-5 cm. Contains slightly less rounded and coarser clasts than Unit 1. Subhorizontally bedded and weakly imbricate, with rare trough cross bedding in sandy zones. Common flat-topped lenses of organic-stained silty sand, one of which appears to have incipient soil development. Unidentified mammal bone fossils are rare and retransported wood fragments common. Multiple wedge-shaped zones about 30 cm wide occur with a spacing of about 7 m along a definite horizon about 2 m below top of unit. Wedge forms defined by orientation of tabular clasts and organic zones that penetrate downward into subhorizontal bedding. Minor slumping within wedge forms. Several less well defined isolated wedge forms occur above the prominent horizon. Unit slightly stained to a brown color.
4	1	Lower disordered silt: Unit highly variable in thickness and appearance. Dominantly grayish brown massive unbedded silt and sand mixed with gravel near sharp disturbed lower contact. The orientation of organic lenses and tabular clasts is chaotic and contorted. Unit occasionally overlain by discontinuous 20 cm thick reddish brown organic zone which overlies a thin discontinuous gray horizon. Projecting from the base of unit are

TABLE 1 (Continued)

Unit	Thick- ness (m)	Description
		multiple vertical wedge-shaped structures that are typically 30-40 cm wide and spaced at about 10 m intervals along the bluff face. Wedge forms penetrate and crosscut underlying gravel to a maximum depth of 3 m and are defined by tabular and elongate clasts, organic lenses, wood fragments, and slump zones oriented parallel to wedge walls within a mixed silty sand matrix. At top of several wedge forms host sediments are deformed upward near margins. Lower contact abrupt and deformed.
5	1	Upper brown gravel: Rounded to subrounded pebble- to small cobble-sized polymictic gravel in a subangular to rounded coarse sand matrix. Mean maximum clast diameter 3-5 cm. Bedding commonly expressed as sub-horizontal orientation of stones. Contains small abraded wood fragments and no more than 25% well-rounded chert and quartzite fragments. Unit slightly stained to a light brown color. Subhorizontal slightly channeled lower contact.
6	2	Disordered silt and gravel: Unit variable in thickness and appearance. Dominantly grayish brown mixed silt, sand, granules, and fine gravels. Lower and upper parts are finer textured, with a central zone containing more gravel. Granule zones, elongate cobbles, and organic lenses show complex chaotic orientations near base, with many clasts having vertical orientation. Projecting from the base of unit are multiple wedge-shaped structures that are typically 50-100 cm wide and spaced at wide intervals along the bluff. Wedge forms penetrate and crosscut underlying strata to a depth of several meters. Wedge forms are similar to those in Unit 4. Several 10-30 cm wide zones of non-vertical clast orientations and silty segregated layers widen upward from the tops of large wedge forms to the channeled upward contact. At one locality along the upper contact a 0-5 cm thick bed of organic silt with sparse wood fragments yielded a 14C date of greater than 35,000 years B.P. (BETA-1823). Abrupt disturbed lower contact.
7	1.5	Gray gravel: Subangular to subrounded pebble- to cobble-sized clasts largely of sedimentary rocks in a very sparse, loose coarse sand-granule matrix. Mean maximum diameter 5-7 cm. Clasts are dominantly tabular to discoidal in shape with a strong southwest imbrication. Bedding generally absent, but a subhorizontal fabric is present. Upper 30 cm is weakly oxidized, increasing in intensity upward. Carbonate encrustations occur at base of nearly all clasts. Lower contact very sharp and moderately channeled.

TABLE 1 (Continued)

Unit	Thick- ness (m)	Description
8	1	Upper disordered silt: Unit dominantly mixed silt and fine sand, but is silty near base and sandy near top. Brown organic silt lenses to 3 cm thick with subparallel stained zones common, especially near base. Organic lenses greatly convoluted, especially near base, where gravel clasts, mixed from the lower contact, show chaotic orientations. Upper 20 cm is a peaty organic zone below spruce forest.
Total		33.5

presence of anomalously large, subangular, scratched and battered basalt boulders in the fine sediment matrix of Unit 2 suggests boulder transport and modification by river ice under periglacial conditions. Similar phenomena occur along the Porcupine River today, during times of violent spring breakup.

The lowest Quaternary gravel (Unit 2) is oxidized to a strong brown color. Although the color contrast between Units 2 and 3 is sharp, there is no direct sedimentologic evidence for a unit contact, no apparent increase in the amount of weathering upward toward the Unit 2-3 contact, and no zones of clay alteration. Instead, oxidation seems equally pervasive throughout the entire unit. The horizontality of the Unit 2-3 contact, the absence of a weathering gradient, the presence of unweathered spruce logs, and the pervasive oxidation of these permeable sandy gravels suggest that groundwater circulation above the flat contact with impermeable Tertiary sediments may be responsible for the staining. This favored hypothesis requires unfrozen conditions at some time following deposition of Unit 3. Permafrost at the bluff must have been absent, very thin, or restricted to a great depth at this time.

Units 4, 6, and 8 are significantly finer textured than the gravel units (Table 1). All are disordered to some extent by congeliturbation, which makes their origin difficult to determine. Woody fragments and organic silt layers occur in each unit. The surface unit (Unit 8) is clearly eolian in origin because no opportunity exists for fluvial deposition and because deposition is occurring now. Unit 4 is similar in texture to Unit 8 and may also be eolian, at least in its upper parts. Unit 6 has disordered interbeds of fine gravel, suggesting a probable fluvial origin. Silty zones within Unit 6 may be either eolian or fluvial. Units 4 and 6 may represent fluvial overbank sediments completing two cycles of fluvial aggradation associated with units 3 and 5, respectively.

The oldest evidence for permafrost conditions at the bluff is a horizon of small IWC within the gravel of Unit 3 about 7 m below the bluff top (Figure 2). Small wedge-shaped features higher in Unit 3 are also interpreted as small IWC, but their lack of regularity makes them suspicious. Two pronounced horizons of IWC that penetrate the underlying gravels are exposed at the bases of Units 4 and 6. These wedge-shaped structures are interpreted as IWC because they exhibit downwarping of host sediments at their upper margins, irregular slump structures within the casts, and a prominent regularity in spacing along the bluff of several meters. These features are most characteristic of IWC (Black 1976, Péwé et al. 1969).

Above the base of both IWC horizons, organic lenses and elongate clasts are either highly contorted or randomly oriented, suggesting that considerable cryoturbation has occurred in these fine-grained deposits. Because they overlie the IWC, these cryoturbated zones are interpreted as former active layers. The thickness of each cryoturbated zone represents a minimum thickness of the former active layers. In the case of Unit 4 the incipient paleosol at the top of the cryoturbated zone suggests that the active layer may have been only 50-70 cm thick.

The youngest episode of wedge growth is indicated by narrow zones of vertically oriented clasts that begin at the top of the massive IWC in Unit 6 and that widen upward. These features are interpreted as either IWC or soil wedges (Black 1976). If they are IWC, they represent either incipient growth of ice wedges within Unit 6 or are the roots of larger former ice wedges that have been removed by erosion. An incipient ice-wedge origin is preferred because there is no evidence for significant erosion and because they lie directly above the former wedges.

Unit 7 originated in a manner very different from the other gravel units. The scoured nature of its lower contact, its relatively low textural and compositional maturity, its sheetlike uniformly imbricate character, and the braided appearance of its surface elsewhere in the valley (Thorson and Dixon, in press) suggest that it was deposited by a high discharge stream during glacial lake overflow from the Yukon Territory. Rapid incision of the Porcupine River after deposition of Unit 7 resulted in isolation of the present bluff area as a terrace at least 10 m above the active floodplain.

Age of Units

Only one radiocarbon date of greater than 35,000 14C yr B.P. (BETA-1823) is available for Canyon Village Bluff. This date, which was obtained from "fresh-looking" small wood fragments from a dense peaty silt at the very top of Unit 6, indicates that all four IWC horizons are older than 35,000 years. There is no evidence to suggest that significant erosional disconformities exist below the dated horizon or that prolonged intervals of weathering occurred on exposed surfaces. Rather, deposition of Units 2-6

appears to represent intermittent aggradation. Deposition of sediments by a migrating meandering stream apparently alternated with intervals when the ground surface was exposed to cryoturbation, eolian and/or overbank deposition, and contraction cracking with attendant growth of ice wedges at depth. The unweathered character of all units indicates that significant soil development did not occur, as for example during a long warm interglaciation. The presence of spruce logs near the base of the exposure suggests either interstadial or interglacial conditions because forest was probably absent from interior Alaska during full glacial conditions (Hopkins et al. 1981, Westgate et al. 1983). Based on these considerations the Unit 2-6 sequence is here interpreted to span all or part of the interval from the last interglaciation (Sangamon; marine isotope stage 5e) to the Middle Wisconsin Interstadial (marine isotope stage 3). This interval is dated globally from about 125,000 to 32,000 years B.P. (Shackelton and Opdyke 1973).

It is possible that the wood fragments dated at greater than 35,000 years B.P. were redeposited from older wood-rich units in the valley. This possibility is largely ruled out by many other ¹⁴C dates in more controlled contexts which indicate that Unit 7 must be older than about 31,000 years B.P. (Thorson and Dixon, in press).

The surface eolian cap (Unit 8) is clearly of recent origin. It resulted from eolian deposition on the terrace by sediments derived largely from the exposed bluff face and from more distant areas. The upward coarsening within this unit can be explained by the progressive approach of the source area (bluff face) to its present position. If Unit 8 is Holocene in origin and the underlying gravel is older than 31,000 years B.P., an interval of at least 20,000 years is not represented by sediments. Weathering on the gravel surface and calcification of the clasts must represent at least part of this interval. Nondeposition of eolian sediments and/or deflation may have occurred during this interval, but no evidence of wind abrasion was found. Apparently, ice wedge growth, significant weathering, or cryoturbation did not occur at Canyon Village Bluff during the maximum of the last glaciation (late Wisconsin).

CLIMATIC IMPLICATIONS

Units 2-6 at the bluff are interpreted as probably late Pleistocene in age and as having formed during episodes of alluvial deposition that alternated with episodes of cryoturbation. Intervals of congeliturbation and paleosol development on exposed surfaces probably spanned the greater share of time during basin aggradation. Development of ice wedges following deposition of Units 3, 4, and 6 must have been followed by melting and collapse; otherwise the wedges would still be present today. Furthermore each IWC horizon must have developed by thawing prior to the formation of the next higher one; otherwise the deposits overlying the IWC horizons would have been deformed as well. For example, ice

wedges formed during the interval represented by Unit 6 cut through the underlying undeformed gravels which overlie the IWC of Unit 4. Thus, each IWC horizon can be interpreted as evidence for one cold-warm oscillation of temperature within the near-surface soil, the cause(s) of which are unknown.

Changes in soil temperature may result from a number of interacting factors, all of which may be operative in this case (Washburn 1980, Black 1976). Fluctuations in ground ice stability may accompany sedimentary cycles associated with meandering streams. Changes in air temperature (either mean annual or during a critical period), changes in the degree of thermal insulation from winter snowpack or ground vegetation, changes in vegetation caused by local wildfires, and changes in the thermal conductivity of the soil may all influence the stability of permafrost. Although the causes of the four cycles of permafrost formation and degradation at the bluff are unknown, their oscillatory nature indicates that the Fishhook Bend area has been in a sensitive regime with respect to the formation and preservation of ground ice since the last interglaciation. This interpretation is consistent with observations by Matthews (1980) and Morlan (1980) suggesting oscillatory climates in the northern Yukon Territory during the same time interval.

The complete absence of IWC horizons or significant cryoturbation of the youngest gravel at the bluff is puzzling when compared with the multiple IWC horizons beneath it and because of the widespread presence of large modern ice wedges in the area. The most plausible explanation for this phenomenon is that ice wedges in gravel can only develop locally under at least occasionally saturated conditions on active floodplains or low terraces. The rapid incision that followed deposition of Unit 7, the presence of an oxidized zone on its surface, and the carbonate encrustations within Unit 8 indicate that this gravel has not been poorly drained enough for ice wedge development to occur.

ACKNOWLEDGMENTS

Field studies at Canyon Village Bluff were supported by the National Geographic Society through a grant to the University of Alaska Museum. E. J. Dixon, project leader, was helpful in numerous ways. Field assistance by D. Hunter, D. C. Plaskett, and K. H. Thorson is greatly appreciated. Field consultations with D. M. Hopkins, O. L. Hughes, J. V. Matthews, N. Rutter, C. Schweger and A. Dyke greatly helped in interpretation of the bluff exposure. T. D. Hamilton and R. D. Reger, who reviewed this manuscript, provided many helpful suggestions.

LOESS-LIKE YEDOM-COMPLEX DEPOSITS IN NORTHEASTERN USSR; STAGES AND
INTERRUPTIONS IN THEIR ACCUMULATION; AND THEIR CRYOTEXTURES

S. V. Tomirdiario

North-East Interdisciplinary Scientific Research Institute,
Academy of Sciences, Magadan, USSR

Loess layers of a yedom complex with a special cryotexture accumulated during the glacial periods in the cryoarid landscapes of Northeastern USSR, while during the interglacials buried soil profiles and thermokarst facies were formed in cryohumid landscapes. This pattern corresponds in principle to that of the classic loess deposits of the periglacial regions of Europe.

Covers or remnants of covers of unique loess-like deposits containing syngenetic polygonal ice wedges of Late Pleistocene age are widely distributed in the Northeastern USSR and Alaska. Soviet authors define this association of rocks as "yedoma complex" or "loess-ice formation" (Tomirdiario 1980) while the Alaskan (Fairbanks) counterparts describe it as eolian loess (Goldstream Formation; Péwé 1975).

Special investigations made by the author for many years in Yakutia and Chukotka indicate that in the more complete yedoma sections two ubiquitous chronostratigraphic horizons are recognizable; the latter comprise proper loess-like unredeposited beds with syngenetic ice wedges and is referred to as the Zyryanka and Sartanian cryochrones. The former comprise chronostratigraphic horizons of peat, soil, and thermokarst facies and belong to Kazantsevsky, Karghinsky or Hologenic thermochrones (Figure 1).

Presently, this stratigraphic scheme was approved as a regional rank division by the All-Union Interdepartmental Conference on Development of Stratigraphic Schemes for the Quaternary Deposits in the Eastern USSR held in Magadan in March 1982. The above-mentioned chronostratigraphic horizons were given local names corresponding to the stratotypes identified for them. Thus, a layer of loess-like deposits containing syngenetic ice wedges of the Ice time (Q^2_{III}) was named Oyagossky Horizon (type section: the Yagossky Yar yedoma on the bank of Dmitry Laptev Strait); a layer of buried soil, peat, and lake-thermokarst facies of the Karghinsky warm interstadial (Q^3_{III}) was named Molotkovsky Horizon (type section: lake-thermokarst deposits near Molotkovsky Kamen' rock on the Anyui River); and a layer of loess-like deposits containing syngenetic ice wedges of Sartanian glaciation (Q^4_{III}) was named Mus-Khaya Horizon (type section: the upper part of the Mus-Khaya yedoma section on the Yana River). Correspondingly, the previously common term "yedoma suite" has been replaced by "yedoma series."

During the Interdepartmental Conference of 1982, it was pointed out, in particular, that since the Oyagossky and Mus-Khaya horizons of proper loess-like deposits of the yedoma series should be considered as having accumulated during the maximal worldwide climatic deterioration and aridization

in the Pleistocene (Q^2_{III}) and (Q^4_{III}), i.e. during the epochs of the commonly known global eolian loess accumulation in landscapes of the permafrost/periglacial ("mammoth") tundra-steppes of Northern Eurasia and America, that these deposits must be of a universal and uniform cryogenic-eolian nature. In the case of the yedomas from Chukotka and Yakutia this concept has been developed by the author (Tomirdiario 1972, 1978, 1980) and Academician Shilo (Shilo and Tomirdiario 1981) as well as by Péwé, Journaux, and Stuckenrath (1977). Investigations by Giterman and Kaplina as well as by the author (Tomirdiario 1980) showed that, as evident from numerous representative spore-pollen analyses in sections of the yedoma series, both horizons of proper loess-like deposits (the Oyagossky and Mus-Khaya horizons in Figure 1) accumulated in areas of very dry steppe conditions, which were even devoid of shrubs. Layers of fossil soil, peat, and thermokarst facies of the Molotkovsky and Holocene horizons accumulated in fundamentally different landscapes that were wetter, boggy, and forested (Figure 1). This conclusion results from palynologic analyses of fossil remains of theriofauna and fossil insect fauna.

All these drastic and cardinal changes of paleo-landscape environments during the time of accumulation of different chronostratigraphic horizons of the yedoma complex (the yedoma series) were reflected, as shown by the author's investigations, in their cryologic structure (Figure 1).

The general scheme is as follows:

(1) Deposits occurring at the base of the yedoma complex (the yedoma series) may belong to any time prior to the Late Pleistocene. However, ancient soil, peat, and lake-alas thermokarst deposits of the Kazantsevsky interglacial (Q^1_{III}) are often found. Ice veins are epigenetic and wedge-like.

(2) The Zyryanka age (Q^2_{III}) of the Oyagossky horizon in the deposits of the yedoma complex is established by the combination of the following features:

(a) steppe or tundra-steppe spore-pollen spectra typical of cold periods of ice epochs (Tomirdiario 1980);

(b) universal distribution of syngenetic ice wedges and eolian loess-like sandy loams also related to the ice epochs;

(c) abundant bone remains of Late Paleolithic mammoth fauna with ages that are beyond the limits of radiocarbon dating.

This unit is characterized by broad ice veins up to 6 m wide; there are common thick schlieren or ribbonlike parallel-concave continuous cryotextures (Figure 1).

(3) The Karghinsky (Q^3_{III}) age of the next, Molotkovsky, horizon is supported by many radiocarbon dates of buried peat and soil containing wooden macroremnants. These dates are within the period of 45-40 to 25-24 thousand years B.P. (Tomirdiario 1980, Shilo and Tomirdiario 1981). A bed of loess-like deposits occurring between the peat horizons (Figure 1) is characterized by steppe spore-pollen spectra and is referred to drier and colder Mid-Karghinian time. This unit exhibits thick schlieren, flat-layered cryotextures. The lower- and upper-lying horizons of peat and fossil soil are characterized by forest spectra and belong to Early and Late Karghinsky warm stages. Here loess-accumulation and ice vein development were interrupted although permafrost persisted. Its cryotexture is massive and ice veins are epigenetic and wedgelike throughout.

(4) The Sartanian age (Q^4_{III}) of the third layer from the base, i.e. Mus-Khaya horizon, is evident from radiocarbon dates of roots of herbaceous steppe vegetation. For example, 3 dates were obtained at the Mus-Khaya type section: the sample taken from 2 m depth below the top of the exposure (MAG-137), was dated as 11500 ± 210 yr B.P., and the sample taken from 15.5 m depth was dated as 23360 ± 720 yr B.P. (Tomirdiario 1980). In the Duvanny Yar exposure, that is the key section for all yedomas of the continental subarctic type identified by us, a sample of rootlets of herbaceous vegetation (MAG-592) taken from 3 m depth, below the top of a 35 m high bluff, was dated at 15850 ± 150 yr B.P. Even in Central Yakutia, near the city of Yakutsk at an elevation of 50 m above the Lena River, samples of analogous rootlets (IM-432, IK-431, IM-430) were taken from depths of 3, 8, and 14 m below the surface and gave dates of 13600 ± 900 yr, 17800 ± 850 yr, and 18700 ± 990 yr B.P.

In all sites of the Mus-Khaya horizon, the spore-pollen complex is characteristically that of paleolandscapes of extremely dry Artemisian steppes and Selaginellan semideserts (Tomirdiario 1980). A drastic increase in dryness and higher rates of loess-accumulation are also registered in the Mus-Khaya horizon of the subarctic type yedomas from both Mamontova Gora on the Aldan River in the south to Duvanny Yar on the Kolyma River in the north. There is a domination of exclusively microsclieren syngenetic flat-layered (microlenticular) cryotextures (filament lenticules of ice in the rock) and a sharp decrease in the width of ice veins (down to 1-2 m) as compared to that of the veins from the Oyagossky horizon (Figure 1).

(5) The Holocene age (Q_{IV}) of the yedoma upper horizon was determined by numerous absolute datings (Tomirdiario 1980). A subhorizon identified here underwent thawing during the Holocene and was subsequently incorporated by the permafrost; its thick schlieren cryotextured rocks are peculiar to humidified and epigenetically frozen terrain. In addition, a modern soil layer is recognizable here. The whole horizon is characterized by forest and

tundra-forest spore-pollen spectra.

The development of microsclieren (microlenticular) and discontinuous cryotextures in the Mus-Khaya horizon is definite indication that this type of rock was transformed into permafrost without having been humidified. A slow-rate freezing of fine-grained soils that have been saturated leads to the production of thick schlieren of segregated ice as well as ice-rock ribbons in them, i.e. to creation of sediments characteristic of the Oyagossky horizon of Zyryanka time. The Zyryanka time was less humid and, as demonstrated by the European data, the eolian loess-accumulation during it was 10 times slower than during the Late Würm (Q^4_{III}). This decrease in sedimentation promoted a drastic widening of ice veins within the Oyagossky horizon (Figure 1). Simultaneously, relatively higher humidity than that of Sartanian time (though still very continental and climatic) led to periodic manifestations of embryonic thermokarst and to the corresponding wetting of eolian deposits, i.e. to the eventual formation (subsequent to second freezing) of deposits with thick schlieren cryotextures (Tomirdiario 1980). However, the wetting process sometimes did not involve the whole sequence of accumulated eolian matter. Hence there are frequent cases of interbedding of thick schlieren and microsclieren within the Oyagossky horizon (Q^2_{III}) in the polygonal rock blocks (Figure 1). As far as the genesis of the ice veins is concerned, high porosity values as well as other features indicate sublimation origin (Tomirdiario 1980). The fact that large ice veins are created under very cryoarid modern climates in eolian deposits has been established by recent investigations of permafrost sand dunes occurring in the islands of the Canadian Arctic Archipelago (Pissart et al. 1977).

In the Arctic, eolian matter is deposited at a slower rate than within the Oyagossky horizon of the subarctic type yedomas. Besides, the slow-rate deposition took place both during the Zyryanka and Sartanian time. In our opinion, that was precisely the reason for the ice veins of the Arctic type yedomas to be unusually broad (as wide as 8-9.5 m). As compared to the yedomas from subarctic areas, they exhibit a reversed ratio between ground ice and enclosing rock. It is during descriptions of such yedomas that a previous hypothesis was put forward implying the distribution of buried glaciers in northern Yakutia. Since these entities are confined exclusively to the Arctic zone, we recognized them as yedomas of specific Arctic or shelf type (Tomirdiario 1980).

The region where these 90% ice yedomas are distributed is restricted to the northernmost part of the Yana-Indigirka lowland as well as to the islands of New Siberian Archipelago; they are also preserved on the islands lying in the Lena delta area and in the Anabar-Olenyok Maritime Lowland. The southern limit of this region lies, as demonstrated by our reconnaissance surveys, at about 72° of northern latitude (Tomirdiario 1982).

We undertook careful examinations of the following key sections for ice yedomas: Oyagossky Yar on the shore of Dmitry Laptev Strait, Khaptashinsky Yar on the shore of the East Siberian Sea, and Bykovskaya yedoma in the Lena River delta (Tomirdiario et al. 1982).

Huge ice veins measuring 8-9.5 m in width and up

to 40 m in height are usually overlain here by a very thin soil veneer measuring 0.5-0.6 m. This layer often thaws during summer and the thawing front penetrates down into the vein ice. This results in its gradual latent thawing. Subsequently, intervein polygonal rock blocks get involved and hence elevated above the yedoma surface; this, in turn, leads to the development of the block-baidzherakhi microrelief on the surface that is typical of this yedoma type (Tomirdiario et al. 1982). This microrelief enables a rough mapping of the area where they are distributed (Tomirdiario et al. 1982). Where the veneer is especially thin (e.g. the Oyagossky and Khaptashinsky units), the Sartanian part of the yedoma (the Mus-Khaya horizon) has already thawed away. However, in the Bykovsky ice yedoma (Bykovsky Peninsula, the Lena River delta) we managed to discover a Sartanian horizon of the Arctic type yedomas preserved below a thicker soil-rock layer. Absolute datings of 22070 ± 410 yr B.P. (LU-1263) were obtained here by the analyses of rootlets of fossil herbaceous vegetation recovered at 8 m depth from the top of a 32 m bluff (Tomirdiario 1982). It was found that, as distinct from the yedomas of subarctic type mentioned earlier, the Mus-Khaya horizon (Q^4_{III}) here also contains huge ice veins as wide (up to 9.5 m) as those from the Oyagossky unit (Q^2_{III}). However, despite the mammoth size of the ice veins, the cryogenic texture here also generally changed from the thick schlieren and ribbonlike parallel-concave member in the Oyagossky horizon to the microlenticular horizontal-layered texture in the Mus-Khaya horizon (Tomirdiario et al. 1982). This is definite indication that the cessation of embryonic thermokarst during the Sartanian time was related primarily to the general climatic dryness of that cryochrone and not to the ground ice formed in any one region.

All in all, the extensive belt of shelf type ice yedomas found by us in the Eastern Arctic testifies to a pronounced "gulf" in the process of loess accumulation which is so intensive in the cryochrones of Late Pleistocene Eurasia. Actually, whenever the Arctic yedomas of loess-ice type measuring 20-25 m in height undergo complete thawing, a layer of mineral matter is left that is only 2-2.5 m thick.

In terms of eolian genesis, this can be explained by the domination of northeastern and eastern winds produced by the Arctic anticyclone during the ice epochs. With such a circulation pattern, the Arctic winds could not carry much dust since they did not meet, on their way, any mountainous edifices within the Arctic ocean which were covered by ice and fine dust at that time. In the meantime, the winds that blew over the coastal areas of the mainland picked up large volumes of dried dust from the vegetation-free slopes of mountainous slopes in Chukotka and Yakutia. This concept is substantiated by comparative grain-size analyses of rocks from yedomas belonging to the subarctic and Arctic types (Tomirdiario 1980, Tomirdiario et al. 1982). It is no accident that the former are made up of rather coarse sandy loams and the latter of fine-grained loams or even silty clays, i.e. perhaps, eolian silts/sediments of the ancient atmosphere of the cold "loess" epochs of the Late Pleistocene.

Even the yedoma from Bykovsky Peninsula occurring at the foot of the Kharaulakh mountain range consists of 85% ice and the rocks from polygonal blocks or "pillars," also made up by loams (Tomirdiario et al. 1982). Therefore, in this area, the mineral matter was also introduced from the north and not from the south; the sediment was not transported from the adjacent southern mountains; on the contrary, it was blown to the piedmont from the north. Besides, the Arctic winds carried the pollen rain. That is why the spore-pollen diagrams (Kaplina 1979, Tomirdiario 1980) showed that steppe grass pollen prevails (Figure 1) and tree pollen is almost totally absent from the yedomas of both types in the Oyagossky and Mus-Khaya horizons. This is a very peculiar feature since these vegetation species, especially such Northeast Asian endemic species as *Populus suaveolens*, *Chosenia macrolepis* and others, managed to persist during the same ice epochs in areas immediately to the south, i.e. in the mountainous valleys of Northeastern Asia.

FROZEN GROUND IN THE ALTAI MOUNTAINS OF CHINA

Tong Boliang, Li Shude, Zhang Tingjun, and He Yixian

Lanzhou Institute of Glaciology and Cryopedology, Academia Sinica
People's Republic of China

Frozen ground in the Altai Mountains of China can be divided into three zones: seasonally frozen ground, sporadic permafrost, and widespread permafrost. In seasonally frozen ground, the depth of the thawed layer is 0.8-1.0 m in the peat layer, 0.9-1.6 m in the loam layer, and over 1.9 m in sandy gravel sediments; the mean annual ground temperature is no lower than -1.0°C . The sporadic permafrost zone is situated between 2200 and 2800 m a.s.l. In general, permafrost islands are distributed in peat layers in marshy depressions and in caves on northfacing slopes. Some palsas with 1- to 2-m ice layers were found. The widespread permafrost zone is situated in the high mountain zone above 2800 m a.s.l. The permafrost thickness is estimated to be less than 400 m, and the mean annual ground temperature is higher than -5°C . The lower limits of permafrost in the last glacial period and Neoglaciation were 750-900 m and 400-600 m, respectively, lower than at present. Permafrost in the sporadic zone was formed during the Neoglaciation, while the lower part of the permafrost layer in the widespread permafrost zone was probably formed during the last glacial period.

The glacial and permafrost expedition organized by Lanzhou Institute of Glaciology and Cryopedology, the Chinese Academy of Sciences, made the first investigation of permafrost in the Altai Mountains within the borders of China in 1980. The region investigated is situated in the southern side of the middle part of the Altai Mountains, from $49^{\circ}08'$ N in the north, southeastward to about 46° N at a distance about 450 km from NW to SE within the border of China. It is 150 km wide in the northwestern part, and approximately 80 km in the southeastern part. It gradually decreases in height from north to south and from northwest to southeast. In the vicinity of watershed in the western part of the investigated region lie the boundaries of three countries: the People's Republic of Mongolia, the Soviet Union, and the People's Republic of China. It is also the highest area in the whole Altai Mountains, with several mountain peaks over 4,000 m high, including Youyi Feng, the highest (4,374 m). Around Youyi Feng is the most widespread area of glaciation in the Altai Mountains, including the largest glacier in the Altai Mountains in China, the Kalasi Glacier. In the southeastern part of the mountain range (about 3,200-3,500 m), no modern glaciers occur.

CHARACTERISTICS OF FROZEN GROUND

Field data indicate that permafrost occurs above 2,200 m in the Altai Mountains within the border of China, while seasonally frozen ground zone lies below 2,200 m (Fig. 1). Seasonally frozen ground is

found in the lower part of middle mountain zone (2,000-2,200 m), the low mountain zone (1,200-2,000 m), hill zone (800-1,200 m) and front-range plain (below 800 m) (Xinjiang Scientific Expedition 1978). Only under surface water bodies or adjacent to heated buildings, seasonally frozen ground is absent. The mean annual ground temperature varies from 4°C to 7°C in this zone. The mean annual air temperature varies from $3-4^{\circ}\text{C}$ in the front-range plain, $2-3^{\circ}\text{C}$ in the hill zone, and 0 to -4°C in the low mountain zone (Fig. 2). The maximum frost penetration in sandy clay is about 1-1.5 m in the front-range plain, 1-2 m in the hill zone, and 1.5-2.5 m in the low mountain zone. Seasonally frozen ground occurs for 5 months, from the beginning of November to the end of March. The time of initial freezing in the plain areas is about two weeks later than in the mountain areas. The maximum depth of freezing occurs at the end of March and it thaws during the last ten days of May. There is little difference in freezing rate in different geomorphological units within the seasonally frozen zone (only 25-35% variation, see Fig. 3). It is remarkable that the frozen depth at Qinghe (1,218 m) in the low mountain-hill zone (Fig. 4) is much greater than that at Sentasi (1,900 m) in the middle mountain zone (Fig. 5). This demonstrates the effect of an air temperature inversion layer in winter, producing lower air temperatures in the zone below 1,200 m. The precipitation increase with elevation is also important. The annual precipitation increases from 100-200 mm in the plain area and 200-300 mm in the low

FIGURE 5 Process of frost penetration during 1960-1961 at Sentasi in the Altay Mountains.

mountain zone, to 400-500 mm in the middle mountain zone. More importantly, the depth of snow accumulation varies with the increase of elevation. Snow cover has a thickness of only 10-30 cm in the plain area, 100-200 cm in the low mountain zone (i.e. Sentasi), and up to 150-250 cm in the middle mountain zone. On the slopes, snow cover usually has a thickness of 60-170 cm, but in the snow accumulation area adjacent to a wind gap, it increases to 400-500 cm, covering the tops of electric poles, i.e. at Qiong Kur (2,600-2,700 m in Fuhai county). At a small town in mountain area of Fuyun county with 170 cm mean annual snow cover, the seasonally frozen layer is only 50 cm in depth, while without snow cover, the depth of seasonal freezing increases up to 150 cm. The mean the mean annual air temperature is $2.0-4.5^{\circ}\text{C}$ in both the front-range plain and the hill zone, but the difference between freezing and thawing index is $1,200-1,600^{\circ}\text{C}\cdot\text{day}$ at the former and -190 to $-1253^{\circ}\text{C}\cdot\text{day}$ at the latter, the former being twice as high as the latter. These are the results of the facts that where the snow cover is thick, the period of snow accumulation is long. Hence, the heat-preserving and heat-insulating effect of snow during the period of abrupt drop of temperature in winter in the investigated region is obvious (Fig. 6). Snow cover increases the mean annual ground temperature and decreases the annual amplitude of ground temperature variation, as a result, decreasing the depth of the seasonally frozen layer (Lanzhou Institute of Glaciology and Cryopedology and Desert Research 1975). In the Altay Mountains within the border of the Soviet Union, snow cover 30-35 cm thick makes the ground temperature at a depth of 30 cm 25°C higher than that without snow cover, and a thickness of 50-60 cm 37°C higher than the air temperature (Shulekin 1954).

Periglacial phenomena within the seasonally frozen zone are: eolian dune, spring icing, and river icing in low mountain zone, seasonal cave ice in the lower part of middle mountain zone, which has a thickness of 60-70 cm, appearing in the middle of October and disappearing at the beginning of May

FIGURE 6 Influence of snow cover on freezing depth (h), mean annual ground temperature (t), and annual amplitude (A).

next year. Occasionally block slopes can be found on the north-facing slope in the western bank of Kalasi lake.

The sporadic permafrost zone is situated from 2,200 m to 2,800 m in the middle and upper part of middle mountain zone. It has an area of approximately $6,300\text{ km}^2$, covering 25% of the area in the entire investigated region. Permafrost islands are present in peat layers in marshy depression and in caves on the north-facing slopes. The area of peat distribution is generally no greater than 15 km^2 . For example, Kalakur ($48^{\circ}44'\text{N}$, $88^{\circ}11'\text{E}$, 2,200 m), 12 km to the east of Kalasi town, has a peat layer 2 m thick in a marshy lake 4 km^2 in area. More than 200 palsas are found around its southern end, some being circular or elliptical and some U-shaped. They are 2-6 m high, with an area of $1,200\text{ m}^2$. Luxuriant herbaceous plants grow on their top. Under the ground surface, there is 30-70 cm of peat overlying alternative underlying gravel loam and coarse sand. On August 27, 1980, the thawed depth was 85-110 cm. On a 1780 m^2 palsa, D.C. resistivity sounding indicated that the permafrost has a thickness of 4.7 m (He Yixian 1983). The adjoining palsa contains ground ice 1-2 m thick and permafrost 5-6 m thick (Li Peiji 1979). According to weather data from the adjacent Sentasi (1,900 m) and Aletay (735 m) weather stations, the calculated mean annual air temperature at Kalakur is -5.4°C , compared with about -6.8°C in the eastern part of the Altay Mountains. So far as we know, this is the lowest temperature at the lower limit of alpine permafrost in China, $2-3^{\circ}\text{C}$ lower than that on the Qinghai-Xizang Plateau and in Qilian Shan. Altitude of the lower limit in the sporadic zone is at least 400-652 m higher than that ever calculated (Lanzhou Institute of Glaciology and Cryopedology 1975, Xu Xiaozu 1982). This is because the annual precipitation is over 500 mm and the depth of snow cover is 150-250 cm in the middle mountain zone, greatly decreasing the heat exchange between air ground surface during the seven months of cold season. According to Maksimova (1977), snow cover 100 cm thick can raise the mean annual ground temperature by 12.8°C (mean annual air temperature -8.9°C , annual amplitude of air temperature variation 52°C , cold season 215 days). It promotes permafrost retreat and makes the lower limit of permafrost rise up to the present elevation of 2,200 m.

In the natural cave (Qiaqiayite 2,660m) formed by glacial sediments on the north-facing slope and in adit or vertical shaft of the mining area (Qiongkur $47^{\circ}45'\text{N}$, $88^{\circ}50'\text{E}$, 2560 m) in the middle mountain zone, cave permafrost has a thickness of 19 m and the ground temperature varies between -0.2 to -0.5°C . Cave ice may be 1.4-2.0 m thick, and occurs in various forms such as ice stalagmites and stalactites as well as forming underground icing.

Cave permafrost is greatly influenced by faults and groundwater. In the adit of Qiongkur, there is an inverted fault 2 m wide. No permafrost exists in the upfaulted block, but permafrost develops in the downfaulted block.

The depth of the seasonally thawed layer in this zone is 80-100 cm in peat, 90-160 cm in loams and over 190 cm in sands and gravels. The mean annual ground temperature is no lower than -1.0°C .

More periglacial phenomena are found in this zone than in seasonally frozen ground zone. They include palsas, earth hummocks, icings, cave ice, stone dish, block stream, block slopes and gelifluction. This is not only due to cold climatic conditions, but also due to richer precipitation in this zone than at lower elevations. Large palsas develop in peatland located in the marshy depressions. The steep slopes provide conditions suitable for the development of stone dish, block stream, block slopes and gelifluction. Small-scale polygons only appear in glaciofluvial loam deposits on the sides of a glacier flow. For example, there are some small polygons at a height of 2460 m in front of Kalasi Glacier with a diameter of about 70 cm, side length of 35-45 cm and cracks of about 1 cm.

The widespread permafrost zone is situated above 2,800 m in the high mountain zone with an area of approximately 4800 km², covering 19% of the area of the entire investigated region. The indicators of permafrost exist on the south-facing slopes. Permafrost is found in every geomorphological unit except a few with structural and geothermal taliks. According to D.C. resistivity sounding data, permafrost does not exist below 2,800 m on the south-facing slope in Kalasi Valley ($49^{\circ}10'N$, $87^{\circ}49'E$). On August 10, 1980, at 2,780m, ice temperature at the depth of 6 m was -2.2°C in the adjacent Kalasi Glacier, but at 3,130 m elevation, the ice temperature at the depth of 6 m was -3.7°C (Fig. 7, Wang Lilun et al. 1983). During the middle ten days of July, firn 1 m thick was still seen on the north-facing slope at 2,820 m in Qiaqiayite ($48^{\circ}59'N$, $87^{\circ}8'E$). Snow temperature at a depth of 26 cm was -0.6°C , although the air tem-

FIGURE 7 Relation between altitude and temperature at the depth of 6 m in Kalasi Glacier (1980).

perature was 12.5°C . Therefore, there is no doubt that permafrost exists under firn. At the end of September, 1980, cave ice was 180 cm thick on the south-facing slope at 2,995 m in the Arshate mining area in the north of Qinghe county in the eastern part of the investigated region. The ice temperature was -2.0°C . Hence, in the whole investigated region, permafrost occurs extensively above an altitude of 2,800 m. The mean annual temperature in this zone is lower than -9.4°C . According to the data in a hole drilled in snow, the annual precipitation is 700-800 mm, decreasing to 600-700 mm in the east. Although there is much wind, the thickness of snow cover is generally greater than 1 m. The depth of seasonally thawed layer is still greater than 180 cm in sandy gravel soil. Using the data in the north-side of the Altay Mountains within the border of the Soviet Union, it can be estimated that the thickness of permafrost is less than 400 m and the mean annual ground temperature is higher than -5°C (Shache 1978).

PERMAFROST LOWER LIMIT IN ALTAY MOUNTAINS

The permafrost region in the Altay Mountains within the border of China is contiguous with the permafrost region in the Altay Mountains within the border of the Soviet Union and the People's Republic of Mongolia. It is situated in the southern fringe of the Eurasian permafrost region (Shache 1978, Mel'nikov 1974).

Within the border of the Soviet Union, the lower limit of permafrost on the north-facing slopes is at the height of 1,400-1,500 m at $49-50^{\circ}N$ on the northside of the Altay Mountains, on the south-facing slopes, it is 2,300 m (Shache 1978). It basically corresponds with data within the border of China. The altitude of lower limit of widespread permafrost has a tendency to undulate, e.g. at $49^{\circ}10'N$, $87^{\circ}40'E$ in the west, the altitude of the lower limit is at 2,800 m, but at $47^{\circ}7'N$, $90^{\circ}18'E$ in the east, the lower limit is still at about 2,900 m, in spite of being

1218.2m a.s.l.

2° further south. This results from difference of climatic conditions between the eastern and western regions (Table 1). Because the investigated region is situated in the hinterland of the Eurasian Continent, only does the Arctic air move along Ebi river, eastward to the Ertix River then extends to the Altay Mountains within the border of China. Therefore, the annual precipitation, depth of snow cover and its effects in the west are greater than those in the east. The eastern region is controlled by the Mongolian and Siberian cold high pressure, and north-east and north winds prevail in winter. In January, the mean air temperature is -23.2°C in Qinghe county, but it is -12.1°C in Heishantou which is situated to the northwest of Qinghe. The difference of mean annual air temperature between these two areas is 3.7°C. The west and north-west winds prevail in summer in the entire region. The difference of temperature between the eastern and western parts is very small. In the east climate is colder and the climate continentality is stronger than that in the west. Therefore, the lower limit of widespread permafrost in the eastern part is at a lower elevation than that in the western part. It is estimated that the lower limit of sporadic permafrost between the eastern and western parts has also similar condition.

The kinds and distribution of vegetation are determined by the ecological environment; particularly climate and the hydrothermal condition of soil are very important factors. Thus a certain relationship exists between permafrost and vegetation. It is helpful to use the distribution of vegetation type to explore the extent of permafrost. In compiling the small scale permafrost map, it is worth trying to use this method. The alpine meadow vegetation with "five-flower" meadow small but very bright-coloured flower mainly grows in the western part. Its lower limit is at 2,300 m and it goes up to 2,600 m to the eastern part. In comparison with the elevation of the lower limit of alpine permafrost, the difference in the western part is only 100 m. It is estimated that the difference in the eastern part is less than the allowable error for compiling the map. Therefore, it is possible to use alpine meadow vegetation to indicate the distribution of permafrost in the Altay Mountains.

HISTORY OF PERMAFROST DEVELOPMENT IN ALTAY MOUNTAINS

The development history of permafrost in the Altay Mountains within the border of China is closely related to Quaternary geological history. According to C1⁴ data, peat layers in the middle mountain were formed at 5,900±150 B.P., a post-glacial hypsithermal product. Thus the palsas

must be Neoglacial, but the lower part of the widespread permafrost layer probably formed before post-glacial climatic optimum period. Permafrost at that time developed more extensively than at present. Very few newborn palsas could be found in the present palsa group. They now mainly occur around the south of the lake basin, i.e. on the north-facing slope. However, there are a lot of U-shaped and annular thaw lakes. Permafrost in the marshy basin is only found underneath the palsa; no permafrost exists 10 m away from the palsa mounds. According to the weather data of recent more than 20 years, comparing data from 1971 to 1978 with the data from 1957 to 1970, the mean annual air temperature has risen 0.1-1.0°C, especially in the eastern part. It is thus very obvious that since the beginning of the nineteenth century, the climate has been basically turning to a warm one (Zhu Kezhen 1972). Permafrost has been correspondingly degenerating. Because of such natural geographical environment, permafrost possesses unstable properties of high ground temperature, decreased thickness, etc. in the investigated region.

Basing on close relationship of paraglaciogenesis between glacier and permafrost and the exposure of many paleoglacial remains in the Altay Mountains, the extent of ancient permafrost is estimated from the correlation between the firn line and the lower limit of permafrost in the same district. At present, the firn line of Kalasi Glacier is at the height of 3,250 m, a difference of 1,050 m in comparison with the lower limit of sporadic permafrost. There are three layers of paleo-cirques at the heights of 2,500 m, 2,630 m, and 2,750 m respectively at Qiaqiyate in the vicinity of Kalasi Lake, and at the heights of 2,600-2,700 m, 2,900-3,100 m and 3,100-3,400 m within the border of Qinghe county in the eastern part, and the present firn line is at 3,500 m. Thus, by calculation, the lower limits of paleo-permafrost were at the heights of 1,450 m, 1,580 m, and 1,700 m in the west, and at the heights of 1,300-1,450 m, 1,600-1,800 m and 1,800-2,100 m in the east respectively. From the heights of paleo-cirques, we know the lower limit of paleopermafrost was at the height of 1,800-2,100 m during the Little Ice Age, not far from the present lower limit of permafrost. The lower limit of permafrost in the Neoglacial was at 1,600-1,800 m, i.e. 400-600 m lower than the present. However, during the last glacial period (Q₃), it would have descended to 1,300-1,450 m, some 750-900 m lower than the present lower limit. According to these results, it can be estimated that the mean annual air temperature during Neoglacial and the last glacial period was 2-3°C and 4-5°C respectively lower than that at present.

CONCLUSIONS

Basing on the above discussion, the distribution of permafrost in the Altay Shan within the border of China can be divided into three zones: seasonally frozen ground (below 2,200 m a.s.l.), sporadic permafrost (2,200-2,800 m a.s.l.), and widespread permafrost (above 2,800 m a.s.l.). Block fields, block streams, block slopes and icing are dominant in the entire region, with some palsas, earth hummocks and cave ice in some places.

Sporadic permafrost must be Neoglacial. Permafrost possesses unstable properties of high ground temperature and decreased thickness. The upper part of the widespread permafrost layer must be Neoglacial too, but the lower part probably formed before the post-glacial Hypsithermal times.

The extent of ancient permafrost can be estimated from the correlation between the firn line and the lower limit of permafrost in the same district. The lower limit of paleopermafrost in the late Pleistocene was at 1,300-1,450 m, in the Neoglacial period at 1,600-1,800 m, and in the Little Ice Age at 1,800-2,100 m. The mean annual air temperature was 4-5°C, 2-3°C and 0.5°C respectively lower than that at present.

Snow cover is thick in Altay Shan. It greatly decreases the heat exchange between air and ground surface in the cold season, raises the mean annual ground temperature, decreases the thickness of seasonally frozen layer and promotes degeneration of permafrost.

Climatic continentality in the eastern part of studied area is stronger than that in the western part. It is favourable to the existence of permafrost. Therefore the lower limit of sporadic and widespread permafrost zone in the eastern part is at a lower elevation than that in the western part.

There is a certain relationship between permafrost and vegetation. It is helpful to use the lower limit of alpine meadow distribution to indicate the lower limit of sporadic permafrost in the Altay Shan.

RESEARCH ON THE FROST-HEAVING FORCE OF SOILS

Tong Changjiang and Yu Chongyun

Lanzhou Institute of Glaciology and Cryopedology, Academia Sinica
People's Republic of China

To investigate the normal frost-heaving forces that act upon foundations, frost-heave tests were conducted under various conditions in both field and laboratory. Test results showed that the frost-heaving force substantially depends upon the frost susceptibility and water content of the soil, temperature, frost penetration depth, and the area of the bearing plates. A number of empirical equations are presented to evaluate the influence of these factors on frost-heaving forces. Based on model tests, the authors propose that the normal frost-heaving force be considered to be composed of two parts--the normal frost-heaving force produced by the restrained ground body beneath the bearing plates and that produced by the unrestrained ground body surrounding the restrained soil column. Therefore, the authors conclude that the value of the normal frost-heaving forces is not very great, but approaches a certain "stable" limit.

In the past 20 or 30 years, many researchers have extensively studied the normal frost heave pressure acting upon foundations during the freezing of their subsoils, and many behavioral relationships and influencing factors have been discussed. In recent years, some researchers have reported methods for roughly estimating the normal frost heave pressure and the distribution of vertical stresses at the freezing front, and published their maximum experimental values. Since 1965, extensive research has been performed on the frost heave pressure both in our laboratory and in the field near by (in the Fenghuo Mountains on the Qinghai-Xizang (Tibet) Plateau, Muli in the Qilian mountains, Mangui in the Da Hinggan Ling of Northeast China, etc.). The main factors influencing frost heave pressures, the effect of the adjacent soil and the correction coefficients for the depth and width of foundations in engineering designs, etc. have been studied in addition to their laws of annual variation and their distribution. Consequently, the laws governing the change of normal frost heave pressures and their formation concept can be further understood. However, their formation and calculation method still need further study.

EXPERIMENTAL RESULTS AND DISCUSSION

Influence of Soil Characteristics on the Normal Frost Heave Pressures

The experimental data show that the influence of soil particle size on the normal frost heave pressure is quite prominent. The normal frost heave pressure decreases as the sand grain size increases (Table 1) under almost the same

temperature and sufficient supply of water to the lower part of soil. In sands with content of sandgrain smaller than 0.1 mm, the effect on the normal frost heave pressures is more evident.

In the same way, the normal frost heave pressure increases as the specific surface area of soil increases. When the specific surface area of soil increases to 62.5 m²/g, the normal frost heave pressure decreases correspondingly.

According to experimental results under similar conditions of temperature, moisture, and bearing plate area, the values of the normal heave pressure of different types of soil are arranged in the following order: sand clay and silt > clayey > sand > clay > fine sand > coarse sand.

Influence of Soil Moisture on Normal Frost Heave Pressure

In the freezing process, frost heave and frost heave pressures are dominated by the initial water content before frost and the migration of water during the freezing process. The experiments show that, under the same soil and temperature conditions (Figure 1), normal frost heave pressure increases with the increase of soil moisture content until the normal heave pressure of ice is reached. In a closed system, the relationship between the normal frost heave pressure and initial content of soil moisture before frost can be well described by the empirical formula:

$$\sigma_{no} = ae^{-\frac{b}{w}}$$

where σ_{no} is the normal heave pressure acting upon the foundation bearing plate with the dimension of km/cm²; w is the initial moisture content in %; a and b are

TABLE 1 Normal Frost Heave Pressure of Different Types of Soil

	Fine sand (grain size) (mm)				Loess	Red clay
	2-1	1-0.5	0.5-0.25	0.25-0.1		
Content of particle size smaller than 0.1 mm (%)	4.36	7.77	6.94	16.04		
Specific surface area (m ² /g)	5.2		17.0	19.5	31.8	62.5
Normal frost heave pressure (kg/cm ²)	0.054	0.076	0.096	1.345	8.02 (average)	6.66 (average)

FIGURE 1 Relationship of normal frost heave pressure to water content and water intake amount.

experimentally determined coefficients related to soil, temperature, and area of foundation plate.

In an open system, though the initial water content before frost affects the normal frost heave pressure to a certain extent, the amount of water supplied during the freezing is more important. Experimental results show that the greater the amount of water supplied, the larger the normal frost heave pressure will be. Thus, the relationship can be approximately expressed by the following linear function:

$$\sigma_{no} = \sigma_{no}^0 + KQ$$

where σ_{no}^0 is the normal frost heave pressure without migrating water in kg/cm²; Q is the amount of migrating water in the freezing process in ml; K is an experimentally determined coefficient related to the soil and freezing conditions.

Hence, the amount of water intake or discharge during freezing is the key factor to determine the increase or decrease of the value of the normal frost heave pressure.

Relationship Between Normal Heave Pressure and Soil Temperature

The gradient of ground temperature is closely related to the speed of the movement of the freezing front in the upper layer of soil. Under the same condition, the higher the freezing rate the less the frost heave ratio and the normal frost heave pressure. It's the same the other way around. Their relationship can be expressed as follows:

$$\xi_{\sigma} = \frac{d\sigma_{no}}{dt} = A + \frac{B}{\sqrt{U_f}}$$

where ξ_{σ} is the increasing ratio of the normal frost heave pressure in kg/cm²; U_f is the frost penetrating ratio in mm/hr.; A and B are experimentally determined factors related to soil, moisture, and area of bearing plate; and t is the time in hours.

It must be pointed out that this equation is only suitable to the normal frost penetrating ratio. When the frost penetrating ratio is smaller than a certain value ($U_f < U_{f1}$), the changes of the rheology of ice body and freezing point of water are caused by the normal frost heave pressure, lowering the increasing ratio of the normal frost heave pressure. Inversely, when the frost penetration ratio is quite large ($U_f > U_{f2}$), the possibility of moisture movement is quite small and the normal frost heave pressure is only caused by the freezing of pore water.

In a closed system, normal frost heave pressures change with temperature. This law can be expressed as follows:

$$\sigma_{no} = \alpha e^{-\frac{\beta}{t}}$$

where t is the soil temperature in negative °C and α and β are experimentally determined factors related to soil type, moisture, and area of bearing plate.

That is to say, normal frost heave pressure increases exponentially with the

decrease of soil temperature, which coincides with that the unfrozen water content of frozen soil decreases exponentially with the decrease of soil temperature. From the relationship between the unfrozen water content and soil temperature, the relationship between the normal frost heave pressure and the unfrozen water content in frozen soil can be deduced:

$$\sigma_{no} = \alpha \left(\frac{m}{w_u}\right)^{\frac{\beta}{n}}$$

where m and n are experimentally determined coefficients.

It is evident that the normal frost heave pressure is inversely proportional to the unfrozen water content in frozen soil.

Relationship Between Normal Frost Heave Pressure and Frost Susceptibility

Experimental data show that the normal frost heave pressure of soil with different frost susceptibility is closely related to the frost heave of soil under foundation bearing plate. Figure 2 shows that it increases proportionally to the frost heave ratio of the soil. Hence, it can be expressed in a parabolic formula:

$$\sigma_{no} = x\eta^y$$

where η is the frost heave ratio of soil in % and x and y are factors related to soil moisture and area of bearing plate.

On logarithmic curve, three turning points can be found, i.e. $\eta=0.9, 3.2$ and 5.8% . In China, these three points exactly reflect the three stages of frost heave of soil: low heave, heave, and high heave.

According to the result of measurements obtained both indoor and in the field, the normal frost heave pressure is directly related to the restrictive condition of

FIGURE 2 Relationship between normal frost heave pressure and frost-heave ratio of soil.

frost heave deformation of soil layer. The higher the degree of restraint, the larger the normal frost heave pressure (Figure 3). This relationship can be described as follows:

$$\sigma_{no} = \frac{M \cdot \lg \eta}{N}$$

where M and N are experimental factors.

Although the restrictive condition of frost heave deformation of soil layer is different, the deformation of ground body around foundation continues to take place. The farther the distance from the observing place to the foundation, the closer it is to the natural deformation of soil by frost heaving.

Based on the deformation curve of ground body around foundation plate, a formula can be deduced from the above relationship:

$$\sigma_{no}^0 = \frac{1}{R} \ln \frac{\eta_0}{\eta_i}$$

$$\text{or } \eta_i = \eta_0 e^{-R\sigma_{no}^i}$$

where η_0 is the natural frost heave ratio in %; η_i is the frost heave ratio when the normal heave pressure being σ_{no}^i in %; and R is an experimental factor related to soil, moisture etc.

Normal Frost Heave Pressure Changes with Depth of Foundation

Generally speaking, with the increase of depth of foundation buried, the thickness of freezing soil layer under foundation plate decreases, as does the normal frost heave pressure. Based on the observational data on the Qinghai-Xizang Plateau and in Northeast China, the law of variation of normal frost heave

FIGURE 3 The normal frost heave pressure under degree of restraint of frost heave.

pressure can be approximately expressed in the following formula:

$$\sigma_{no}^z = \alpha_0 H_z^{\beta_0}$$

where σ_{no}^z is the normal frost heave pressure when the depth of foundation buried being z in kg/cm^2 ; H_z is the relative depth, i.e. the percentage ratio of the depth z of the foundation buried and the maximal freezing depth:

$$H_z = \frac{z}{H_f} \times 100\%$$

H_f is the maximal freezing depth in m ; it should be pointed out that this maximal freezing depth must include the incremental thickness of freezing soil layer due to the effect of foundation; z is the depth of foundation buried in m ; α_0 and β_0 are experimentally determined factors related to the soil, moisture, and area of bearing plate.

Normal frost heave pressure reduces with the decrease or reduction of the thickness of the freezing soil layer under the foundation plate. This law is affected by two factors: the thickness of freezing layer and the change of soil temperature. The former may regard the normal frost heave pressure as a superimposed form of frozen layers at a definite thickness and the latter increases with the increase of the depth and thus the normal frost heave pressure presents a corresponding decrease.

Influence of Bearing Plate Area on Normal Frost Heave Pressure

Under almost the same boundary condition, the value of the normal frost heave pressure is different with the different area of foundation plate. The experimental results both in the laboratory and in the field show that the smaller the area

of bearing plate the larger the normal frost heave pressure; and when area of bearing plate is quite enormous, it finally tends to a stable value related to certain conditions (such as soil type, moisture, temperature, depth of frost penetration, and area of bearing plate). When the value of the normal frost heave pressure tends to a sharp segment, it's corresponding plate area is $400-1600 cm^2$ (Figure 4).

Therefore, the relationship between normal frost heave pressure and the area of the foundation plate can be well described by the expression:

$$\sigma_{no} = a_F e^{\frac{b_F}{F}}$$

where F is the area of foundation plate in cm^2 and a_F and b_F are experimentally determined factors related to soil type, moisture, temperature etc.

In a common case, the foundation plate above the earth is inevitably acted upon by the frost heave of ground body restrained by the bearing plate and of ground body unrestrained outside the bearing plate. According to the experimental results in the laboratory, this "stable value" is near the value of normal frost heave pressure caused by the ground body restrained by the bearing plate under similar conditions of soil, moisture, and frost penetration. The experimental results also show that the frost heaving of the ground body outside the bearing plate affects significantly the normal frost heave pressure under the bearing plate and that the normal frost heave pressure increases with the increase of ratio of sample diameter to plate diameter, until the ratio is more than 6 to 8 times.

So, it is considered that normal frost heave pressure measured at the test site

FIGURE 4 Relationship between normal frost heave pressure and bearing plate.

consist of two parts — i.e., the normal frost heave pressure produced by the restrained ground body directly lying beneath the bearing plate and that produced by the unrestrained ground body. It is also considered that the former must be a constant value under certain boundary conditions.

To sum up, the normal frost heave pressures are the results of various factors. They aren't a huge value uncomparable.

Through the research of correlation factors it is known that the value can be comprehended. Hence, we can study the "standard value" of the normal frost heave pressure of different soil and moisture with unified test method and under approximate boundary conditions, such as the restrained condition of soil, area of bearing plate, and frost penetration ratio. The standard value after being corrected can be used in engineering design.

IN-SITU DIRECT SHEAR TESTS AT THE FREEZE/THAW INTERFACE AND IN THAWED SOILS

Tong Zhiquan

Northwest Institute of the Chinese Academy of Railway Sciences
Lanzhou, People's Republic of China

To build railroads in permafrost regions requires an understanding of the shear strength of soils at the freeze/thaw interface while evaluating the stability of embankment slopes, foundations, and cut slopes. Considering the relatively high water content in the freeze-thaw transition zone in soil, many researchers have suspected that the freeze/thaw interface could be the weaker surface of shearing. To clarify this, the authors conducted indoor and outdoor direct shear tests at the interface and in thawed soils. Results both in situ and in the laboratory showed that the shearing strength at the freeze/thaw interface is greater than in thawed soils, as are both the interfrictional angle and the cohesion force. The weaker surface of shearing was not at the freeze/thaw interface, but in thawed soil with high water content. Therefore, to evaluate the stability of roadbeds in permafrost regions, shear-strength values should be taken from thawed soils with high water content.

When building a railroad in a permafrost region we must know shearing strength at the frozen-thawing boundary interface in order to compute the stability of embankments, foundations and cuts. Because of the comparatively rich water content in the frozen-thawing transition zone of thawing soil, we were concerned that the frozen-thawing boundary could be the weak surface of shearing. Certain experiments were conducted to check this expectation. Because of the different experimental conditions between laboratory and field sites, we conducted large in-situ direct shearing tests on clayey soil at the frozen-thawing interface and on completely thawed ground and compared the result with those of laboratory tests.

IN-SITU LARGE DIRECT SHEARING TEST

Description of Test Site

The region of Mt. Fenghuo is a permafrost region through which the planned Qinghai-Xizang Railroad Line will pass. This region was chosen as the location to carry out in-situ direct shear tests on a frozen-thawing interface and on fully thawed ground. The ground surface there was covered by turf and was underlain by a clayey soil containing crushed stone 3-5 mm in diameter. The depth of the natural permafrost table was within 1.1-1.4 m of the surface. This region is one where the permafrost has been relatively stable for a long time, the annual average temperature being within -4 to -7°C . The water content distribution from the ground surface to the frozen-thawing boundary appears as a K-type (Figure 1) with the larger values occurring at 0.2 m depth and near the frozen-thawing boundary. Tests were carried out under conditions of natural water content. The different dry bulk densities γ_d of the

soil were: 1.55 g/cm^3 for the first test, 1.50 g/cm^3 for the second and 1.47 g/cm^3 for the third. Although the test site was composed of a clayey soil, the size distribution and the physical properties of the soil were a little different in accordance with different test-pit. The ranges of the size distribution of soil and its physical properties are given below. The dimension of soil particles vary within: 0.5-0.05 mm (35-49%), 0.05-0.005 mm (32.6-39%), and below 0.005 mm (18.4-26%); the physical indexes vary within the range: Liquid limit 24.4-35.7%; plastic limit, 14.4-22.5% and index of plasticity, 9.5-13.2%.

Testing Facilities

The equipment used for the test was a large direct shearing device capable of conducting experiments in situ on samples with areas as large as $1,000 \text{ cm}^2$, being 31 times that of normal laboratory samples.

FIGURE 1 Distribution of Water Content from Ground Surface to Frozen-thawing Boundary.

Test Procedures

First a test-pit was excavated having a working surface of $2 \times 1.4 \text{ m}^2$. This area is appropriate for both the fully thawed ground and the frozen-thawing interface cases. The test was conducted according to Chinese standards for in-situ large undrained quick shearing except that certain precautions were made for the case of the frozen-thawing interface. The tests were conducted as follows:

a. After excavation to a depth of 0.2 m above the frozen-thawing interface, a soil cylinder 40 cm in diameter was left in middle of the pit for preparing the sample.

b. A soil cylinder of 35.7 cm diameter was trimmed with the shearing ring of the device and left perpendicular to the frozen-thawing interface. The shearing ring was then pressed gradually downward until it reached the frozen-thawing surface. The direct shear apparatus was then installed and adjusted as quickly as possible.

c. Protection from thermal disturbance must be especially stressed during the installation

of the testing device and during the conduct of the shear test to ensure that the shearing plane is coincident with frozen-thawing interface throughout the entire test.

d. The interface was measured and sampled immediately after shearing and its water content was determined.

Test Results

The results of the in-situ large shear tests on the clayey soil frozen-thawing interfaces and the fully thawed ground are listed in Table 1.

For the conditions of natural water content and natural density, a comparison of the shearing strengths at the frozen-thawing interface with the shear strengths of completely thawed ground is shown in Figure 2. The information in Figure 2 is from Table 2.

It is seen from the test that the shearing strength of a clayey soil frozen-thawing interface is greater than that for completely thawed ground.

FIGURE 2 A Comparison of Shearing Strength at a Frozen-Thawing Interface and Completely Thawed Soil Obtained by Large In-Situ Direct Shearing Tests.

The frozen-thawed boundary interface forms in the course of the thawing of frozen ground. Frozen ground is composed of four phases—solid (mineral particles), plastic (ice), liquid (water unfrozen) and gas (air) with ice as the basic link. The ice is significantly anisotropic, such that the mechanical strength is maximum in the direction of the crystal axis. Because the four phases in frozen have different thermal conductivities and their thawing rates are different, the frozen-thawed interface formed during thawing is not an ideal smooth surface but an uneven and rough one. The shear

plane intersects ice crystals on frozen-thawing surface at different angles. This case does not exist in completely thawed ground, therefore, the internal friction angle of the frozen-thawing interface is greater than that of the completely thawed ground. Furthermore, the cohesion of the former is also a bit larger than that of the latter. It is now clear from the above results that the main reason that the shearing strength of the frozen-thawing interface is larger than that of the completely thawed ground is because of the larger internal friction angle the former possesses.

FIGURE 3 Comparison between Shearing Strength of Frozen-Thawing Interface of Clayey Soil and Completely Thawed Clayey Soil.

SMALL-SCALE LABORATORY DIRECT SHEAR TESTS

Soil Properties and Sample Preparation

The soil used for the laboratory direct shear test was the same clayey soil taken from the area of Mt. Fenghuo in the permafrost region of the Qinghai-Xizang Plateau. The granulometric composition and physical properties of which are the same as those of the soil taken on the spot where the in-situ tests were conducted.

The samples used were remoulded, and their densities were so controlled as normally done in controlling density of fill base materials for roads, i.e. the samples were compacted with a small tamper under the conditions of identical density but at different water contents.

Method of Testing

The common laboratory undrained rapid shear test was adopted as the method of testing. Samples were frozen and then thawed from the top down with an infrared bulb until the frozen-thawing interface coincided with the preferred shear place. The samples were then sheared.

Test Results

The results of the laboratory small-scale shear tests on the clayey soil frozen-thawing interface and the completely thawed soil are presented in Table 2.

A comparison between the shearing strength of the frozen-thawing interface of the clayey soil and the completely thawed clayey soil under fixed water contents and identical densities is shown in Figure 3. The information in Figure 3 is from Table 2.

The test indicates once again that the shearing strength of the frozen-thawing interface is greater than that of the completely thawed soil and the internal friction angle and cohesion of the former are also larger than those of the latter respectively.

COMPARISON BETWEEN IN-SITU LARGE AND LABORATORY SMALL-SCALE DIRECT SHEARING TESTS

A common result of both tests is that the shearing strength of the frozen-thawing interface is greater than that of the completely thawed ground. The slight difference between the results is that the indexes of shearing strength obtained in the laboratory tests are the greater, which is probably because the samples tested in laboratory were composed of remoulded soil, had a smaller area of shear and had undergone only a single freeze-thaw cycle. Whereas the in-situ tests were conducted under natural conditions, the samples tested were much larger and had undergone many freeze-thaw cycles. Thus the different test conditions along with the natural variation of soil structure probably caused the differences in the test result.

Moreover, as we found in laboratory tests, the internal friction angle and cohesion of samples decreased with increase in water content. However, an abnormal phenomenon occurred in the course of in-situ tests---the cohesion obtained in tests II and III was greater than in test I despite the larger water content. This is probably because there were a few grass roots near the shear surface of tests II and III, which acted as a reinforcement.

CONCLUSIONS

1. Under the same conditions the shearing strength of a frozen-thawing interface is greater than that of the completely thawed ground. This implies that the former is not the weak surface of shearing strength, while, in fact, the weak surface lies in fully thawed ground with high water contents.

2. The weak zone of a slope in a permafrost region lies in the completely thawed soil with high water contents. Therefore, it is imperative to choose the shearing strength indexes of

completely thawed soil of high water content in computing the stability of embankment slopes, foundations, and cut slopes for constructing railroad beds in permafrost areas.

CLASSIFICATION OF ROCK STREAMS

A. I. Tyurin

Geology Department
Moscow State University, USSR

Rock streams (felsenmeer) are classified according to their origin. Rock stream formation occurs under a certain combination of a number of climatic, lithological and geomorphological conditions. A number of processes participate in the formation of coarse-fragmented material of rock streams and its movement, namely: rock weathering, heaving of fragments from the weathered substrate, suffosion of fine sediments, interstitial ice formation, and desorption. Each rock stream is composed of a certain set of facies units, which are predetermined by its origin. Therefore, the suggested classification of rock streams is based on the principal mechanisms governing the formation of the coarse-fragmental mantle which constitutes rock streams. During the rock stream formation often one of the abovementioned rock-stream forming factors predominates. Four types of rock streams can then be distinguished: 1) "rock weathering" type, 2) "coarse-fragmented heaving material" type, 3) "fine sediment-suffosion" type, and 4) "gravity" type. If factors dominate during the rock-stream formation, then the following additional types of rock streams are formed: 5) "rock weathering and coarse-fragmented heaving material" type and 6) "rock weathering and fine sediment-suffosion" type. According to the nature of source areas feeding the rock streams, 14 subtypes are identified. The sources feeding the rock streams can occur uniformly throughout the area, along the system of cracks and also locally, at rock escarpments and remnants.

The classification of rock streams should take into account all the major aspects of their formation; schemes of rock stream classification in the literature are, chiefly, of a morphological character.

The rock stream formation occurs under a certain combination of a number of climatic, lithological and geomorphological factors. Among the conditions required for the rock stream (felsenmeer) formation are the following:

(1) Availability of slopes with steepness ranging from 2-3° up to the value that does not exceed the angle of repose of coarse-fragmented material.

(2) Occurrence of fissured but weathering-resistant moraine rocks close to the current surface. The thickness of seasonally thawed or seasonally frozen layers should exceed the thickness of the loose surficial deposit mantle. The rock stream formation can also occur in deep bedrock, provided lithological characteristics of seasonally thawed and seasonally frozen layers are favorable.

(3) Considerable fluctuations of temperatures on the substrate rock surface, causing a thermogenic desorption.

(4) Congelation and segregated ice formation within the seasonally thawed zone resulting in a cryogenic desorption. Frost heaving of stones and suffosion due to subsurface flow contribute to intensive development of rock streams.

Rock stream formation is widespread in mountain areas, characterized by relatively mild, moderate amplitude upward movement (frost heaving), a severe (nival) climate and the presence of frozen sub-

strate. Rock streams are rarely encountered in flatlands and under conditions of alpine relief, where purely gravity processes (rockfalls, talus) prevail.

Frost-facies analysis made possible the classification of rock streams suggested here. There are 3 stages in the process of rock stream formation: (1) origin, (2) progressive development and (3) attenuation. The first stage ends when a coarse-fragmented material layer with the simplest desorption mechanism of movement is formed on the slope surface. This can take place as a result of various processes; for example, weathering of rocks outcropping at the current surface; weathering of rocks underlying a shallow layer of loose deposits with subsequent heaving of fragments to the surface; heaving of coarse-fragmented material from dispersed substrate. The initial and subsequent structures of rock streams are different. During the initial stage of formation, the rock stream is represented only by the suffosion-destructive subfacies; the interstitial ice subfacies appears afterwards and is gradually replaced by the siltation one (Romanovskii and Tyurin, 1979). The composition of the rock-stream subfacies in the course of its later development stage directed downslope is as follows: (1) the subfacies of rock weathering and heaving of fragments to the surface, (2) heaving and (3) siltation subfacies. Engineering-geologic characteristics of each subfacies and of their combinations are different. The abovementioned rock stream subfacies do not cover the diversity of rock streams. The formation of a subfacies depends on (1) its nature, (2) relationship between the depths of the seasonally thawed

layers and loose deposits, (3) water availability on the slope and subsurface flow intensity, (4) connection with external sources of material (talus, rockfalls, avalanches, etc.), (5) the processes in the seasonally thawed layers, etc. Each rock stream is composed of a strictly defined subfacial combination, but all of the subfacies are predetermined by a primary subfacies, i.e. by the genesis of the rock stream coarse-fragmented material. Because rock-stream facial composition is determined by their genesis, it is necessary to classify them according to this attribute. The point is to understand the basic mechanism governing the formation of coarse-fragmented mantle of rock streams. On this basis six types and 14 subtypes of rock streams are recognized. The first type includes rock streams formed as a result of hard rock weathering followed by the production of small quantities of dispersion material—"rock streams of weathering." The second type is represented by rock streams formed during the rock weathering with the subsequent heaving of fragments to the surface—"rock streams of weathering and heaving." The third type consists of rock streams being the product of the fragmented material heaving to the surface—"rock streams of heaving." The fourth type includes rock streams formed due to rock weathering and suffosion of dispersed filler material—"rock streams of weathering and suffosion." The fifth type is made up of rock streams formed as a result of suffosion reworking of fragmented material—"suffosion rock streams." The sixth type—"gravity rock streams"—are formed from gravity deposits. Rock-stream subtypes are defined on the basis of their relationship to the material sources feeding the rock streams. Fragmented material can be supplied uniformly throughout the area, along the system of fissures and locally by rock outcrops.

The first type of rock streams is divided into 3 subtypes: (1) rock streams of uniform weathering are formed during the weathering of rocks outcropping on the current surface slopes. Rock outcropping on gentle slopes, however, is rare. The same subtype includes also rock streams formed as a result of weathering of rocks underlying shallow unconsolidated deposits. When the first layer of the coarse-fragmented material is formed, loose deposits vanish; they collapse into the forming layers and are washed out with subsurface flow. They do not affect the rock stream formation process. Rock streams of weathering combine two subfacies: suffosion-destructive and interstitial ice. The siltation subfacies is limited in area and frequently missing.

(2) Rock streams resulting from differential weathering of rocks along systems of cracks are represented by the structural rock stream slope facies. Within the upper parts of slopes rock streams can sometimes be represented by the facies of rock-stream flows, insignificant in extension and width. Downslope the suffosion-destructive subfacies of a rock stream is transferred into the interstitial ice subfacies, which is encountered locally, and marks the initial crack systems.

(3) Rock streams produced due to local frost shattering of rocks (escarpments and remnants), are characterized by lithological heterogeneity. In cases where escarpments are capped by hard

rocks, frost processes proceed most efficiently at the escarpment base. It is there that maximum wetting occurs along with the greatest development of processes associated with the suffosion of the dispersed material. Parallel retreat of the escarpment takes place. At the same time the coarse-fragmented mantle is preserved on sloping surfaces (3-5°); this mantle later on develops independently as a rock stream. The following set of subfacies is usually observed in the direction away from the escarpment. The suffosion-destructive subfacies, which has the form of a "frost face," is followed by the siltation one and, further on by the heaving subfacies. Rock streams formed due to the erosion of bedrock outcrops are more frequently represented by the facies of rock-stream slopes, than by the facies of rock stream flows.

There are two subtypes constituting the second type of rock streams: these are the result of (1) frost weathering (uniform throughout the area) and (2) heaving of fragments to the surface. The given subtype of rock streams is the combination of three subfacies. The upper part of the slope is occupied by a subfacies, the name of which corresponds to that of the rock stream; the rock stream was represented by this subfacies at the beginning of its formation. Downslope it is replaced by the coarse-fragmented material heaving subfacies. The thickness of the seasonally thawed or seasonally frozen layers here corresponds to or is slightly less than the thickness of the loose deposit mantle. The third siltation subfacies appears at the later stage of formation, destroying the heaving subfacies. Within a given subtype other combinations of subfacies seem also likely. The siltation subfacies can be transformed into the heaving subfacies; this means transformation of "weathering and heaving" type of a rock stream into the "heaving" one. The second subtype includes rock streams made up as a result of differential weathering of rocks along joints with the subsequent heaving of fragments to the surface. Rock streams of this subtype are composed of two groups of facies of (1) concealingly polygonal rock stream slopes and (2) flows. Facies of concealed polygonal rock-stream slopes are marked by (1) rock weathering along frost cracks and heaving of fragments to the surface (concealed polygonal remnants) and (2) complex combination—with interstitial ice, weathering and heaving, as well as siltation; sometimes the heaving subfacies is formed.

The third type of rock streams includes two subtypes: (1) rock streams formed due to uniform heaving of coarse-fragmented material from unconsolidated deposits. (These rock streams make up the rock stream slope facies, represented by subfacies of uniform heaving.) This subfacies always turns into a siltation one downslope; (2) rock streams generated by selective heaving of coarse-fragmented material along fissures. (This rock-stream subtype, unlike the preceding one, includes rock streams represented by a group of facies of (1) structural rock stream slopes and (2) flows.) The structural rock stream slope is usually characterized by the concealed polygonal outcrops subfacies with predominant heaving along frost cracks. Downslope this subfacies changes for the siltation one. Rock-stream flow facies usually include the

rock stream stripe facies, sometimes replaced by the rock stream rampart-flow facies downslope.

The fourth type of rock streams comprises two subtypes: (1) uniform rock weathering and suffosion-reworking of unconsolidated deposits. These are formed by weathering of rocks which yields small quantities of fines and is followed by intense surface and subsurface flows. Rock streams are represented by the rock stream slope facies, including a complete set of subfacies from the suffosion-destructive to the siltation one; (2) rock streams formed as a result of selective rock weathering along cracks, as well as due to suffosion reworking of unconsolidated deposits. Each given subtype of rock streams includes the facies of rock stream slopes and flows. The rock stream slope can be represented downslope by the subfacies of concealed-polygonal remnants with prevailing weathering and crack suffosion, which are replaced by the siltation subfacies. Most often rock stream flows are represented by the rock stream rill facies, replaced downslope by the rock stream stripe facies, which may change into the rock stream rampart-flow facies.

The fifth type of rock streams has also two subtypes: (1) rock streams formed as a result of widespread suffosion reworking of loose fragmented deposits. (This rock stream subtype differs mainly from the abovementioned type in that it lacks additional supply of fragmented material on account of rock weathering.) The suffosion of dispersed material in seasonally thawed or seasonally frozen layers is accomplished both in its upper and lower part. Gradually, the whole section gets washed out, producing the rock stream mantle. The siltation subfacies formed downslope may be transformed into the suffosion one; (2) rock streams formed due to suffosion working of loose deposits along fissures. These are typical of the slopes with angles of up to 15° and where the mantle of alluvial-deluvial deposits exceeds 4 m in thickness. The thickness of the seasonally thawed or seasonally frozen layers here does not usually exceed 2.5-3.0 m. Each subtype is represented by the facies of both rock stream slope and flow. The rock stream slope facies is formed on the subfacies of concealed-polygonal remnants, under the dominating influence of suffosion along frost cracks. Downslope the rock stream slope facies is replaced by the suffosion subfacies of insignificant extension (up to 5-10 m). This is then replaced by the siltation subfacies.

The sixth type is the gravity rock stream, among which three subtypes are distinguished: (1) rockfall-talus (colluvial) rock streams formed at the base of rock walls or on slopes with the steepness less than the angle of repose of coarse-fragmented material. The upper part of the section of colluvial deposits is actually an originating rock stream. Further on, processes of suffosion and frost sorting will form a complete rock stream section to the full thickness of the seasonally thawed or seasonally frozen layers; (2) the formation of "sliding" rock streams is stimulated by the sliding of rock blocks. Heaving or detached from the massif, blocks can slide down the dispersed substrate in the form of "wandering stones." Accumulation of the blocks on the slopes causes the formation of the "film" coarse-fragmented material

mantle. The upslope is divided into separate blocks—"point rock stream"; (3) avalanche rock streams. These rock streams are the result of avalanche transport of the coarse-fragmented material. Their formation takes place locally, at the periphery of the avalanche alluvial fan. The major part of the fragmented material gets saturated with fines, which is the reason why rock streams are formed after the preliminary reworking of drifting products during the processes of suffosion and frost heaving.

It is not easy to determine the basic rock stream forming process. For example, the heaving of the coarse-fragmented material along frost cracks and the suffosion of dispersed fillers are always combined. The morphology of the frost crack surface helps to determine which processes prevail. Where the coarse-fragmented material along the crack rises above the polygonal surface or is at the same level, the prevalence of the heaving over the suffosion is suggested. The negative surface indicates an inverse correlation. The processes of weathering, heaving and suffosion have equal contributions in the formation of some rock streams. This is reflected in the combinations of subfacies.

The above classification takes into consideration the genetic aspect of rock stream formation. This classification can be supplemented with a number of auxiliary classifications and schemes, for example, allowing for rock stream morphology, its topographic position, stage of development, intensity of movement, and connection with material supply regions. All the auxiliary schemes should be considered as derivatives of the genetic classification.

Determining the position of rock streams in the genetic classification of each region will help develop scientifically-grounded recommendations for their utilization.

A COMPARISON OF SUCCESSIONAL SEQUENCES FOLLOWING FIRE ON
PERMAFROST-DOMINATED AND PERMAFROST-FREE SITES IN INTERIOR ALASKA

Keith Van Cleve, Forest Soils Laboratory,
University of Alaska,
Fairbanks, AK 99701

Leslie A. Viereck, Institute of Northern Forestry,
Fairbanks, AK 99701

The structure and function of upland interior Alaskan forest ecosystems has been examined across two secondary successional sequences. One, the most common in interior Alaska, follows fire in black spruce stands on permafrost sites. The other, less common sequence, follows fire on warmer, generally south aspect sites and passes through a shrub and hardwood stage to white spruce.

On black spruce sites, the thickness of the forest floor is a key factor responsible for maintaining moist soil, cold soil temperatures and permafrost. Soil degree days range from 1250 to 1000 degree days 1 to 5 years following fire. In mature black spruce temperature ranges from 500 to 800 degree days. The active layer thickness in later stages of this succession is usually from 40 to 60 cm. Following fire it increases for several years and may reach 1 meter in thickness. In the south aspect white spruce sequence, soil temperature approaches 1400 degree days in heavily burned forests in contrast with 900 to 1000 degree days in mature white spruce.

On the black spruce successional sequences, cold soil temperature results in lowest rates of soil biological activity, nutrient cycling, and, in turn, lowest tree productivity. Net annual above-ground tree production ranges from about 7 metric tons per hectare on the warmer, south aspect hardwood-white spruce sequence to less than 1 metric ton per hectare on the black spruce sequence.

INTRODUCTION

There are many patterns of succession in the boreal forest related to such factors as type of disturbance and the state factors of ecosystem development (Jenny 1980). In this paper we compare secondary succession in upland forests developing on south compared with north aspects. Upland forest communities largely reflect secondary successional processes dominated by fire. Topography is an important state factor controlling nutrient cycling and succession. Warm, south aspect sites support productive, more rapid nutrient cycling communities in contrast to cold, low-productivity, slow nutrient cycling in north slope communities. Along with fire, permafrost is an additional physical control of nutrient cycling and productivity on cold aspects. Fire acts as a rapid decomposer and, depending on intensity of burn, replenishes or depletes nutrient pools. Early successional stages reflect this geochemical control with regard to nutrient cycles. Permafrost acts as an effective seal to inhibit drainage and nutrient loss. Community development may proceed through stages of rapid growing willow, alder, aspen and birch with subsequent dominance by nutrient conservative white spruce or black spruce. Depending on burn severity and seed source, black spruce may replace itself on cooler level or north aspect sites. Wildfire frequency of less than 100 years makes determination of the climax vegetation difficult and hypothetical, but there is a definite tendency in the older black spruce stands toward increased development of permafrost and moss and lichen layers with a corresponding drop in density and productivity of the black spruce.

Regardless of successional track, nutrient cycling proceeds from a state of available soil nutrient pool enrichment for P and cations following fire to nutrient depletion as these elements

are accumulated in biomass. During this time period nitrogen increases, as reserves lost in fire are replenished, mineralized, then gradually decline as N is accumulated in biomass.

The buildup of a thick organic mat which results in colder soil temperatures and a tying up of the available nutrients is important in determining the productivity and the vegetation that ultimately occupies the site. The presence of permafrost, the slow decomposition rates, the increasing importance of moss layer productivity compared with tree productivity, the palludification of some sites, the development of a bog and forest cycle, and the high frequency of fires are all factors that have led to a questioning of the classical concepts of succession and climax by many northern ecologists. These concepts will be discussed in this paper in relationship to the nutrient cycle and ecosystem processes. Methods employed in soil and vegetation sampling and in chemical analysis of these materials are found in Van Cleve et al. (1981), Van Cleve et al. (in press) and Viereck et al. (in press).

VEGETATION

The sequence of secondary succession on contrasting upland sites has been described in some; detail in Van Cleve and Viereck (1981). On dry upland sites, especially south-facing slopes, the mature forest cover type is white spruce, paper birch, aspen, or some combination of these species. On contrasting cold, north-facing slopes the dominant forest type is black spruce although extensive birch and willow stands may, at times, follow fire on these sites. Succession following fire

usually follows distinctly different sequences on the two contrasting sites as is illustrated in Figures 1-4.

UPLAND WHITE SPRUCE SUCCESSION

In the typical fire sequence on dry upland sites the following stages have been recognized and described (Figure 1). Following the fire and an intervening few days to weeks when no live vegetation is present (Stage I), there develops an herb and seedling stage (Stage II). The usual first invasion is by light seeded species such as fireweed (*Epilobium angustifolium*) and willow shrubs, especially *Salix bebbiana* Sarg. and *S. scouleriana* Barratt. A number of species resprout from stumps and roots, especially shrubs such as *Viburnum edule* (Michx.) Raf., *Rosa acicularis* and the willows, and aspen and birch. The next stage in the developing vegetation is dominated by shrubs (Stage III), primarily willows, and the deciduous tree saplings (Figure 1). Density of birch and aspen may be as great as 30,000 stems/ha and shrub cover as much as 50%. Spruce seedlings may be abundant at this time but their slow growth makes them relatively inconspicuous in the stand.

In the dense hardwood stage (Stage IV), young aspen and birch trees form a dense canopy that tends to shade out much of the understory that has developed since the fire. Heavy leaf litterfall prevents the development of a continuous moss layer but moss species of the mature spruce stages such as *Hylocomium splendens* and *Pleurozium schreberi* become scattered on mounded areas. This stage usually occurs during the period of 25-50 years following the fire (Figure 1). For the next 50 years deciduous trees dominate the site (Stage V), although white spruce may become conspicuous in the understory. Both the aspen and birch stands become more open and the density drops to about 700 trees/ha for aspen and 300 for birch.

At about 100 years after the fire, white spruce becomes dominant (Stages VI-VII), often with a components of birch trees. Tree densities are approximately 500/ha. As the stands become older, the hardwoods are less abundant. The greatest change is the development of a dense and thick layer of feathermoss. The mature spruce stage, with only scattered remnant birch and with a continuous moss mat, is reached at about 200 years following the fire (Figure 1).

UPLAND BLACK SPRUCE SUCCESSION

Revegetation following fire in the black spruce type is usually rapid (Figure 2). Stage I is brief: within weeks of the fire, sprouts from underground plant parts of shrubs and herbs are abundant. Even where burning is severe and all of the underground plant parts are killed, invasion by mosses and liverworts and the establishment of seedlings of light-seeded species is usually accomplished by the spring of the following year. The first stage of revegetation, the seedling-herb stage (Stage II), usually lasts from 2-5 years, depending on the site and fire conditions. Areas of bare mineral soil are covered with *Marchantia polymorpha*,

Ceratodon purpureus, *Polytrichum commune* Hedw., *Epilobium angustifolium* and other light-seeded herbaceous species.

Spruce seedlings usually become established during this stage, often in the *Marchantia* and *Ceratodon* mats. Plant cover during this stage increases quickly from 0 to as much as 40 or 50%. It is during this stage that most of the vascular species that will continue on through the vegetation sequence are established (Figure 2). In the shrub stage (Stage III), the shrubs that have originated from sprouts and shoots continue rapid growth and dominate the vegetation, but the herb layer also continues to increase.

The tree canopy begins to dominate at from 25-30 years following the fire (Figure 2). The young stands of 40-60 years are dense (Stage IV), with as many as 4,000 to 7,000 trees and saplings/ha; and seedlings may be as dense as 12,000/ha. The most significant event that occurs during this stage is the invasion and rapid development of the feathermosses, *Hylocomium splendens* and *Pleurozium schreberi*, which along with some *Sphagnum* species, may develop as much as 50% cover. With the establishment of these mosses, there begins the development of a thick organic layer. Once the tree canopy is well established, the changes in the vegetation sequence are slower and more subtle. During the older stages, the tree canopy is mostly closed although the density is less, averaging 2,200 stems/ha. The moss layer remains about the same as in the younger tree stage except for an increase in feathermosses and a decline in both fruticose foliose lichens.

In Alaska, the development of the black spruce type into a mature stand of over 100 years follows without any major changes. Tree densities are about the same, 1,700/ha for black spruce, and a few paper birch may persist into the mature stage. The spruce tend to be in clumps produced by layered branches, and there are more openings in the canopy. Because of this, the shrub layers, especially the low shrubs, are better developed than they are during the 60- to 90-year period when the canopy is more closed. Moss cover in mature stands is dense and covers nearly 75% of the forest floor, but the lichen cover continues to decline on these mesic sites so that total lichen cover of both foliose and fruticose forms average only 2%.

SOIL TEMPERATURE AND FOREST FLOOR THICKNESS

In general, compared with the upland white spruce, the stages comprising the upland black spruce successional sequence display the thickest forest floors. As a result, black spruce ecosystems are characterized by the coolest, wettest forest floors and mineral soils (Van Cleve et al. 1983). These conditions dictate that fire removes a portion of the accumulated forest floor in black spruce but seldom burns all of

this surface organic layer. In contrast, fire on south-facing slopes consumes all or most of the organic layer.

Following fire in black spruce, the organic layer depth may be only 4-8 cm. The change in surface albedo results in soil warming and increased active layer depth. This phenomenon may last well into succession or until spruce is reestablished and feathermoss covers nearly 100% of the ground surface. The organic layer thickness in mature white spruce may approach 8-12 cm in contrast to 16-20 cm in mature black spruce (Figure 1a and 2a).

In the first year following fire, soil heat sums may reach 1,250 in black spruce and exceed 2,000 in white spruce. Temperature summation above 0°C for period May 20 to September 10 for the 10 cm soil depth). These values decline to between 500 and 800 and in excess of 1,000 degree days, respectively, in mature stages of the two forest types (Figures 1a and 2a).

No permafrost is encountered in the south aspect successional sequence. Active layer thickness in mature black spruce ranges from 40 to 60 cm. Following fire, this increases for several years and may exceed a meter, returning to original depths 25-50 years following disturbance when spruce and feathermoss are established.

PRODUCTIVITY

Our data base for standing crop biomass immediately following fire in the two successional sequences is not complete. Observations at one white spruce site 5 years following fire indicate a standing crop biomass of dead white spruce or nearly 29 kg·m⁻² (Figure 1b). Estimates from black spruce ecosystems indicate that aboveground biomass may be reduced by up to one-half or more in tree and forest floor components.

Recovery of the south aspect ecosystems is rapid following fire and reflects sprouting from tree and shrub root systems (Stages I and II). Maximum biomass accumulation, about 25-30 kg·m⁻², occurs between 100 and 200 years (Stages V and VI, Figure 1b). Beyond 200 years this total will decline in the over mature forest because of tree death.

Recovery of black spruce ecosystems is slower following fire. Fifteen to sixteen years following fire, live standing crop of aboveground tree biomass may equal 340 g·m⁻² (Figure 2b). This is approximately 6% of the tree biomass accumulated in black spruce at 100 years, and 50% of the biomass accumulated in postfire aspen (688 g·m⁻²) at about 20 years (Van Cleve and Oliver 1982). Maximum standing crop of tree biomass, aboveground, is also attained between 100 and 200 years but may reach only 10 kg·m⁻², 1/3-1/2 the maximum accumulated in the white spruce sequence.

A large portion of the organic matter in mature black spruce (Stages V and VI) is encountered in the forest floor (Figure 2b). The forest floor may contain 3-4 times the biomass encountered in tree tops plus roots (13 vs. 3.4 kg·m⁻²; Van Cleve et al. 1981). In white spruce ecosystems the forest floor does not appear to

comprise more than 1/4-1/3 the biomass (6-8 kg·m⁻²) accumulated in aboveground tree parts (Figure 1b).

Mineral soil is an additional important organic matter reservoir. In black spruce ecosystems, mineral soil carbon content ranges from 4 to nearly 10 kg·m⁻² compared with 3-6 kg·m⁻² in mineral soil across the white spruce successional sequence. A significant correlation exists between soil carbon content and heat sum ($r = 0.72$, $\alpha = 0.05$) for stands sampled across both successional sequences (Viereck and Van Cleve, in press). Carbon content declines at the rate of 5.4 g·m⁻² per 1 degree day increase in heat sum.

Probably the greatest contrast between these two successions lies in annual production. Maximum annual aboveground tree production in white spruce succession, 700 g·m⁻² in Stage IV aspen, is nearly 5 times greater than maximum production (150 g·m⁻²) encountered in Stage VI black spruce (Figures 1c and 2c). Mature white spruce (Stage VI) annually produce over twice as much biomass aboveground (390 g·m⁻²) compared with black spruce. An additional contrast between the two successions lies in the fact that in mature black spruce successional stages (VI), bryophytes may annually produce nearly the same, or slightly more, organic matter than that produced by the trees aboveground. For the mosses this may amount to 120 g·m⁻² compared with 100 g·m⁻² for the trees. In mature stages of the white spruce succession, bryophytes may annually produce 1/3 the organic matter produced aboveground by trees. In earlier stages of this succession, the nonvascular plants are an insignificant component of the forest ecosystem.

Across the combined sequences, annual aboveground tree production is closely related to soil heat sum ($R^2 = 0.93$). Low productivity (< 200 g·m⁻²), black spruce sites correspond with 700 degree days or less. Higher productivity aspen, birch, and white spruce (> 300 g·m⁻²) are found on sites where the heat sum ranges from 800 to 1,300 degree days.

Vascular plant litterfall does not exceed 40-50 g·m⁻² per year in black spruce compared with maxima exceeding 200 g·m⁻² in the white spruce succession (Figures 1c and 2c).

NUTRIENT CYCLING

In nearly every category of ecosystem structure and function, with the exception of nonvascular plants and the forest floor, the various stages of the white spruce succession show a greater accumulation and a more dynamic flow of chemical elements through system compartments compared with the black spruce succession. Responding to greater annual production, more nutrient elements are accumulated at a faster rate in trees of the various stages of the white spruce succession (Figures 3 and 4). For example, in advanced

stages of succession, approximately twice as much N ($25 \text{ g} \cdot \text{m}^{-2}$) and P ($3 \text{ g} \cdot \text{m}^{-2}$) and 4 times as much K ($23 \text{ g} \cdot \text{m}^{-2}$) is accumulated in white as in black spruce trees. On the average, between 7 and 9 times more N ($4.3 \text{ g} \cdot \text{m}^{-2}$), P ($0.5 \text{ g} \cdot \text{m}^{-2}$) and K ($2.4 \text{ g} \cdot \text{m}^{-2}$) are found in annual increment of trees across the white spruce succession. Furthermore, between 3 and 4 times more N, P, and K is required to support annual aboveground white spruce compared with black spruce tree production (Figures 3a-3c and 4a-4c).

The more dynamic nature of south aspect ecosystems is further emphasized when nutrient flux in litterfall is considered. From 3 to 10 times more N, 5 to nearly 30 times more P, and 5 to 20 times more K is returned to the forest floor in vascular plant litter in the white spruce succession (Figures 3d and 4d).

The generally greater accumulation of forest floor biomass results in total pools of N, P, and K in this ecosystem compartment being approximately equal (63 , 7 , and $20 \text{ g} \cdot \text{m}^{-2}$, respectively) in the black spruce and white spruce successions. However, the average concentration of these elements in black spruce (0.8% , 0.09% and 0.2% , respectively) is significantly less than that encountered in white spruce (1.2% , 0.1% and 0.4% , respectively). The genetic horizons of the forest floor also tend to be most acidic in the black spruce succession with pH ranging from 5.5 in the O1 layer to 4.1 in the O22 layer. The O22 horizon in black spruce generally displays highest lignin concentration (15 to $>20\%$) compared with forest types encountered in the white spruce succession ($8-15\%$).

Mineralization of forest floor organic matter and release of chemical elements for recirculation within the ecosystem also displays marked contrast between the two successions. The residence time (pool size/input to pool) ranges between 2 and 3 times longer for biomass (50 years), N (61 years), P (99 years), and K (74 years) in the forest floor of the black spruce succession.

DISCUSSION AND CONCLUSIONS

From previous discussion it is obvious that marked similarities and differences exist between the two successional sequences. One overriding similarity is the cold-dominated nature of the regional taiga climate. This condition determines that temperatures favorable for biogeochemical activity may occur only during the 140-day period from mid-April to mid-September. Within this interval the 90-day period during which tree growth may occur may be restricted by insufficient water. This is especially the case from mid-June to mid-July, the period of most favorable temperature and light regimes.

The state factor topography (Jenny, 1980) modifies microclimate with the result that the north aspect black spruce sequence is the coolest and wettest (least solar radiation) while the white spruce sequence occurs on warmer, drier south aspects. The drainage restriction imposed by permafrost helps to maintain higher soil and forest floor moisture regimes in black spruce. Substantial nutrient reserves may be "locked up"

in frozen soil, while leaching losses may occur as soil solution flows across the permafrost interface on north aspects. In well-drained south aspect soils, little or no moisture loss through mineral soil may occur because evapotranspiration leaves no moisture for leaching.

Observations of the seasonal course of soil moisture using the neutron probe and measurements of water and nutrient flux using tension plate lysimeters indicate little or no moisture or nutrient flux out of south aspect soil profiles which are up to a meter deep over bedrock. With the possible exception of spring runoff of snow meltwater over the frozen soil, and during an undetermined but probably short period (up to 5 years) following fire, the south aspect successional sequence may be essentially closed to nutrient loss.

It is clear that soil temperature, as modified by thickness of forest floor, exerts a dominant control over productivity and nutrient cycling regardless of successional sequence. The most productive forests and the greatest flow of nutrients which support tree growth are encountered in the warm, south aspect white spruce succession. In the black spruce succession, temperature interacts with forest floor chemistry (concentration of N, P, K, lignin, acidity) to slow organic matter decomposition with the result that substantially reduced supplies of important nutrient elements are available for tree growth. Furthermore, bryophytes are effective competitors for the limited nutrient supply. However, black spruce make efficient use of limited resources through long-term foliage retention (> 20 years) and internal recycling of nutrients within the tree.

GROUND MOVEMENTS AND DENDROGEOMORPHOLOGY IN A SMALL ICING AREA
ON THE ALASKA HIGHWAY, YUKON, CANADA

Perennial groundwater discharge in a tributary of Donjek River causes severe icing problems at km 1817.5 (mile post 1130) on the Alaska Highway. Surveys of a section across the icing area revealed vertical ground movements of up to 0.92 m between winter and summer. Subsurface ice bodies up to 0.75 m thick appear to form in some winters, degrading in the following summer(s). The ground movements and the ice bodies are indicative of the formation and degradation of frost mounds. Airphotos of the study area indicate that icing activity was either induced or enhanced by construction of the highway. The distribution of reaction wood in white spruce growing on the valley bottom indicates several episodes of tilting, in various directions. The reaction-wood chronology shows that ground movements occurred in this area long before construction of the highway. Construction of the highway may, however, have affected the rate of groundwater discharge and the magnitude of icing and frost-mound activity.

INTRODUCTION

Problems caused by formation of icings along the Alaska Highway in Yukon and Alaska were first described by Eager and Pryor (1945) and later by Thomson (1966). It appeared that highway construction in a number of instances either induced the icing formation or increased the extent of icing activity. Icing problems were found to be most prevalent and troublesome where the highway crossed small streams fed by perennial discharge of groundwater. One such crossing, where control of icing

problems became very costly, has been studied since 1979 (van Everdingen 1982a).

The study site is located on the northeast edge of Shakwak Valley, at km 1817.5 (near old mile post 1130), about 4.5 km southeast of the crossing of Donjek River (Figure 1). The highway crosses a small tributary of Donjek River near the lower end of a stream-cut ravine about 740 m above sea level. The stream originates 2.5 km northeast of the icing site at an elevation of about 870 m; it discharges into Donjek River some 350 m west of the highway crossing at an approximate elevation of 710 m. The stream was called "Burlap Creek" by van Everdingen (1982a), because of the presence of a number of burlap fences put up for icing-control.

The original 1943 alignment of the highway did not cross Burlap Creek (see Figure 1). The existing alignment was constructed during the period 1949-1951 when the present Donjek River bridge was built. Observations in 1956 did not indicate any problem at the study site (S. Thomson, personal communication 1980), and serious icing problems, including plugging of the 1.4 x 1.6 m wooden culvert by ice, and icing extending across the highway, did not occur until the early sixties. In late 1981, the highway embankment was raised and widened, and new culverts were installed (see Figure 2).

The water supply to the icing area, the buildup of icing during the 1979-1980 winter (recorded by timelapse photography), and its maximum extent and thickness were described by van Everdingen (1982a). The presence of ground ice upstream of the highway, and vertical ground movements detected during 1980, led to the tentative conclusion that frost mounds develop locally beneath the icing. The present paper describes additional observations on the type and magnitude of ground movements in the icing area, followed by the results of airphoto and dendrogeomorphological studies aimed at establishing whether the occurrence of these ground move-

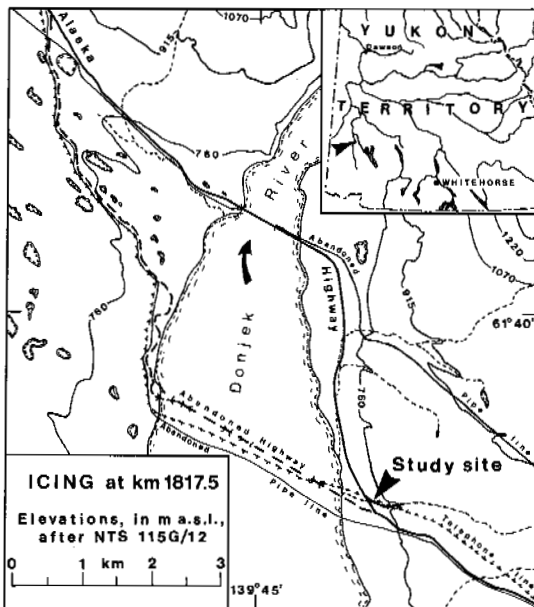

FIGURE 1 Location of study site.

ments is related to the construction of the highway.

GROUND MOVEMENTS AND EROSION

Surficial materials in the study area consist mostly of morainic deposits containing a high proportion of sand, gravel, and boulders. In the stream valley proper, gravelly till is overlain by tephra (White River ash) and peat. No bedrock exposures exist in the vicinity of the site.

A number of low mounds and low, wide ridges have formed in the icing area each winter since 1979. During spring and summer, fractures penetrating the peat and ash layers developed along the crests of the ridges (Figure 3). Massive ice was exposed in several places at the bottom of such fractures. A test pit dug in the fall of 1980 revealed 75 cm of clean ice, overlain by 40 cm of mixed peat and volcanic ash and 30 cm of peat; the ice rested on

FIGURE 3 Fracture along crest of low frost ridge, exposing volcanic ash and ground ice (small divisions on rod in cm).

saturated sandy gravel (van Everdingen 1982a). Similar observations of ground movements and ground ice in icing areas were reported by Kane (1981) from Alaska.

Repeated level surveys have since been made of a section across the icing area some 200 m upstream from the highway crossing (Figure 2), using markers installed above the maximum icing level on a number of trees, to determine maximum thickness of the icing and the extent of vertical ground movements. The results of surveys in September 1980 and in March and July 1981, presented in Figure 4, show a maximum icing thickness in the section of 2.43 m, maximum vertical ground movement of 0.92 m, and maximum differential movement of 0.14 m/m. These observations confirm that frost mounds similar to frost blisters develop locally in the icing area.

Figure 2 indicates the approximate positions of gullies that are being eroded, through the peat and ash deposits to the water-bearing gravelly till or sandy gravel, by surface runoff (meltwater and groundwater discharge). Repeated observations indicate that the position of the gullies is controlled by the distribution of frost mounds and by the position of crest fractures in frost ridges.

The water discharged farther up the valley disappears underground again in a number of places (Figure 2), flowing through underground channels formed by subsurface erosion, or "piping", of volcanic ash. Small secondary deposits of the ash are found below the outlets of some of the underground channels (Figure 5).

During the early stages of this project, it was assumed that construction of the highway embankment across the stream valley caused gradual compaction that reduced transmissivity of the underlying unconsolidated water-bearing materials. This would

FIGURE 4 Cross section showing results of level surveys on 19 September 1980, 26 March and 16 July 1981.

FIGURE 5 Volcanic ash redeposited after erosion by water flowing below the organic mat.

have led to increasing water-table heights upstream of the highway and eventually to groundwater discharge, gullying, and formation of icings, and possibly, frost blisters. The latter phenomena have been observed earlier in similar situations along the Alaska Highway (Eager and Pryor 1945, p. 64) and Dempster Highway (van Everdingen 1982b, p.263). It is possible that deeper penetration of seasonal frost in the embankment contributes to the restriction of groundwater flow (Carey 1973, p. 31).

AIRPHOTO STUDY

As a first check on the assumed relationship between embankment construction and the observed groundwater-discharge phenomena, all airphotos available for the area were checked, starting with the most recent ones.

The only color photography of the area, taken on 4 April 1978 (Kenting NW 5478-4/5), shows minor icing activity over the first 200 m above the crossing. Photos taken on 29 May 1964 (A18395-97/99), show the icing extending as far as 340 m above the crossing. Photos of 30 July 1957 (A15728-112/114) were taken too late in the year to show any remaining ice, but the icing area is clearly recognizable on these photos.

Photos taken on 19 July 1949, before realignment of the highway for the new bridge (A11000-265/267), do not give any indication of icing activity. The earliest airphotos of the area (A1089-104-29/31), taken in 1942, before the start of highway construction, could not be obtained.

The results of the airphoto study suggest that icing activity (and possibly also ground movements) in the area started after realignment of the highway during the 1949-1951 period.

DENDROCEOMORPHOLOGY

The occurrence of frost mounds in the icing area affects the vegetation, as evidenced by numerous "drunken" white spruce (*Picea glauca* [Moench] Voss, Figure 6). Development of gullies can have similar effects on trees that start leaning towards the gradually widening channels. In addition, exposure of parts of their root systems may lead to suppression of growth. The unusual proportion of standing dead or dying trees in the icing area is likely the result of the annual submersion of root systems. Raup (1951) observed mortality of up to

25% of standing trees in similar situations elsewhere. Willows and alders, with higher inundation tolerance, are not noticeably affected.

The tilting of trees as a result of ground movements and gully development generally induces formation of *reaction wood*, in response to the unidirectional gravitational stress caused by the tilt. In gymnosperms (most coniferous species), the reaction wood develops around the downward side of the tilt as compression wood (Fritts 1971, Kramer and Kozlowski 1979).

Reaction wood appears in cross sections as dense, darker-colored, asymmetric or eccentric crescents that are usually widest in the first year after tilting. Both the annual width and the length of the horns of the reaction-wood crescents diminish in subsequent years as the tree recovers, until only normal wood is produced when the tree top is growing straight up again. This process will be interrupted if tilting recurs in either the same or a different direction. Multiple tilting in different directions will produce complex reaction-wood patterns, as well as the compound trunk curvatures displayed by the tree in Figure 6.

The presence of reaction wood in trees thus generally indicates that tilting has taken place, and should therefore make it possible to determine the timing and direction of tilt (e.g., Shroder 1980, Zoltai 1975). Samples from several white spruce in the icing area on Burlap Creek were collected in 1981 for a study of the distribution of reaction wood and relative ring widths, to determine whether such dendrogeomorphological evidence would reveal any correlation between highway construction and the occurrence of ground movements in the icing area.

Ring counts and width measurements were done in two or more directions on each cross-section sample (Figure 7), using 25 times magnification. The results are presented in Figure 8.

Tree No. 1 (Figure 7a and 8a), on the lower north slope of the valley, was sampled to provide background information on climatic effects that

FIGURE 6 Tilted tree No. 4 near the surveyed section, showing compound trunk curvature.

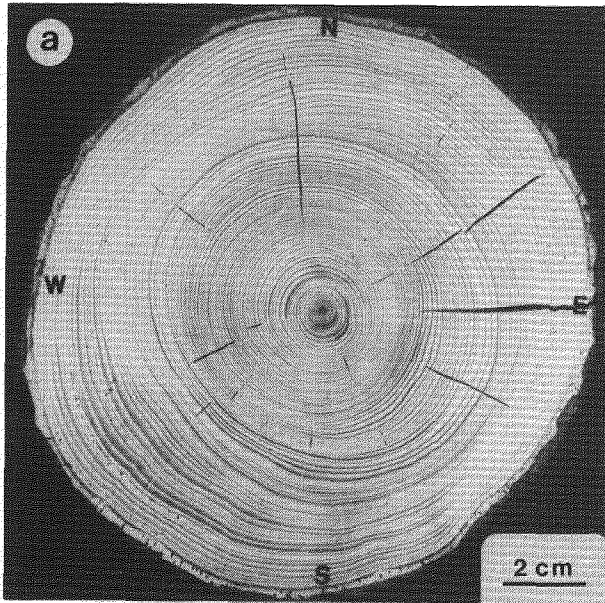

FIGURE 7 Cross sections of trees cut in the study area in July 1981 (top views). Locations indicated in Figure 2. (a) Tree No. 1. (b) Tree No. 2. (c) Twin trees No. 3 and 4.

might be reflected in variations of ring width in the trees in the icing area. Minor reaction wood in the southeast quadrant in Figure 7a suggests that this tree may have experienced slight tilting.

Tree No. 2 (Figures 7b and 8b), located on the north bank of one of the gullies, and trees No. 3 and 4 (Figures 7c and 8c), growing from a common bole on the south bank of the same gully, are examples of the influence of ground movements. The ring counts for the cross-sections of trees No. 3 and 4 differ by only 10 rings, and their tilting histories are similar; ring-width graphs are therefore shown for the larger stem only (Figure 8c).

The variations in ring width in tree No. 1 may reflect climatic influences on growth, but the curve does not correlate well with other chronologies derived from the Slims River area, about 95 km southeast of Donjek River, and used for dendroclimatology (Drew 1975, Allen 1982). Inspection of the minimum-width curves for trees Nos. 2, 3 and 4 shows that the variations in ring width in both tree No. 1 and the Slims River area are poorly represented by the trees in the icing area.

The distribution of reaction wood in trees No. 2 and 4 indicates several episodes of tilting, in widely varying directions. The two trees were most recently tilted in approximately opposite directions, away from the intervening gully, rather than towards it as might have been expected. This is interpreted as indicating the recent presence of a frost mound or ridge at the site of the gully; this interpretation is supported by the presence of ground ice below the peat on the banks of the gully.

The results further indicate that tilting of trees in the icing area occurred long before construction of the Alaska Highway. There is some indication in the tree-ring record, nevertheless, that highway construction may have had an effect on

ground movements after 1949. Table 1 lists ratios between maximum and minimum ring widths for individual reaction-wood peaks indicated by letters in Figures 8b and 8c. The ranges of these ratios before and since 1949 show no overlap in either tree. In tree No. 2 the average ratio increased from 2.13 before 1949 to 5.64 after 1949; in tree No. 4 the average increased from 3.68 to 21.64.

The tree-ring records thus suggest that the magnitude of ground movements in the icing area increased following highway construction between 1949 and 1951. This likely reflects increased groundwater potentials in the icing area, which would contribute to the development of higher (and possibly steeper) frost mounds.

FIGURE 8 Plots of ring width vs. time. (a) Tree No. 1, two directions. (b) Tree No. 2, five selected directions. (c) Tree No. 4, six selected directions. Shaded areas represent differences between actual and minimum width measured for each ring; letters indicate peaks listed in Table 1.

RECENT CONSTRUCTION

In late 1981, the highway crossing of Burlap Creek was reconstructed. The roadway was widened from 8.5 to 13.7 m approximately, and the grade level was raised from about 2.9 to about 4.0 m above the level of the streambed at the upstream side of the highway; the basal width of the road embankment was increased from 20 m to 30 m. These changes can be expected to cause further compaction and reduced transmissivity in the underlying

materials. Consequently, one can expect a further increase in the rate of groundwater discharge upstream of the highway, as well as increased icing activity and frost-mound development.

As part of the reconstruction, the wooden box culvert was replaced by two main culverts (1.4 m x 30 m, rolled section, steel) and an overflow culvert (0.60 m x 26 m). One of the large culverts has contained ice throughout 1982; the other contained some ice as late as July 22 in 1982. The effectiveness of the overflow culvert is limited,

because its top is only 14 cm above the top of the active main culvert. It is therefore likely that changes in the magnitude of icing formation in the creek upstream of the highway will primarily reflect the influence of the increase in loading by the highway embankment, rather than any improvement in the drainage characteristics of the crossing.

CONCLUSIONS

Available airphotos suggest that icing activity in Burlap Creek above the Alaska Highway became noticeable only after rerouting of the highway across the creek in the period 1949-1951.

Dendrogeomorphological evidence revealed that tilting of trees in the icing area (resulting from growth and decay of frost mounds and ridges) was a recurring phenomenon long before the highway was built. Rerouting of the highway across Burlap Creek appears to have caused a large increase in the magnitude of the phenomenon.

The increased icing activity and frost-mound development resulted from an increase in groundwater potentials upstream of the highway, caused primarily by compaction of water-bearing materials underneath the highway embankment.

The recent modifications in the embankment at the crossing can be expected to enhance both the icing activity and the development of frost mounds.

In order to avoid creation of serious icing or frost-mound problems, northern highway (and pipeline) crossings of small streams fed by perennial groundwater discharge should be designed in such a way that their effect on upstream groundwater potentials is minimal. Installation of subdrains may be necessary in a number of cases.

ACKNOWLEDGEMENTS

J. A. Banner, National Hydrology Research Institute, assisted in the field work for the project. W. P. Hidinger and J. W. Flummerfelt, Yukon Territorial Government, provided information on highway construction and maintenance in the study area. The Kluane Lake Research Station, Arctic Institute of North America, served as a base for part of the field studies.

ICE-WEDGE CASTS AND INVOLUTIONS AS PERMAFROST INDICATORS AND THEIR STRATIGRAPHIC POSITION IN THE WEICHSELIAN

Jef Vandenberghe

Institute for Earth Sciences, Free University, P.B. 7161, 1007 MC Amsterdam, Neth.

Ice-wedge casts and large size involutions are typical periglacial features in the Weichselian deposits of northwestern Europe. The ice-wedge casts consist of a central part with vertical lamination and a faulted marginal part. The casts are often arranged in a subparallel pattern, which represents an initial stage in the development of a true polygonal network. They are always closely associated with overlying intense involutions with amplitude of ca. 1.5 m. These involutions are often flat-bottomed and developed in a symmetrical way. They are explained as "periglacial load structures". Degradation of the ice-rich permafrost top caused a state of oversaturation in poorly drained areas. Consequently all cohesion was lost and a reversed density gradient originated. Other types of smaller sized deformations do not require the presence of a permafrost.

In the Weichselian sediment series two levels of ice-wedge casts connected with intense involutions are recorded. They point to permafrost conditions at the start of the Middle Weichselian and at about 20-25.000 years BP. In between these two periods climates were relatively milder.

INTRODUCTION

Relics of periglacial processes have been studied many times in the Late Pleistocene eolian deposits of Western Europe (references in Vandenberghe 1983). In this contribution only wedge structures and involutions that occur in the Weichselian coversand plains in northern Belgium and the southern part of the Netherlands will be considered (Figure 1). All these structures are thus formed in loosely packed eolian fine sands and loams which may be locally reworked.

Together with the pollen analyses and the sedimentary structures the periglacial phenomena may give definite indications on the paleo-environment and the paleoclimate. However, many periglacial phenomena reported from various publications are not well dated. Therefore the position of the periglacial processes must be fixed in a stratigraphic framework.

WEDGE CASTS

The conspicuous wedge casts in the study area consist of two genetically different parts: a lower and an upper one (Figure 2). The lower part extends over 1 to 1.5 m and can be subdivided in an external and an internal section. The internal section 15 to 25 cm wide shows a characteristic, wedge-like lamination with parallel arrangement. It is obviously filled with sediment coming from the adjacent layers and not brought in from the surface (e.g. by wind) at the time of the wedge formation. This may be derived from the sediment layering, while additional proof comes from sediment-petrological analyses. The external section consists of blocks which have been displaced downward stepwise along extension faults. It does not show any flow structures.

Vertical lamination and block faulting are limited to the lower wedge form of the cast. The upper part of the cast (ca. 1.5 m deep) shows no clear boundaries but reflects the flow pattern of the sinking part of an involution. Originally sedimentary structures are strongly disturbed, but generally a concave bending may be recognized (Figure 2). At the transition to the lower zone sediments which have sunk down penetrate further in the central section of the lower part of the wedge for a short distance (10 to 25 cm). Thus the two parts form a unique feature with a total depth of 2.5 to 3 m created in the same time span.

These wedge casts are rather common in Western Europe and are generally interpreted as ice-wedge casts. However, the described individual features of the casts have to be explained in terms of processes, while the supposed former existence of ice wedges has to be demonstrated. Although Black (1976) states that "criteria to prove the former existence of ice wedges outside present permafrost regions are not available" the same author and Dylik & Maarleveld (1965) give a number of "indicators suggesting the presence of former ice wedges".

The existence of permafrost is Black's (1976) first criterion. The main group of wedge casts could be dated in Belgium and The Netherlands rather accurately as formed between 20 and 25.000 years BP (Vandenberghe 1983). During approximately the same period large pingo's existed in The Netherlands (De Gans 1981). They prove the presence of permafrost at that time in the concerned region. The existence of a permafrost table has also been proven by the large involutions penetrating to a common depth of ca. 1.5 m over hundreds or thousands of metres (Vandenberghe & Van de Broek 1982; next section).

One of the most remarkable features of the described casts is the blockwise movement to the centre. This needed a considerable cohesion of the cen-

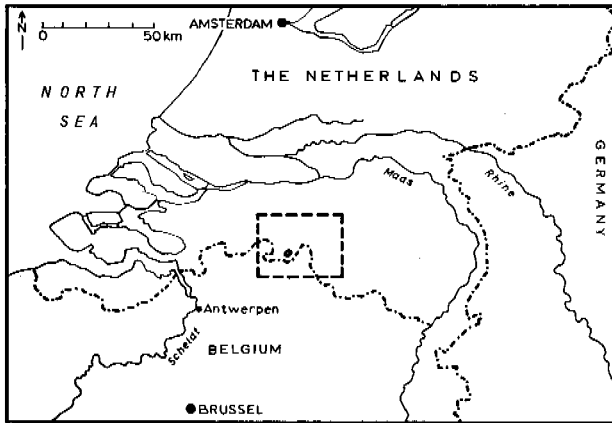

FIGURE 1 Situation map.

posits which often consist of loamless, loosely packed, water-containing sands. Apparently the movement as blocks was only possible in a solid state, which only could be a frozen state. As has been shown the displacements took place 1.5 to 3 m below the surface, this means in the permafrost because active layers did not reach this depth. On the other hand, the lowering in a graben-like structure points to a release of lateral pressure. This might be caused by tensional forces due to local collapsing or tectonic faulting nearby. However, such phenomena have never been observed in the vicinity of the wedge casts in the numerous exposures that have been investigated. A much better explanation for the pressure release may be found in the disappearance of the original wedge material. The start of the melting of ice in a wedge will induce tensile faulting in the still frozen ground. At the same time the ground surrounding the wedge will become liquefied and consequently fill the space left by the melting ice. As melting of the ice is an episodic feature, temporarily narrow fissures originate between the ice core and the adjacent layers giving rise to the characteristic vertical lamination of the lower central part of the cast. It does not seem to be disturbed noticeably by the sinking movement of the blocks. Therefore it is thought that the internal structures as well as the external ones develop progressively and rather simultaneously during the ice-wedge melting.

In accordance with Black (1976) flow and slumping of the surrounding saturated fine sediments must occur when the ice wedges are melting (lower central part and upper part). However, it has already been said that according to the field observations further infilling took place by block fall (external section). Moreover, one of the characteristics of ice-wedge casts reported by Dylik & Maarleveld (1967) are the "traces of collapsing from the wall, often combined with small faults". In contrast to the observed infilling structure, the degradation of supposed tensional cracks should show fluidization features in water-saturated sediment or cause homogenization in dry, poorly cohesive sands. However, in both cases and in the described deposits block faulting is difficult to explain.

Another important criterion used by Black (1976) for recognizing ice-wedge casts is the local preservation of the characteristic upward bending of the

FIGURE 2 Ice-wedge cast with clear internal (i) and external section (e) in the lower part (2); concave bending in the upper (1) involuted part (from Vandenberghe & Krook (1981) with permission of 'Geologie en Mijnbouw').

layers adjacent to the original ice wedge. However, Dylik & Maarleveld (1967) argue that downturned contact layers are characteristic of "fossil ice fissures". In the study area no fossil upturned structures have been found. In our opinion it is impossible that the upturned pressure structures should not be destroyed by flow and slumping in the space left by the disappearing ice.

Finally, both Black (1976) and Dylik & Maarleveld (1967) state that ice wedges are occurring in polygons with large diameter. Up to now three cases have been investigated. A first one, described by Gullentops & Vandenberghe (1981), reveals a clear polygonal pattern with distances of 7 to 10 m and rather orthogonal intersection. In two other cases, however, a subparallel arrangement of ice wedge casts is observed. These casts are completely of the same type as those in the first case. Analogous to the linear patterns of initial cracks on a progressively drying clay ("incomplete mud cracks"), the subparallel pattern of ice-wedge casts may represent the start of non-sorted polygon propagation. According to Lachenbruch (1962) "an orthogonal intersection suggests that one of the cracks predates the other". Where horizontal stresses are anisotropic initial cracks develop in a systematic array and only afterwards secondary cracks induce the orthogonal pattern (Lachenbruch 1962). From this reasoning it can be concluded that at some places the development of the polygonal pattern of Weichselian ice-wedge casts was only in its initial stage while elsewhere a real polygonal network already had been formed.

INVOLUTIONS

We have distinguished three categories of involutions which have a genetic significance and which are not recognized in other descriptive classifications (e.g. Maarleveld 1976).

- a) folds of wide wavelength and small amplitude involving rather weak disturbances (a_1); irregular solitary structures (a_2);
- b) large (generally 1.1 to 1.8 m high), strongly folded convolutions; they are often flat-bottomed, occur over larger areas and are developed in a symmetrical way;
- c) small undulations and foldings (generally less than 0.6 m) which may occur isolated (c_1) or in groups (c_2); mostly regularly developed; single "tear-structures" are examples of the former group, while the well-known "druipstaarten" or "drop structures" are examples of the latter group.

a) The first category occurs often in situations where originally sediments were not laterally homogeneous (a_2) or the original lateral homogeneity has been disturbed previously e.g. by involutions of the second and third categories (a_1). This means that lithology and structure, and consequently the physical parameters, are changing in the horizontal section. In such a situation unequal cryostatic pressures may develop due to different freezing rates and volume changes. In this manner differential motions may be initiated. Examples of a_1 -structures have been illustrated by Vandenberghe (1983) and a_2 -structures by the experiments of Pissart (1970). Furthermore, this process requires a rather intensive freeze-thaw alternation and sufficient soil moisture. The significance of these structures for paleoclimatic reconstruction is rather small.

b) The repetitive and symmetrical development of the second category points to events with more than local significance. However, the original homogeneous horizontal layering precludes explanations where lateral heterogeneity is a necessary condition as in (a). Thus there is no reason to suppose lateral cryostatic pressures nor differential volume changes during the freezing to have produced the observed involutions. Furthermore, the deformations of this category show distinct flow characteristics which are difficult to explain if the intrusions should penetrate into frozen material (French 1976).

Load structures seem to be the best explanation (so-called "load casts" of Kuenen (1958)). Moreover the similarity of the observed field structures with the experimentally obtained load structures is striking (e.g. Anketell et al. 1970). However, two conditions have to be fulfilled for the process. Besides a reversed density gradient, it is necessary that the carrying capacity of the lower sediments is so small that the overlying material can sink down into it. Such a reversed density gradient was not demonstrated by density measurements on the actual sediment series, even when water saturated (Vandenberghe & Van den Broek 1982). Also the high shear strengths of the sediments in the present conditions, observed by the same authors, would oppose

FIGURE 3 Flat-bottomed involution; forms part of a regular series on top of a former permafrost.

any movement. Thus load structures require another setting than the present one. In this respect the flattened bottom (Figure 3) and the constant depth of many involutions are important indications. They point to the existence of an impervious layer. Moreover, in all studied cases water-saturated conditions - necessary to obtain reversed density gradients and low shear strengths - are difficult to imagine in the absence of an impervious layer. Remarkably, there are no lithological contrasts at the base of the involutions. Such a flat impervious horizon in otherwise permeable sediments points to the existence of former permafrost. This is confirmed by ice-wedge casts starting downward from the base of the convoluted zone.

As the relatively ice-rich top of the permafrost (Pollard & French 1980) is melting, large amounts of water are liberated. Then, in a flat landscape with fine sediments poorly drained oversaturated conditions result because the permafrost is acting as an impervious layer. When the meltwater volume exceeds porosity, the lower sediment is made less dense and a reversed density gradient may originate. Moreover, the excess pore water pressures cause the loss of intergranular contacts leading to liquefaction so that cohesion disappears. Thus the two conditions for load structures are present ("periglacial load structures"). Recently Washburn et al. (1978) obtained pocket structures due to vertical forces arising from natural density differences in thaw-frost experiments. Original density differences, however, are not a prerequisite as real involutions also occur in completely homogeneous sediments.

Undoubtedly close connection exists between ice-wedge casts and involutions (see also previous section and figure 2). At the top of a melting ice wedge a downward movement of the overlying soil will be initiated preferentially (Figure 2). The number of up- and downward moving cells is, however, not dependent on the presence of ice wedges provided enough water was produced at the top of the permafrost. Moreover, ice-wedge casts may be deformed, especially at their top, or completely disturbed. Consequently the number of ice-wedge casts is less than the number of original ice wedges and stands in no relation with the number of individual involu-

tions. The origination of the involutions of this category in the yearly developing active layer is contradicted firstly by their amplitude which is larger than the supposed thickness of the active layer during the cold periods in the concerned regions (Maarleveld, 1981). Secondly, a recurrent involution process in the active layer leads to a completely homogenized, structureless upper layer contrary to the regular and symmetrical structures which are observed.

c) Small scaled but rather strongly folded involutions are also formed as load structures (c_1 and 2). However, there is no indication of the presence of permafrost (only small amplitude, no flattened bottom, no associated ice-wedge casts). Although the development of load structures requires conditions of oversaturation (see b), this situation may be seasonal and thus due to local and shallow frost and melt action.

Conditions of oversaturation due to melting (categories b and c) can only be realized in sediments of low permeability. This explains the intensity of involutions in loamy sediments with impeded drainage. On the other hand well-drained coarser sediments, even in the presence of permafrost, show only weaker and/or scarcer deformations.

STRATIGRAPHIC POSITION

As periglacial features are excellent paleoclimatic indicators, it is important to place them in a stratigraphic sequence (Figure 4). The qualitative estimate of the climatic environment of the Weichselian Pleniglacial is based on criteria derived from the periglacial phenomena (Maarleveld 1976) and on vegetation characteristics as revealed in pollen diagrams. Most striking is the occurrence of two stratigraphic levels of ice wedge casts which are associated with overlying large and intense involutions. They represent two periods with permafrost conditions (Vandenberghé & Krook 1981). On top of each level of involutions an extensive desert pavement occurs. The older cold phase is to be situated between 50.000 years BP and the Brörup-interstadial (Vandenberghé & Van den Broek 1982). This corresponds with the age of 62.000 to 70.000 years BP attributed to the cold phase at the beginning of the Middle Weichselian by Mook & Woillard (1982). The maximum age of the younger cold phase is 26.000 years BP, while it is older than the final development of the overlying gravel bed and the Upper Pleniglacial coversands on top of it. Probably this cold period corresponds to the maximum of the last big extension of ice sheets and glaciers dated at about 18 to 22.000 years BP by many authors. Between the two ice wedge levels only scattered periglacial phenomena are found: e.g. small involutions, narrow frost cracks, etc. The long interval between the two very cold periods was thus relatively milder with some minor oscillations. This has also been found at several occasions in North-America where the beginning of the Middle Wisconsin interstadial complex is dated at 65.000 BP. The period between \pm 20.000 BP and the end of the Pleniglacial was in any case a very dry one, characterized by the total absence of fluvial activity and the presence of eolian sands and desert pavements. Although indications of permafrost -

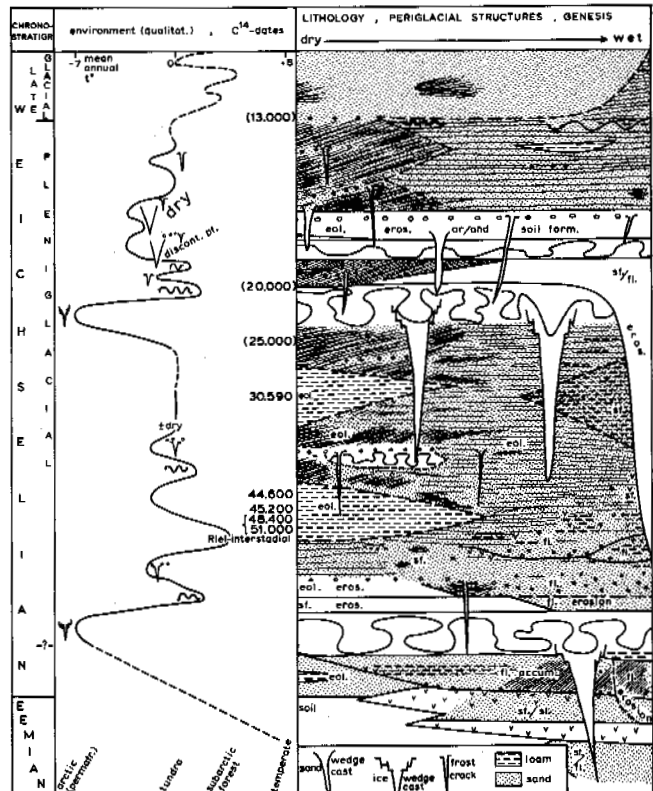

FIGURE 4 Stratigraphy of Weichselian deposits and environmental conditions in the southern Netherlands and northern Belgium.

apart from a few sand wedge casts - are missing, it was a very cold period. Probably for reasons of dryness and not for reasons of temperature all permafrost phenomena which need ice are absent. In accordance with Mook & Woillard (1982) the first cold maximum in the Weichselian corresponds with the deep-sea stage 4 (between 61 and 73.000 years BP), the succeeding long milder period with oxygen-isotope stage 3 (between 29 and 61.000 years BP) and the second cold maximum with the middle and final part of stage 2 (29 to 11.000 years BP).

CRYOHYDROCHEMICAL PECULIARITIES OF ICE WEDGE POLYGON
COMPLEXES IN THE NORTH OF WESTERN SIBERIA

Yu. K. Vasilchuk and V. T. Trofimov

Moscow State University, Moscow, USSR

General conclusions are drawn from new data derived from 280 samples of wedge ice and 210 samples from the deposits bounding the wedges which were analyzed for the chemical composition of their dissolved salts. Slightly mineralized and strongly mineralized ice of Pleistocene and Holocene ages was identified. It is emphasized that saline sea water is involved in the formation of highly mineralized syngenetic wedge ice in the northern areas of Western Siberia.

INTRODUCTION

Most investigators believe that chemical composition of syngenetic ground ice is closely related to the hydrochemical conditions existing at the time of formation and serves as a reliable criterion for paleogeocryological constructions. The data on chemical composition of ice wedges of some regions of the USSR are, however, rather scarce (e.g. Volkova and Romanovskiy 1974, Kondratjeva et al. 1976, Lakhtina 1978, Gasanov 1981, Anisimova 1981). The data on hydrochemical composition of ice wedges of Western Siberia are also incomplete. They are discussed in the works of Danilov, Solomatin and Shmideberg (1980) and Trofimov et al. (1975). Because of this scarcity of chemical data, the authors analyzed the composition of water-soluble salts in ice wedges and in the deposits enclosing them from the Yamal and Gydan Peninsulas.

The primary objective of this study, undertaken in a vast and almost inaccessible area with few exposures, was to analyze the chemical composition of ice wedges from different thermal zones which were enclosed in deposits of different age and origin. To date, 280 samples collected from ice wedges and 210 samples from the deposits enclosing the ice wedges have been analyzed. In order to determine if variations in chemical composition, both in cross-section and along the length of an ice wedge occur, the samples were collected along vertical and horizontal transects and over a "net pattern." It was established that the ice is often divided into mineralogically distinct zones within the wedge form that vary along the length and cross section (Figures 1 and 2). This phenomenon is most pronounced within cross-sections characterized by a higher salinity. Configuration of the zones of different salinity is not always regular; these are often essentially asymmetric. Their occurrence is apparently due to successive changes in depositional and hydrochemical conditions at the time of ice wedge formation.

It should also be stated that localization of the area of ice wedge cracking over a period of time long enough to create a zone of a certain salinity is needed to form such zones in the body of a wedge. Without such a localization, the zones with distinct differentiation of salinity are not formed because ice of small, infilled cracks either

entirely "desalinate" the ice of a wedge (if these are fresher) or increase its general salinity.

RESULTS

Low salinity of ice wedges has been confirmed by most data from previous studies. This has led to the general conclusion that the salinity of ice wedges does not exceed 0.1 g/l (Anisimova 1981). Although most ice wedges analyzed in this study are characterized by a rather low salinity, some sections exhibit higher mineralization in syngenetic ice wedges (Figure 3).

Ice wedges with an overall mineralization of more than 0.2 g/l accounts for more than 10% of those in the north of Western Siberia (Figure 3B). Further, in 28% of the samples, the content of the chlorine ions exceeds 0.02%, while in 8% of the samples it is higher than 0.1% (see Figure 3C). The two characteristics, namely, high mineralization and a high chloride content, are probably the most convincing indicators of paleo-conditions. According to other components, whose distribution is also heterogeneous, the indication of paleo-conditions of ice wedge formation is complicated and less distinct. The content of sodium and potassium ions is particularly significant—it is less than 0.02% in more than 80% of the samples (see Figure 3D).

In spite of the rather rare occurrence of salinity variations in ice wedges, such variations should not be neglected, because they are direct indicators of marine or lagoonal marine regimes of sedimentation during their formation. It is also interesting that the relationship of more and less saline ice in Pleistocene and Holocene syngenetic wedges is somewhat different.

Thick, Late Pleistocene syngenetic ice wedges occurring in II-IV sections of marine and lagoonal marine (bay) terraces in the north of Western Siberia are characterized by low salinity. According to Pitjeva's classification (1978), all are fresh, mainly of hydrocarbonate- or chloride-sodium composition. Mineralization of ice increases from 0.02 to 0.1 g/l in wedges occurring in sediments of marine-lagoon deposits, to 0.1-0.5 g/l in those of marine deposits. Zones of different mineralization were isolated within Late Pleistocene

syngenetic wedges, otherwise characterized by a rather low salinity. For example, in a thick ice wedge located in Late Pleistocene strata of organic and mineral deposits ranging in age from 30,000 to 22,000 radiocarbon years BP near the Seyakha settlement in the center of the East Yamal, mineralization increases upwards from 0.04-0.08 to 11-0.14 g/l. This increase may indicate an increase in the amount of saline bay water forming the syngenetic wedge. A comparable increase occurs in analysis of aqueous extracts from organic and mineral deposits enclosing the wedges. The upwards increase of mineralization from 1.02 to 1.18-1.60 g/kg is mainly the result of higher contents of sodium and potassium ions, which are typical salts in sea water.

Among the Late Pleistocene wedges, those with low mineralization are rather common. Even mineralization of syngenetic ice wedges is often low in the strata of marine terraces; the amount of dry residue does not exceed 0.05 g/l. The lowest mineralization is found in the upper parts of wedges, including relict Late Pleistocene wedges and Holocene epigenetic ice that was formed more recently (Trofimov and Vasilchuk 1982, Vasilchuk 1982). These facts are important when analyzing ice wedges in the field. As is well known, the upper "desalinated" part of wedges is most frequently sampled in exposures, wells and some prospect holes.

On the whole, the salinity of ice wedges enclosed in Holocene strata is somewhat higher than those in Late Pleistocene strata (Figures 3 and 4). On the other hand, it varies greatly in the ice of wedges formed in the alluvial deposits and, on the other, in marine and lagoon deposits (Figure 4).

Study of Holocene syngenetic wedges in floodplains and the lowest level river terraces revealed that these are fresh in the upper reaches of rivers, their mineralization being lower than 0.1 g/l (Figure 5A). Downstream, salinity tends to increase to a considerable extent. In the mouths of rivers in the strata of the lowest level terraces of laidas (lagoon-marine) and floodplains, the mineralization of ice in wedges is often more than 0.2 g/l, sometimes reaching values of about 0.8-1.2 g/l (Figure 2). Wedges fall within the class of slightly mineralized ones, according to Pitjeva's classification (1978).

Cryohydrochemical analysis proved to be most informative in comparing the mineralization of ice wedges of floodplains and laidas (lagoon-marine) in the north of Western Siberia (Figure 4). The number of samples analyzed by the authors, from the wedges of these two types of Holocene sediments, is approximately the same (Figure 4A). The occurrence of ice wedges with a value of dry residue exceeding 0.2 g/l in the Holocene alluvial strata of floodplains proved to be close to zero (Figure 4B); they are, however, encountered in more than 22% of the samples taken from Holocene lagoonal-marine and marine strata of laidas (Figure 4C). Mineralization exceeding 0.4 g/l was found in 16% of the samples collected from the strata of laidas. There is no doubt that a value of mineralization exceeding 0.2 g/l should be regarded as a direct indication of marine or bay water participation in the formation of wedge ice. But, it is also rather common that rather fresh syngenetic ice wedges

occur even in the relatively saline Holocene marine deposits (Figure 5B).

To explain this phenomenon, it is necessary to study the mechanism of formation of syngenetic wedges in the subaqueous regime. The solution of this problem may be found by comparing mineralization of syngenetic ice wedges presently forming on floodplains and laidas and that of the water sources which are likely to flow into the frost cracks. The analysis reveals that:

(1) Mineralization of ice filling the present frost cracks (those of the current year) on floodplains and laidas is often close to zero and in most cases does not exceed 0.02 g/l. Ice fillings with higher mineralization are probably formed also, but none was encountered in this study.

(2) Mineralization of water from rivers and lakes ranges from 0.05 to 0.15 g/l, increasing slightly in the mouths of valleys where salty lakes are likely to occur and river water may be strongly salinated during high tide. The salinity of the Kara Sea water is 7-16 g/l, even near the coast.

(3) Mineralization of an ice cover, both within the Kara Sea coastal parts and the bays, is always less than that of the original water source, practically never reaching the value of 1 g/l. The study of Saveljev (1980) explains this phenomenon. It should be noted that the ice samples were collected in summer during the period of ice destruction, i.e. when "freshness" of ice is the highest (Saveljev 1980). In autumn during the initial stage of ice formation, its mineralization may be much higher.

(4) Chemical composition of supragelisol water of the seasonally thawed layer has rather similar values of mineralization, varying from 0.07 to 0.14 g/l. Sometimes, but not very often, however, lenses of water with mineralization of up to 3.5 g/l are encountered at the base of the seasonally thawed layer (e.g. at the divides of the Pemakodayakha River headwaters, North Yamal (Trofimov et al. 1975).

(5) The amount of soluble salts in the deposits enclosing the wedges is generally much higher than that in the wedge ice. It is seldom lower than 1-2 g/kg in alluvial and marine lagoon deposits, but 2.5-5 g/kg (sometimes up to 10-20 g/kg) in marine (coastal-marine) deposits.

Proceeding from the above, the origin of differences in salt content of ice wedges in different depositional conditions are as follows. Within high terraces and divides, it is exclusively atmospheric water that freezes within the cracks in ice wedges (those of the epigenic type). On high floodplains and laidas, small ice wedges are also formed from atmospheric water flowing into the frost cracks (if the crack is open to the surface) or from the water of the seasonally thawed layer (in the case of intrastratal frost cracks). Water of higher mineralization may occasionally penetrate into the cracks when there is a salty lake nearby or as the result of an extremely active tide or, more often, a surge. Such tides and storm surges may occur only in summer when the sea or bay surface is free from ice. By this time, however, the majority of the frost cracks are already closed and thus, in only a few instances will this water freeze within the ice wedge.

The data obtained on cryohydrochemical

variability testify to the possibility of formation of syngenetic ice wedges under subaqueous conditions. In northern regions of the Yamal and Gydan peninsulas, polygonal ground has been repeatedly observed under the water surface on the bottom of shallow lakes. It is seen at a few localities beneath bays and the shoreline zone of the sea. Less often, polygonal ground occurs in the shoals of river channels. Undoubtedly, a similar situation was present in the Pleistocene and Holocene periods. But subaqueous polygonal ground may be inherited, being formed after flooding of sediments containing ice wedge polygons that had formed previously under subaerial conditions. This does not rule out the possibility of the subaqueous growth of wedges. A complex structure of syngenetic wedges in saline marine (lagoon-marine) sediments with their differentiation into separate wedges reflected in their general salinity (Figures 1 and 2) and the high content of water soluble salts (including chlorides), indicate that these syngenetic wedges may have been formed under subaqueous conditions in the nearshore zone of bays and seas.

Certainly, the question arises: why do syngenetic wedges that are so poorly salinated occur in marine, saline deposits? To discuss this question, one should consider that the frost cracking of wedges under a shallow sea takes place in winter when the overlying water layer is frozen. The ice cover may fracture above the wedges, forming open cracks that extend to the surface. As a result, the fractures may become filled with ultra-fresh snow that, on the one hand, prevents the penetration of sea water into the frost cracks and, on the other, greatly desalinates it. But it does not exclude the possibility that saline sea water may penetrate into the body of wedges along the fractures. It is known that the ice covering the sea contains a significant amount of brine. Of importance is the fact that the lowest temperature of freezing for CaCl_2 is -55°C (Saveljev 1980) and for NaCl it is -22.6°C . During a year, significant amounts of brine percolate into the sea ice during the process of metamorphism. As shown by the data collected by Saveljev (1980), a higher temperature in the ice cover during spring (March-April) leads both to an increase in the liquid phase and formation of capillary veins inside the ice through which intensive percolation of brine moves downwards. Chlorine ions are the first to migrate. Water of the brines often mixes with snow in the frost cracks, causing desalination. Passing lower into the wedge, it freezes as temperatures lower, forming a small elementary wedge or zone of ice whose salinity is one tenth or one fifteenth of that of the sea water (original) and one third or one fourth of the salinity of the ice cover. Its mineralization, however, is often one or two orders higher than that of atmospheric moisture that fills frost cracks under subaerial conditions. This occurs even after the water has flowed down the walls of frost cracks in rather saline rocks.

CONCLUSION

Although there are various factors preventing the formation of highly saline, syngenetic ice

wedges, the results of this study indicate that rather saline (with mineralization exceeding 0.2 g/l) syngenetic ice wedges occur in a series of outcrops of Late Pleistocene and Holocene sediments. The presence of saline ice wedges makes it possible to identify the genesis of the sedimentary strata as marine or lagoonal-marine and testifies to extremely severe climatic conditions at the time of deposition, otherwise subaqueous growth of ice wedges would have been impossible.

LONG-TERM USE OF FROST TUBES TO MONITOR THE ANNUAL
FREEZE-THAW CYCLE IN THE ACTIVE LAYER

Leslie A. Viereck and Deborah J. Lev

Institute of Northern Forestry, USDA Forest Service,
Pacific Northwest Forest and Range Experiment Station
Fairbanks, Alaska 99701

ABSTRACT

In 1968, frost tubes were installed into the permafrost in a white spruce-black spruce/Ledum groenlandicum/Hylocomium stand near Fairbanks, Alaska, and the annual cycle of freezing and thawing was monitored from then through 1982. The annual freezeback of the active layer began in mid-October. The date the active layer was completely frozen varied with snow depth and air temperature: complete freezing was as early as December 13 and as late as January 28. Snow cover was usually permanent by October 8 and the last snow was usually melted by May 6. Thawing from the surface downward in the spring was directly related to the thaw index. Thawing began as early as April 20 and as late as May 7. Maximum thaw depth ranged from 54 to 61 cm, with an average of 58 cm. Footsteps of the observers compacted some vegetation along their route resulting in a slight depression in the lower surface of the active layer under their trail, but there was no significant difference in the thaw depths adjacent to the frost tubes after 14 years. Use of frost tubes is a reliable way to determine the annual freezing and thawing cycles in the active layer for periods of at least 14 years.

INTRODUCTION

In interior Alaska, permafrost underlies most of the forested stands in low-lying areas and on north-facing slopes. Seasonal variation in the rate and depth of both annual thawing and freezing of soil may be important to ecosystem processes, but little information is available on such soil activity. Information is accumulating on the effects of fire and other disturbance on the thickness of the active layer (Mackay 1977a; Racine 1980; Viereck 1973, 1982; Viereck and Schandelmeier 1980; Wein and Bliss 1973). Changes in mean annual temperature are predicted for northern regions, a result of increasing atmospheric CO₂. It is therefore important that baseline information be obtained on thickness of the active layer in natural stands in many areas. Baseline data are especially important in areas such as Fairbanks, where an increase of 2°-3°C mean annual temperature might result in considerable melting of permafrost. Thie (1974) found that in a region near the southern limits of permafrost, the area of permafrost had been reduced from 60 to 15% by climate amelioration in the past 120 years. Permanent or long-term monitoring of the active layer will be important in showing the effects of climatic change on permafrost.

This paper reports on the annual freezing and thawing cycle of the active layer over a 14-year period (1969-82). In 1968, three frost tubes were installed in a 70-year-old mixed stand of black spruce and white spruce located about 5 km north of the Fairbanks campus of the University of Alaska, at an elevation of 215 m. Their

installation was part of a study to determine how effective frost tubes were in measuring the depths of soil freezing and thawing. Design of the frost tubes and a report of their performance is presented in Rickard and Brown (1972).

SITE DESCRIPTION

The frost tubes were installed in a stand classified as Picea glauca-P. mariana/Salix glauca/Ledum groenlandicum/Pleurozium schreberi (Viereck and Dyrness 1980). The stand developed after a fire in about 1914. White spruce trees were dominant, with a density of 2,000/ha, an average diameter of 6.0 cm, and a height of 10 m. A few black spruce trees, with a density of 400/ha and an average diameter of 6.4 cm, were interspersed. Ages of the trees ranged from 50 to about 70 years. The tree canopy was about 30 percent.

A tall shrub layer (>2 m), consisting primarily of decadent willows (Salix glauca L.) has a cover value of 20% with a stem density of approximately 15,000 stems/ha. A low shrub layer (<1 m), primarily Ledum groenlandicum Oeder., Vaccinium uliginosum L., Vaccinium vitis-idaea L., and Spiraea beauverdiana Schneid., forms a nearly continuous cover on the forest floor. A thick carpet of feathermosses, both Hylocomium splendens (Hedw.) B.S.G. and Pleurozium schreberi (Brid.) Mitt. covers most of the area, except in depressions where Sphagnum warnstorffianum DuRoi is common. Peltigera apthosa (L.) Willd. is the only abundant lichen, locally forming mats on the feathermosses.

The soil in the area is a Minto silt loam (Rieger et al. 1963). These soils are developed in micaceous silty material and are often overlain by ice-rich permafrost. A typical Minto silt loam has approximately 10% sand, 80% silt, and 10% clay. At the study site, permafrost underlies the soil, but thermokarst is conspicuous adjacent to the site. The overlying organic layer varies from 24-40 cm in thickness and comprises an O1 (F) layer 15-20 cm thick over an O2 (H) humus layer, 5-10 cm thick. The living moss layer averages about 5 cm thick, ranging from 2 cm under the spruce trees to 10 cm in the most dense hummocks.

METHODS

Each frost tube consisted of an outer 3.4-cm diameter polyethylene tube, sealed at the bottom and permanently frozen into the permafrost, and extending 1 m above the moss mat surface. An inner, removable polyethylene tube, 2 cm in diameter, contained a fluorescein-saturated sand mixture that changed from green to yellow-pink when freezing. Extreme care was taken to keep disturbance of the natural vegetation to a minimum when installing the tubes. Three snow stakes were also installed adjacent to the tubes.

Readings were made at irregular intervals during the 14-year study. During especially important periods, such as the first thawing in May or June and freezing in October and November, the site was visited weekly. Another important period was in mid-December to late January when the soil profile became completely frozen. The site was also visited each week during that period. After the tubes became frozen the site was visited once a month or after major snow storms, to determine snow depth. In middle to late summer, when changes in thaw depth were only 1-2 cm per week, the site was visited at 2-week intervals to minimize disturbing the vegetation and surface organic layers.

Because visits to the sites were irregular, data were organized by pentads, or 5-day periods. There were thus 73 pentads for each year. Because visits to the site were infrequent during late winter, data on snow depth were summarized by groups of 3 pentads; in other words, 15-day or half-month periods. This proved especially useful in summarizing the 14 years of data.

Two indexes, one for freezing and one for thawing, were calculated using 0°C as a base and daily mean temperatures from the National Weather Bureau station at the Fairbanks airport. A day with an average temperature of +5°C would contribute 5° to the thaw index, whereas a day with an average temperature of -5°C would contribute 5° to the freeze index. These are indexes; actual temperatures at the site could have varied by several degrees from those at the Fairbanks airport, especially during periods of extreme cold and strong temperature inversions.

In 1977, mosses, lichens, herbs, and low shrubs on the site were described using three circular plots centered on the frost tubes.

Density and diameter of trees and tall shrubs were determined on one 250-m² circular plot centered on the middle frost tube (no. 2).

In September 1981, 18 m² of the study area was divided into a 25-cm grid and the vegetation mapped. At each corner of the grid, distance was measured to the moss surface and to the base of the active layer. From this profile of the vegetation surface and the lower surface of the active layer, the configuration of the upper boundary of the permafrost layer could be determined. In addition, the thicknesses of the living moss, O1 (F) and O2 (H) layers, and mineral soil to permafrost were recorded at 18 points in the grid. During the summer of 1981, the depth to the frozen layer was probed with a steel rod at 10 points in a line adjacent to the frost tubes and at 10 points in the trail created by the observers. These measurements were made 12 times during the summer of 1981.

RESULTS

Thawing

Figure 1 shows the seasonal progression of freezing and thawing at the study site. Thawing from the surface downward in the spring is directly related to air temperature (thaw index) and the persistence of snow from the previous winter. Usually thawing of the upper 10 cm of soil occurs before all of the snow has melted. Thawing began as early as April 20 in 1970 and as late as May 7 in 1982, with an average beginning thaw date of May 1. Thawing is rapid, with 50% of the thaw depth reached by June 30, and 75-80% by the end of July. The maximum thaw depth, which ranged from 54 to 61 cm and averaged 58 cm, occurred from mid-August to mid-September.

The thaw depth closely follows the accumulated thaw index. The first days with an average temperature above 0°C usually occur in mid-April, although it may be late April in some years. In 1972, thaw did not begin until May 5.

There is a close linear relationship between thaw depth and the time since thaw began for the period from mid-April to the end of August. There is also a linear relationship between thaw depth and the thaw index. A regression of the thaw depth against the thaw index gives a coefficient of determination (R^2) value of 0.97. The regression equation for the thaw depth is

$$Y = 0.0675T + 6.9591, \quad (1)$$

where Y = the depth of thaw, and T = the thaw index in °C.

Maximum thaw depth for the year varied by 7 cm during the 14-year period. When maximum thaw depth is compared with the total accumulated thaw index for the year, there is no correlation. This may indicate that other factors, such as the freezing index from the previous winter or precipitation from the summer, may influence the maximum thaw depth for any given year.

It is possible to draw only general relations between late-lying snow and the thawing of the

FIGURE 1. Annual freeze-thaw profile of the study site (A), thaw and freeze indexes (B), and snow depth (C). Points are average and range for the 14-year period, 1969-1982. Time is shown in pentads (73 five-day periods per year) and by months.

soil. For tundra regions, Goodwin and Outcalt (1975) used a computer model to show that winter snow depth affected both the time of active layer thaw and the maximum depth to which it thawed. In our study in the Fairbanks area, where spring thawing is rapid and the summer thawing season long, snow depth the previous winter did not seem to affect timing of thaw. For example, in 1971, year of the heaviest and latest snow during the study, soil began to thaw on May 5, even though snow remained on the ground for an additional 17 days. In a light snow year such as 1980 or 1981, soil began to thaw on May 5, but the snow had completely melted by that date.

Freezing

The annual freezeback of the active layer from the surface downward begins during October. Freezing is usually rapid and the whole active layer can be frozen as early as December 13. The average date, however, is January 7. The latest date of total freezeback was January 28 (in 1979). The fall and winter of 1978-1979 were relatively warm and there was only a moderate (50-cm) snow accumulation by late January.

Annual freezeback shows more variability than does the thawing. This is probably related to two factors. First, the annual freeze index has a much wider range and standard deviation than does the thaw index (freezing index averaged

2998°C, ranging from 2162° to 3673°C, with a standard deviation of 513; thaw index averaged 2019°C, ranging from 1858° to 2226°C, with a standard deviation of 109). The second factor is variation in timing of snowfall, especially early and heavy snow before the ground is deeply frozen. Thick and early snowfall insulates the ground from cold air temperatures and slows the descent of freezing into the ground.

As with thawing, the depth of the freezing line showed a close linear relationship to the elapsed time since freezing began for the period from early October through December. It also showed a linear relationship to the freezing index. Using only the freezing index as a variable against the depth of freeze line, the following equation was obtained:

$$Y = 0.02167F + 10.977 \quad (2)$$

where Y = the depth of freeze in cm and F = the freezing index in °C. The coefficient of determination (R^2) value for this regression was 0.645.

There is also some annual freezing of the active layer upward from the top of the permafrost. This 5-10 cm of freezing upward begins in mid-September and continues until it meets the freezing line descending from the surface in mid-December to late January.

The effect of snow depth on the freezing rate of soil is difficult to express mathematically because time of snowfall, density of snowpack, and timing of the cold spells (i.e., before or after a heavy snow) all influence the rate of freezing. Figure 1 shows the average snowfall and range averaged for periods of three pentads for the 14 years of the study. Permanent snow cover usually occurred by October 8 (range: September 23 to October 25) and the last snow was usually gone from the site by May 6 (range: April 28 to May 20). Maximum snow depths at the site varied from 27 cm during the winter of 1969-1970 to 107 cm in the winter of 1970-1971. The maximum snow depth averaged 60 cm for the 14-year period. Adding snow as a second variable in the regression equation for freeze depth increases the R^2 value by only a small amount.

The effect of snowfall can best be shown in Figure 2, which compares depth of snow, freezing index, and depth of freeze line for two contrasting winters—1970-1971, when snow accumulation reached 100 cm by mid-December, and 1980-1981, when snow depth reached only 28 cm in early December and settled to 22 cm by mid-January. The freezing index was about the same through the end of December (1315°C for 1970 and 1345°C for 1980). January 1971 was much colder than January 1981, however, with an accumulated freezing index of 2377°C in 1971 compared with 1579°C in 1981. In spite of the similarity in freezing indexes in the early part of the two winters, the active layer froze much more slowly in 1970 than in 1980. Large amounts of early-season snow provided insulation to the soil and slowed freezing in 1970.

Effects of human disturbance

Despite the care taken in installing the frost tubes and in visiting the site, a trail developed about 70-100 cm from the tubes. When measurements were taken in 1981 (described in "Methods"), it was obvious that the trail had caused a linear depression in the vegetation; in the depression, sphagnum moss was replacing the feathermosses and shrubs.

Probes taken during summer 1981 indicated the depth of thawing from the surface of the vegetation downward was not significantly greater under the observers' trail than it was under the undisturbed vegetation. A statistical comparison of the differences in thaw depth was not attempted because the data did not meet the criteria for an appropriate test. Examining thaw depths determined both by the probing and frost tubes indicates the values are similar except for May 16, when the difference between the average of measurements of the three frost tubes and the 10 probe measurements is 4.8 cm. The probe measurements taken in the trail are similar to those taken in the undisturbed vegetation, but because the surface is lower, they indicate a slight increase in the thaw depth under the trail.

FIGURE 2. Freeze-thaw profile (A), freezing index (B) and snow depth (C) for September 3 to January 30, 1970-1971 and 1980-1981.

Profiles taken across the trail at each frost tube showed that there has been some deeper thaw into the original permafrost as a result of the trail (Figure 3). This thawing of permafrost under the trail does not seem to have affected the thaw depth of the active layer at frost tubes 1 and 2 but may have resulted in a slight increase in the thaw depth at frost tube 3. Human disturbance is always a factor in studies of permafrost under natural conditions. Such disturbance makes it extremely difficult to monitor natural changes in the active layer over long periods of time.

DISCUSSION

Brown and Grave (1979) summarize information on measurements of the active layer in the taiga and tundra of North America and the Soviet Union. They give maximum thaw depths for vegetation types and geographic areas but do not provide information on the variation in the active layer thickness during the thawing season or year-to-year variations. Most studies on which they report measured the thickness of the active layer in 1 year only, usually from mid-August to mid-September, the time previously determined (Brown et al. 1969, Dingman and Koutz 1974) as that of maximum seasonal thawing. Rouse (1982)

FIGURE 3. Profiles of the forest floor and active layer adjacent to the three frost tubes, showing the effect of the trail on thaw depth.

did show both the seasonal thaw and freeze line for forested and tundra areas near Churchill, Manitoba. He also showed that there was some variation in the active layer thickness during the 2 years of his study, which was related to the length-of-thaw period as well as to net radiation received at the site.

Dyrness (1982) reported a gradual increase over a 4-year period of about 8 cm in the active layer thickness (actually reported as the thickness of the thawed mineral soil) of control plots in a black spruce stand. Dyrness suggested that the annual increase in active layer thickness could probably be attributed to removal of the overstory trees even though the forest floor vegetation was undisturbed. Viereck (1973) reported a similar change in active layer thickness of a black spruce stand in which the overstory had been removed for a study on biomass. In a study of the effects of an oil spill on permafrost in a black spruce stand in the Fairbanks area, Johnson et al. (1980) showed an increase in thawing over a 2-year period of about 20 cm following an oil spill, but only a 0.4-cm difference between years in an undisturbed control.

A number of complex models have been developed for predicting thaw and freeze depths using thermal conductivity and diffusivity of the soil and heat fluxes at the surface and in the

soil (for example McGaw et al. 1978, Outcalt et al. 1975, Scott 1966). Most of these models are for tundra. These models could not be used in our study because no measurements of temperature or solar radiation were made at the site.

Some attempts have been made to correlate the depth of thawing with more gross aspects of climate, solar inputs, and topography. Dingman and Koutz (1974) showed a weak correlation in one watershed in interior Alaska between thickness of the active layer and an equivalent factor of latitude, and a slightly higher correlation between the thickness of the active layer and a potential insolation index. Brown and Grave (1979) report an increase in active layer thickness at Prudhoe Bay, Alaska, as a function of distance along a strong summer temperature gradient from the coast to warmer inland localities. Dyrness and Grigal (1979) found changes in the active layer thickness along a slope transect that were related to slope position, vegetation, and organic layer thickness. More detailed observations are needed on variations in active layer thickness with time, with disturbed and undisturbed vegetation, and with environmental factors to aid in the development of predictive models.

Comparison of Measurements

Comparison of thaw depths measured by steel probe and frost tube show close agreement between the two methods. Mackay (1977b) has shown that probing may overestimate active layer thickness in some soil types because the probe enters the frozen zone with little or no resistance. He found, however, that in fine soils with high ice content, as in our study, the probe did measure thaw depth accurately. The frost tube, however, can measure freezeback in the fall, which is impossible with the steel probe.

SUMMARY AND CONCLUSIONS

Frost tubes are useful devices for measuring annual freezing and thawing in undisturbed vegetation and were successfully used in this study for 14 years. There is good correlation between depth of thaw, and a thaw index determined as accumulated degree days above 0°C. Freezeback of the active layer in winter is more variable than thaw because of a wider range in the freeze index and the timing and depth of snowfall. Human disturbance to the site was minimal and had an insignificant effect on the thaw depths after 14 years.

ACKNOWLEDGMENTS

We thank Mr. Gordon Herreid who gave permission to conduct the study on his property, and Mrs. M. J. Foote who took field measurements from August 1970 to August 1971.

DYNAMIC PROPERTIES OF NATURALLY FROZEN SILT

Ted S. Vinson¹, Charles R. Wilson², and Peter Bolander³

¹Dept. of Civil Engineering, Oregon State University, Corvallis, OR 97331 USA

²Alaska Test Labs, Anchorage, Alaska 99502 USA

³U.S. Forest Service, Eugene, Oregon 97401 USA

Resonant frequency and cyclic triaxial tests were conducted on naturally frozen silt samples. Dynamic elastic properties (expressed in terms of dynamic Young's and shear moduli) and energy absorbing properties (expressed as damping ratio) were determined. The influence of various dynamic loading parameters (confining pressure, temperature, frequency, and strain amplitude), water content, and anisotropy on dynamic properties was evaluated. Confining pressure and water content were generally found to have little effect on either dynamic moduli or damping ratio. The test results indicate dynamic moduli decrease with increasing strain amplitude and increase with increasing frequency and ascending temperature. The damping ratio generally increases with increasing axial strain amplitude and decreases with increasing frequency and descending temperature. The soil/ice structure (i.e., lens thickness, orientation, and spacing) does not appear to influence the dynamic properties of naturally frozen silt.

INTRODUCTION

To overcome the problems associated with obtaining and transporting frozen soil samples to the laboratory for testing, many researchers and practicing engineers have used reconstituted frozen samples to evaluate the behavior of naturally frozen soils. While these studies have contributed to a phenomenological understanding of the behavior of frozen soils, the specific applicability of the test results to solve field problems is questionable. In the words of Anderson and Morgenstern (1973), "This is particularly so because the structure of frozen soil, in situ, differs markedly from that of material prepared in the laboratory." In recognition of this fact, emphasis is now being placed on in situ tests, field performance studies, and laboratory studies that employ samples of frozen soils taken in situ. A modest amount of data from this work has been published to evaluate the thaw-consolidation behavior, creep behavior and strength, and thermal conductivity of naturally frozen soils. Only a meager amount of data, however, has been obtained on the dynamic properties of naturally frozen soils, and much of this information is associated with test conditions that are not applicable to all classes of wave propagation problems.

As part of a long-term study to evaluate the dynamic properties of naturally frozen soils over a range of test conditions associated with wave propagation problems of frozen soil deposits (e.g., foundation vibrations, geophysical exploration, blasting, ground response analyses during strong motion earthquakes), resonant column and cyclic triaxial tests were performed on specimens of naturally frozen silt. Parameters that could influence the dynamic properties of naturally frozen silt, such as confining pressure, temperature, frequency, strain amplitude, water content, and soil/ice structure, were considered. The results from the study are reported herein.

NATURALLY FROZEN SILT SAMPLES

The silt samples associated with the research program were obtained in the U.S. Army Cold Regions Research and Engineering Laboratory (USA CRREL) Permafrost Tunnel located at Fox, Alaska, 16 km north of Fairbanks. The walls of the tunnel expose perennially frozen silts of Pleistocene age. Sands and gravels bonded with interstitial ice are also visible, but to a lesser extent. It is generally accepted that the silts are aeolian in origin. The silts were transported from a broad treeless flood plain of the Tanana River (Sellmann 1967).

The samples were collected at several locations in the USA CRREL permafrost tunnel. To evaluate anisotropy of dynamic properties, 7.6 cm diameter samples were obtained by core drilling with a Haines auger on axes parallel, perpendicular, and at 45° to the existing horizontal strata. Based on the grain size distribution, Atterberg limits and a visual inspection of ice features, the samples were classified as ML-OL-Vs, MH-OH-Vs, ML-OL-Vr (Linell and Kaplar 1966). The average water contents for the 20 samples employed in the study ranged from 56 to 109%.

DESCRIPTION OF TEST SYSTEMS AND PROCEDURES

The current research program is unique in that it employs both the resonant frequency and cyclic triaxial testing methods on each specimen. This permits a direct comparison of the results obtained from the two methods. Further, use of both test systems permits an evaluation of dynamic properties over a range of test conditions associated with all classes of wave propagation problems of frozen soil deposits (Vinson 1978).

The resonant column test system applies a non-destructive, steady state, vibratory load to a right cylindrical frozen soil specimen in either

the longitudinal or torsional mode. The test system employed in the present study, shown in Figure 1, is similar to the system developed by Stevens (1975). The theoretical considerations associated with resonant column testing are given by Stevens (1975) and Vinson (1978). Briefly, complex Young's or shear moduli are determined from the frequency at resonance. Complex Young's moduli are determined for a specimen excited in the longitudinal mode, while shear moduli are obtained from the torsional mode of vibration.

To conduct a test, specimens were freeze-bonded to the top and bottom platens of the test system. A thin film of cool water was sprayed on each specimen and allowed to freeze to prevent sublimation during experimental setup and testing. Three thermistors were freeze-bonded to the specimen to monitor temperatures during the test. A triaxial cell was placed over the specimen and, if required, a confining pressure was applied in the cell using commercial grade nitrogen gas. Temperature control during testing was maintained with an environmental chamber placed around the test system. The test system and environmental chamber were located inside a walk-in cold room.

To establish a resonant condition the operator vibrated the specimen at the base with an electromagnetic motor in either the longitudinal or torsional mode, with the frequency at a low level. As frequency was increased, the signals from accelerometers attached to the top and bottom platen were monitored for resonance. At resonance the ratio of the top to bottom platen accelerometer outputs is a maximum, the first maximum being associated with the fundamental resonant frequency. Successive maximums indicate harmonics.

The theoretical considerations associated with cyclic triaxial testing have been presented by Vinson (1978). Specimens were subjected to a cyclic axial load, and specimen load and deformation were recorded. From the load-deformation response dynamic Young's modulus and damping ratio were determined.

The cyclic triaxial system employed in the present study is shown in Figure 2. Cyclic triaxial tests were conducted on specimens after the resonant column testing was complete because of the potentially destructive nature of the cyclic triaxial test. Following removal from the resonant column test system, the specimen was placed in the cyclic triaxial grips. Cool water was injected between the grip and the specimen to insure bonding. Following a 7-day set period, the specimen and grip assemblage were attached to a load frame located inside a walk-in cold room. An environmental chamber was used to control temperature; a triaxial cell was employed to apply a confining pressure.

The resonant column and cyclic triaxial test systems were designed to accommodate a right cylindrical specimen with a diameter of 7.2 cm and a length of 30 cm. A swing metal lathe inside a walk-in cold room was used to trim the smaller diameter test specimens from the 7.6 cm diameter field samples. The ends of the test specimen were faced off perpendicular to the longitudinal axis using a steady rest.

FIGURE 1 Resonant column test system.

FIGURE 2 Cyclic triaxial test system.

TEST PROGRAM AND RESULTS

Resonant column and cyclic triaxial tests were conducted according to test histories which allowed an evaluation of the influence of confining pressure, temperature, strain amplitude, and frequency to be made for each test specimen (Wilson, 1982). For the various combinations of test parameters, the dynamic Young's modulus ranges from 0.7 to 16.5 GN/m², the dynamic shear modulus from 0.7 to 5.5 GN/m², and the damping ratio from 0.01 to 0.26. Following dynamic testing the ice lens thickness, orientation, and spacing were noted for each specimen, and the average water content was determined.

Dynamic Moduli Test Results

Representative relationships between dynamic moduli and confining pressure are shown in Figure 3. In general, it may be noted that there is a slight decrease in moduli with confining pressure. The decrease is generally less than 5%. This result is unexpected based on previous research to evaluate dynamic moduli of frozen cohesionless soils, which indicate no change in dynamic moduli with increasing confining pressure (Vinson et al. 1977). Overall, the decrease in modulus is considered to be negligible, and data for all confining pressures were combined to develop relationships with other dynamic loading parameters.

Representative relationships between dynamic moduli and temperature are shown in Figure 4. Kaplar (1969) and Stevens (1975) show that the decrease in dynamic moduli is relatively small for frozen silts for the temperature range -17 to -4°C. Therefore, the temperature range of -10 to -1°C is considered sufficient to evaluate the effect of temperature on the dynamic moduli. As

FIGURE 3 Dynamic modulus versus confining pressure.

expected, dynamic Young's and shear moduli decrease with ascending temperature. The rate of decrease increases with ascending temperature. These results are in good agreement with previous results obtained on reconstituted artificially frozen silt specimens (Vinson et al. 1977). The relationship between dynamic moduli and temperature for fine-grained soils has been shown to be directly related to the unfrozen water content (Nakano and Froula 1973). Also, the increase in

FIGURE 4 Dynamic modulus versus temperature.

FIGURE 5 Dynamic modulus versus frequency.

dynamic moduli may be due to the increase in the stiffness of ice with decreasing temperature. Haynes (1973) attributes the strength increase in frozen silt with descending temperature in part to the strength increase in the ice matrix with descending temperature.

Representative relationships between dynamic moduli and frequency are shown in Figure 5. In the high frequency range associated with the resonant column test results there appears to be a slight increase in dynamic moduli with increasing frequency. In the low frequency range associated with the cyclic triaxial test results, dynamic moduli increase with increasing frequency. The increase in modulus in this range of frequencies is in good agreement with the results from previous investigations (Vinson et al. 1977). Further, the influence of frequency on dynamic modulus is an indication of time-dependent effects, such as stress relaxation or creep, on the dynamic elastic properties of viscoelastic materials such as frozen soils. Since relaxation effects will tend to cause increasing stress reduction with time under a constant strain, it follows that for a strain-controlled cyclic triaxial test a decrease in strain rate will result in a corresponding increase in stress reduction over a cycle of loading and, thus, a decrease in dynamic Young's modulus. Also, the ice matrix is strengthened with increasing strain rate (Haynes 1973). The increase in strength and stiffness of the ice matrix undoubtedly contributed to the increase in modulus with increasing frequency.

Representative relationships between dynamic moduli and axial strain amplitude are shown in Figure 6. Dynamic moduli are not appreciably affected by axial strain amplitudes in the range associated with resonant column testing. Dynamic moduli decrease with increasing strain amplitude in the range 10⁻³ to 10⁻²%.

The results shown in Figure 6 are unique in that moduli of identical test specimens are com-

FIGURE 6 Dynamic modulus versus axial strain amplitude.

pared. Hence, differences in dynamic moduli associated with water content (or density) and soil/ice structure do not influence the comparison. Recognition of the strain dependence of dynamic properties may be important to ground response predictions associated with several categories of wave propagation problems, specifically, earthquake and blast loadings of frozen ground deposits (Vinson 1978).

The relationship between dynamic Young's modulus and water content is shown in Figure 7. At -4 and -10°C dynamic moduli appear to decrease with increasing water content. Dynamic moduli may increase slightly with increasing water content at -1°C. It may be more appropriate to conclude, however, that the influence of water content at warm temperatures is negligible. The thickness,

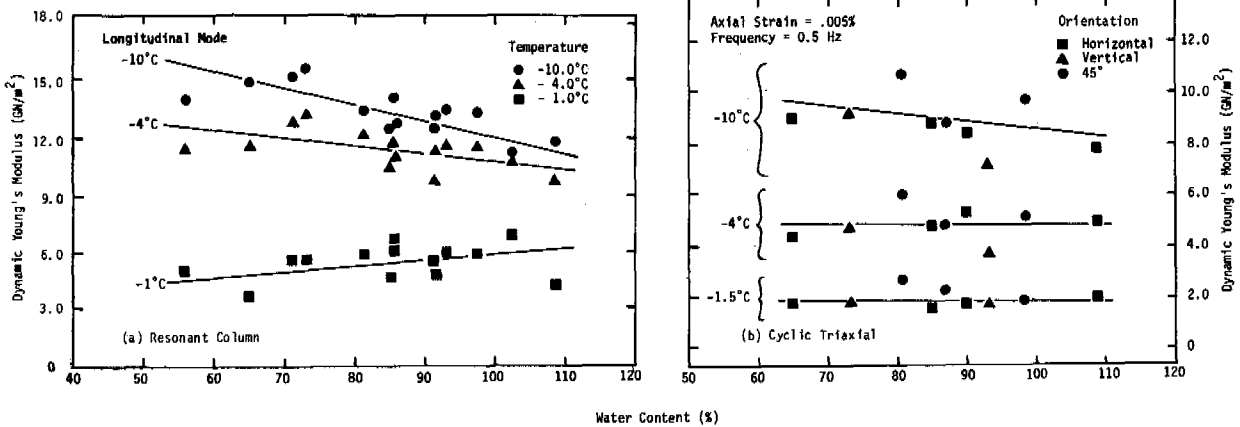

FIGURE 7 Dynamic modulus versus water content.

orientation, and spacing of the ice lenses does not affect dynamic moduli.

The test results shown in Figure 7 are associated with test specimens with visible ice lenses from 0.3 to 5 mm in thickness. For many of the specimens the ice lenses were randomly or irregularly oriented; for other specimens the ice lenses were stratified or distinctly oriented. The soil/ice structure could not be correlated to dynamic modulus. In the authors' opinion the soil/ice structure did not appear to influence the values of the dynamic Young's modulus for the range of structures represented by the test specimens employed in the study.

The effect of specimen orientation on dynamic moduli has been shown in Figures 4a, and 7b. Dynamic moduli appear to be slightly greater for samples cored at the 45° orientation compared to samples cored horizontally or vertically.

Damping Ratio Test Results

Emphasis in this paper has been given to dynamic moduli of frozen silt. Damping ratios were also determined in the test program. A summary of the test results associated with this work follows.

Representative relationships that illustrate the influence of dynamic loading parameters on damping ratio are shown in Figure 8. The damping ratio is not appreciably affected by strain amplitude in the range of strains associated with resonant column testing. Damping ratio increases with increasing axial strain amplitude in the range of strains associated with cyclic triaxial testing. The damping ratio decreases with ascending temperature and increasing frequency. The decrease in damping ratio with descending temperature may be a function of both the increase in the strength of ice and the decrease in unfrozen water content with decreasing temperature. The influence of frequency on damping ratio may be a function of creep effects due to sliding between ice or soil particles, or both, during dynamic loading. In the same way that stress relaxation effects influence the relationship between dynamic moduli and frequency, creep would tend to cause greater dis-

placements between grains and thus, greater values of damping ratio at lower frequencies than at higher frequencies. No definitive relationship between sample orientation and damping ratio could be established. In general, however, the differences in damping ratio associated with sample orientation were small and may be considered to be negligible. While there is scatter in the test results it appears damping ratio increases slightly with increasing water content and confining pressure. The increase is negligible, however.

CONCLUSIONS AND PRACTICAL SIGNIFICANCE OF TEST RESULTS

The dynamic properties obtained in the present study were found by Wilson (1982) to be in good agreement with the results obtained by previous investigators who evaluated dynamic properties of reconstituted artificially frozen silt. Any differences between the dynamic properties obtained in the present study compared to dynamic properties obtained in previous studies could be explained by differences in testing techniques or silt material characteristics. The major factors that influence dynamic properties of frozen silt identified in the present study (i.e. strain amplitude, frequency, and temperature), were reinforced through the comparison with the test results from previous studies.

Further, the test results from the present study and the comparison with the results from previous investigations suggests that the dynamic properties of frozen silt are influenced primarily by soil material characteristics (e.g., grain size distribution, soil mineralogy) and, to a lesser extent, by water content. The soil/ice structure (i.e., lens thickness, orientation, and spacing) does not appear to influence dynamic properties of frozen silt. Based on this conclusion, it would appear that it is not necessary to test specimens obtained from naturally frozen in situ samples if artificially frozen test specimens are prepared in the laboratory at the same water content as the in situ material.

THAW PLUG STABILITY AND THAW SETTLEMENT EVALUATION
FOR ARCTIC TRANSPORTATION ROUTES: A PROBABILISTIC APPROACH

C. L. Vita
R&M Consultants, Inc., Seattle, Washington
c/o P.O. Box 6087, Anchorage, Alaska 99503 USA

A unified, probabilistic approach to the evaluation of thaw plug stability and thaw settlement is outlined for practical application to arctic or subarctic transportation routes. The approach can explicitly account for uncertainties, geotechnical variability, and limitations in available geotechnical data/information. Using Bayesian probability concepts, landform identification, and statistical characterization of landform soil property parameters, it can provide site-specific estimates of thaw plug stability and thaw settlement. The methodology is suited to situations where regional or local landform soil property parameters can be statistically well known, but site-specific data may generally be either unavailable or sparse. Estimates can be based only on landform information or systematically updated and improved with site-specific data to the extent they are available. Estimates include the mean and the variance of both thaw plug stability limit equilibrium factor of safety (FS) and average thaw settlement magnitudes (TS); using these, estimates can be made of the probability of instability (Pf) and of reliability/probability levels on the settlement estimates, including the probability of any given estimate being above or below a given critical value. Differential settlement is not treated.

INTRODUCTION

Segment-by-segment evaluation of potential thaw plug stability and thaw settlement along arctic or subarctic transportation routes must address uncertainties associated with sparse site-specific subsurface soil data, loading conditions, subsurface thermal response, and the mechanics of stability. The purpose of this paper is to outline a practical yet rigorous approach for (1) systematically quantifying these uncertainties, and (2) rationally augmenting sparse site-specific subsurface soil data with data available from other sites having the same geologically characteristic landform; these are integrated as illustrated with results of a case study. Procedures presented here provide geotechnical tools for project planning, analysis, and design of an arctic or subarctic transportation route.

THAW PLUG STABILITY--FACTOR OF SAFETY

The resistance of a thawing slope to mass movement is commonly characterized by a limit equilibrium factor of safety (FS) for the expected critical failure surface A with FS defined as the ratio C/D, where C (capacity) is the sum of all forces resisting movement along A, and D (demand) is the sum of all forces contributing to movement along A. In theory, if FS could be evaluated with absolute precision, it would give a true measure of the future stability of a slope: $FS \geq 1.0$ would imply certain stability and $FS < 1.0$ would imply certain movement. In practice, FS cannot be evaluated with such precision due to uncertainties in the failure mechanism, soil conditions, loading

conditions and thermal response; these uncertainties make FS a random variable.

FS can be modeled as a site-specific random variable and evaluated probabilistically using estimates of the mean or expected value of FS, $E[FS]$, and the variance of FS, $V[FS]$, using a second-order approximation of the mean, a first-order approximation of the variance (Benjamin and Cornell 1970), and assuming a reasonable probability density function (PDF) model, $PDF[FS]$, e.g., lognormal:LN, normal:N, or beta:B. In the case study $PDF[FS]$ is assumed to be N for $1.0 \leq FS \leq E[FS]$. Given $E[FS]$, $V[FS]$, and $PDF[FS]$, the estimated probability of instability or "failure," Pf, a random variable defined as $P[FS < 1.0]$, can be calculated as $Pf = P[FS < 1.0/E[FS], V[FS], PDF[FS]]$. Whenever appropriate, multiple estimates of Pf based on alternative sets of reasonable assumptions or interpretations can be weighted and averaged, and/or used to form a PDF on Pf using a beta distribution (Harr 1977), and then assessed for sensitivity and technical/economic implications. In general, uncertainty in Pf can be made as small as desired by obtaining sufficient information. Also, a (PDF-free) probabilistic stability margin, U, can be defined as $U = (E[FS] - 1)/SD[FS]$; $SD[FS]$ is the standard deviation of FS, equal to the square root of $V[FS]$ (the standard deviation of any variable equals the square root of its variance).

The above procedure can be followed for any mathematical form of FS generally defined by

$$FS = fs(X_i) + e \quad i=1,2,\dots,k \quad (1)$$

The function $fs(X_i)$ represents the stability model C/D based on the X_i random variables used to model

geotechnical, geometric, and loading conditions; X_i may include effects of slope geometry, soil shear strength, depth of failure surface, groundwater conditions, excess pore pressures, massive ice, dead loads (embankment and soil weight) and live loads, stress distribution effects, thaw plug geometry, and so forth. Variable e accounts for bias and random error (determined, if adequate data is available, by calibration of predicted performance with observed field performance), reflecting potential inaccuracy and uncertainty in the stability model $fs(X_i)$ itself. $E[FS]$ and $V[FS]$ are then estimated via

$$E[FS] = fs(\bar{x}_1, \bar{x}_2, \dots, \bar{x}_k) + \bar{e} \\ + \frac{1}{2} \sum_{i=1}^k \sum_{j=1}^k \frac{\partial^2 fs}{\partial x_i \partial x_j} \Big|_m C[X_i, X_j] \quad (2a)$$

$$V[FS] = \sum_{i=1}^k \sum_{j=1}^k \frac{\partial fs}{\partial x_i} \Big|_m \frac{\partial fs}{\partial x_j} \Big|_m C[X_i, X_j] + V[e] \quad (2b)$$

$C[X_i, X_j]$ are the covariances of the parameters of Equation 1. All derivatives are evaluated at the means, m , of the X_i parameters, \bar{x}_i (a bar above a variable denotes its average or expected value). \bar{e} accounts for bias and $V[e]$ accounts for random error in $fs(X_i)$.

Using an effective stress Mohr-Coulomb failure model with attention focused on the uncertain soil strength parameters, $fs(X_i)$ can be written as the sum of two components: $(G \cdot C' + F \cdot \tan \phi')$, where C' and $\tan \phi'$ are the average effective soil strength parameters along the critical failure surface; G is a function of all X_i related to cohesion (C'), and F is a function of all X_i related to friction ($\tan \phi'$). Note that G and F could include reduction factors to account for the effect of massive ice on FS (e.g., as presented by Vallejo 1980). Application of Equations 2a and 2b yields

$$E[FS] = E[G] \cdot E[C'] + E[F] \cdot E[\tan \phi'] + \bar{e} \quad (3a)$$

$$V[FS] = E[G]^2 \cdot V[C'] + E[F]^2 \cdot V[\tan \phi'] + Z \quad (3b)$$

Here, Z represents in summary form all uncertainty from Equation 2b, including random error in the model, other than due to $V[C']$ and $V[\tan \phi']$.

Cost-effective procedures for estimating the expected values and variances of C' and $\tan \phi'$ may be based on regression analysis results: the soil strength parameters are predicted from the standard soil index properties of representative samples recovered (site-by-site) during subsurface boring and sampling investigations. The necessary predictive stochastic relationships between soil strength properties and soil index properties and the associated statistical parameters can be developed from a geotechnically and statistically designed strength testing program using a limited, but acceptable, number of generally representative soil samples. This approach can form the entire basis for estimating C' and $\tan \phi'$ for a given slope or it can supplement any available site-specific strength data. The model used here

is based on average frozen dry density, $\bar{\gamma}_{df}$, as the predictive soil index property, whereby

$$\tan \phi' = \tan[\sin^{-1} \beta \cdot \bar{\gamma}_{df}] \quad (4a)$$

$$C' = \rho \cdot \bar{\gamma}_{df} / \cos \phi' \quad (4b)$$

in which ρ and β are data-based regression constants.

AVERAGE THAW SETTLEMENT

The estimated average thaw settlement potential of a stratum or strata of average thickness h is TS , where $TS = h(1 - \bar{\gamma}_{df} / \bar{\gamma}_{dt})$; $(1 - \bar{\gamma}_{df} / \bar{\gamma}_{dt})h$ is the average thaw strain (Crory 1973) over the stratum and $\bar{\gamma}_{df}$ and $\bar{\gamma}_{dt}$ are stratum frozen and thawed dry densities averaged over the thickness h . An estimate of the mean and variance of TS where $X_1 = h$, $X_2 = \bar{\gamma}_{df}$, and $X_3 = \bar{\gamma}_{dt}$ is given by

$$E[TS] = h \cdot (1 - \bar{\gamma}_{df} / \bar{\gamma}_{dt})h \\ + \frac{1}{2} \sum_{i=1}^3 \sum_{j=1}^3 \frac{\partial^2 TS}{\partial x_i \partial x_j} \Big|_m C[X_i, X_j] \quad (5a)$$

$$V[TS] = \sum_{i=1}^3 \sum_{j=1}^3 \frac{\partial TS}{\partial x_i} \Big|_m \frac{\partial TS}{\partial x_j} \Big|_m C[X_i, X_j] \quad (5b)$$

Confidence intervals on TS for given probability/reliability levels including estimates of the probability of TS being above (or below) any given value can be estimated using $E[TS]$, $V[TS]$ and an appropriate PDF[TS] model (N , LN , or B). Also, the coefficient of variation of TS , given by $CV[TS] = SD[TS] / E[TS]$, gives a simple and useful measure of uncertainty in TS .

LANDFORM-BASED ESTIMATION OF SITE-SPECIFIC SOIL PARAMETERS

As developed above, the estimation of FS and TS requires prediction of average frozen dry densities for each site. Landform-based procedures (Kreig and Reger 1976, Vita 1982, 1983a, 1983b) provide a rational approach for making meaningful predictions where site-specific subsurface data are sparse or nonexistent: (1) the landforms occurring at a site are identified by airphoto interpretation and field exploration, (2) site-specific subsurface data are collected, (3) these data are statistically augmented by subsurface data obtained from the same landform at all other sites in the region to create an expanded data base, from which (4) landform/site data estimates of site-specific soil property parameters can be made.

A model for making estimates by this procedure of any site-specific soil property parameter, $\theta(S)$, is as follows. Without site-specific data available, estimates of $\theta(S)$ can be based only on landform data available from other sites. As results of site-specific data become available from field/laboratory programs, they are

summarized by a sample likelihood function (giving the relative likelihoods of $\theta(S)$ given the site-specific data), and Baye's theorem is used to make an updated landform/site data estimate of $\theta(S)$, $\theta(S)^*$, based on the landform (prior data) and the available site-specific data (sample data).

Here $\theta(S)$ is $\bar{\gamma}_{df}(S)$ in a stratum. In general the observed PDF of γ_{df} will closely resemble an inverse lognormal distribution, which may be transformed to a normal distribution; for most practical purposes directly assuming a normal distribution is adequate. For γ_{df} following a bell shaped PDF, using results modified from Vita (1982), the updated landform/site data estimates of the mean and variance of $\bar{\gamma}_{df}(S)$ are given by

$$E[\bar{\gamma}_{df}(S)] = \frac{\bar{x}(S) \cdot n + \bar{x}(Lf) \cdot \alpha}{n + \alpha} \quad (6a)$$

$$V[\bar{\gamma}_{df}(S)] = \frac{\{(n-1) \cdot s(S)^2 + (w-1) \cdot s(Lf)^2 + n \cdot w \cdot [\bar{x}(Lf) - \bar{x}(S)]^2 / (n+2)\}}{(w+n) \cdot (w+n-3)} \quad (6b)$$

where: n is the number of available samples from the site; $\bar{x}(S)$, $s(S)^2$ and $\bar{x}(Lf)$, $s(Lf)^2$ are the sample mean and variance of the site and landform γ_{df} data respectively; α is the estimated ratio of $V[\gamma_{df}(Lf)]$ to the variance of the observed distribution of $E[\bar{\gamma}_{df}(S)]$ for all other sites in the subject landform; and w is calculated from Equation 7. Equations 6a and 6b are based on Bayesian probability theory (Raiffa and Schlaifer 1961) assuming (as observed) that γ_{df} (or its transform) is normally distributed with unknown mean and variance. Prior sample weights α and w are conservatively chosen assuming (1) for $n=0$ (no sample data): $E[\bar{\gamma}_{df}(Lf)]$ is the best estimate of $E[\bar{\gamma}_{df}(S)]$; the best estimate of $V[\bar{\gamma}_{df}(S)]$ is the variance of $E[\bar{\gamma}_{df}(S)]$ for all sites comprising the landform; and $V[\gamma_{df}(S)]$ is equal to the landform data-based estimate of $V[\gamma_{df}(Lf)]$ for N available samples from the landform; and (2) α is conservatively estimated from available data ($\alpha=1$ being most conservative) and is less than the ratio of $V[\gamma_{df}(S)]$ to $V[\bar{\gamma}_{df}(S)]$. It then follows that w can be calculated from

$$\frac{N-3}{N-1} \cdot \frac{(w+n-1)}{(w+n) \cdot (w+n-3)} = \frac{1}{\alpha+n} \quad (7)$$

Note that α is dependent on site size (ranging from 1.0 for sample-sized "sites" to \sqrt{N} for a landform-sized site); on landform geological/statistical characteristics ($\alpha=1$ reflects greatest site-to-site variability, α being relatively larger for statistically homogeneous landforms); and on the quality, quantity, and statistical uncertainty of available multiple site data ($\alpha=1$ reflects greatest uncertainty).

Site data-based estimates are made (utilizing site-specific data only) by neglecting landform prior data and letting $\alpha=w=0$. Note that Equation 6b is undefined for site data-based estimates where $n \leq 3$; the assumption that $\bar{\gamma}_{df}(S)$ is uniformly distributed over a maximum possible range R introduces the least possible bias and gives $V[\bar{\gamma}_{df}(S)] = R^2/12$, centered at $\bar{x}(S)$, which is at

least as conservative as is the estimate of R ($R \leq 2,400 \text{ kg/m}^3$). In the following case study $R=1,100, 800$, and 640 kg/m^3 for $n=1,2$, and 3 , respectively. Site data-based estimates of $E[FS]$, $V[FS]$, and Pf are then compared with updated estimates using landform prior data. If they are significantly different (Vita 1982, 1983a, 1983b), the landform prior data can be correspondingly de-emphasized in estimates of Pf by decreasing α and/or weighting and averaging estimates or by forming a PDF on Pf using a beta distribution.

The foregoing tacitly assumes that sampling and testing biases and limitations are controlled and that any skewing affects on parameters are adequately rectified. Also, for landforms characteristically composed of significantly different soil types (e.g., tills), landform parameters may be made soil type-dependent and updated site-specific estimates conditioned on observed soil types. Further, updated site-specific estimates for situations where landforms are uncertain and/or occur in complex associations can be made by conditioning estimates on the expected probability of occurrence of the various potential conditions (the sensitivity of such estimates to the uncertainty, particularly the potential extreme conditions, should be properly evaluated).

REPRESENTATIVE RESULTS AND CASE STUDY

Figure 1 displays generally representative characteristics of the above equations, and includes specific results for a several-acre permafrost site located near Fairbanks in a landform composed of colluvial silt. The site was selected for illustration because it had sufficient soil data to compare predictions based on typically limited data (small n) with predictions based on substantial data (large n —representing much more soil data than would be available for a typical segment site along a route).

A total of $n=40$ samples (each from one borehole) were obtained from the potential critical failure zone at 3-4m depth. Sample-by-sample results for the first 10 ($n=1,2,\dots,10$) samples are shown; results based on all 40 samples are shown for comparison. Actual site and landform γ_{df} data have been used; other parameters are considered representative but are assumed. Two cases are illustrated: Case 1 (Figure 1c) actual site data with $\alpha=3$, representing a relatively statistically homogeneous landform; and Case 2 (Figure 1d) actual sample γ_{df} data reduced by 320 kg/m^2 (20 pcf) with $\alpha=1$, representing a statistically variable landform or one where so little information on other sites is available that a minimum α is considered prudent. Case 2 simulates a site which is in fact substantially more ice rich than the landform as a whole. Both updated landform/site data estimates ($\alpha \geq 1$) and site data-based estimates ($\alpha=w=0$) are shown.

Case 1 (actual γ_{df} data) shows the efficiency of the updated landform/site data method when the site is in fact similar to the landform: uncertainty in FS and TS is significantly decreased at small n relative to the site

data-based estimate. Therefore, the site as is can be qualified as acceptable or unacceptable based on a given Pf criterion with less site-specific data.

Case 2 (actual γ_{df} data minus 320 kg/m²) shows the effect of a "negative surprise" site--one that is in fact much more ice-rich (and therefore less stable) than the landform as a whole. The benefits of the updated landform/site data method for Case 2 sites are derived through comparison with the site data-based predictions: at small n, potentially significant differences become obvious--suggesting the need for further exploration, analysis, and/or changed design to achieve the desired Pf design criterion.

Figure 1 suggests important characteristics and implications of FS and TS as site-specific random variables. For example, to achieve any given Pf criterion, E[FS] cannot be constant for every slope but must be related to the uncertainty in site-specific conditions, e.g., as reflected by SD[$\bar{\gamma}_{df}$]; similarly for settlement, site-specific effects of uncertainty must be considered. Also, from Figure 1c and Figure 1d it is clear that (as is common to all probabilistic assessments of complex, variable and uncertain states of nature) Pf is itself a random variable, and that uncertainty in Pf will tend to decrease with increasing data (and can be made as small as desired by obtaining sufficient information).

In all cases the potential effect of unanticipated negative conditions should be considered since, regardless of specific technique, subsurface conditions are never completely defined in exploration or analysis--such that critical geotechnical details may go undetected or be inadequately interpreted and eventually result in unsatisfactory performance. Clearly, sound interpretive and integrative judgment is fundamental to successfully developing and utilizing geotechnical evaluations in the design process. Nevertheless, any technically responsible method for evaluating stability must be clearly defined and rational, must objectively account for uncertainty, and must be capable of objective calibration or validation based on observed field performance. Ultimately, any requirements to reduce impacts on facilities from unanticipated negative conditions must rely on appropriate, resilient design.

STONE POLYGONS: OBSERVATIONS OF SURFICIAL ACTIVITY

John D. Vitek

Department of Geography, Oklahoma State University,
Stillwater, Oklahoma 74078 USA

Small stone polygons, approximately one meter between centers, have developed in a 675 m² depression at 3,865 m in the Blanca Massif of the Sangre de Cristo Mountains in southern Colorado, USA (37°35' N., 105°30' W.). The absence of vegetation and human disturbance permitted observations to determine the rate of horizontal displacement of stones in the centers of the polygons. Photographs taken of the centers in August 1975, 1978, 1979, 1980, and 1982 provide the evidence from which displacement can be measured. Gaps in the photographic record occurred because the site was underwater in August of 1976, 1977, and 1981. A sample of 173 identifiable stones, greater than 1.3 cm in length, moved an average of 4.76 cm during a 7 year period; one stone moved 18.3 cm during these observations. The average rate of movement per stone was 0.68 cm per year from 1975 to 1982. In general the stones moved toward the gutters. Clast motion can be attributed to heaving and thrusting by frost action, needle ice, and perhaps lacustrine ice.

INTRODUCTION

The locations of stone polygons in alpine areas can be divided into two categories: sites that are relatively well drained and sites in depressions that are periodically covered by water. In the first situation, the stone polygons are large, often exceeding several meters in diameter, and regarded as relict landforms. The vegetation growing in the fines of the center of a polygon hinders, if not prevents, movement of rock fragments. Furthermore, stability of this micro-landform is indicated by lichens on rocks in the gutter. In the second location, the absence of vegetation can frequently be explained by the presence of water. Stone polygons are common micro-landforms in depressions subjected to periodic flooding and in the shallow areas of alpine lakes (Dionne 1974 and Shilts and Dean 1975). Because the water level in the lakes or depressions can fluctuate greatly, opportunities exist to study the surficial pattern and movement of clasts in the centers of stone polygons. The absence of vegetation plus the availability of water ensures the action of frost processes on these landforms.

Previous researchers have used several techniques to assess change in stone polygons over time. Cailleux and Taylor (1954) studied the superposition of photographs of stone polygons exposed over 13 years and concluded that no change had occurred. The same authors also observed that painted stones moved more than 10 cm in 2 years in the center of one stone polygon. Tallis and Kershaw (1959) noted that small stone polygons, 45-60 cm in diameter, formed in one winter and were obliterated by wet weather in the following summer. Pissart (1964) measured the movement of 6 stones over 17 years in the center of a disrupted stone polygon. One stone moved 21 cm in this study. French (1976) summarized the methods that have been employed to monitor the amount of movement in stone polygons. These methods include the use of painted objects, the deformation of layers,

leveling and direct measurement, vertical and ground photography, frost heave recorders, geochemical analyses, and carbon-14 dating. Despite the variety of efforts, few generalizations can be made about the rates of motion for clasts in the centers of stone polygons.

The purpose of this research is to document the amount of horizontal displacement of surficial stones in the centers of small stone polygons that are located in a depression on a moraine at 3,865 m. With a 7 year record, this research can provide answers to questions such as: What is the rate of stone displacement in the centers of stone polygons, and what is the predominant direction of displacement? Moreover, the rates and direction of stone displacement may provide additional evidence for evaluating the hypotheses of stone polygon formation. Finally, accurate estimates of the impact of frost action are becoming more significant as human activities continue to encroach upon alpine areas.

STUDY AREA

Within the Sangre de Cristo Mountains of southern Colorado, USA (37°35' N., 105°30' W.), a small depression, 675 m², at 3,865 m (Figure 1) contains stone polygons with approximately one meter between centers (Figure 2). The depression is located in the upper portion of the northeast-facing Dutch Creek cirque, a compound cirque that was probably ice-free since the end of the Pleistocene. No evidence of Neoglacial ice exists in the vicinity. Glacial till on the floor of the elongated cirque is composed of primarily felsic and hornblende gneisses and some metabasalt and metagraywacke, all of Precambrian age.

The site, first observed in August 1975, is devoid of lichens and shrubs, although a few clumps of grass have occasionally sprouted in the centers of the polygons. The general absence of vegetation can be explained, in part, by the presence of

FIGURE 1 An oblique aerial view of the study area in the Sangre de Cristo Mountains of Colorado. The arrow points to the area with stone polygons.

of the study area, is one hypothesis for the source of this fine material. Within the drainage area of the depression, only one small channel has developed, thereby suggesting that the influx of fines has had an effect on the development of stone polygons. This relationship will be investigated at a later date.

The study site is located in a tundra environment approximately 200 m above the tree line. No evidence has been observed to suggest that the study site was once forested. The nearest climatic station, the Great Sand Dunes National Monument, is 16 km northwest but is too low (2,499 m) to be of significant value in assessing the nature of the weather and climate at the depression. Although the climate station on Niwot Ridge in the Front Range is 270 km north, a similar elevation (3,750 m) and aspect on the landscape permit interpolation of general conclusions. Andrews (1973) reported precipitation averages 102 cm yr^{-1} and temperature averages -3.8°C on Niwot Ridge. Frost action is a very effective agent of surficial change when the freezing point, 0°C , is crossed frequently during the periods when water is available. The presence of talus, stone stripes, rock glaciers, and a patterned fen (Vitek and Rose 1980) attest to the effectiveness of frost action in the study area.

METHODOLOGY

The rates of many changes in a periglacial environment are perceptible only with long-term observations. The micro-landforms in the study area have had approximately 9,000 years in which to evolve, hence the actual rates of development and change may be extremely slow. Stone polygons represent one type of response to the interaction of atmospheric conditions and processes with lithologic and topographic variables. In effect, stone polygons have developed at this location rather than some other form of patterned ground. Knowledge of the types and rates of change in the stone polygons may provide information about past and future development.

The lack of sites in the Sangre de Cristo Mountains in which stone polygons may be active contributed to the conservative approach for the analysis of these forms. With repetitive photography, the stone polygons can remain undisturbed until such time that details of internal characteristics are essential to the interpretation of surficial activity. Painted stones were not added to the centers of the polygons to detect the rates of displacement in order not to disrupt the system. Recently, Caine (1981) reported that the addition of painted objects biases the measurements of change. Without paint, more effort is necessary to trace the movement of stones, but the results should provide more accurate estimates of the natural process.

The small size of these stone polygons allowed the centers to be photographed on one frame of a 35 mm camera with a 50 mm lens, thus minimizing the distortion introduced by photography (Figures 3 and 4). A 150 mm reference scale was placed within each stone polygon to aid in the alignment of photographs on a yearly basis. An assumption was made that the position of larger stones in the gutters would not change significantly over the

water. Standing water was observed in the gutters in 1975, although the level of the water was 25 cm below the surface. Maximum water level in the depression is defined by the vegetation around the depression. In the summer of 1976, for example, the water level coincided with the limit of vegetation. In 1981 during a rainstorm, the water level rose more than 25 cm in less than 48 hours. Observations on May 1, 1977, and May 6, 1981, at the beginning of spring melt, revealed lacustrine ice over the depression. Sufficient melting had already taken place and I was not able to determine if the ice was frozen to the surface of the stone polygons.

The fines in the center of the stone polygons are on an average 30% sand, 39% silt, and 31% clay. Additional textural analyses are planned when the site is excavated. Detailed studies of mineralogy have not been completed but will be useful in explaining the source of silts and clays. Extensive eolian activity in the San Luis Valley, west

FIGURE 2 A view of the stone polygons in a depression at 3,865 m. An ice axe, height of 80 cm, provides a measure of scale.

FIGURE 3 A 1982 (t_7) photograph of the stone polygon center referred to in the text as center A. Scale is 150 mm (6 in).

length of the study. Although the pattern of gutters and centers appears fixed, stones in the gutters may be disturbed by frost action, rodents, or people. Alignment of photographs confirms, however, that the disruption of stones in the gutters is minimal.

Laboratory experiments have proven that stones move to the surface and toward the edge of experimental systems subjected to alternate freeze-thaw (Corte 1962, 1966; Kaplar 1965; Mackay and Burrous 1979). Nicholson (1976) recently used field observations to conclude that a combination of the circulatory movement model and the radial movement model can explain many forms of patterned ground. Although the photographic method used in this analysis was designed to evaluate only the horizontal component of motion in a three dimensional system, the appearance of new stones on the surface through time also confirms the presence of vertical motion.

FIGURE 4 A 1982 (t_7) photograph of the stone polygon center referred to in the text as center D. Scale is 150 mm (6 in).

FIGURE 5 Horizontal displacement of stones monitored in center A from 1975 to 1982. The arrows indicate the direction of clast movement and the asterisks indicate clasts that could not be located in 1982.

Maps of stone position in the centers of polygons were created from photographic enlargements (28 x 36 cm). Maps from different time periods were aligned using a Kail reflecting projector to correct scale distortions introduced in the production of the photographs. For simplicity and accuracy, the stones that were mapped exceeded 1.3 cm in length because they could be easily identified from year to year. By comparing color slides taken during the 7 years, only 10 stones from the initial sample have been lost. The linear distance a stone moved was calculated as the distance the center of the stone moved relative to its initial position. Although stones are three dimensional objects, motions such as rotation or tilt have not been evaluated in this study.

ANALYSIS

Positions of the stones within four stone polygons (labeled A, B, C, and D) were recorded on August 6, 1975 (t_0). Although shadows were present when these photographs were exposed in midafternoon, they have not posed a major problem in interpreting change. In subsequent years, however, the photographs were taken during overcast conditions to eliminate any effect that shadows might have in masking true position. Because the depression was covered with water in August 1976 (t_1) and 1977 (t_2), the centers were not photographed for the second time until August 1978 (t_3). At this time initial photographs were taken of 12 additional centers. All 16 centers were photographed in August 1979 (t_4), August 1980 (t_5), and August 1982 (t_7).

Summary statements for this analysis include changes in the horizontal position of stones in four centers from 1975 (t_0) to 1980 (t_5) and from

1980 (t_5) to 1982 (t_7). Yearly summaries cannot be produced because of the gaps in the photographic record. In retrospect, comparison of two photographs for total change introduces less error than the summation of four changes between five photographs or six comparisons over seven years. The resultant maps of change (see Figure 5 for an example of the map of center A) were summarized in tabular form (Table 1). Total horizontal displacements on centers A (Figure 3) and B were greater than on centers C and D (Figure 4). In essence, centers A and B have similar physical characteristics in that smaller stones comprise the centers compared to scattered larger stones on centers C and D. The larger stones should offer greater resistance to the forces of motion, hence the average total displacement would be less. The range of distances moved by individual stones on sites A and B also supports the conclusion of greater resistance to movement in sites C and D.

For comparative purposes, horizontal displacement can also be expressed as a rate of movement on a yearly basis. Table 2 provides values based upon a 5 year record, a 2 year record, and the average per year based upon 7 years. Centers A (Figure 3 and Figure 5) and B exhibit virtually the same rates of change for the 5 year and 2 year periods. Although stones moved across centers C and D (Figure 4) at the same rate for 5 years, during the last 2 years, the rate of movement in center C tripled while that in center D only doubled. The mean values derived for 7 years must be evaluated carefully because one value, high or low, can skew the results. Similar rates at centers A and B over seven years may be accurate measures of change because the sites have similar physical characteristics. Greater resistance to

motion in the form of larger stones on centers C and D would yield lower rates of change. Increases in the rates of change between 1980 and 1982 for centers C and D, however, suggest that additional observations are necessary before mean values are accepted as accurate.

Movement of stones can be attributed to three processes: frost action (heaving and thrusting), the growth of needle ice, and lacustrine ice. On Niwot Ridge, Colorado, Fahey (1974) measured 25-30 cm of vertical displacement in frost boils, i.e., areas without vegetation but where sufficient water was available. Because these stone polygons are devoid of vegetation and have an ample water supply, frost action should generate the forces necessary to move stones. The centers of the stone polygons are a matrix of fine material surrounded by rock gutters, so the freezing plane may penetrate from the sides in addition to the top, thereby affecting the forces on the surface stones. The presence of other periglacial landforms in the immediate vicinity confirms that frost action is an effective agent of change in this area.

The impact of needle ice on surface phenomena has been documented by many researchers, including Mackay and Matthews (1974), Hastenrath (1977), Heine (1977), and Meentemeyer and Zippin (1981). Needle ice was observed in the centers of several stone polygons in May 1981. Unfortunately, the depression contained sufficient water and ice to cover the centers studied in this analysis. Several other centers, however, that were above the level of the water exhibited needle ice. Small stones were uplifted by the ice, whereas larger stones appeared undisturbed. Moreover, needle ice has been observed in June, July, and August over the past 7 years in conjunction with other investi-

TABLE 1 Summary of Measurements for Seven Years: 1975-1982.

Site	N(1975-1982)	Avg. total displacement per sample	Standard deviation	Range of values (1975-1982)

gations in the vicinity of the stone polygons. Based upon these observations, needle ice is considered as one of the processes responsible for the movement of stones in the centers of the polygons.

The final mechanism that may contribute to stone movement is lacustrine ice. Ice shove ridges are common in areas subjected to the forces of expanding ice (Washburn 1980). Although no definitive ridge exists around this depression, lacustrine ice was observed in 1977 and 1981. At the time of these observations, however, spring melting had already begun and the ice cover was incomplete. Given the rigors of the climate at this elevation, lacustrine ice may freeze to the surface of the stone polygons and contribute to stone movement upon expansion and cracking or upon break-up in the spring. Wind-driven ice could also dislodge stones. In summary, all three processes probably contribute to the horizontal movement of stones in the centers of stone polygons.

CONCLUSION

Monitoring 173 stones in the centers of four stone polygons for 7 years revealed an average total horizontal displacement of 4.76 cm, or an average yearly rate of displacement of 0.68 cm. The observed maximum horizontal displacement was 18.3 cm, although some of the lost stones could have been moved greater distances. Based upon the variability observed in these four centers, additional information is necessary to determine the relationship between stone size and distance moved. This analysis traced stones greater than 1.3 cm in length. A future project will calculate displacement based upon stone size. Moreover, additional studies with stones smaller than 1.3 cm are possible, such as the changes in percent of surface covered by stones in response to the vertical migration of stones.

Through August 1982, four centers of stone polygons had been photographed for 7 years and 12 others for 4 years. Data collection via photographs will continue for several more years before additional conclusions are drawn. Calculating mean values from short records could result in significant error. While the values given for average total displacement and yearly rate of change are accurate based upon the procedures employed, only additional observations can confirm if the sample period was representative of the rates of change.

ACKNOWLEDGMENTS

I would like to express my appreciation to David R. Butler, Oklahoma State University, and John R. (Rick) Giardino, Texas Tech University, for their helpful comments on the draft of this manuscript. I wish to thank the Department of Geography at Oklahoma State University for a portion of the financial support for this project. Finally, to Peg Vitek, Andy Deutch, Sue Berta, Mark Gregory, Susan Panciera, and Neil Salisbury, a sincere thank you for your support in the field.

A HIERARCHICAL TUNDRA VEGETATION CLASSIFICATION ESPECIALLY DESIGNED FOR MAPPING IN NORTHERN ALASKA

Donald A. Walker

Institute of Arctic and Alpine Research
University of Colorado, Boulder, Colorado 80309 USA

This paper presents a tundra vegetation classification scheme that is designed for describing vegetation at four levels: (1) very-small-scale maps, (2) LANDSAT-derived maps, (3) photo-interpreted maps, and (4) plant community descriptions. A system of nomenclature is described that links the four levels.

INTRODUCTION

Land-use planning in tundra regions utilizes knowledge of vegetation more than any other terrain factor. The vegetation gives insight to a host of environmental variables, many of which are related to permafrost, including soil properties, depth of the active layer, temperature regime and snow regime. There are three primary methods of interpreting vegetation: (1) plant community descriptions at ground level, (2) aerial photographs, and (3) multi-spectral satellite data. Currently there is no classification system that relates the map units from one method to those of the other two. Viereck and Dyrness (1980) developed a hierarchical method of vegetation classification for Alaska, but it is not specifically designed for mapping and is particularly difficult to apply to LANDSAT-derived classifications. The classification scheme presented here (Table 1) meets three basic criteria:

- At the LANDSAT level, the land cover units are based on those characteristics of the vegetation that can be classified consistently from LANDSAT data.
- At lower levels, the classification system is consistent yet flexible enough to describe the great variety of tundra communities. At the community level, the system is open-ended so that units that do not accurately describe the vegetation of a given area need not be used.
- The lower level units can be grouped within the higher level units with a minimum of overlap so that there is clear compatibility between levels.

The highest classification level, Level A, is very general and useful for very-small-scale vegetation maps of Alaska. Level B consists of LANDSAT-level land cover units that can be interpreted using digital multi-spectral satellite data. Level C consists of vegetation subunits that can be interpreted from aerial photographs if supplemented with adequate ground truth. Level D consists of individual plant communities, determined by ground surveys. The following discussion presents the classification system

"from the ground up," starting with level D.

LEVEL D--PLANT COMMUNITY NAMES AND UNITS FOR VERY-LARGE-SCALE MAPS

Level D units describe specific vegetation classes that correspond approximately to the stand types of Marr (1967) the associations of Daubenmire (1952) or Braun-Blanquet (1932), and the plant community or community type of Whittaker (1967). At this level there are many units and the system is open, such that any newly described vegetation community can be easily added. The nomenclature used for describing vegetation at this level always follows fixed guidelines. The following discussion explains the nomenclature system for plant communities and noncomplex map units and then for complex map units. Complex map units contain two or more distinct vegetation communities, and each community covers at least 30% of the map unit. Level D is appropriate for very-large-scale maps of small areas (e.g. a 1:1,000-scale map of a 5 acre ecology study site).

Noncomplex Units

Plant community names have four parts that are always arranged in the following sequence: (1) a site moisture term, (2) the dominant plant taxa, (3) the dominant plant growth forms, and (4) an overall physiognomic descriptor. The site moisture term can be dry, moist, wet or aquatic. These are subjective terms based on the soil moisture at the end of the growing season. The site moisture term is followed by the names of the dominant plant taxa, one or more from each of the representative shrub, herb, and cryptogam layers of the canopy. The number of taxa is kept to the minimum required to adequately distinguish the community from others on the map; the total normally does not exceed six.

The dominant growth forms follow next and can be any of the following: (1) tall shrub (>1.5 m), (2) low shrub (0.2 to 1.5 m), (3) dwarf shrub (<0.2 m), (4) sedge, (5) grass, (6) rush, (7) tussock sedge, (8) forb, (9) moss, (10) crustose lichen, and (11) fruticose lichen. The term graminoid is used when two or more of the dominant

		VIIIb. Moist Low Shrub Tundra	Moist <i>Betula nana</i> ssp. <i>exilis</i> , <i>Ledum palustre</i> ssp. <i>decumbens</i> , <i>Salix planifolia</i> ssp. <i>pulchra</i> , <i>Vaccinium</i> spp., <i>Cladonia</i> spp. Low Shrub Tundra (moist birch tundra)
			Moist <i>Betula nana</i> ssp. <i>exilis</i> , <i>Vaccinium uliginosum</i> , <i>Potentilla fruticosa</i> , <i>Shepherdia canadensis</i> , <i>Salix</i> spp., <i>Festuca altaica</i> Low Shrub Tundra (south facing shrub tundra in foothills)
	VIIIc. Moist Shrubland (closed riparian shrubland)	Moist <i>Alnus crispa</i> , <i>Betula nana</i> ssp. <i>exilis</i> , <i>Salix</i> spp. Low Shrub Tundra (alder shrub tundra)	
		Moist <i>Salix alaxensis</i> , <i>Salix</i> spp. Tall Shrubland (willow riparian shrubland)	
		Moist <i>Betula nana</i> ssp. <i>exilis</i> , <i>Betula glandulosa</i> Low Shrubland (birch riparian shrubland)	
E. Partially Vegetated and Barren	IX. Partially Vegetated (violet)	Riparian areas:	
		IXa. Dry, Barren/ Low Shrub Complex (open riparian shrubland)	Typical communities and ground cover listed under VIIIc and Xa.
		IXb. Dry Barren/ Dwarf Shrub, Forb Grass Complex (forb-rich river bars)	Typical communities listed under Vc, Xa, also mixed forb grass and dwarf shrub communities such as: Dry <i>Bromus pumpeilianus</i> , <i>Festuca rubra</i> , <i>Astragalus alpinus</i> , <i>Androsace chamaejasme</i> , <i>Salix ovalifolia</i> Grass, Forb, Dwarf Shrub Tundra (Forb-Pitch river bars)
			Dry <i>Dryas integrifolia</i> , <i>Artemisia borealis</i> , <i>A. glomerata</i> , <i>Salix ovalifolia</i> , <i>Androsace chamaejasme</i> Dwarf Shrub, Forb Tundra (Dryas river bars near arctic coast)
		IXc. Dry Barren/ Forb Complex	Dry <i>Epilobium latifolium</i> , <i>Artemisia arctica</i> , <i>Wilhelmsia</i> <i>physodes</i> Forb Barren (active river channels)
		IXd. Dry Barren/ Low Shrub Forb Complex (open riparian shrubland)	Dry <i>Salix alaxensis</i> , <i>Salix</i> spp. <i>Hedysarum</i> spp. <i>Astragalus</i> <i>alpinus</i> , <i>Equisetum arvense</i> , <i>Oxytropis campestris</i> , <i>O. borealis</i> , <i>Anemone parviflora</i> Low Shrub, Forb Tundra (river bars inland)
		Sand Dunes:	
IXe. Dry Barren/ Grass Complex (sand dune grassland)	Dry <i>Elymus arenarius</i> Grass Tundra (sand dune grassland)		
IXf. Dry Barren/ Dwarf Shrub, Grass Complex (sand dune steppe)	Dry <i>Artemisia borealis</i> , <i>A. glomerata</i> , <i>Beschampsia caespitosa</i> <i>Festuca spicata</i> Dwarf Shrub, Grass Tundra (sand dune steppe)		
IXg. Dry Barren/ Low Shrub Complex (sand dune scrub)	Dry <i>Salix alaxensis</i> , <i>S. glauca</i> , <i>Elymus arenarius</i> , <i>Carex</i> <i>obtusata</i> , <i>Dryas integrifolia</i> Low Shrub, Tundra (sand dune scrub)		

TABLE 1 (Continued)

Level A VERY SMALL SCALE UNITS	Level B LANDSAT LAND COVER UNITS (suggested map colors)	Level C PHOTO-INTERPRETED MAP UNITS	Level D TYPICAL PLANT COMMUNITIES
		Beaches, river deltas, and estuaries: IXh. Wet Barren/ Wet Sedge Tundra Complex (barren/ saline tundra complex)	Typical ground cover listed under IIb
		IXi. Dry Barren/ Forb. Graminoid Complex (coastal barrens)	Dry <i>Cochlearia officinalis</i> , <i>Stellaria humifusa</i> , <i>Puccinellia phryganodes</i> , <i>P. andersonii</i> , <i>Salix ovalifolia</i> , <i>Potentilla pulchella</i> Forb. Graminoid Tundra (coastal saline barrens)
		Mountainous areas: IXj. Dry Barren/ Dwarf Shrub, Graminoid Tundra Complex (dry alpine tundra)	Typical ground cover listed under Xd, Vc, or the following, among many others: Dry <i>Dryas octopetala</i> , <i>Salix phlebophylla</i> , <i>Carex microchaeta</i> , <i>Kobresia myosuroides</i> , <i>Saxifraga bronchialis</i> , <i>Hierochloa alpina</i> , <i>Potentilla hyperctica</i> , <i>Minuartia arctica</i> Dwarf Shrub, Graminoid Tundra (dry alpine tundra)
		IXk. Moist Barren/ Moss, Forb, Dwarf Shrub Tundra (moist alpine tundra)	Moist <i>Hylocomium splendens</i> , <i>Saxifraga bronchialis</i> , <i>Saxifraga tricuspidata</i> , <i>Salix phlebophylla</i> , <i>S. chamissonis</i> , <i>Cladonia</i> spp., Moss, Forb, Dwarf Shrub Tundra
	X. Light-colored Barrens (Note: Most areas classed as barrens are likely to have some vegetation but ground cover is less than 30% (black))	Xa. River gravels	Completely barren or with typical communities listed under IXb, IXc, IXd
		Xb. Sand dunes	Typical communities listed under IXe, IXf, IXg
		Xc. Barren gravel outcrops	Typical communities listed under Vd or the following, among many others: Dry <i>Dryas octopetala</i> , <i>Lupinus arcticus</i> , <i>Potentilla biflora</i> , <i>Smelowski calycina</i> , <i>Saxifraga tricuspidata</i> , <i>Salix phlebophylla</i> , <i>Silene acaulis</i> Dwarf Shrub, Forb Barren (gravel outcrops)
		Xd. Talus slopes and blockfields	Dry <i>Rhizocarpon</i> spp., <i>Lecidea</i> spp., <i>Umbilicaria</i> spp., <i>Cetraria</i> spp. Crustose Lichen Barren (Blockfields and Talus)
		Xe. Gravel roads and pads	Completely barren
		XI. Dark Colored Barrens (gray)	XIa. Wet mud
	XIb. Wet or dark-colored gravels		Completely barren
	XIc. Bare peat		Mostly barren areas along the coast caused by storm surges or man-made disturbances, communities listed under IIIb
	XId. Talus slopes and block fields		Same as Xd
F. Ice	XII. Ice (white)	XII. Ice	Completely barren

grass-like plants are in different families. Only the growth forms contributing at least 30% of the readily visible ground cover are included in the community name.

The last portion of the community name is the physiognomic descriptor, which is a term that applies to the appearance of the general vegetation landscape. The term tundra is used for most arctic and alpine nonforested areas with generally continuous ground cover. The term barren is used in areas where there is less than 30% ground cover. The term shrubland applies only to shrub-covered areas that are traditionally not considered tundra, such as dense riparian shrubs along large rivers. Shrub dominated vegetation in water tracks that are common in the foothills are generally considered shrub tundra, as are shrub-dominated units on mountain slopes and on open flat terrain. Examples of community names can be found in the right hand column of Table 1.

Complex Units

Complexes of vegetation are particularly common in the Arctic, where patterned ground is prevalent. Areas where complexes are mapped include ice-wedge polygons, sorted block fields, strangmoor, water tracks, frost-scar areas, and

solifluction stripes and lobes. Often one community is consistently associated with a particular element of the surface form, such as polygon rims, while another community is consistently found on another element, such as the polygon basins and troughs. A consistent method of describing complexes utilizes the basic community nomenclature described above. For example, the following description is for a map unit in a foothill area with water tracks.

Water-track complex:

- a) Interfluves and upland areas: Moist *Eriophorum vaginatum*, *Salix planifolia* ssp. *pulchra*, *Ledum palustre* ssp. *decumbens*, *Sphagnum* sp., *Cladina arbuscula* Tussock Sedge, Low Shrub Tundra.
- b) Water tracks: Wet *Salix planifolia* ssp. *pulchra*, *Betula nana* ssp. *exilis*, *Carex aquatilis*, *Sphagnum* sp. Low Shrub Tundra.

Note that the community names follow descriptions of the microsites on which they occur, and the complex is named according to the dominant patterned-ground feature or landform. The unit description includes only those plant communities that are associated with distinctive

patterned-ground elements (e.g. polygon rims, water tracks, polygon troughs etc.) and that cover more than 30% of a map unit.

LEVEL C--PHOTO-INTERPRETED MAP UNITS

Level C can be used for photo-interpreted maps at scales from 1:6,000 to 1:63,360. On aerial photographs there are two main characters that are useful for identifying tundra vegetation. The first is color or a gray tone. The darkness of tone is often indicative of the moisture status of the site. Darker areas are normally wet, and lighter areas tend to be moist or dry due to an abundance of erect dead graminoid vegetation and/or crustose lichens. There are, of course, exceptions to this. Sometimes dry areas will also be dark due to barren peat or an abundance of dark-colored fruticose lichens, such as *Alectoria nigricans* and *Cornicularia divergens*, or wet areas may be light-toned due to muck on pond bottoms. On color-infrared photographs, color is important. For example, red tones are indicative of deciduous shrubs and are important in interpreting categories of tussock tundra vegetation with varying amounts of shrub cover.

The second useful character is texture. Many textures are indicative of surface forms and thus are useful for recognizing vegetation complexes. The presence of ice-wedge polygons, frost boils, solifluction lobes, strangmoor, blockfields, talus, and rugged rocky terrain can be recognized on the basis of texture. On very-large-scale photographs, texture can also be helpful in identifying shrub vegetation and cottongrass tussocks.

Photo interpretation of tundra vegetation is difficult because nearly all the communities are low growing and the clues for distinguishing units are frequently quite subtle. It should be stressed that the critical element for accurate vegetation maps is extensive ground reference data. With adequate ground experience, site moisture regime and dominant plant growth forms can normally be interpreted.

Noncomplex Units

The species composition of tundra vegetation can very rarely be reliably interpreted from aerial photographs. Thus at Level C, the nomenclature drops the plant taxa names and consistently uses the remaining parts of the nomenclature outlined for Level D, i.e., the site moisture term, the dominant plant growth forms, and the physiognomic descriptor. An example of a Level C unit is Moist Tussock Sedge, Low Shrub Tundra. Other examples may be found in Table 1.

Complex Units

Complex units are treated in a similar fashion with the term complex attached to the end of the unit name and the components of the complex separated by a slash (/). An example for a low-centered ice-wedge polygon complex is Wet Sedge/Moist Sedge, Dwarf Shrub Tundra Complex. The physiognomic term tundra is included only for

the last portion of the complex. The physiognomic term for the first portion of the complex is included only if it is different from the last. The first part of the complex name is the dominant portion. The Level C equivalent of the water track complex mentioned in the previous section is Moist Tussock Sedge, Low Shrub/Wet Low Shrub Tundra Complex. The term water track complex could be used as a shorter synonym in general discussion. For the formal map unit titles, however, every attempt should be made to use the complete names since this increases the amount of information available on the map and makes all the units comparable.

LEVEL B--LANDSAT-INTERPRETED MAP UNITS

LANDSAT methods have certain advantages over photo interpretation. These include the digital format of the data, and the speed with which maps of large areas can be made. The minimum LANDSAT mapping area is one pixel or picture element that corresponds to a ground area of 0.44 ha (1.1 acre). This is considerably smaller than minimum map unit size at all but the very largest photo-interpreted map scales.

The big disadvantage of LANDSAT methods is that the final map units are based solely on surface reflectance. Promising methods that may aid in interpretation of tundra vegetation from LANDSAT data include: 1) using multiple LANDSAT scenes from several seasons, and 2) use of digitized landform and terrain data from geographic information systems. The combination of spectral reflectance and terrain information can be used to produce computer models that are capable of interpreting more vegetation units than can be mapped with spectral data alone. There have been some attempts to use digital elevation data from topographic maps to help model problem categories on the basis of slope aspect and elevation (for example, Justice et al. 1981). These methods have not, however, been used extensively on the Arctic Slope due largely to the very flat landscape where interpolation of elevation values from widely spaced topographic contours can produce inaccurate interpretations.

A classification for LANDSAT-derived maps should recognize the limitations of the data. There are two primary characters of the northern Alaskan vegetation that affect its spectral reflectance and are most important with regards to LANDSAT-derived vegetation classifications. These are the amount of water on the surface and the percentage of deciduous shrubs in the vegetation canopy. Numerous other factors, such as the total percentage of plant cover, the amount of erect dead graminoid vegetation, the color of the substrate, the amount of lichen cover, and the nutrient status of the site, also affect the reflectance. Figure 1 is a cluster diagram for a typical LANDSAT scene from northern Alaska illustrating the spectral signatures in two bands for the major Level B classes. The 12 Level B units are based primarily on moisture status, the amount of shrubs in the canopy, and, in the case of the partially vegetated and barren units, the total percentage of plant cover. A full discussion of the units can be found in Walker et al. (in press).

LEVEL A--VERY-SMALL-SCALE MAP UNITS

Level A consists of only six units that are useful for very general vegetation maps of Alaska. The units are Water, Wet Tundra, Moist Tundra, Shrubland, Partially Vegetated and Barren, and Ice. These units are comparable to the classes used for the major ecosystem map of Alaska (Joint Federal-State Land Use Planning Commission 1973) and the USGS land cover classification

FIGURE 1 Cluster diagram for a LANDSAT scene of the Prudhoe Bay region, Alaska (scene no. 21635-21044), bands 5 and 6. The land cover designations and map colors indicate how the clustered were grouped in the final classification. Each ellipse encloses 80% of the pixels assigned to the respective cluster. The clustering algorithm is part of the EDITOR LANDSAT analysis software system used on the TENEX-DEC System PDP 10 computer available from Bolt Beranex and Newman Inc., Boston, Mass. (Courtesy of USGS Geography Branch, Moffet Field, California.)

system for remote sensor data (Anderson et al. 1976).

CONCLUSION

The hierarchical classification scheme presented here offers a first approximation at a link between two methods of vegetation mapping that are being widely used in northern Alaska--one based on LANDSAT technology and the other based on photo interpretation. It ties both of these methods to a comprehensive means of describing tundra vegetation on the ground. It is presently a flexible system that will undoubtedly continue to evolve as more experience is gained in mapping tundra vegetation.

ACKNOWLEDGMENTS

This work was sponsored by the U.S. Army Cold Regions Research and Engineering Laboratory (CRREL). The classification system was developed during contracts with CRREL, the Sohio Alaska Petroleum Co., and ARCO Alaska, Inc. The U.S. Fish and Wildlife Service (USFWS), the U.S. Geological Survey (USGS), and the North Slope Borough have provided extensive logistical support and funds. The USGS Geography Branch at Moffet Field, Calif., and Reston, Va., was responsible for the technical expertise required for the LANDSAT classifications. Patrick J. Webber, Director of INSTAAR and others too numerous to mention here have helped me in developing this classification.

THE INFLUENCE OF SUBSEA PERMAFROST ON OFFSHORE PIPELINE DESIGN

David B. L. Walker¹, Don W. Hayley², and Andrew C. Palmer³

The way in which permafrost affects the design of land-based pipelines carrying hot fluids is well documented and has been the subject of a considerable amount of engineering analysis in the last decade. This paper considers the related problem of designing offshore pipelines in areas where subsea permafrost is encountered. A thermal analysis using a finite element model is described, and results based on measured soil data are presented for the cases where a pipeline is supported in a causeway and where it is trenched into the seabed. This is followed by a discussion of settlement analysis, considering such questions as the determination of thaw strain and the influence of arching in the soil. The selection of a criterion to determine "allowable" pipeline curvatures and the question of treating the statistical variability of soil and permafrost conditions along the pipeline route are also covered.

INTRODUCTION

The thawing of subsea permafrost below a warm submarine pipeline creates a potential hazard if it leads to excessive pipeline settlement. Several solutions have been advanced; these include the elevation of the pipeline above the seabed on piles or in a berm and the provision of an active refrigeration system. While these techniques have extensive applications on land, they are unlikely to be economic for all but short lengths of offshore pipelines in shallow water.

The preferred solution is to trench the pipeline into the seabed (to protect against ice scour) and, by providing sufficient insulation around the pipe, to restrict the thawing of permafrost and the resulting settlement to an acceptable degree. The way in which this can be calculated is the subject of this paper. Results of a thermal analysis are presented, leading into a discussion of the important considerations governing the mechanical response of the pipeline and the surrounding thawed material.

Since it is not intended that a site-specific design problem should be addressed, hypothetical pipeline sizes and operating temperatures have been selected in the analysis. However every attempt has been made to use measured soils and climatic data to make the study representative of inshore Alaskan Beaufort Sea conditions.

THERMAL ANALYSES

Thermal Modeling

Transient heat conduction through the seabed was predicted using a two-dimensional finite element model (Hwang et al. 1980, Hwang 1976). A number of one-dimensional analyses were also carried out to determine initial conditions and to

match these to measured data. The model geometry remained fixed during each simulation and no adjustments were made to accommodate pipeline settlement.

Properties of soils required for geothermal analyses include latent heat, specific heat and thermal conductivity. Geotechnical engineering practice is to evaluate soil thermal properties indirectly by reference to known correlations to soil index properties such as texture, moisture content and bulk density. With seabed soils, salinity must also be considered, since this affects not only the soil freezing temperature, but also its latent heat due to the presence of unfrozen water.

The salinity of ice-bonded permafrost is generally on the order of 10 ppt or about a third of that for normal seawater; however the salinity of unfrozen seabed soils can exceed that of seawater by up to 25% (Harrison and Osterkamp 1982). The relationship used in this study between soil freezing point and salinity is derived from the sea ice model presented by Ono (1966).

The latent heat of soils is computed by multiplying the latent heat of water by the volume of water that must change phase in order to thaw the soil. This volume equals the total moisture content minus the moisture content that remains unfrozen at the particular soil temperature. The unfrozen moisture is considered as the sum of the moisture absorbed by soil minerals (McGaw and Tice 1976) and the unfrozen moisture within the brine pockets of pore ice (Ono 1966).

The relationship between unfrozen water content and temperature for varying salinities is shown in Figure 1. The soil is typical of the fine grained seabed permafrost within the study region and can be classified as a sandy silt with a total water content of 32%. The latent heat required to thaw this soil will typically be 50-75% of that required for a similar fresh water soil.

FIGURE 1 Effect of salinity on unfrozen water content.

FIGURE 2 Model geometries (not to scale).

Salt rejection is observed in frozen soils at temperatures below -8°C . This process was not modeled since temperatures are primarily in the range of -1.5 to -3.5°C .

Thermal conductivity of cohesionless soils was estimated using Johansen's method as described by Farouki (1981). The estimated conductivity provided a reasonable comparison with the limited data available from proprietary field studies.

The specific heat of ice-bonded permafrost was computed as a weighted average of the soil grains, unfrozen moisture and frozen moisture.

Model Geometries and Boundary Conditions

Figure 2 shows the geometries of the three cases under consideration. Water depth is an important variable. Cases 1 and 2 consider shallow conditions, i.e. water depths less than 2m. Due to the presence of bottom-fast ice during the winter, the mean annual seabed temperature is substantially lowered and hence relatively cold permafrost (-3°C) is encountered within 2m of the surface. Typical soils data for shallow conditions are summarized in Table 1.

Case 3 is typical of deep water (greater than 2m) where the seabed temperature is warmer and remains approximately constant throughout the year. In this case, the depth to the relatively warm permafrost (-0.9°C) is treated as a variable.

In each case, twin 16 in (406mm) diameter pipelines are modeled carrying hot oil at a temperature of 66°C . Insulation thickness is treated as a variable. A vertical axis of symmetry midway between the pipeline allows modeling of half of the actual section.

The causeway was assumed to have a crest width of 15.2m with side slopes of 1 in 10. The freeboard was set at 4.6m in a water depth of 1m. The pipelines were buried 1.4m below the surface, 1.05m on either side of the axis of symmetry.

The boundary conditions for the exposed surface of the causeway were derived from meteorological data on measured air temperatures, wind speed, snow depths and solar radiation. Figure 3 illustrates the boundary condition applied to the submerged surface of the causeway and to the adjacent seabed. This was obtained from a separate one-dimensional analysis, where, by adjusting conductivities, seabed temperatures were derived that matched measured data.

FIGURE 3 Boundary condition used on submerged surfaces for shallow water cases.

Constant temperature and adiabatic boundary conditions were prescribed for the base and vertical surfaces of the grid respectively. Initial

seabed temperatures were established from the one-dimensional analysis to compare closely with available measured data.

An alternative configuration to the causeway consists of the pipelines buried directly in the seabed. A water depth of 1m was selected for Case 2, where the pipelines were assumed to be operating in a backfilled ditch with 1m of granular bedding provided below the pipes. The bottom of the pipe was placed at a depth of 2.4m in a trench with a base width of 6m and side slopes of 1 (V) in 2 (H) (see Figure 2).

Case 3 considered a location in 3.4m of water, where the depth to ice-bonded permafrost was treated as a variable, between 6 and 15m below the seabed. This was achieved by adjusting soil salinities and hence freezing points. The granular bedding was eliminated below the pipe as shown in Figure 2. The boundary conditions were similar in both analyses with the exception of the exposed surface below sea level. For the deeper water case where seasonal freezing does not extend to the bottom, the temperature was varied over a 1°C range (cf. 15°C in shallow water).

Causeway Results

Thermal simulations were run for pipes having 0, 50 and 100mm of insulation. Figure 4 indicates the extent of thaw after 5 years of operation. (Abrupt changes in the thawing isotherm position reflect changes in soil properties.)

FIGURE 4 Causeway condition during September of year 5.

Permafrost aggradation under the causeway is observed along the full width of the causeway. With insulated pipe, the entire causeway freezes each winter, while the bare pipe maintains a thaw bulb all year. During the summer months, approximately 2m of gravel thaws out on the flanks of the causeway, and under the insulated pipes thawing extends down to about 4m from the surface, but is still contained within the causeway itself.

From the above, it is apparent that to prevent thaw settlement, the provision of 50mm of

insulated coating around the pipelines is adequate. The possibility of frost heave however, due to the presence of the causeway itself promoting the freezing of seabed soils, cannot be overlooked.

Seabed Trench Results

A full parametric study has not been conducted at this stage; only water depth, depth to permafrost surface and insulation thickness are treated as variables.

Figure 5 compares the worst case, that is where the permafrost table lies 6m below the seabed (Case 3a) with the next most severe condition, where the pipeline trench intercepts the permafrost 2m below the seabed (Case 2). Dropping the permafrost table to 9 and 14 m beneath the seabed (Cases 3b and 3c) produced progressively less rapid thawing.

FIGURE 5 Depth of thaw below seabed (midway between pipes) versus time.

Two phenomena are observed here: dropping the permafrost table reduces thawing by introducing more unfrozen material acting like insulation around the pipe. In the first of the Case 3 simulations however, this is more than offset by the warmer initial ground temperatures when compared with Case 2.

Case 3b (permafrost table initially 9m below seabed, 100mm insulation) showed that only 1.2m of thaw had taken place after 5 years, and none at all was observed in Case 3c when the table was dropped to 14m.

A typical cross-section of the thaw bulb is given in Figure 6, showing the Case 3a results after 5 years.

Unlike the causeway analysis, it is not possible to reach definite conclusions at this stage about the acceptability of the degree of thawing observed. In the worst case, even with 100mm of pipeline insulation, up to 4.5m of permafrost was thawed beneath the pipe before steady state was reached. Nevertheless it should be recognised that from our existing borehole data this represents unusual conditions (that is, encountering "warm" permafrost only 6m below the seabed). For more typical conditions where the permafrost table is 10-15m into the seabed, steady state was reached after 1-2m had been thawed. Throughout, it should be recognised that conservative assumptions about heat loss to the ocean have been made, in that complete backfilling of the trench with uniform seabed material is assumed.

FIGURE 6 Case 3 thaw bulb profile.

PIPELINE SETTLEMENT

Introduction

The prediction of the size of the thaw bulb under a warm pipeline overlying permafrost is a relatively straightforward computation, provided accurate soils data are available. The settlement calculation on the other hand is more complex and there are reasons to believe that simplified models may be overly conservative. Three aspects of the problem will be discussed here:

- the computation of the deflected shape of the trench profile.
- the interaction of the pipe with the trench and the determination of an acceptable pipeline curvature.
- the statistical treatment of soil variables.

Settlement

There are two aspects of this problem which any model must address, namely the computation of thaw strain and the influence of soil arching.

In a continuum model of a frozen soil, the total stress is shared between an effective

FIGURE 7 Voids Ratio versus Stress.

stress in the soil skeleton and an ice stress. A simple one-dimensional model of thaw consolidation is described by Figure 7, where the axes are stress and voids ratio, and the continuous curve expresses the relation between stress and voids ratio observed in a conventional consolidation test on unfrozen soil, in which the effective stress is increased continuously, and free and complete drainage of pore water is allowed. If the soil is frozen at voids ratio e_0 , and then subjected to a total stress s_1 , the effective stress is s_0 and the ice stress $s_1 - s_0$. If now the soil thaws, the voids ratio decreases to $(\gamma_i/\gamma_w)e_0$, where γ_i and γ_w are the densities of ice and water, and the effective stress increases to s'_0 . Since the total stress is still s_1 , a pore pressure $s_1 - s'_0$ is induced. If drainage is not permitted, this portion of the total stress can continue to be carried by the pore water, and no settlement will occur. If drainage can occur, the pore pressure falls, and the total stress is progressively transferred away from the pore water, so that the effective stress increases to s_1 and the voids ratio falls to e_1 ; the corresponding thaw strain is $(e_0 - e_1)/(1 + e_0)$. In some soils with segregated ice, s_0 is almost zero, while in coarse-grained soils, the consolidation curve is almost parallel to the stress axis, so that thaw strain is almost independent of s_1 . Only then does it make sense to speak of thaw strain as a material property, and usually it will depend on the final stress level.

Morgenstern's theory of one-dimensional consolidation introduces the concept of thaw-consolidation ratio, a measure of the extent to which pore pressures in the thawed region can dissipate in relation to the speed of advance of the thaw front. Like all idealizations, it leaves out factors that may sometimes be important; for example, it takes no account of unfrozen water in the frozen soil, or of partial saturation, or, like our own thermal model, no account of thermal diffusion or convective interaction between the diffusion of heat and water.

The stress field under a pipeline is obviously more complicated than in one-dimensional consolidation. In some areas, deformation may be dominated by shear strains, which do not imply volume change, do not require pore water to diffuse, and therefore can occur as an immediate response to stress change. A complex progressive interaction develops during thaw consolidation, as pore pressures diffuse and the relative magnitudes of shear and volumetric strain alter, both with time and with position within the stress field.

Thawing under a submarine pipeline induces a complex three-dimensional situation, but many of the features of the simple model persist. Firstly, settlement induced by large volumetric strains implies drainage, and therefore will not occur at once, but only after times of order L^2/c_{vc} , where L is the drainage path length and c_{vc} the coefficient of consolidation; this would still be the case even if thawing were instantaneous, and drainage rather than thaw rate will often determine the rate of development of thaw settlements. Secondly, the extent of thaw

strain depends on the stress field; if stress redistribution during thawing reduces the increases in effective stress that would occur otherwise, the thaw strains and settlements will be correspondingly reduced.

Figure 8 is a schematic transverse and longitudinal section of a submarine pipeline in a backfilled trench in seabed soil containing a mass of ice-rich material subject to large thaw strains. When the pipeline goes into operation, the ice-rich material begins to thaw, and consolidation begins immediately beneath the pipe, at a. Arching will reduce the effective stress at a (and therefore reduce the thaw strain) by redistribution of the vertical compressive stress laterally, away from the "softer" area of thaw strain, so that the stress is increased on either side at b and c. To a lesser extent, arching also redistributes load longitudinally. A second effect results from the flexural stiffness of the pipeline, which resists bending and tries to bridge the area of thaw settlement, so that instead of being carried by soil underneath, the weight of the pipe and its contents (and some of the overburden) is transmitted longitudinally by shear forces in the pipe to areas d and e. Finally, arching also occurs in the backfill above the pipe, so that its weight is partially redistributed.

FIGURE 8 Pipeline schematic.

All of the above effects serve to reduce soil deflections under the pipe and if ignored, there is a serious risk that an analysis may be excessively conservative.

Behaviour of the Pipeline

It can be seen from Figure 8 that the effect of thawing permafrost under a pipe depends on the horizontal extent of the permafrost feature. This will determine the importance of the arching effects described above and will directly influence the behaviour of the pipeline, since the allowable deflection is clearly a function of the span length over which it is observed.

It is not hard to show that a critical span length (and hence permafrost feature length) exists for any given vertical soil deflection, such that the pipeline curvature is maximised. This geometric consideration offers the potential for a reduction in the amount of analysis required, since only critical spans need be

addressed.

A realistic model for determining allowable pipeline curvatures (and hence settlement) takes as its limiting condition the onset of a condition which threatens environmental damage or the continuing operation of the pipeline, by the initiation of buckling of the pipe wall and the possibility of excessive local strains leading to crack initiation and rupture.

The pipeline is a robust structure and can be bent a long way, far beyond yield, before any damage that significantly affects its operation will occur. A land pipeline is relatively thin; the Alaska pipeline has a diameter/thickness ratio of 96, but even so has been found to withstand very large curvatures before rupturing. A submarine pipeline is comparatively thick; typically the pipelines considered in the thermal analysis have a diameter of 406mm and a wall thickness of 13mm, giving a diameter thickness ratio of 32 and a buckling curvature of 0.082m^{-1} , corresponding to a radius of curvature of 12m. It follows that a realistic assessment of the risk of pipeline damage associated with thaw settlement need not be based on an allowable stress concept, but can allow much larger bending strains based on an allowable percentage of the strain to cause buckling. In this it follows the recent development of code requirements for submarine pipelines.

Statistical Analysis

There are two alternative approaches to the problem of interpreting site information about the horizontal variability of ice content and thaw strain. In one approach, previously described by Palmer (1972), the variability of settlement from point to point is represented by a probability density distribution, and the horizontal variability is represented by an autocorrelation function. The autocorrelation and the distribution are inputs to a statistical simulation of a trench bottom settlement profile, and the response of the pipeline to the simulated profile is determined by structural analysis. The alternative approach is to use statistical methods to estimate an extreme (probable worst case) ice feature, and then to determine the response of the pipe to that feature. For the reasons explained above, the length of the feature is important, and calculation of the extreme feature must take account of pipe response. This method is analogous to the "design wave" approach to hydrodynamic analysis of forces on offshore structures.

It is important to understand that both approaches are statistical, and that the difference between them lies in logical sequence rather than in using statistics in one instance and not in the other.

CONCLUSIONS

- o To predict accurately the effect of bringing a warm pipeline into contact with subsea permafrost, it is essential that good soils data be obtained from the field. Parameters

REFERENCES

- such as soil salinity, moisture content, soil type, initial temperature distribution and occurrence of ice-bonded material will substantially affect the results.
- o In the particular cases analysed, it was apparent that a causeway provides an adequate solution to the problem of thaw settlement.
 - o When seabed trenches were considered, it was clear that the occurrence of warm permafrost features 5-6m from the surface in "deep" water conditions presents a greater potential for thawing than the existence of cold permafrost at the level of the seabed itself in "shallow" water conditions.
 - o From considerations of thaw strain and the influence of soil arching, it is concluded that simplified models that fail to adequately account for these effects may seriously overestimate the magnitude of the thaw settlement.
 - o Compared with most land pipelines, typical submarine pipelines have substantial buckling resistance and can tolerate considerable settlements. Criteria to determine "allowable" settlement should not be limited to elastic behaviour.
 - o A statistical analysis of variability of soil and permafrost conditions along a pipeline route is required to determine an acceptable design.

EROSION IN A PERMAFROST-DOMINATED DELTA

H. Jesse Walker

Louisiana State University, Baton Rouge, Louisiana 70803

Field trips to the Colville River delta have provided the opportunity to repeatedly examine and monitor the types and rates of erosion occurring at a number of locations. Field measurements have been made in several distinct environmental situations, including high banks composed of Gubik materials, peat banks in locations of lake tapping, a pingo and adjacent lake fill, and the head of a mid-channel bar. In all cases permafrost is involved, and in some, ice wedges are important. Rates of retreat are variable. During the past 30 years a number of banks have been eroding at average rates of between 1 and 3 m per year; rates that have a high annual variability. At times of block collapse, retreats of up to 12 m may be almost instantaneous. However, in areas of block collapse the average annual rates of erosion are usually similar to those elsewhere because collapsed blocks serve as buffers to further retreat for 1 to 4 years.

INTRODUCTION

In 1961 a long-term research project on the hydrology, geomorphology, climatology, and near-shore oceanography of the Colville River delta in Arctic Alaska was initiated. Between 1961 and 1982, 10 field seasons made possible the collection of data on the types and rates of erosion at a number of deltaic locations. Several reports have been issued dealing with different aspects of the river channels and banks (Ritchie and Walker 1974, Walker 1969, Walker 1978, Walker 1983, Walker and Arnborg 1963, and Walker and Morgan 1964). None has concentrated on rates of erosion, which is the emphasis of this paper.

THE DELTA: RIVERBANKS AND EROSION FACTORS

The Colville River delta, the largest delta in Arctic Alaska, is situated in the zone of continuous permafrost. Two of its many distributaries, the Main Channel (about 45 km long) and the Nechelic or West Channel (about 40 km long) carry nearly all (90% during breakup and 99% during normal flow) of the water. Their banks are composed of various materials, including gravels, sands, silts, peat, and ice. Genetically and morphologically they are equally as varied. Part of the Nechelic Channel borders the Gubik Formation, which is more than 50,000 years old at this site (Hopkins, personal communication, 1980). The other banks are much younger (probably none more than 4,000 years old) and include such forms as sand dunes, interdune swales, old lake beds, mid-channel and point bars, mud flats, ice wedges, and pingos. A characteristic they all have in common is permafrost.

Field data collected in 1971 show that 59% of the banks are erosional, 35% depositional, and 6% neutral (Ritchie and Walker 1974). Erosion dominates along right banks (72%), whereas deposition is most common along left banks (54%).

The possibility of bank erosion in the Colville River delta is limited to about 4 months per year.

During the other 8 months most riverbanks are protected by ice, snow, and frozen ground. In some situations snow drifts become thick enough to last well into the flood season.

Some of the water in the channels is sufficiently deep, so that it does not freeze to the bottom. Such subaqueous banks, even though permafrost free, are not subjected to erosion during winter because water flow is minimal. In the main channels, river water is replaced by seawater and water temperatures beneath the ice drop below 0°C.

Although wind does have some erosive effect on river bars and banks, most modifications are caused by the mechanical and thermal energy of moving water and the thermal energy from the air and solar radiation. These two processes have been referred to as "thermal abrasion" and "thermal erosion" by Aré (1978).

In the case of the Colville River delta, these processes are usually initiated in May at the time the melt season begins. Snow melting, river-ice breakup, and active layer thaw are all important and once initiated, proceed rapidly. Extreme flooding, which ranges from less than 1 m at the front of the delta to over 5 m at its head, normally lasts from 2 to 3 weeks. During this short period of time much of the annual erosion occurs.

Although the dominant dynamic processes affecting erosion are thermal abrasion and thermal erosion, there are a number of other factors that affect its character and rate. Type, texture, ice content, height, and orientation of the bank; direction, frequency, and intensity of the wind, especially as they affect wave action; and duration of water contact with the riverbank are all important variables.

RIVERBANKS AND EROSIONAL RATES

Six sites representing different bank types, orientations, and rates of erosion have been selected for analysis. These include banks representing (1) the Gubik Formation; (2) thick, dense

peat; (3) an old lake bed and pingo; (4 and 5) tapped lake entrances; and (6) the head of a mid-channel island with dunes/wales (see Figure 1).

FIGURE 1 Map of the Colville River delta showing the location of erosion-monitoring sites.

The Gubik Formation (Site 1)

The Gubik Formation, which borders part of the left bank of Nechelic Channel, is being rapidly eroded at two cutbank locations. At these locations the bank rises some 8 m above normal river stage and is never overtopped by floodwater. The Gubik is composed of gravels; sands; silts; organic matter, including some large forms, such as mammoth tusks and tree trunks; and ice of various types, especially ice wedges.

Floodwater, which begins to flow before river-ice breakup, first melts the snow at and below the water surface and then begins to develop a thermoerosional niche (Walker and Arnborg 1963) that deepens and widens as flooding continues. In the case of the Gubik this niche may be cut into the bank by as much as 10 m, leaving a massive cornice hanging above (Figure 2). In some cases, depending mainly on fluctuations in stage, multiple niches may develop (Figure 3). Overdeepening of these niches leads to block collapse (Figures 4 and 5). Normally such collapse occurs along ice wedges. Thus, individual blocks represent portions, and in some cases nearly all, of particular ice-wedge polygons (Figure 4). If collapse does not occur, sloughing from a rapidly thawing niche roof and oversteepened bank seals off the niche (Figure 2). During summer, thaw and sloughing gradually convert the collapsed blocks into pyramidal piles and reestablish the angle of repose of the riverbank that was destroyed during flooding.

This process establishes a new bank position that will be preserved until the next flood season. The pyramidal piles serve as buffers and help reduce the rate of retreat of the bank behind them. The two types of bank retreat, more rapid block collapse and slower thaw and sloughing, tend to offset each other over a period of years, so that in plan view long-term retreat forms a bank with a relatively smooth arc (Figure 4).

FIGURE 2 Thermoerosional niche, cornice, and sloughing material in the Gubik Formation.

FIGURE 3 Two niches and eroding ice wedge in the Gubik Formation.

From 1949, when the first aerial photographs were made of this part of the delta, to 1982, the maximum retreat along this bank has been about 45 m for an average of nearly 1.4 m per year (Figures 6, 7, and 8). However, during any one year at any particular location, the actual retreat has been as much as 10 m. At the present rate of erosion along the northern half of this bank, the river will shift about one river width in 75 to 100 years

(Figure 8). At such rates the total volume of material eroded from this kilometer-long section is about 20,000 m³ per year.

Thick, Dense Peat (Site 2)

Most of the right bank of the Main Channel and portions of the right bank of the Nechelic Channel are composed of thick layers of dense peat that support extensive ice-wedge polygon systems (see Figures 9 and 10).

Normally, erosion along such banks is slower than along the predominantly mineral banks, such as those in the Gubik Formation. Thermerosional niches do develop in peat banks, although they generally do not develop to a depth that causes block collapse (Figure 10). Exceptions do occur, especially when silt or sand layers lie within or at the base of the peat blocks, as was the case of the example shown in Figure 11.

The rate of erosion of ice wedges, which may occupy as much as 20% of the bank face (Figure 10), is faster than that of the separating peat. Such differential retreat results in a serrated bank, a type that is typical of most peat banks in the delta. Ice gouging and shaving by blocks of ice transported during breakup are sufficiently common along peat banks that these banks normally have a relatively smooth surface.

FIGURE 11 Peat block just before collapse. The niche developed in a basal sand layer.

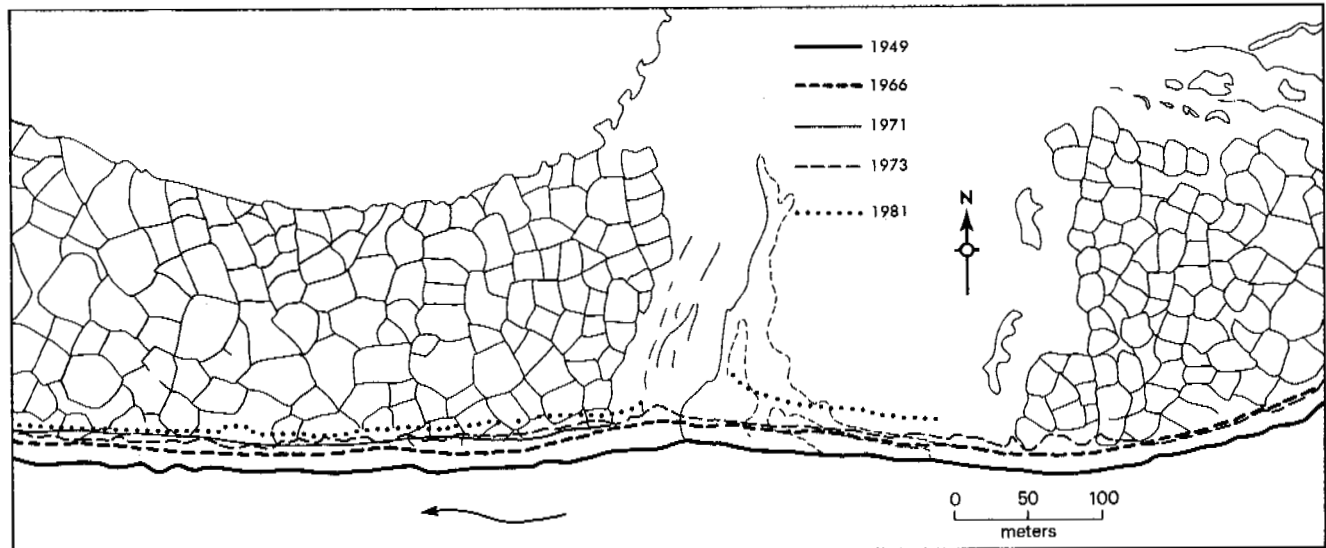

FIGURE 9 Map of site 2 along the right bank of the Upper Nechelic Channel. The serrated edge of an eroding lake shoreline is also depicted.

FIGURE 10 Peat bank typical of site 2. Note ice wedge beneath flag.

Although the niches that develop in this type peat bank are not deep, thawing of their roofs causes widening. The peat shreds and clumps that drop from the roof (Figure 10) are easily removed during high water.

The rate of erosion along the section of site 2 averaged between 0.8 and 0.9 m per year during a 32-year period. This particular bank is subjected to ice jams almost every year and, therefore, probably has a higher average erosion rate than most peat banks in the delta.

Old Lake Bed and Pingo (Site 3)

There are many locations within the delta where the river is now cutting into old lake beds. Most

FIGURE 12 Map of site 3 showing drained lake bed and pingo.

of these banks are composed of fine sands, silts, clays, and organic matter. This material is easily thawed and eroded and in most instances has relatively small ice wedges. The lake bed represented at site 3 is a river meander that was abandoned, converted into a lake, filled with sediment, and eventually tapped (see Figure 12). Since tapping, the river continued to cut into the old lake basin and by 1980 had eroded more than halfway through. Accompanying erosion has been a continuing buildup of the old lake bed because each year's flood brings a new layer of sediment as the bed is overtopped.

The present rate of erosion of this former lake bed is 1.8 m per year; a rate that is uniform along its entire length. At the present rate of erosion the old lake bed will be completely breached by the year 2000.

At the time the long oxbow lake was tapped, a pingo formed near the middle (Figure 12). This pingo has been eroding at a rate slightly less than that of the surrounding lake bed. Sloughing from the pingo face during erosion at water level is sufficient to keep the ice core covered. At the present rate of cutting, the pingo will be destroyed within about 50 years.

Tapped Lake Entrances (Sites 4 and 5)

One of the many results of river migration is the frequent tapping of delta lakes. Within the delta, lakes at various stages of tapping, filling, and destruction are numerous (Walker 1978). Site 4 (Lake Nanuk) and site 5 (unnamed lake) represent two relatively recent examples. Lake Nanuk (Figure 13) was tapped before the first aerial photographs were taken of the Colville delta (1948), whereas the lake at site 5 was tapped in 1971.

The bank on the south side of the Lake Nanuk entrance channel is composed of dense peat, that on the north side, of peat overlying sand. The Nanuk entrance is migrating northward at about 1 m per

year, although in some years the erosion is more (see Figure 14).

FIGURE 13 Entrance to Lake Nanuk.

FIGURE 14 Peat overhang on north side of entrance to Lake Nanuk.

At site 5 there has been little change in the entrance, both sides of which are thick peat, between the time of tapping (1971) and the present. One of the peat blocks that collapsed into the channel at the time of tapping had not been completely destroyed by 1980.

Mid-Channel Island (Site 6)

The last example is the head of a mid-river island located in the Main Channel. The island is composed of sand dunes and interdune swales. These swales are mainly sandy peats in which small ice-wedges have developed (see Figures 15 and 16). This location receives the brunt of the river flow during flood and is impacted heavily by ice during breakup. Although a thermoerosional niche develops, it is modified rapidly by ice shove. The combination of thermal abrasion, thermal erosion, and ice gouging are responsible for an erosion rate of about 2.2 m per year at the head of the island. Rapid retreat of the island is also bringing about a gradual change in shape. Thirty years ago the island was much more pointed than it is today.

FIGURE 15 Map of island at site 7.

SUMMARY

Monitoring bank retreat at a number of cut-bank locations within the Colville River delta has shown that erosion rates vary with bank composition, bank height, and degree of exposure to erosional and transportational processes. Long-term annual average rates range from much less than 1 m in thick, dense peat to over 2 m in highly mineralized banks such as those formed in the Gubik Formation.

Although this paper has concentrated on erosion of deltaic tributary banks, it should be noted that in general the processes discussed are also operative along the margins of other arctic water bodies. For example, high rates of erosion can occur along the shorelines of lakes, lagoons (Lewellen 1970), and the Arctic Ocean (Aré 1978 and McDonald and Lewis 1973).

FIGURE 16 Photograph of erosion at the south end of the island at site 6.

ACKNOWLEDGMENTS

Data used in this report were collected during a number of field seasons made possible by grants and other support from the Office of Naval Research, the Naval Arctic Research Laboratory, the North Slope Borough, and Louisiana State University.

SORTED PATTERNED GROUND IN PONDS AND LAKES
OF THE HIGH VALLEY/TANGLE LAKES REGION, CENTRAL ALASKA

James C. Walters

Department of Earth Science, University of Northern Iowa
Cedar Falls, Iowa 50614 USA

Well-developed sorted patterned ground is widespread on gently sloping shores and bottoms of shallow lakes and temporary ponds in the High Valley/Tangle Lakes region of the Amphitheater Mountains, on the south side of the central Alaska Range. This area is within the zone of discontinuous permafrost and has a mean annual air temperature of -4°C . The numerous lakes and ponds occupy depressions in middle to late Quaternary silty tills which blanket the valleys. Sorted patterned ground forms include stone circles, stone polygons, stone pits, and stone stripes, with circles and polygons being most common. All patterned ground sites, whether presently underwater or subaerially exposed, occur in situations of fluctuating water levels. It is suggested that the features formed by frost sorting, frost heaving, and mass displacement when lake shores and pond bottoms were subaerially exposed during drier periods. Although the patterned ground appears to have developed at some time in the past, many sites show evidence of being at least semi-active today.

INTRODUCTION

Patterned ground features sometimes occur subaqueously (Conrad 1933, Lundqvist 1962, Mackay 1967, Dionne 1974, 1978, Shilts and Dean 1975). These features are commonly assumed to have originated subaerially and to later have been submerged. However, observations by Mackay (1967), Shilts and Dean (1975), and Washburn (1980, p. 125) suggest that in some situations patterned ground may form underwater. Sorted patterned ground is widespread in shallow lakes and ponds of the High Valley/Tangle Lakes region of south-central Alaska. This paper examines the sorted patterned ground features in this area and discusses their possible origin.

Over 300 lakes and ponds containing sorted patterned ground along their gently sloping shores and bottoms were identified by aerial reconnaissance, air photo interpretation, and field observations. The numerous lakes and ponds occupy depressions in the silty till which blankets the area. Underwater patterned ground is found throughout the broad valleys, from the lowest elevations (along the Tangle Lakes) of 870 m up to the highest elevations (in High Valley) of 1,200 m.

DESCRIPTION OF THE STUDY AREA

Glacial Geology

Located on the south side of the central Alaska Range, the High Valley and Tangle Lakes areas exist as broad valleys within the Amphitheater Mountains (Figure 1). These valleys were glaciated four times during the Quaternary (Péwé 1961), the glaciers advancing into the area from the Alaska Range to the north. Péwé (1961) considers the earliest glacial advance to be early to middle Quaternary age. Although till from this advance is

not exposed in the area, the ice must have overridden the 1,800 m peaks of the Amphitheater Mountains as evidenced by isolated erratics found on top of an unnamed peak just to the east of the upper Tangle Lakes in the study area. Péwé (1961) reports erratics up to 4.5 m in diameter on this peak and also Paxson Mountain, approximately 12 km east of the study area.

The second glacial advance is considered middle to late Quaternary age (Péwé 1961). It evidently did not override the Amphitheater Mountains but left a silty till in the valleys and on the lower slopes of the Amphitheater Mountains.

The third and fourth glacial advances took place in late Quaternary time and have been grouped together and named the Denali glaciation by Péwé (1961). These two advances are closely related in extent as well as age. They moved through gaps in the Amphitheater Mountains and were joined by local cirque ice. Deposits of these glaciers, especially the late Denali advance, cover much of the earlier glacial material. The ice of the late Denali advance thinned and stagnated during retreat, leaving ice-contact features such as kames, kettles, eskers, crevasse fillings, and pitted surfaces. The Tangle Lakes area is a region of well-developed ice-stagnation topography.

Climate

The High Valley/Tangle Lakes region is within the zone of discontinuous permafrost and has a mean annual air temperature of approximately -4°C . The area experiences a continental climate, which can be generally characterized as dry with extreme summer and winter temperatures, light precipitation, and light surface winds. Local weather records kept at Paxson (approximately 17 km east of the study area) from 1969 to 1973 give the following information: mean maximum temperature 1.1°C , mean minimum temperature -12.2°C , record high 29.4°C ,

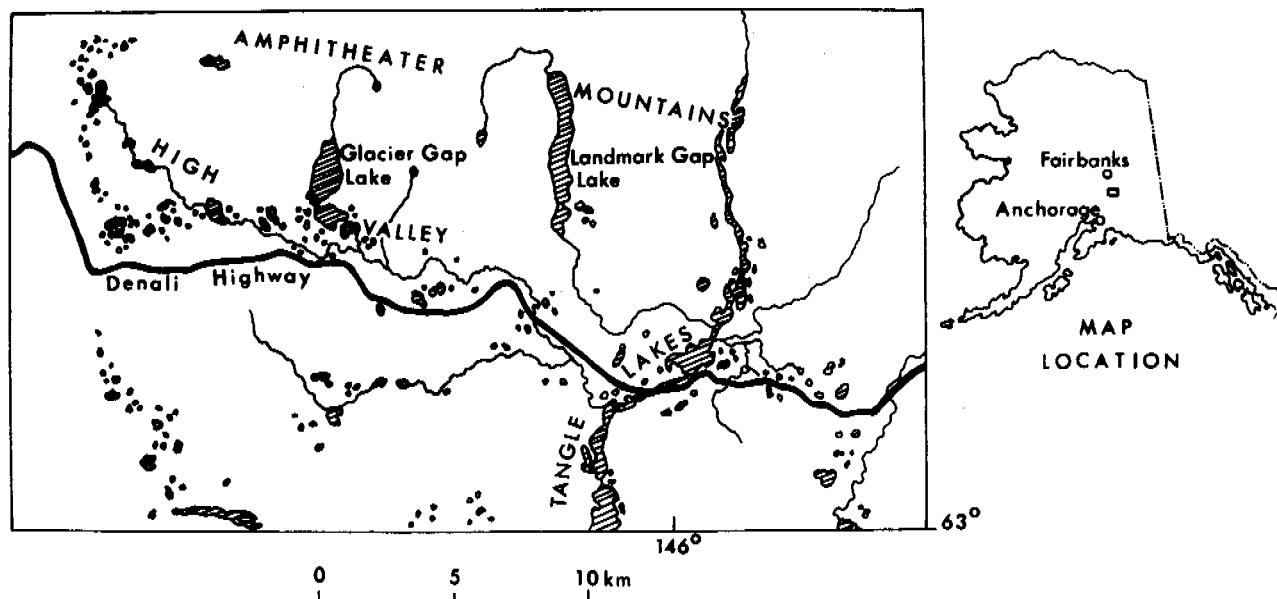

FIGURE 1 Map of the study area.

and record low -50.5°C . Mean annual rainfall during this period of time was 44.2 cm, and mean annual snowfall was 278 cm (Miller et al. 1976).

DESCRIPTION OF THE PATTERNS

Lakes and ponds are widespread in the study area, and sorted patterned ground features are associated with many of them. Most of the shallow ponds display sorted patterns along their entire bottoms, whereas in the larger lakes the patterns are typically restricted to the shallower shelf areas along the lake margins. The ponds and smaller lakes are simply kettles and other depressions in hummocky till; the larger lakes, specifically Glacier Gap Lake and Landmark Gap Lake (see Figure 1), occupy basins cut by ice as glaciers flowed southward out of the Alaska Range.

Sorted patterned ground forms include stone circles, stone polygons, stone pits, and stone stripes (Figure 2). Circles and polygons are the most common forms and vary in diameter from about 0.4 - 2 m. These types of patterns are found on level to very gently sloping ($< 2^{\circ}$) surfaces. Stone pits are less common and occur in similar situations, but stone stripes are found perpendicular to shorelines on slopes of $3 - 10^{\circ}$. No patterns were observed on slopes greater than 10° or in water depths of more than about 2 m. Trenches excavated through sorted circles revealed that stones in the border areas tend to have their long axes vertical, and scattered pebbles and cobbles near the surface in the central areas show the same tendency. The surfaces of the central areas are usually convex, with as much as 20 cm of relief between the center and the tops of stones in a bordering trough.

The fine-grained material associated with the

patterns is predominantly a loam or silt loam. It is characterized by a low liquid limit (20 - 26%) and a very low plasticity index (1 - 5%), conditions common in subaerial nonsorted circles (mudboils) and sorted circles. During the summer, this material is quite fluid and easily flows in response to agitation. This thixotropic effect makes trenching of patterns a very difficult chore, but it also favors the processes of mass displacement, frost sorting, and frost heaving, which can be initiated by slight increases in cryostatic pressure during fall freezeup.

The sorted patterned ground sites can be grouped into three main categories: those which are unvegetated and frequently underwater, those partially vegetated and occasionally inundated, and those almost completely vegetated, with evidence of inundation only rarely. In sites with patterns which are frequently underwater, boulders and cobbles making up the borders of the patterns are covered with greenish-black stain, apparently biochemical in origin. Staining is not present on those stones or portions of stone surfaces which are buried in the adjacent fines (Figure 3). It is also absent on the surfaces of large boulders where they project above water level. Sites which are often subaerially exposed show a less intense staining of stone surfaces, and in addition the stones typically have some lichen growth on them. It is not uncommon to find lichens on rock surfaces now 10 - 25 cm underwater.

All patterns, whether presently underwater or subaerially exposed, occur in situations of fluctuating water levels. Field observations over a 2-year period and examination of air photos from past years show that smaller lakes and ponds in which the patterns exist are occasionally subaerially exposed. In the larger lakes, the patterns are usually restricted to the shallower shelf areas along the lake margins which are sometimes emerged.

Patterned ground is developed in each of the three tills found in the area. As mentioned

FIGURE 2 (a) Aerial photograph of sorted patterned ground in a pond of the Tangle Lakes area. Stone circles, stone polygons, stone pits, and stone stripes are present. An off-road vehicle trail in the upper right corner provides scale. Photo taken July 26, 1982. (b) Aerial photograph of sorted patterned ground in a pond of the High Valley area. A variety of patterns is present, but there is a lack of patterns in the deeper water of the pond center; only some stone pits and individual boulders are found here. The large boulder projecting above the water surface on the right side of the pond is about 1.5 m across. Photo taken July 26, 1982.

earlier, till of the earliest glacial episode (early to middle Quaternary age) is not known in the area, the advance being recognized only by large erratics found on peaks on the Amphitheater Mountains. Although all sorted patterned ground types occur in each of the three tills, they do vary somewhat depending on the material present.

Patterns in Till of Middle to Late Quaternary Age

In most of the study area, deposits of this glacial advance have been covered by drift of later glacial activity. However, much of the High Valley region escaped later glaciation and thus contains a rather extensive area of this earlier till. Underwater sorted patterned ground is not as common in this till as it is in the later tills, and only 32 patterned ground sites were examined. In the shallow lakes and ponds, sorted patterns are

FIGURE 3 A cobble, which had been partially embedded in fines of the central area of a sorted circle, removed to show the extent of staining on its upper surface. Staining is not present where it was embedded in the fine-grained material. The cobble is 15 cm long on its longest axis. Water depth is approximately 25 cm.

found along their entire bottoms, but larger and deeper lakes display patterns only along their shallower shelf areas. The pebbles, cobbles, and boulders making up the borders of the patterns are mostly subangular to subrounded and 10 - 40 cm in diameter. The fine material in the centers of the patterns is basically a silt loam.

It is common to find sorted patterned ground on old emerged lake terraces bordering the present lakes. The terraces are no more than about 0.5 m above the present shorelines and are almost completely vegetated with *Salix* shrubs and grasses, making the patterns difficult to recognize. A trench dug across a vegetated stone circle showed a moderately well-developed soil profile (Table 1, Figure 4). These vegetated patterns on emerged terraces appear to be inactive.

Patterns in Till of Late Quaternary Age (Early Denali Advance)

Till of this glacial advance is found along the borders of the High Valley area and in the center of High Valley where glacier ice flowed through Glacier Gap. Moraines of this advance contain numerous lakes and ponds, and subaqueous patterned ground is associated with many of them. The patterned ground is quite well developed, and 165 sites were examined.

The pebbles, cobbles, and boulders along the borders of the patterns are mostly subangular to subrounded (85 - 90%), with only a few being angular or rounded (10 - 15%). These border stones show quite a range in diameter, but 15 - 40 cm is common (Figure 5). The larger stones typically occur in the middle of the borders with the smaller stones at the margins. Trenches excavated across patterns subaerially exposed on lakeshores and pond bottoms showed no development of soil profiles, but near-vertical mottle streaks are commonly found in the center of the patterns (Figure 6). The texture in the area of the mottles is a loam to a clay loam, just as it is for the surrounding material.

TABLE 1 Soil Profile in the Center of a Sorted Circle on an Emerged Lake Terrace.

Cover: Vegetation in the center of the pattern consists of grasses, forbs, mosses, and lichens with clumps of *Salix* to 0.5 m; some *Ledum decumbens* and *Vaccinium uliginosum* to 15 cm.

Horizon	Depth (cm)	Description
O1	5-3	Undecomposed to partially decomposed organic matter; mainly <i>Sphagnum</i> , grasses, and lichens.
O2	3-0	Dark reddish brown (5 YR 3/2 moist) partially to well decomposed organic matter; some silt; abrupt smooth boundary.
A1	0-2	Very dark grayish brown (10 YR 3/2 moist) silt loam; moderate fine granular structure; friable, slightly sticky, slightly plastic; abundant very fine to medium roots; some pebbles poking up from below; clear wavy boundary.
B2	2-7	Brown (10 YR 4/3 moist) gravelly loam; common distinct dark brown (7.5 YR 4/4 moist) mottles; massive structure; friable, slightly sticky, slightly plastic; common fine to medium roots; gradual boundary.
Cg	7-27	Grayish brown (2.5 Y 5/1 moist) very gravelly loam; some distinct dark brown (7.5 YR 4/3 moist) mottles; massive structure; friable, nonsticky, slightly plastic; encountered water table at 29 cm.

FIGURE 4 Cross-section of a sorted circle on an old emerged lake terrace. See Table 1 for a description of the soil profile. Smaller gravels are not included in the sketch. Drawn from field sketches and photographs.

FIGURE 5 Sorted stone circles on the floor of an emerged pond. The surface of the central area is convex and slopes toward the coarse borders. Note the larger stones in the middle of the bordering troughs and the smaller stones along the margins. Note also that the smaller stones along the inner margins and in the central areas of the patterns show unstained surfaces. These stones appear to have been recently exposed and have not yet developed staining on their surfaces.

FIGURE 6 Cross-section of a sorted circle on the floor of an emerged pond. Sample 1 = dark grayish brown (10 YR 4/2 moist) to brown (10 YR 4/3 moist) gravelly loam; sample 2 = strong brown (7.5 YR 4/5 moist) to yellowish red (5 YR 4/6 moist) loam to clay loam, 1.5 - 2 cm wide mottle streaks; sample 3 = brown (10 YR 4/3 moist) sandy clay loam. Note the vertical orientation of stones in the troughs. Smaller gravels are not included in the sketch. Drawn from field sketches and photographs.

Samples of the fine material just below the coarser material in the troughs is a sandy clay loam. Color of the mottles is strong brown (7.5 YR 4/5 moist) to yellowish red (5 YR 4/6 moist). Color of the surrounding material is dark grayish brown (10 YR 4/2 moist) to dull brown (10 YR 4/3 moist).

Patterns in Till of Late Quaternary Age (Late Denali Advance)

This is the most extensive glacial deposit in the study area. All of the Tangle Lakes area and the Glacier Gap area of High Valley are covered

with till of the late Denali advance. Well-developed patterned ground is abundant, and a total of 125 sites were investigated.

In the Tangle Lakes sites the borders of the patterns contain cobbles and boulders which are subrounded to rounded (80 - 90%), with some subangular (5 - 15%) and some well rounded (5 - 10%). Diameters of the border stones range from 15 to 50 cm, with some up to 1 m (Figure 7). Patterns in the High Valley area display cobbles and boulders along the borders which are mostly subangular to subrounded (80 - 90%), with some angular or rounded (10 - 20%). Diameters typically range from 10 to 35 cm (Figure 8).

FIGURE 7 Sorted stone circles in a pond of the Tangle Lakes area. Note the size and degree of roundness of the boulders making up the pattern borders. The large, partially emerged boulder in the foreground is approximately 1 m long.

FIGURE 8 Sorted stone circles in a small pond of the High Valley area. Note the smaller size and greater angularity of the stones making up the pattern borders in this area as compared to the previous figure. The pole is in 30.5 cm (1 foot) divisions. Water depth is about 10 cm at the pole.

Trenches were dug across some patterns subaerially exposed along lakeshores. They revealed conditions very similar to those shown in trenches excavated across patterns occurring in till of the

early Denali advance. No soil development was apparent, and although small circular mottles occur in some exposures, no mottle streaks were observed. The texture of the fine-grained material in the center of the patterns varies from a clay to a silty clay, and in color it varies from brown (10 YR 4/3 moist), to dark yellowish brown (10 YR 4/4 moist), to weak red (2.5 YR 5/3 moist).

FORMATION OF THE PATTERNS

It is clear that the underwater sorted patterned ground features probably form subaerially rather than subaqueously, as evidenced by the fact that all patterns occur in situations of fluctuating water levels. The features are fundamentally no different from subaerial sorted patterned ground except for their occurring underwater. The silty till in which they are developed has a low liquid limit and a low plasticity index. As stated earlier, these characteristics are important factors in the processes of mass displacement, frost sorting, and frost heaving, processes responsible for the formation of sorted patterned ground (Washburn 1980, p. 166-170). Although these periglacial processes may vary in degree of importance for different types of sorted patterned ground features in the same area or for the same types of features in different areas, freeze-thaw and ice segregation are the underlying causes. Over a period of time, coarser material is forced to the outside of the pattern and the fine-grained material is concentrated in the center. During wet years or wet portions of certain years, the depressions in which the patterns occur are filled with water, but a cover of water is not essential to the formation of the patterned ground.

The High Valley/Tangle Lakes sorted patterned ground has been observed by T. L. Péwé over a period of several years, and he is inclined to suggest that they have not formed underwater (T. L. Péwé, personal communication, 1982). Dionne (1974, 1978) has described very similar features in subarctic Quebec and concludes that they formed subaerially through frost heaving and frost sorting in the recent past. The High Valley/Tangle Lakes patterned ground appears to also have formed at some time in the past, perhaps during the very late Quaternary when glaciers in the Alaska Range and small local glaciers in the Amphitheater Mountains advanced.

Although sorted patterned ground in the study area is probably not forming today, as the presence of inactive, vegetated patterns on emerged lake terraces suggests, there are some indications that many sites are still somewhat active at present. Permafrost studies show that frozen ground is often absent in the well-drained till ridges and hills, but fine-grained sediments in shallow depressions are often frozen below depths of 0.5 - 1 m. The thickness of the frozen layer is unknown, but it is probably on the order of several meters. Active nonsorted circles (mudboils), small sorted circles, and sorted steps commonly exist in low spots, on ridges, and ridge slopes, respectively, in the immediate vicinity of the underwater patterned ground sites. Depth to the frost table in these situations during the month of July 1982 was

measured at 24 - 55 cm. The presence of active periglacial features and a fairly shallow active layer immediately adjacent to ponds and lakes with underwater patterned ground, suggests that frozen ground underlies the shallow water-filled depressions as well. It also suggests that periglacial processes might be presently active on the shores and bottoms of the lakes and ponds when they are subaerially exposed.

Although long-term studies are necessary to determine if the patterns are still active, observations over a 2-year period indicate that some frost action and movement is taking place. Boulders along the margins of patterns are sometimes found which have been split or fractured, apparently by frost action. Cobbles and pebbles with unstained surfaces or portions of their surfaces unstained are often found along the inner margins of the patterns as well as in the central areas along with the fines (Figure 5). These stones have been recently exposed and have not yet developed staining on their surfaces.

CONCLUSIONS

The depressions in which sorted patterned ground occurs in the High Valley/Tangle Lakes region are ideally suited for the development of such features. The silty till, with its low liquid limits and low plasticity indexes, promotes frost sorting, frost heaving, and mass displacement, processes responsible for the formation of sorted patterned ground. It is suggested that the patterns formed through such periglacial processes when lake shores and pond bottoms were subaerially exposed during drier periods. The fact that the patterns are often covered with water is apparently not essential to the origin of the features, except that extra moisture is available in these sites and the periodic cover of water inhibits vegetative growth. The lack of vegetative cover in frequently inundated patterned ground sites causes them to resemble active patterned ground. Most sites are probably inactive, but many areas of patterned ground appear to be experiencing some frost action and movement at present.

ACKNOWLEDGMENTS

I am grateful to T. L. Péwé, J.-C. Dionne R. D. Reger, and Lou Waller for providing helpful information. Personnel at the Geophysical Institute at the University of Alaska in Fairbanks kindly searched their files for pertinent aerial photographs and allowed me the use of their facilities to examine them. I was ably assisted in the field by B. J. Walters and M. J. Kuhlman. This study was partially supported by a University of Northern Iowa Summer Faculty Fellowship.

PERIGLACIAL ACTIVITY ON THE SUBANTARCTIC ISLAND OF SOUTH GEORGIA

D. W. H. Walton and T. D. Heilbronn

British Antarctic Survey, Natural Environment Research Council,
Maddingley Road, Cambridge, United Kingdom, CB3 0ET

ABSTRACT

Very little information is available on periglacial features and activity on the subantarctic islands. From measurements on South Georgia gelifluction is observable to a depth of 12 cm at very active sites but most sites show movement only to 8 cm. For small scale stripes sorting is generally 5-6 cm deep with the majority of sorting activity in autumn. Altitude appears to affect sorting through the incidence of freeze-thaw cycles, with east facing sites showing most activity. Stripe orientation is not related to wind direction. The rate of clast movement downslope was linearly related to clast length and site slope.

INTRODUCTION

Although a recent bibliography on antarctic soils and periglacial features listed 386 references (Walton 1980), relatively few of these relate to periglacial activity. Until recently, on the subantarctic islands only one investigation has been completed on the rates of periglacial processes (Smith 1960). An unpublished survey (Thom 1980) of the variety and extent of patterned ground on South Georgia (latitude 54-55°S, longitude 36-38°W) identified this lack of process data as an important unfilled link in describing the genesis of the periglacial features.

South Georgia (Figure 1) is a heavily glacierized island with a cold, moist subantarctic climate (Smith and Walton 1975). The bedrock is mainly fine-grained tuffs and grey-wackes (Stone 1980) and is highly fissile. Large areas of glacial till of varying ages are exposed in summer (Clapperton 1971). Studies were carried out on the north coast near Cumberland Bay to establish rates of downslope movement in sorted stone stripes with respect to aspect, altitude, slope, and season. A recent paper (Heilbronn and Walton 1983) describes the morphology of these and other periglacial features in detail.

METHODS

A series of sites with small scale stone stripes and a 14° slope, all in the vicinity of Cumberland Bay, were selected to cover a range of altitudes and the four cardinal aspects (Table 1). Twenty cm strings of 1 cm long wooden dowels and 10 cm strings of 2 cm long metal roller bearings were inserted vertically into the soil and excavated after 1 and 2 years to measure downslope movement of a vertical section of the profile. At several other sites of different slopes, regular photographs were taken of 11 fixed 50 x 50 cm quadrats. From these, measurements were made of downslope movement of 8-21 native clasts in each quadrat with a length axis

FIGURE 1 Map showing the position of South Georgia, and the research sites.

TABLE 1 Characteristics of Sites Used for Dowel and Roller Strings

Sites	Aspect	Altitude	Strings
MV	east	75	roller
RR	northwest	83	roller
TR	south	120	roller
DM	southwest	190	roller
ZB	southwest	225	roller
N	north	125	dowel
S	south	120	dowel
E	east	125	dowel
W	west	140	dowel

FIGURE 2 Downslope movement of the soil profile in sorted stripes at four sites of different aspects, using wooden dowel strings, after one (i) and two (ii) years. Site details in Table 1. Figures are mm movement.

from 7 to 85 mm. The data for downslope movement for up to 21 clasts in each fixed quadrat were regressed against clast size, giving a mean movement rate per unit clast length for each site. To investigate the relationship between movement and angle of site, the slope of each regression line (downslope movement factor) was plotted against the slope of each site and a linear regression fitted. These data complemented a long term study over 6 years (1975-1981) of the annual downslope movement of 34 introduced clasts on a 6-10° slope of SW aspect.

RESULTS

Activity with Depth

Downslope movement at all the sites was slow, except close to the surface. All the dowel (Figure 2) and roller strings (Figure 3) showed major movement and, occasionally, complete loss of the top one or two units from the string. Loss was attributed to needle ice formation and the subsequent gravitational displacement downhill when the ice crystals collapsed.

At all sites except ZB (Figure 3), year-by-year movement of the top roller was similar, with the distance in year 2 about twice that in year 1. Movement in the rest of the profile was less predictable over the 2 years with TR showing least movement and DM most. Even after 2 years, there was little evidence of movement below 8 cm at any of the roller sites. Evidence from the dowel sites (Figure 2) supported these observations, although at W site slight movement was detected down to 12 cm after 2 years. The lower part of the second string at E unfortunately entered a soil cavity, and its movements are therefore suspect.

Activity with Aspect and Altitude

Amongst the dowel sites the west facing one showed the deepest movement and the south facing the least overall movement. At the north facing site, slightly more movement was evident after the first year than after 2 years. For most dowel strings, needle ice formation in the first year was sufficient to heave out at least the top dowel.

Assuming that movement of the top dowel and top roller was principally due to needle ice formation, downslope displacement of the top roller bearing showed a positive relationship with altitude (Figure 4) at all except the MV site. Using the standard adiabatic lapse rate (0.6°C/100 m) the temperature gradient between RR and ZB would have been -0.85°C, likely to have caused an increased frequency of needle ice formation which would have enhanced downslope surface movement.

It is considered that the enhanced movement at the highest sites is not an aspect effect since both ZB and DM face southwest and RR faces northwest, a much more favourable aspect in terms of the radiation environment and yet producing only 12% of the movement measured at ZB. The similarity in results between RR and TR (south aspect) also supports the relationship between altitude and movement, rather than aspect and movement for surface material.

FIGURE 3 Downslope movement of the soil profile in sorted stone stripes at five sites of different altitudes, using metal roller bearings, after one (1) and two (2) years. Site details in Table 1. Drawings are half life size.

FIGURE 4 Annual downslope movement of the top roller bearings (0-2 cm) at five sites of different altitudes. Sites as in Table 1.

Activity with Slope

Downslope movement of native clasts was monitored at 11 sites ranging in slope from 1° to 20° . Regression lines for clast length against movement were fitted to each data set and the significance of the fitted lines varied from $p=10\%$ to $p=0.1\%$ at different sites. At all except two sites there was a steady decrease in annual movement with increasing clast size. The slope of these regression lines was taken as an indication of the mean rate of movement per unit clast length for each site and these regression slope values (downslope movement factor) are plotted against site slopes in Figure 5. The correlation coefficient for the regression line in Figure 5 is -0.64 but this includes the data for all 11 sites. If the two sites which did not show a decrease in annual movement with increasing clast size are excluded the correlation coefficient rises to 0.90 .

The fitted linear regression in Figure 5 is thus a simple testable model for a preliminary investigation of the relationship between clast size and slope angle for sorted stripes on South Georgia. To test the model, values for regression slopes were calculated for clasts at three other sites not used in deriving the original relationships. For one site (in Bore Valley), movements during 1975-1976 (A) and 1978-1981 (C) were calculated separately. A second Bore Valley site was calculated for 1980-1981 (D), and a site at Gull Lake (B) for 1975-1976. When plotted in Figure 5, these all fall close to the regression line and within 90% confidence limits, suggesting the model is a reasonable one.

Activity with Time

The data from the longterm study site in Bore Valley (Figure 6) show total cumulative downslope movement for 34 clasts on the 7 m transect over a 6 year period from five unequally spaced field

FIGURE 5 Regression of a mean annual downslope movement factor on slope at eleven sites. Sites A-D were not used in the regression - see text. (Regression $y = -0.025x$, $r = -0.64$, $P = 5\%$).

FIGURE 6 Cumulative downslope movement in sorted stone stripes of 34 introduced clasts over a period of 6 years. (Regression $y = 17.21x - 41.86$, $r = 0.994$).

measurements. Most clasts moved sideways as well as down the slope, and no clear difference in final position occurred between those clasts originally in fines and those in coarse

material. Movement downslope varied from zero to 19 cm within 1 year, and for individual clasts there were considerable between-year variations. After the first year the mean annual rate of clast movement generally fits the regression line quite well. This is interesting, because over this period considerable differences were observed yearly in both snow depth and duration and presumably therefore in the number of freeze-thaw cycles. Detailed examination of the annual rates shows that within the first year, movement (98 cm) was much less than in the immediately following years (264 cm), while for 1980, movement slowed to 135 cm, increasing again in the final year to 210 cm. Records from the meteorological station 2 km away at King Edward Point suggest that snow lie differed between years, with the winter snow in 1976 and 1980 persisting for longer than in the winters of 1977-1979. At this site the mean clast movement per year over 6 years was 58 mm, with a range of annual means from 29 to 78 mm. Measurement made on a steeper (14°) and wetter site in Sphagnum Valley from January 1981 to January 1982 gave an annual mean movement of 177 mm. Although initial movements of tracer clasts are sometimes much higher than those of native clasts (Caine 1981), it seems likely that much of the difference occurred because of a longer period of solifluction in Sphagnum Valley caused by continued drainage into the site throughout much of the summer period.

DISCUSSION

In the only previous paper to examine periglacial activity on South Georgia, Smith (1960) reported on the movement of surface stones and stakes. On a 21° slope, Smith found, in 1956, mean surface downslope movement of 470 mm for twenty 10 cm marked stones. Although this was measured over only 7 months, this corresponds to an annual movement because during the remaining 5 months the ground was frozen and snow covered.

On the steepest site examined in the present study, a 20° slope, and with the largest clasts used (70 mm long), annual movement was only about 60 mm. With the exception of the Sphagnum Valley site, downslope movement of 80 mm clasts did not exceed 105 mm at any site. Recent detailed studies by Caine (1981) of the movement of introduced clasts has shown that an overestimation of up to 300% in the rates of surface movement is possible immediately following the introduction of the tracer clasts. Smith used large clasts, which exacerbate the problem, because they take longer to incorporate into the surface layer, and no settling period was allowed before starting his measurements. Smith's data for surface movement are likely to be considerable overestimates, even if his site was a very wet one. Interestingly, in the first year, movement at the Bore Valley site was lower than in any of the following years, in direct contradiction to Caine's findings.

Smith also assessed a component of mass wasting, gelifluction, by using stakes buried to various depths. He considered that mass flow took place down to 25 cm on a site with a 21° slope. At none of the present sites used to study activity with depth was mass flow observed below 12 cm even after 2 years. Two explanations seem possible here. First, it is possible that Smith's stake site was much wetter than any of those in present use, and this would greatly have assisted mass flow. Second, a comparison of snow duration between his site in 1957 and our sites in 1980-1982 shows that his site did not gain significant snow cover until early July, almost 2 months later than at our sites. His site would therefore almost certainly have been exposed to both lower temperatures and more autumnal freeze-thaw cycles than ours. A comparison of mean monthly temperatures for the 3 years (Table 2) shows that although the mean annual temperature was lowest in 1980, the critical period in April, May, and June was appreciably colder in 1958 than in 1980 and 1981.

Although the dowel string showed deepest activity at the west facing site, the most pronounced surface activity, i.e., that attributable to needle ice, was at the east facing site. This agrees with Mackay and Matthews (1974), who found that differential thaw of needle ice in striped ground was concentrated in the period when the sun was lying in the southeast (equivalent to northeast in the Southern Hemisphere).

This indirect evidence for the effect of insolation in the production of striped ground on South Georgia is in direct contrast to the conclusions reached by Hall (1979) for Marion Island and Iles Kerguelen (Hall, 1983). Hall found that stripes on Marion Island were almost always aligned northwest, parallel with the wind. Although on Kerguelen the relationship was not quite as clear, Hall did find evidence for a correlation between katabatic winds and stripe alignment, and he considered that stripe development was generally most marked on sites exposed to wind. Although he could not provide an explanation for this, he dismissed directional melting by insolation as being of minor significance due to high and persistent cloud cover over the subantarctic islands. Bellair (1969), on the other hand, suggested that freeze-thaw cycles were less significant than wet-dry cycles in producing sorted stone stripes parallel to the major wind direction on Iles Kerguelen and Iles Crozet. On South Georgia there is no evidence for stripe alignment parallel to either the general direction of prevailing winds or local katabatic winds. Insolation is however much higher than on Marion Island and it is possible that wind is only an important formative factor under continuously cloudy conditions.

The constant downslope movement of surface material creates an unstable substrate for plant growth. Heilbronn and Walton (in press) have shown that on South Georgia limited colonization of sorted stone stripes is possible. Although the binding of the roots slows plant movement downslope to less than 50% of that shown by native clasts of the same size, the plants appear to be of little significance in stabilizing the gelifluction activity until their roots reach down to at least 10 cm. In agreement with Washburn (1979), there is no clear evidence on South Georgia that plant-bound gelifluction material is the principal cause of the production of benches and lobes.

CONCLUSIONS

Measurements of downslope movement in small-scale sorted stone stripes on South Georgia suggest that gelifluction is the major process, observable down to 12 cm at very active sites but with most sites only showing movement down to 8 cm. Altitude exerts a significant effect on surface sorting through an increased frequency of needle ice formation, with east facing slopes showing most activity. Sorting in these stripes is generally only 5-6 cm deep. The rate of downslope movement was linearly related to clast length and to the slope of the site. Mean annual movement rate for 34 clasts over 6 years at one site was related to the duration of snow lie. Stripe orientation was not related to wind direction as on other subantarctic islands.

IMPACT OF FREEZE-THAW OF SWAMP ON AGRICULTURAL PRODUCTION
IN THE SANJIANG PLAIN OF CHINA

Wang Chunhe

Changchun Institute of Geography, Academia Sinica
People's Republic of China

The Sanjiang Plain in northeast China is rich in water and soil resources, but as a result of the interaction of several natural factors, about 2 million hectares of cultivated and uncultivated land are subject to the development of swamps, which results from the hydrogeological and thermal properties of soils, the distribution of rainfall, and, especially, the characteristics of the freeze-thaw process. Swamps and frozen soil are interdependent and promote each other. The soils are silty with a permeability ranging from 0.0013 to 0.635 cm/day, so they are poorly drained; the thermal conductivity of humic and peaty layers covering the surface is only 0.0011-0.0023 cal/cm sec deg, and its heat capacity is only 0.4-0.5 cal/cm³ deg. Rainfall is concentrated in the period before the freezing season, so seasonally frozen ground is usually saturated and the thawing process during spring is very slow. Spring meltwater does not drain well vertically because of the poor permeability of the ice-rich unthawed active layer. This reduces the harvest, influences transportation, and damages engineering construction. Through practice, valuable experience has been gained in using bulldozers to promote thawing, drilling through the frozen layers to allow water to drain, and utilizing the freeze-thaw action in drought years to preserve soil moisture.

GEOGRAPHIC CONDITIONS

The Sanjiang alluvial plain, a wide tract of the confluence plain of three rivers, the Heilongjiang, the Songhuajiang and the Wusulijiang in the northeastern part of China, covers an area of over 42,500 square kilometers, rich in fertile soil and water resources, and is one of the important commodity grain bases of China. Because the plain, in tectonics, belonged to the Hejiang interior fault basin, it has experienced differential wide subsidence since the Mesozoic, with low and smooth relief, gradient ratio of 1/10,000 to 3/10,000, and generally 50-60 meters above sea level. The surface layer of the east plain is a 3-17 m layer of clayey soil, while in the west plain the soil is sandy loam and fine sand. Below the surface layer is a unified water-bearing layer with 5-10 m of fine sand and 50-200 m of gravel. Below that are lacustrine mud stone with gravel and sand, continental coal-series stratum, and neutral and acidic volcanic and sedimentary rock of the Mesozoic and the Cenozoic.

The area has a humid climate, with annual mean air temperature of 1.4-3.0°C. The temperature in the coldest months is -18 to -21°C, the extreme lowest temperature is -42°C and the freezing season lasts 7 to 8 months with a freezing depth of 1.5 to 2.5 m. Annual precipitation is 500 to 700 mm, but non-uniformly distributed. It often rains in autumn, and freezing occurs before discharge of flood water. As a result of the effects of these natural factors, swamps develop. There are currently more than 29,000,000 mu of swamp land and swampy wilderness, amounting to 45.74% of the total area of the whole plain.

RELATIONSHIP BETWEEN FREEZE-THAW AND SWAMP

The surface layer of the eastern part of the plain consists mostly of clayey soil, formed by glimmerston, smalite and askanite. The specific gravity is 2.67-2.72, wet unit weight is 1.7-2.6 gm/cm³, and dry unit weight is 1.47-1.72 gm/cm³. Because the soil is fine, the texture is heavy and more than 60% is powdery soil with partical size diameters 0.05-0.005 mm (Figure 1). The coefficient of permeability is generally 0.0013-0.635 cm/day. The thermal conductivity of 10-20 cm of grass root and peat layer on the surface

IMPACT OF FREEZE-THAW ON
AGRICULTURAL PRODUCTION

Spring Waterlogging Caused by Autumn
Flood Water

Precipitation in the area is only 500-700 mm, but it is unseasonably distributed during the year, being highly concentrated in autumn. Rainfall in September and October is generally about 20% of the total annual precipitation; in some years it is 36-40% of the total. There were 14 years of autumn waterlogging among the last 26 years of observation. Autumn flood water freezes on the surface and upper part of the soil layer, which not only interferes with autumn harvest, but also causes spring waterlogging the next year. Over-wet soil and thick snow cause the soil to freeze slowly and form an ice-rich layer, intensifying spring waterlogging. Next spring, the meltwater of ice, snow and the ice-rich layer itself can not permeate through frozen layer, but remain on the surface to cause serious spring waterlogging (Figure 3). Spring sowing is delayed, and crop output is reduced greatly. In the most serious cases, spring sowing can not be done at all. According to the Jiansanjiang State Farm Authority, serious spring waterlogging in 1957, 1960, 1963, 1973 and 1982 was caused by autumn flood water in the previous years. So a bitter lesson was learned, "Autumn flood water cause spring waterlogging and such a spring waterlogging will last two years."

layer is 0.0011-0.0023 cal/cm.sec.deg, 2-4 times smaller than normal soil and rocks. The heat capacity is 0.4-0.5 cal/cm.deg (swamp Dept. 1981) Because of dense swamp vegetation, thick snow accumulation, stagnant water in the swamp, and a great quantity of latent heat released while freezing, freezing rate is slower than farmland, soil and rocks, and freezing surface is rather stable. While freezing, influenced by temperature gradient and by the comprehensive action of various stresses such as adsorption capacity of ice crystals, differences of films, chemically potential differences, capillary force etc, water migrates to form ice-rich layer; the water content of soil increases by 10-19% over its value before freezing as water moves towards freezing front (Figure 2). This redistribution and enrichment of soil water contributes to the development of swamp.

Since the porosity of the grass roots and peat layer is 72-93%, being just like a sponge, the water retention is high, generally 149-552%, and saturation water retention is up to 830-1030% (Swamp Dept, 1976), 10-20 times higher than mineral soil and bedrock. The water capacity of saturated frozen grass roots and peat layer is very high. While thawing, much heat is consumed to slow thawing rate. Thawing depth in swamp land is 0.5-1.0 m less than on farmland. Generally the date of complete thawing of the frozen active layer is 30-50 days later than dry farmland, this is favourable, of course, to the preservation of frozen soil. Because of sunshade, reflection and transpiration of thick swamp vegetation in summer, and the consumption of heat in evaporating stagnant water, the ground temperature in swamp is 6-8°C lower than meadow and 8-13°C lower than bare farmland. Daily variation of temperature is small, vertical gradient is great, the frozen soil is protected. Since a large amount of heat energy is received and consumed in ground ice melting, the frozen active layer can not be thawed quickly. Precipitation and meltwater of ice and snow do not penetrate well through such a frozen layer, but remain on the surface and in the upper layers of soil, and freeze in the autumn. As a result, excessively wet swamp forms. These distinctive thermodynamic and hydrogeologic properties of swamp slow thawing rate, protect the frozen layer in the soil, and promote the genesis and development of swamp.

Figure 2. Curves of water contents before freezing and after thawing.

Figure 3. Water regime in soil of swampy wilderness. (Based on data of Test Station for Draining Waterlogging of Survey Designing Institute of Northeast General Agricultural Reclamation Bureau.)

Snow Calamity

The snowfall of the plain is generally 40-70 mm. There are 120-140 days annually with snow on the ground. Maximum observed snow thickness was 40-68 cm, and on some roads between forests the snow was more than one meter thick. On the roadsides near forests, wind blew snow to form snow drifts. This resulted in snow blocking roads and difficult transportation in winter. Snow meltwater in Tongjiang-Fuyuan district is 15-20% of runoff (The Office of Leading Group 1976). In some places snow meltwater caused over-wet soil to intensify spring waterlogging and influence spring sowing. In certain years the first snow covered crops. For example, it snowed 40 mm on October 11, 1972, covering a considerable amount of cut-down soybean, which was harvested with difficulty.

Freeze Hazards

Freeze-thaw greatly damaged buildings and other structures. When the ground around poles become over-wet and the post holes fill with water, poles have been frozen out of ground in winter, and also have subsided and tilted in spring; some have even fallen or been uprooted. Saturated soft muck and silt in swamp deposits swell on freezing, and subside or buckle on thawing. This has caused crevices in walls of houses, doors and windows which are twisted askew, gables inclined outwards and sunk inwards, heaved or sunken terraces, and even the collapse of some houses. Because of unreasonable expansion while freezing and subsidence while thawing, culvert pipes were apt to come apart. Freeze-thaw can also deform bridges, cause canal percolation, and seriously distort roads and railways, blocking traffic.

PREVENTION, CONTROL AND UTILIZATION OF FREEZE-THAW

In developing and controlling swamps, people have gained much useful experience and learned costly lessons on utilizing freeze-thaw, and preventing freeze and snow calamities.

Use of Machines on Frozen Soil of Swamp

In digging 113 km of main channel of the Bie-lahong River and constructing 226 km of railway from Fulitun to Qianjin, good methods have been developed for working on frozen swamp land soil by machine.

Shovelling thawed layers properly. From the second ten days of March, some dozens of bulldozers began to remove snow to contribute to the thawing of the surface sod. At that time the highest ground temperature was 7.9 °C, and the lowest was -21.6 °C (Survey Designing Institute 1980). The surface was thawed in daytime, but frozen at night. Bulldozers can push aside the

layer being thawed. After removing all thawed mud and sod, one can construct on hard soil below 1.0 m.

Sawing ice into small pieces and taking them away by machines. When the frozen layer was less than 50 cm thick, the frozen soil can be cut into 2.0 × 1.2 m or 1.0 × 1.0 m pieces, and these frozen soil clods can be taken away, then construction work can proceed on dry soil directly.

Using ice as a wall to intercept flow. If a construction site is needed, the frozen layer around it can be uncovered and a ditch 30-50 cm wide can be dug. If the ditch is filled with ice, the ice can be used as a wall to intercept flow onto the site.

There are also some additional methods: for example, using a dam to divert meltwater, followed by the removal of ice away after freezing.

Drilling Through Frozen Layers to Allow Drainage

If spring meltwater of ice and snow and precipitation can not infiltrate through frozen layers nor drain away because of low and flat relief, this will cause spring waterlogging which seriously delays spring sowing. In the west part of the plain, there is 0.5-3.0 m of underground water section in water-bearing strata. One can blast or drill through the frozen layer in low catchment areas to make meltwater flow into the underground water-bearing strata. This removes the standing water, ensuring timely spring sowing.

Thinning Surface Snow to promote thawing

Snow cover in the area always thaws slowly. Meltwater often caused stagnant water locally, hampering spring sowing and transportation. These problems can be overcome by using different machines in the spring to spread and thin snow on the surface, or by rolling and mixing snow and soil. Because dirty snow can absorb more heat than white snow, the thawing rate is speeded and spring sowing can be carried out properly to ensure a bumper harvest.

Predicting Spring Drought

Weather forecasts and agricultural production records have been used to predict spring drought the following year. When drought is anticipated, the following procedure can be used. After harvest in autumn, soybean stubble is not harrowed and fields are not plowed. This enhances the capture of wind-blown snow in the fields. The freezing rate of the soil is thus slowed to promote water migration while freezing, causing an ice-rich layer to form. Next year, leveling the field and spring sowing properly, using water from the thawing of the ice-rich layer, and packing the ground firmly to preserve soil moisture will reduce the effect of drought and permit a good harvest.

PROPERTIES OF FROZEN AND THAWED SOIL AND EARTH DAM CONSTRUCTION IN WINTER

Wang Liang, Xu Bomeng, and Wu Zhijin

Water Power Research Institute, Northeast Design Institute
 Ministry of Water Resources and Electric Power
 People's Republic of China

To solve problems of winter construction of earth dams, we conducted an experimental study on paving sloping clay core, making frozen clay blanket, and laying sloping weathered sand core for cofferdam in winter, and made an extensive investigation on the construction of medium and small-sized earth dams. We found that the pace of winter construction can be speeded up while still maintaining quality on the basis of the following characteristics of frozen and thawed soil: (1) The compactibility of filled soil under negative temperature can be as good as that under positive temperature when soil is in the supercooled state. (2) The permeability of thawed soil is higher than that of unfrozen soil, the consolidation process is faster, and there are no significant differences between the quick shear strengths of the two soils. Therefore, the mechanical properties of the clay soil with water content close to the plastic limit shows no significant change after compacting and freezing. (3) When it is submerged in water, frozen clayey soil thaws and crumbles quickly on its surface, filling in voids between frozen masses and increasing its density. It can be used for construction. (4) Roughening has no notable influence on the compressibility and permeability of the binding layers and on their shearing strength; it can be omitted for binding layers.

The filling construction of earth dams is made difficult by the freezing of soil, especially when the compactibility of filled soil in winter and the impairment to engineering due to the change in the properties of soil during freezing and thawing are not exactly known. Filling construction in winter with clayey soil is generally suspended prolonging the period of construction, increasing costs, and subsequently delaying the efficient use of the engineering works.

Considering the requirements of practical engineering construction, we first carried out the experimental study on paving sloping clay core in winter, making frozen clay blanket, laying sloping weathered sand core for cofferdam in winter, etc. At the same time, we also made an extensive investigation on the construction of medium and small-size earth dams in winter. This paper introduces some results in experiments on the freezing and thawing properties of soil and their application to the construction of earth dams in winter.

COMPACTIBILITY OF SOIL IN
 LOW TEMPERATURE

For the cementation power of ice, frozen soil has high ability to counter outside load. Therefore, in winter construction, filling entirely with frozen soil is unadvisable. But if the frozen soil mass is surrounded by warm soil, the compactibility will not be greatly affected. Besides, the warm soil will melt part of the frozen soil and alleviate the bad effect of frozen soil. So a definite amount of frozen soil might be mixed in filling, and generally not exceeding 30% is recognized as suitable. But the allowable content of frozen soil is related to the properties of soil, its moisture content, the ambient temperature, the method of rolling and the process

of construction, etc. Figure 1 shows a curve of compressive properties of soil (Table 1) at Bai-shan cofferdam.

It indicates that a higher frozen soil content (over 30%) is allowable.

In the process of winter construction, the freezing of filled soil is relevant to the duration of construction, the thickness of filled soil, the super cooling of soil, etc. As shown in Figure 2, the temperature variation after soil filling indicates that when air temperature is -11°C the temperature of clayey soil (moisture content being 17%, equivalent to plastic limit) at a depth of 5 cm under the effect of heat preservation of the soil layer merely drops to 0°C after 4 hours.

It is known that soils of different types with different moisture contents have different freezing temperatures. In general, the stable freezing temperature of clayey soil is lower than 0°C. Moreover because of the supercooling nature of soil, before ice crystals are formed, the soil temperature will be even lower than its stable freezing temperature, and lasts a certain period of time. The super cooling soil still has a higher compressibility than warm soil. For example, the clayey soil at Qinghe reservoir (see Table 1 for its physical properties), when its moisture content is 21.5%, has a super cooling temperature at -2°C to -3°C under an ambient temperature of -5°C to -6°C, and the duration of super cooling comes up to several tens of minutes (Figure 3).

Though the time is quite short, yet in the fight for compactibility of soil, it is still very profitable and preferable. From the above experiment it is sufficient to understand that, in winter construction, as suitable heat preservation measures for the clayey soil of the earth embankment are taken, and proper arrangement for construction procedure to shorten the time for loading, transporting, laying and compressing soil is affected, sufficient utilization of the same quality of compactibility of filling soil as that in the construction under ordinary temperature could be attained.

FIGURE 3 Freezing process of Qinghe soil sample

PERMEABILITY AND MECHANICAL PROPERTIES OF FREEZING-THAWING SOIL

In the process of freezing and thawing, soil undergoes a series of complicated changes. Under the action of negative temperature, the clayey soil mass with certain moisture content is expected to have moisture migration and phase equilibrium changes within it. Simultaneously, for the heterogeneity of temperature, freezing form and structure in it, the soil will form ice laminated layers in horizontal, vertical and inclining direction with different thickness making the soil structure layered and net-veined. The formation of ice laminated layers divides the

soil mass into many small collective bodies, increases the volume of soil and diminishes its density, on the one hand, and the moisture content of these collective bodies decreases and the density increases on the other hand. The new structure of soil divided and cemented by many ice laminated layers brings about very complicated changes in the nature of soil after its thawing. Moreover, such changes vary with the state and process of the soil after thawing.

Permeability of Freezing-Thawing Soil

Clayey soil with different freezing structures at the beginning stage of thawing can have its moisture quickly drained through the crevices between the mineral collective bodies, therefore its permeability is higher than that of unfrozen soil. In Table 2, from a group of experimental results at Qinghe reservoir, we can see that when the soil begins to thaw, its permeability coefficient is about 50 times that of the unfrozen soil in average.

TABLE 2 Permeability coefficient of freezing-thawing and non-frozen soil

Condition of sample	Non-frozen soil			Freezing and thawing soil		
W%				17.9	21.0	21.0
ρ_d g/cm ³	1.68	1.69	1.69	1.69	1.69	1.69
K cm/sec	7.56 $\times 10^{-9}$	3.07 $\times 10^{-9}$	1.57 $\times 10^{-8}$	1.42 $\times 10^{-7}$	7.53 $\times 10^{-7}$	3.16 $\times 10^{-7}$

Along with the increase in moisture content, the ice laminated layers or crevices will also increase and thicken, thus greatly raising the permeability coefficient of the freezing and thawing soil. For example, under the same dry density, while the moisture content increases from 18% to 21%, the permeability coefficient increases about 2 to 5 times.

After thawing of the soil, under the action of load, the crevices formed by the ice-laminated layers gradually close up and the filled soil will be gradually drained and consolidated, while the collective bodies take in moisture and swell. Eventually, the structure of soil gradually becomes homogeneous, the permeability coefficient of soil diminishes, and the ability of seepage prevention of the soil is improved. The result of experiment with frozen soil of Qinghe earth dam shows that at a dry density of 1.68g/cm³, the permeability coefficient is 1.64 $\times 10^{-7}$ cm/sec., while under a pressure of 0.5-1.0kg/cm², the permeability coefficient reduces to 3.9 $\times 10^{-8}$ cm/sec.

Compressibility of Freezing-Thawing Soil

When frozen soil thaws, though the mineral collective body encircled by ice laminated layers takes in water and swells, this process is comparatively slow, while the ice laminated layer between the collective bodies will first melt up and the melted water will drain quickly, making the collective bodies get closer together and the soil mass more compact. Of the two processes the latter is dominant. Moreover, such compacting of soil can be effected under the action of its own weight. Thus, freezing and thawing soil has a quicker process of consolidation and a greater compactibility. Figure 4 shows a group of results of compressive tests on Qinghe clay soil.

FIGURE 4 Compressibility of freezing and thawing soil and non-frozen soil

From curve(a) in the figure we can see that when moisture content is 24% and the load is 0 - 1kg/cm² its compression coefficient is two times that of unfrozen soil. This indicates that soil with a higher moisture content after freezing - thawing may give excessive great settlement, bringing detrimental effects to engineering works. When the moisture content in soil corresponds to plastic limit, its compressibility after freezing and thawing has nearly no difference as compared with that of unfrozen soil (Figure 4 b). This is because the soil under this moisture content in the process of freezing has no prominent phenomenon of moisture migration and ice segregation, its volume undergoes no frost heaving, its freezing structure is in a perfect entity, and after thawing its property has only a very small change compared with the original unfrozen soil.

Shear Strength of Freezing and Thawing Soil

The drainage condition of soil is an important factor in the shear strength of freezing-thawing soil. Though the initial moisture content of soil is relatively high, under certain load and drainage conditions the freezing-thawing soil has a greater compressibility, thus increasing its dry density, sometimes even to such an extent that it would be higher than that before freezing and consequently enlarging its shearing strength. As shown in the curve of Figure 5, at a moisture content of 24%, the consolidated quick shearing strength of freezing and thawing soil is even higher than that of unfrozen.

FIGURE 5 Consolidated quick shear strength of freezing-thawing soil and non-frozen soil (consolidate 3 hr.)

Under certain conditions, this property of improving strength at the later stage of filling could be properly utilized in practical engineering.

However, if drainage is poor and the water in soil could not be drained quickly, then under the action of load there would be greater pore water pressure, which greatly lowers the shearing

strength in freezing and thawing soil. Many reports at home and abroad expound that the quick shearing strength of freezing and thawing soil is lower than that of unfrozen, about half of the unfrozen soil. At the initial stage of thawing, these loose collective bodies always peel off on the slope surface layer by layer with the melted water flowing. When there is a water flow passing freezing and thawing erosion follows. Sometimes, though there is no peeling off on the surface, with the deepening of melted layer, the soil at the upper layer may gradually consolidate due to better drainage condition and the permeability coefficient also lessens, making water in the just thawing layer difficult to drain and causing prominent lowering of strength on the thawing surface. As a result, the slope becomes unstable, and with the deepening of thawing layer, the range of sliding slope also enlarges. In north China regions, the destruction of side slope from above mentioned reason could often be seen. Therefore, to the side slope with exit of ground water or relative high moisture content, appropriate measures must be taken to prevent such slope slipping, which often happens in the time of thawing.

From Figure 5b it could be seen that, when the moisture content in soil approaches plastic limit, the consolidated quick shearing strength of the freezing and thawing soil, just as in the case of its compressibility, is not different from that of unfrozen soil.

From above mentioned properties of freezing and thawing soil, we can see that when the moisture content of soil is at plastic limit, no prominent change will occur in the structure and other properties in the freezing and thawing soil.

Using unfrozen soil with a plastic limit moisture content in quick construction at negative temperature one can get the same good quality of compactness as at positive temperature and the quality of the filled soil will not be affected by freezing and thawing action.

THE COMPACTIBILITY OF LAYERED FROZEN SOIL MASSES AFTER SUBMERGED IN WATER AND THAWING.

Crumbling Nature of Frozen Soil Mass in Water

Tests on the crumbling of frozen soil in water show that frozen clayey soil with a definite moisture content, when submerged in water, thaws and crumbles with a much higher speed and a much larger amount than that of warm soil. Figure 6 is the results of crumbling tests of a group of clayey soil (CI), the curves in which show that generally the amount of crumbling of frozen soil is over 80%, while that of warm soil not over 40%; and that for frozen soil put into water after thawing, its amount of crumbling between those of frozen soil and warm soil. With the lengthening of the time of thawing, the degree of cementation among those collective bodies increases, its amount of crumbling in water will go down close to that of warm soil.

This favourable property of crumbling of frozen soil comes mainly from the following fact; when the frozen soil cut into many small collective bodies by the ice laminated layers is sub-

merged in warm water, the ice laminated layers quickly thaw and the collective bodies subject to peeling off layer by layer in small pieces. The higher the water temperature, the greater the speed of crumbling. Moreover, the crumbled soil bodies of the frozen clayey soil is different from that of the warm soil, for the migration of moisture during freezing, the moisture content decreases and its density increases in the collective bodies. (Table 3)

It is clear from above, freezing improves the crumbling property of clayey soil, making the method of pouring the earth into water adaptable for construction.

TABLE 3 Properties of soil mass collapsed in water

FIGURE 6 Relation of collapse percentage of soil in water and time

Thaw-Subsidence and Consolidation Process of Layered Frozen Soil Masses

After the submergence of layered frozen soil masses in water, first, quick thawing happens on the surface of the frozen masses and at the points of contact, and the collective layers of the soil crumbled down and peeled off fill up the pores and crevices. At the same time relative displacement and squeezing among the frozen masses occurs. These make the big pores and crevices as the layered frozen soil masses (about 30%) shrink. The process of thawing and peeling off develops continuously until the shrinking pores and crevices among the frozen masses are entirely filled up. The soil bodies filled in the pores and crevices under the action of overlying load quickly increase their density, however still smaller than the natural density. Then, the frozen soil masses continuously thaw, but the collective bodies already stop crumbling, melt water quickly drains, making the collective bodies get even closer together. The density of this part of soil

will be greater than the natural density. Since those capable to keep equal to or larger than the natural density often occupy an important part, the average density of the layered frozen soil masses after settlement and compacting approaches the natural density. With the increase of the size of the frozen soil masses and the improvement of grading distribution, their density will still increase. The above process could be finished in a quite short time and was proved by a large amount of experimental results both in laboratory and on field. Figure 7 shows an experiment of settlement and compacting of stacked-up body of frozen soil in thawing with a thickness of 1.28m.

FIGURE 7 Thawing process of piling frozen soil mass during submersion in water

The testing sample is taken from the Longfengshan reservoir (Table 1), the moisture content of the frozen mass is 24%, porosity of large pores is 28.3%, the water temperature for testing is $3-7^{\circ}\text{C}$, the initial density after stacking up is 1.24 g/cm³, settlement and compacting is fundamentally finished in 5-6 days, and the density attained is 1.55 g/cm³. Later, under its own weight and the pressure of permeability, it continues the process of settlement and compacting on one hand, and the collective bodies with lower water content take in water from the crevices and swell on the other. At this time, the increase in density of the filling body is not great, but the structure tends to be more homogeneous. The permeability of water changes from passage along the concentrated crevices to passage through the homogeneous pores. The figure shows that on the tenth day the permeability coefficient is 1×10^{-4} cm/sec, while after 100 days it reduces to 1.1×10^{-5} cm/sec. During this period, the density of soil has little change.

If frozen soil mass is submerged in water after its thawing, then the mass body is dispersed into a loosely stacked collective body which will take in water and lower its density, thus making the settlement compacting body have a smaller density and larger permeability.

The above mentioned property of frozen soil makes it possible to use the soil of higher viscosity in the construction of horizontal seepage prevention blanket by the method of dumping earth into water or submergence in water.

CONSTRUCTION OF ROLLED EARTH DAM IN
WINTER

With the knowledge of above mentioned freezing and thawing properties of frozen soil, if proper measures are taken, the successful construction of earth dam in winter is perfectly possible. For large size construction since the considerably strict requirements of engineering quality, essentially warm soil should be used for construction, the moisture content of soil materials should near the plastic limit so as to keep the soil temperature as high as possible, successive working procedures should be connected to each other as close as possible, the methods of high-speed construction are to be adopted, the super cooling temperature of the soil should be sufficiently utilized, and the soil compacting should be performed before it freezes. Thus the similar effect of compactibility under positive temperature is also obtainable under negative temperature.

At the earth dam of Qinghe reservoir, Liaoning Province, which is 39.4 m high with sand gravel shell, a clayey sloping core was built. The main soil material used is medium plastic clayey soil (C I). It was at the beginning of the winter season, the air temperature was not below -10°C , and the method of high-speed construction was adopted. With sheep-foot roller, it could be compressed to the designed density (1.66 g/cm^3). If the temperature is still lower, the guaranteed rate of compactibility would be lowered, so a simple warm shed house provision was used. A warm shed is wind-proof and can increase soil temperature, but it is difficult to raise the temperature. When the outside temperature is -20°C , the temperature on the soil surface in the warm shed is -12°C . If unfrozen soil (a little freezing in the process of transportation and compressing) is used in construction, the quality requirements can generally be satisfied.

In order to solve the problem of construction under low temperature in open air, tests with heavy tamping plate (2.2 ton) have been carried out. It is a round iron tamper with 7 sheep-feet. In experiments, the height of drop is 2.5-3.0 m, and different beating conditions are applied. The result of tests shows that with a filling thickness of 70-80 cm, tamping 5-8 strokes, air temperature at -12°C , the temperature of soil higher -2.5°C and frozen soil mass content at 20%, the density of minimum compactness of all satisfies the requirements of engineering design. Even at air temperature -28.4°C , with some freezing in the surface layer, the compactness of designed density is also reached. But if after filling, tamping to required compactness has not been executed in time, soil materials are frozen or frozen masses are concentrated in the bottom part, the filling soil could not be tamped to required compactness even when the thickness of filling is reduced to 50 cm and the tamping strokes increased to 24 times.

Generally if rolling is applied in construction, before filling, the compressed layer should be roughened first to facilitate the binding between the two layers. But roughening in winter construction is not only difficult but also takes time, thus further lowers the soil temperature

and is not favourable for filling. Large amount of experimental study show whether roughening or not has no notable influence both on the compressibility and permeability of the binding layers, and on their shearing strength. The only effect is the increase of shearing deformation at maximum shearing strength, which would not give damage to the construction. Therefore, the process of roughening for the binding layer could be omitted, so that the labour for roughening could be saved, the construction be speeded up, and the quality of winter filling be improved. In the construction of earth dams at Qinghe, etc. In ordinary seasons, this process of roughening had been cancelled, and in the period of their long-term running, no question has revealed.

In the construction of cofferdam at the Baishan water-power station, the height of the dam being 25 m, the weathered sand was used to make seepage prevention body. Before winter, the method of filling soil into water was applied, utilizing the property of soil material in water, i.e. its quick dispersing, settling and compacting, the dry density reached 1.6 g/cm^3 and permeability coefficient $K = A \times 10^{-4} \sim 10^{-5}\text{ cm/sec}$. While in winter, for the construction of the part above water, the content of frozen soil before rolling and compressing was controlled lower than 50%, compressed density is 1.7 g/cm^3 at this moment, $K = A \times 10^{-4} \sim 10^{-5}\text{ cm/sec}$. During the construction of the cofferdam, heavy truck (total weight about 40 ton) used in transporting soil did the work of rolling and compressing and the construction advanced successfully. But due to the very low temperature in winter construction, it was difficult for some very particular part in the filling to perfectly meet the requirement. So attention was paid to the quality of the filter. In the course of running, though particular part of filling showed insufficiency in compactness and presented the phenomenon of concentrated seepage flow, yet the soil particles dispersed while getting in touch with water had not been carried away by seeping water flow, and were still settled and compressed gradually, exhibiting the ability to resist permeation. In the course of operation for several years, the cofferdam is in perfect condition.

To the small size earth dam generally below 10 m high, if the construction is to be made in the open air, usually a mixture of frozen soil and warm soil is used in the building of dam body and a certain process of compressing and compacting is to be done. So far as there is no perforating through hole in the dam body giving place to concentrated seepage, generally speaking safe running is ensured. But the moisture content in the soil material should not be too high, otherwise, in the process of thawing, slope slipping may occur at some part of the dam body.

In winter construction, it is perfectly possible to excavate unfrozen soil from some comparatively deep layer for concentrated usage as a part of soil material in building the dam body so that the dam may have better ability to resist seepage and the safety of the dam be warranted. In the course of impoundment, some part of the foreslope of the dam with poor compactness of filling may also get settling and compacting in the

submerging water and gradually exert its ability to prevent seepage. But for its low strength, the slope on the upper reaches side should be made gentler.

CONSTRUCTION OF FROZEN SOIL BLANKET IN WINTER

Based on the characteristic of settling and compacting of layered frozen soil masses in water while thawing, successful experience had been obtained first in utilizing frozen soil for construction of blanket at Longfengshan reservoir in Heilongjiang. The height of the dam is 27 m, its length 716 m, the length of the blanket is 70 - 90 m, the dam foundation is a Quaternary alluvial sand gravel layer, and its thickness is 10 - 27m.

The frozen soil masses used in building blanket were taken from the field of explosion, with various sizes, generally 30 - 50 cm, larger ones reaching 70 cm. In the course of construction, frozen masses were directly thrown into water, and in certain sections the frozen soil masses were first stacked up and then water was filled, and frozen soil masses underwent thawing, settling and compressing. The dry density of frozen soil was about 1.55 g/cm³, and for the blanket after thawing, settling and compressing, even if the samples taken between the frozen masses had their dry density (except in the 50 cm surface layer) reaching over 1.50 g/cm³, and their permeability coefficient reaching $AX10^{-5}$ - $AX10^{-6}$ cm/sec, having certain ability to prevent seepage. Further higher density in the blanket could be obtained by using frozen soil of better grading so as to reduce the amount of large size pores in the stacked up body.

If the method of construction by first stacking up the frozen soil masses and then filling water to melt them is used, the filling of water should be done as soon as possible so as to make the frozen soil masses thaw and settle in water (not to let the frozen soil masses melt before the water is filled). While filling water, its level should be kept under the surface of the stacked up body at a certain height so that the stack can sufficient exert the action of its own weight in the thawing, settling and compressing of frozen soil.

Besides, the characteristic of easy collapsing of frozen soil in water is also used in some reservoirs, to construct the blanket by breaking ice on the surface of the reservoir and pouring frozen soil into the water.

In the construction of blanket from frozen soil, the construction procedure is simple, the operation is easy, a good way to overcome the difficulties in attaining required compactness in filling in winter. It is significant in early exhibition of engineering effectiveness, and lowering the engineering cost. The frozen soil blanket at the Longfengshan reservoir had been built more than 20 years ago, and is running normally. This method is also applied in the construction of other reservoirs, such as East Is Red in Heilongjiang, Yinhe, etc. and good effects are obtained, indicating that using frozen soil in the construction of blanket is a successful method.

CONCLUSION

1. Under the action of negative temperature the water migration will occur in clayey soil with a certain moisture content and the soil will form ice-laminated layers, dividing the soil mass into many small collective bodies. The collective bodies have lower moisture content and higher density than the original soil mass before freezing. When thawing the moisture can be quickly drained through the crevices between the mineral collective bodies, therefore compared with the unfrozen soil, the frozen soil has higher permeability, greater consolidation coefficient and settlement, lower quick-shear strength and higher consolidation quick-shear strength, better crumbling property in water.

2. High-speed filling construction of the clayey soil with moisture content close to plastic limit makes it possible to utilize upper-cooling temperature of the soil. In this way the same compacted quality would be obtained as at positive temperature. The mechanical properties of the soil could remain unvaried in the main before freezing and after thawing and engineering works will not be impaired.

3. The blanket constructed by dumping frozen soil masses or submergence of the layered frozen soil masses in water would have a density close to the natural soil and certain impermeability. These methods can also be used to strengthen blankets.

4. The seepage prevention body of cofferdam made by using weathered sand with loam with certain content of frozen soils in winter can meet the requirements of engineering when the heavy trucks are used for rolling and compressing. But it is necessary to pay attention to the quality of the filter back the seepage prevention body to prevent from failure at particular part by seeping water flow.

In conclusion provided the characteristics of frozen soil and the freezing and thawing soil are correctly used and proper measures are taken for different engineering conditions, filling construction with clayey soil in winter can guarantee the quality of engineering works. The long-term operation of the engineering works indicates that filling construction of earth dams in winter is applicable.

PALSAS AND CONTINUOUS PERMAFROST

A. L. Washburn

Quaternary Research Center, University of Washington, Seattle, Washington 98195 USA

This report describes peaty mounds in continuous permafrost, especially near Resolute, Cornwallis Island, Arctic Canada. Dome-shaped permafrost mounds here are up to about 60 cm high and 8 m in diameter. They are covered with tundra vegetation, have an active layer some 20 cm thick, and are characterized by a permafrost core of icy peat and/or silt. Some mounds also occur as similarly low but more irregular forms, others as parts of low plateaulike rises up to 1,600 m² in area. Most of the observed mounds are in or near present or former drainage lines that remain moist much of the summer. Field relations suggest that the ice of some mounds is primarily segregation ice, that the ice of others may include injection ice, and that some mounds are related to disintegration of plateaulike rises. It is concluded that most of the peaty Resolute mounds that are some 50 cm or more high and 2 m or more in diameter should be regarded as palsas.

INTRODUCTION

The term *palsa* originally designated "...a hummock rising out of a bog with a core of ice" (Sepälä 1972). Although there are now a variety of usages of the term, all pertain to perennial mounds, mostly in discontinuous permafrost. However, palsas or palsalike forms are also becoming known from the zone of continuous permafrost, as reviewed below, including occurrences in the vicinity of Resolute, Cornwallis Island, Arctic Canada.

EARLIER OBSERVATIONS

Palsas or palsalike features within the zone of continuous permafrost have been reported from Svalbard, the Soviet Union, Arctic Canada, and Alaska.

In Nordaustlandet, Salvisgen (1977) observed peat mounds in two areas, the largest mounds having a height of ~1 m and diameters of 3-4 m. One mound was characterized by ice up to 70 cm thick beneath a peaty cover some 30 cm thick, of which 11-12 cm consisted of a sand layer. Salvisgen questioned whether the term *palsa* should be applied to these forms.

In Spitsbergen, Federoff (1966 p. 172-173) reported "palses" at Sassendal. They were elliptical, had a median height of 50 cm and short diameters of 2-3 m, and were associated with organic soil. At Kapp Linné, Åkerman (1973) and Jahn observed palsalike mounds that were "...up to 1.5 m high, built of segregation ice and occur in the area of polar moors" (Jahn 1975, footnote, p. 99); Åkerman (1980 p. 79, 1982 p. 47-48) described the same mounds as palsas.

In the Soviet Union, palsas in continuous permafrost occur in the southern part of the Yamal and Taymyr peninsulas and in Siberia, judging from Grigoriew's (1925 p. 346-348) discussion of peat-earth mounds (*Torf-Erdhügel*) in Siberia (some of which, however, were seasonal frost mounds), and comparison of Frenzel's (1959, Abb. 15, p. 1028) map of *palsa* bogs and flat hilly bogs (*Palsmoore* and *Flachhügelmoore*) with Soviet maps of permafrost

distribution (cf. Washburn 1979, Figure 3.3, p. 25; Figures 3.9-3.10, p. 31-32). More specifically, continuous permafrost palsas, 0.5-3.5 m high and rarely exceeding 15 m in diameter (exceptionally up to 100 m), occur in the vicinity of the Viljui hydroelectric power station in western Yakutia (Åkerman 1982 p. 45-46).

In Arctic Canada, Jankovska and Bliss (1972, 1977) described peat mounds 1-2 m high and 5-15 m in diameter, with peat 1.5-2.0 m thick, occurring as high-center polygons on the north coast of Devon Island. W. Barr's report of "Peat mounds, 2-3 m high containing 30-cm thick layers of ice...." on Devon Island (in R. J. E. Brown 1973 p. 29) refers to the same area.

On Bathurst Island, Blake (1974 p. 235, 239) investigated two peat mounds. The largest was ~1.4 m high and 3.7 m in diameter and was frozen below a depth of 40 cm on August 11, 1963. The mound consisted of peat and ice lenses to a depth of ~3.3 m. Below this, ice extended to the bottom of the core hole at a depth of 5.0 m. The other mound was frozen below a depth of 21 cm on July 2, 1963. Peat extended to a depth of 2.6 m, below which was sand.

On northern Ellesmere Island, Flügel and Mäusbacher (1981) described two peat mounds. The largest was 40 cm high, ~5.5 m in diameter, and had a frozen core in early August. King (1981) described three types of peat mounds in the same area, some up to 2 m high and as much as 20 m in diameter.

On Amund Ringnes Island, Hodgson (1982 p. 28) reported palsas, which he described as

Small ice-cored mounds, 1 to 5 m in diameter and up to 1 m high...in some level and poorly drained fine grained deposits insulated by a complete moss/lichen cover.... A 75 cm-high mound that was cored...comprised a 20 cm organic-rich active layer, 60 cm of icy fines and sand, and 35 cm of pure ice, underlain by fines having low ice-content.

The mounds were commonly 50 cm high, and beneath some there was as much as 1 m of ice (Hodgson 1982 p. 21).

Bird (1967 p. 203) described ice-cored peat mounds, oval to elongate and 1-2 m high and 15 m or more long, from several places in continuous permafrost in Arctic Canada. Although perennial, the mounds were apparently short-lived forms whose core consisted entirely of massive clear ice. Somewhat similar but much smaller forms less than 50 cm high were described from Banks Island by French (1971).

In northern Alaska, Nelson and Outcalt (1982 p. 39-43) observed palsas or palsalike mounds adjacent to the trans-Alaska pipeline where road construction had interfered with the natural drainage. They believed that "Palsas can no longer be characterized as geographically restricted to the equatorward permafrost boundary, or even to the discontinuous zone" (Nelson and Outcalt 1982 p. 43).

PEATY MOUNDS IN THE RESOLUTE AREA, CORNWALLIS ISLAND

Peaty mounds in a variety of forms occur in the immediate vicinity of Resolute (latitude 74°43'N, longitude 94°57'W) (Figures 1 and 2). The bedrock is exclusively dolomite and limestone (Thorsteinson and Kerr 1968). The region has been glaciated, and much of it was formerly submerged. Deposits due to glacial, marine, slope, and weathering processes (Cruickshank 1971) provide a general debris cover. Frost-wedged bedrock is everywhere near the surface and is locally exposed over considerable distances. Much of the Quaternary history is still obscure, but areas below ~100 m emerged from the sea less than 10,000 years ago.²

The climate is cold and arid. The mean annual air temperature and precipitation at Resolute (1951-1980) are -16.6°C and 131 mm. Permafrost is ~400 m (1,300 ft) thick (R. J. E. Brown 1970, Table 1, p. 10) and, depending on the nature of the surface cover and soil, the active layer ranges from some 20 to 80 cm thick, and possibly up to 100 cm in places. Because of the climate and carbonate bedrock, vegetation is sparse, some areas being almost completely barren except in depressions and downslope from long-lasting snowdrifts. In areas remaining wet for considerable periods, sedge-moss meadow communities prevail (Edlund 1982). The soils involved have been mapped as tundra and bog soils (Cruickshank 1971, Figure 2, p. 199). The mounds are restricted to these soils but are much less widely distributed.

Several low peaty mounds are well developed on the south side of Five-Mile Lake (Figure 2). The surface in their vicinity is flat and essentially horizontal. Except for occasional patches of bare ground, there is a general but commonly thin vegetation mat, some 5-10 cm thick, overlying stony silty sand. Turf hummocks 10-15 cm high and 10-30 cm across are present, along with comparably low but irregular turf ridges up to 2 m long. A 60-cm-high peat mound with marginal cracks (Figure 3) was cored to a depth of ~125 cm with a modified CRREL 3-in. (7.2-cm) core barrel. The core sections, which were various shades of brown, revealed the stratigraphy and plant remains indicated in Tables 1 and 2.

An area of low mounds occurs at the north base of "Airport Ridge" (Figure 2). The mounds are so low they could easily escape notice, being only some 20 cm high (Figure 4). They lie amid vegeta-

ted stony silt and are characterized by a mossy cover, whose surface vegetation was dying in places as shown by a grayish tinge. On August 2, 1981, the frost table lay at a depth of ~20 cm except in bare spots, whereas beyond the mounds it was at a depth of ~30 cm in mossy vegetated areas and ~40 cm in bare gravelly areas. The mounds were present throughout the 1981 and 1982 thaw seasons. Coring of a mound to a depth of 47 cm on July 15, 1982, revealed the stratigraphy indicated in Table 3, as recorded in the field by B. Hallett, C. Gregory, and R. Anderson.

Slightly farther east an east-draining shallow depression is bordered by an irregular, low longitudinal peaty mound some 50 cm or more high (Figure 5), lying parallel to the depression but divided into sections, in part by vehicle tracks. The mound is perennially frozen beneath a thin active layer.

A few, more prominent mounds occur between McMaster River and the low hills to the north (Figure 2). Some of these mounds comprise a plateaulike rise in the drainage depression of a small stream; the rise is 1-2 m high, ~1,600 m² in area, and may be, in part, an erosion remnant left by the stream. The highest mound stands prominently above the rise (Figure 6). Other mounds here are lower, are less prominently dome shaped, and are separated by polygonal depressions. Some of these lower mounds show shell-bearing silt patches at their crest.

ORIGIN

It is generally agreed that palsas in discontinuous permafrost are due to frost heaving and that in many places they originate by differential heaving where snow cover is especially thin or lacking (Seppälä 1982). The heaving of palsas is usually ascribed to segregation ice but has also been reported as due to injection ice. Additionally, palsas have been ascribed to the disintegration of a peaty plateau.³ A summary of these various concepts is presented elsewhere (Washburn 1983).

With respect to segregation ice, the areas where the Resolute mounds occur were formerly submerged, and near-surface permafrost would not have developed until emergence. Thus growth of segregation ice from upward-drawn water would have been possible as the surface sediments froze downward. However, this source for the mound ice seems improbable, considering the time needed for peat development and for mound inception and growth. Possibly general thinning of a thicker active layer may have permitted gradual growth of segregation ice. In any event, movement of unfrozen water within permafrost, a process that is becoming increasingly widely recognized (Cheng 1982, Mackay 1983), would have permitted this as peat accumulated and the active layer thinned locally because of increased insulation provided by the peat. As the permafrost table rose locally, such ice could build up by water moving downward as well as upward. The mounds on the south side of Five-Mile Lake appear to conform to this model, because their topographic position does not favor the availability of water under hydraulic pressure and development of injection ice.

On the other hand, water under hydraulic pressure between a downward-freezing active layer and the permafrost table would be favored at the base

of a slope. This situation could lead to injection ice as well as segregation ice beneath and within a peaty layer. To the extent that the ice delayed thawing, aided by lower temperatures because of a thinner snow cover accompanying mound growth, the ice content and mounding might become perennial. Because of their topographic position and clear ice layers with vertical bubble trains, the low mounds at the north base of "Airport Ridge" may be such embryonic forms involving both injection ice and segregation ice.

The low mounds on the small plateaulike rise between McMaster River and the hills to the north are probably due to permafrost cracking and separation of peaty centers, and are more appropriately regarded as high-center, nonsorted polygons than incipient palsas. However, the highest mound here and another nearby are more isolated, much more palsalike, and may be aggradation forms rather than owing their origin to permafrost cracking.

Are palsalike mounds in continuous permafrost really significantly different from palsas in discontinuous permafrost? The term palsa has been used in a variety of ways, and in an attempt to clarify the question of "What is a palsa?" the following broad definition, which encompasses most of the usages, has been suggested (Washburn, 1983):

Palsas are peaty permafrost mounds, ranging from c. 0.5 to c. 10 m in height and exceeding c. 2 m in average diameter, comprising (1) aggradation forms due to permafrost aggradation at an active-layer/permafrost contact zone, and (2) similar-appearing degradation forms due to disintegration of an extensive peaty deposit.^[4]

Thus defined, palsa is a useful general term. It can be made specific by modifiers, as needed, describing (1) morphology (dome-shaped, etc.), (2) occurrence (discontinuous or continuous permafrost), (3) constitution (mainly organic or mainly mineral soil), (4) ice type (segregation-, injection-, or mixed-ice), and (5) origin (aggradation or degradation forms).

Accordingly, the Resolute and other perennial peaty mounds described above as exceeding ~50 cm in height and 2 m in diameter are here accepted as continuous-permafrost palsas.⁵ Also, more specifically, the Five-Mile Lake mound would be a segregation-ice (?) organic palsa. This work supports Åkerman's (1982) view and earlier suggestions that palsas occur in continuous as well as in discontinuous permafrost.⁶

NOTES

¹I am most grateful to the Director, G. Hobson, and the staff of the Polar Continental Shelf Project of the Canadian Department of Energy, Mines and Resources for excellent support. I am also indebted to J. Åkerman, J. Brown, M. Eronen, H. French, B. Hallet, R. Mackay, F. Nelson, S. Outcalt, A. Pissart, M. Seppälä, C. Tarnocai, and S. Zoltai for helpful discussions--views on palsas differ, and responsibility for conclusions is mine alone; also to E. B. Leopold, B. M. Tucker, D. Vitt, and D. Clemens for determining plant remains in the palsa core from Five-Mile Lake, and to M.

Stuiver for radiocarbon dating of the palsa core and the marine shells.

²Marine shells from an altitude of 102 m on "Airport Ridge" show a radiocarbon age of 9610 ± 40 years B.P. (University of Washington Quaternary Isotope Laboratory No. QL-1612). "Airport Ridge," so named for the purposes of this report, is the north-south trending ridge on the east side of the Resolute Airport.

³Not necessarily a peat plateau in the sense of a peatland requiring more than 40 cm peat accumulation (National Wetland Working Group 1981).

⁴Where high-center peaty polygon forms can be identified with certainty, they should be so designated and not termed palsas.

⁵High-center polygons excluded (see Note 4).

⁶Åkerman's (1982) article was received after submission of the present paper. I am grateful to the editor for permission to make some changes and insert reference to Åkerman's article and to the National Wetland Working Group's (1981) report.

TABLE 1 Core Stratigraphy of Peat Mound on South Side of Five-Mile Lake.[†]

Depth (cm)	
0-5	1. Mossy surface vegetation
5-20	2. Fibrous peat--grading down to
20-35	3. Icy fibrous peat, fibers have dominantly horizontal orientation, ice disseminated, ice content* (20-25 cm) = 566%--grading down to
35-86	4. Icy fibrous peat like 3 but fibers have dominantly wavy, in places flamelike, orientation, ice disseminated, ice content (61-71.5 cm) = 707%--grading down to
86-99.5	5. Icy fibrous peat, more ice than in 4, ice both disseminated and in irregular clear ice masses†--grading down to
99.5-111.5	6. Icy pebbly silt, minor content of peat fibers but many nearly vertical; irregular clear ice masses dominant, some measuring up to $\sqrt{2} \times 4 \times 7$ cm--grading down to
111.5-124.5	7. Increasingly pebbly silt similar to 6 but with fewer peat fibers, contains shell fragments, ice content# (111.5-118.5 cm) = 228%, (118.5-124.5 cm) = 42%.

[†]Radiocarbon dating at the University of Washington Quaternary Isotope Laboratory provided peat ages as follows: Depth 20-25 cm, 1680 ± 60 years B.P. (QL-1739); depth 61-71.5 cm, 2430 ± 60 years B.P. (QL-1740); depth 111.5-124.5 cm, 5410 ± 50 years B.P. (QL-1741).

*Ice content given as $(W_w/W_s) \cdot 100$.

†The clear ice masses from here to depth 124.5 cm contained isolated spherical bubbles irregularly distributed, also (in the larger ice masses) dominantly vertical bubbles up to 2 cm long and a fraction of a millimeter in diameter. No bubble trains noted.

#Because of the greater dry density of gravel than peat, comparison of ice contents on a percent weight basis can be misleading and even opposite on a volumetric basis.

TABLE 2 Plant Remains in Core from Peat Mound on South Side of Five-Mile Lake. Spot checks by E. B. Leopold and D. Clemens (pollen and spores) and B. M. Tucker (mosses)--Department of Botany, University of Washington; surface sample determined by D. Vitt--Department of Botany, University of Alberta.

Depth (cm)	
Surface	<u>Brachythecium turgidum</u>
18-20	Rare moss spores; 1 Caryophyllaceae pollen grain
44-46	<u>Orthothecium chryseum</u> (Schwaegr.) B.S.G.; abundant moss spores; abundant Rhizopods
59-61	<u>Drepanocladus</u> sp.; abundant moss spores; Rhizopods very abundant; also present: resting cysts of dinoflagellate algae, 1 <u>Selaginella</u> spore
71.5-73.5	<u>Cratoneuron</u> sp.; moss spores very abundant; also present: Rhizopods, resting cysts of dinoflagellate algae, <u>Selaginella</u> sp. megaspores
86-88	<u>Cratoneuron</u> sp.; moss spores common; also present: Rhizopods, rare fern spores
99.5-101.5	Abundant moss spores; also present: <u>Pediastrum</u> -type green colonial algae, 1 fern spore
101.5-103.5	Small moss spores; also present: Rhizopods, 1 <u>Pinus</u> pollen grain, 1 trilete spore

Note: The moss genera are characteristic of wet environments; Drepanocladus grows in water. From 59-61 cm downward there is a decrease in Rhizopods and algae, both of which require moist environments. The Selaginella and fern spores suggest the presence of vascular plants.

PALEOCLIMATIC INFERENCES FROM RELICT CRYOGENIC FEATURES IN ALPINE REGIONS

William J. Wayne

Department of Geology, University of Nebraska, Lincoln, Nebraska 68588 0340 USA

Features indicative of intensive frost action and of permafrost observed in the Ruby, Schell Creek, and Snake ranges of Nevada and the Cordón del Plata of the Mendocan Andes, which include lobate and small linguoid (ice-cemented) rock glaciers, sorted circles and stripes, garlands, and stone-banked lobes, permit a reconstruction of some of the paleoclimatic conditions adjacent to the ice in alpine areas that were glaciated during the Pleistocene. The distribution of paleocryogenic forms on surfaces where snow cover is minimal suggests that the mean annual air temperature above and adjacent to the valley glaciers in these desert mountain ranges in both hemispheres during the last Pleistocene glaciation would have been 5°-6°C lower than the present ones at the same altitudes. During the Holocene neoglaciations, the lowering of temperature probably was 1.5°-2°C.

INTRODUCTION

Temperature anomalies during the Pleistocene glacial maxima varied widely. Many investigators (e.g. Flint 1971, p. 725) indicate that the mean annual air temperature overall was about 5°C lower than the present. The overall average temperature of the oceans 18,000 B.P. was only 2.3°C below that today (CLIMAP 1976), but temperature as much as 18°C lower than the present have been interpreted from paleocryogenic features in central Europe, and anomalies nearly that great have been reported for the areas marginal to the North American ice sheet (Washburn 1980). In alpine regions, the ridges that stood above valley glaciers undoubtedly were colder than they are today, but few studies have provided data with which to estimate conditions that existed there when ice tongues were at their maximum extent.

Permafrost should have been widely distributed above glacial ice in many mountainous regions, and preserved landforms characteristic of former permafrost should provide a guide to some of the paleoclimatic conditions in those regions. Cryogenic landforms that might be used for such reconstructions would have formed primarily in sites where, because of wind or orientation, snow cover was minimal; sites that received greater amounts of moisture would have been protected so that cryogenic features would be uncommon and those observed probably would not reflect the maximum changes in temperature (Brown 1969, Nicholson and Granberg 1973, Harris and Brown 1978). Features reported in this study were observed in the Ruby, East Humboldt, Schell Creek, and Snake Ranges of Nevada, U.S.A. (Figure 1); a few observations made in the Cordón del Plata, Mendoza Province, Argentina are included for comparison. The types of active, inactive, and relict cryogenic features observed in these mountains include ice-cored and ice-cemented rock glaciers; stone-banked and turf-banked lobes; sorted circles, nets, and stripes; and string bogs.

Washburn (1980, p. 123) and Harris (1982) have summarized the temperature ranges that have been suggested under which some cryogenic landforms

develop (Table 1). Ice wedges develop in fine-grained sediments at mean annual temperatures of -3°C to -5°C and lower, but some small (diameter <2m) circles and nets seem to form with temperatures between +5°C and -2° (Goldthwait 1976). Stone stripes and stone-banked gelifluction lobes are comparable forms on steep slopes. Turf-banked gelifluction lobes are common in regions of permafrost, but also may form where mean annual temperatures are slightly above 0°C. String bogs do not require perennially frozen ground for their formation.

FIGURE 1 Index map of Nevada

TABLE 1 Environmental Conditions Under Which Cryogenic Features Commonly Observed In Dry Alpine Regions Form (1)

	Temperature (°C)	Precipitation and/or Moisture Conditions
Ice wedges	-6 to <-15	<600 mm
Cryoplanation	-12 to ?	- - - -
Large sorted circles and stripes (2 m dia.)	-3 to <-15	Saturation
Small sorted circles and stripes (2 m dia.)	0 to -3	Saturation
Rock glaciers, ice-cemented	-4 to <-10	>500mm, <1,500mm
Rock glaciers, ice-cored	+1 to <-10	- - - -
Gelifluction lobes	+2 to <-10	Saturation
String bogs	+3 to -1 (?)	Saturation

(1) Modified from Washburn (1980, p. 123) Reger and Péwé (1976), Harris (1981b, 1982), and based in part on discussions with A. E. Corte.

The Ruby-East Humboldt Mountains are in east-central Nevada, between 40° and 41°N latitude (Figure 1); to the southeast, between 38°30' and 40°N latitude, are the Schell Creek and Snake Ranges. The crest of the Ruby-East Humboldt Range exceeds 3,400 m in some places, that of the Schell Creeks is 3,500 m, and Wheeler Peak, the highest point of the Snake Range, reaches 4,000 m in altitude. Precipitation in east central Nevada, most of which falls in the winter, is about 250 mm on the piedmont but rises to 1,200 mm above 3,000 m. The altitude of the mean annual 0°C isotherm in the Ruby Mountains has been calculated to be 3,500 m. If the 150 m/degree latitude southward rise in the 0°C isotherm noted for Siberian mountains by Nekrasov (1978) should be close to the figure for Nevada, the 0°C isotherm at Wheeler Peak, 1°45' of latitude south of the Lamaille station in the Ruby Mountains, would be about 3,760 m, or 240 m below the peak. Records are inadequate to determine whether inversions, such as those reported by Harris and Brown (1982) for the Rocky Mountains of Alberta, exist on these mountains. Shaded slopes are at least 2°-3° colder than the mean air temperature at the same altitude. Across exposed surfaces, wind velocities are great throughout the year, so the winter snow cover is thin in many places.

ACTIVE CRYOGENIC FORMS

Active cryogenic features in the Nevada Mountains studied are few. A rock glacier occupies a north facing (shaded) cirque floor on Wheeler Peak in the Snake Range, from 3,430-3,275 m, and turf-banked lobes are common on the slopes above 3,600 m; most of the surfaces above 3,600 m would best be described as block slopes (White 1976). A few peaks in the Schell Creek Mountains approach a zone of potential permafrost, although no perennially frozen ground has been recognized in the range.

The crest of the Schell Creek Mountains, like the northern part of the Snake Range, is dominantly quartzite that has been shattered by frost action. Fossil patterned ground extends as low as 2,800 m, but the only active cryogenic features seem to be block slopes and block streams; neither requires permafrost to form. The highest peaks of the Ruby Mountains fail to reach the altitude of 0°C mean annual air temperature, and no permafrost has been found in the range. Active cryogenic forms include block streams at 3,000 m and string bogs between 2,750 and 3,000 m (Wayne 1982).

In the dry Central Andes of Mendoza Province, Argentina, small active glaciers are present above 4,000 m in many of the cirques. Sporadic permafrost in the form of active ice-cemented rock glaciers is present in shaded cirques and valley walls above about 3,500 m (Wayne 1981b). Frozen ground was encountered below an active layer one m thick in late January, and is associated with stone-banked gelifluction lobes, sorted and nonsorted stripes, sorted nets, and gutters that may have formed over ice wedges from 3,900-4,200 m.

The calculated 0°C mean annual isotherm is 3,300 m, the altitude of the lowest of the active rock glaciers. These rock glaciers are the termini of small debris-covered glaciers and probably contain some glacial ice. Active ice-cemented rock glaciers, which are part of the body of active discontinuous permafrost (Barsch 1978), are present only above 3,500 m, where the calculated mean annual air temperature is about -1.5°C. Observed summer temperatures along the shaded slopes and cirques where these landforms develop are approximately 3°C lower than are the air temperatures in more open areas, so it is likely that the local temperatures needed for development of ice-cemented rock glaciers are in the range of -3° to -5°C (Table 1).

PLEISTOCENE-HOLOCENE GLACIAL ACTIVITY

Each of these ranges has been glaciated at least two times during the later Pleistocene and from one to three phases of Neoglacial activity have been recognized (Corte 1957; Sharp 1938; Wayne 1981a; Wayne 1982; Wayne and Corte 1983). In the Ruby-East Humboldt Mountains, the oldest glacial deposits represent the Lamaille Glaciation, which is being correlated with Bull Lake/Illinoian deposits and Oxygen Isotope Stage 6 (Wayne in press). The younger Angel Lake moraines are Pinedale/Wisconsinan equivalents, and are correlated with Oxygen Isotope Stage 2. No Neoglacial ice tongues formed, but rock glaciers have been active at least two times during the Holocene, the most recent probably during the Little Ice Age.

The glacial chronology of the Snake and Schell Creek Ranges has been examined in less detail; moraines equivalent to the Lamaille and Angel Lake deposits of the Ruby Mountains are present in both, however, as are inactive and fossil rock glaciers of both Wisconsinan and Holocene age. Two and possibly three Holocene rock glacier or glacier advances are recorded in the post-Wisconsinan deposits at Wheeler Peak. Unfortunately, no buried organic matter has been found, so radiocarbon dating of these deposits has not been possible.

DISTRIBUTION OF CRYOGENIC FEATURES INDICATIVE
OF FORMER PERMAFROST

During the Pleistocene glaciations, both lower temperatures and higher precipitation than the present combined to form or greatly expand glaciers in these dry mountain ranges. Where snow cover was sufficiently thin to allow the lowered air temperature to affect the ground, several kinds of landforms characteristic of, although not necessarily restricted to permafrost regions developed during the glaciations. Relict forms recognized in the field include rock glaciers, both ice-cored and ice-cemented, sorted circles and nets, debris islands, sorted stripes, stone-banked and turf-banked lobes, and surfaces that may have formed by cryoplanation.

Collapsed rock glacier debris is present in three areas of the Ruby-East Humboldt Range where the crest exceeds 3,000 m. One group of two is south of Pearl Peak at 40°13'N latitude. A second group, numbering 13, is in the northern part of the Ruby Mountains between 40°25' and 40°40', in the region where glacier tongues were longest. The third group of seven is in the East-Humboldt Mountains at the north end of the range, between 40°53' and 41° latitude. Of the 22, I have examined 11 in the field.

Most (17) of the rock glaciers are lobate forms that undoubtedly developed as a result of mobilization of frozen scree and hence were part of the permafrost body when they formed (Barsch 1978; Haerberli 1978). Fifteen of the 17 are oriented between N 30° W and N 45° E. None are oriented toward the south.

Of the five linguoid rock glaciers, one, the most southerly of the range, has the form of a collapsed debris-covered glacier that developed the structure of a rock glacier, as have many in the Mendozan Andes (Wayne 1981a). The other four probably formed as debris falls on the waning Angel Lake ice tongues and became rock-glacierized.

Most of the 22 features identified as fossil rock glaciers were active during the Angel Lake glaciation and show only a single phase of development, but 4 of the lobate ones and 3 linguoid rock glaciers have been active at least twice, most recently during one or more of the Neoglacial cold periods (Figure 2). Those of Angel Lake age range from 2,680 m near the north end of the range (latitude 41°N) through 2,780 m in the central part (latitude 40°35'N) and 2,870 for the most southerly in the range (latitude 40°13'N). Rock glaciers identified as early Holocene reached 2,750 m in the central East Humboldt Range and 3,000 m in the main section of the Ruby Mountains. One late Holocene rock glacier in the Ruby Mountains expanded to 3,050 m, and another that may have formed as a rock fall over ice during the earlier Lamoille glaciation is lower than the rest at 2,700 m.

Patterned ground is well developed in the East Humboldt Range, but only small areas are present in the Ruby Mountains to the south. With two exceptions, all the patterned ground is regarded to have formed during Angel Lake Glaciation. No troughs or gutters suggestive of relict ice wedges were recognized in any of the Nevada mountains. Most of the patterned ground observed consists of sorted circles, sorted stripes, and garlands, all

FIGURE 2 Relict lobate rock glacier 150 m wide and 340 m long in northeast-facing cirque, Right Fork of Lamoille Creek, Ruby Mountains; late Angel Lake with Holocene reactivation phase.

FIGURE 3 Stone stripes and garlands on southwest-facing slope, Third Boulder Creek, East Humboldt Range

FIGURE 4 Cryoplanation (?) surface above cirques, north of Wines Peak, Ruby Mountains, altitude 3,125-3,175m.

large, but on some slopes nonsorted stripe patterns were seen. A few large sorted circles or debris islands have formed on gently sloping surfaces at 3,025 m above Angel Lake. Stone stripes are striking features on south- and west-facing slopes of 25°-33° (Figure 3) but are absent from north-facing slopes in the same valleys. They are best developed on medium grained granitoid rocks, which yield large blocks, and the soil stripes are dominantly silt. Gutter to gutter distances average 15 m. Their lower margins, in many places marked by garlands, seem to represent the trim line of the glacier along the slope. In some valleys, 3 or 4 lines of boulder accumulations show up above the lowest set, marking successively lower trim lines. The farthest south that stone stripes were observed is on the slopes of Wines Peak, at about 40°31'N latitude, where strongly developed stripes of Angel Lake age formed on a north-facing slope. Indistinct stripes, possibly of Lamoille age, are on a smooth surface above the cirques from 3,125-3,175 m in altitude (Figure 4). Stripes composed of boulders that are deeply weathered and may be Lamoille in age are also present at 2,700 m in the lower part of Lamoille Canyon.

In the Schell Creek Mountains, rock glacier debris of the Holocene cold periods is limited to altitudes above 3,100 m (Figure 5), but those of Wisconsinan age are lower. A sorted net of late Wisconsinan age was observed at one place on a northwesterly-facing slope at 3,000 m. Sorted stripes on a south-facing slope terminate in garlands at 2,750 m in altitude.

On Wheeler Peak, Holocene inactive and relict rock-glacier debris extends beyond the active rock-glacier front to about 3,230 m (Figure 6), and some of the late Wisconsinan topography as low as 3,150 m probably formed as an ice-cored rock glacier rather than a moraine. Much of the peak above about 3,300 m is covered with frost-riven debris and would be best referred to as block slopes (Figure 7). Even though much of the frost-shattering undoubtedly developed during the Wisconsinan and, perhaps, earlier glaciations, the part of the peak higher than 3,760 m is above the calculated mean annual 0°C isotherm and the process surely is active now.

DISCUSSION

In the Ruby Mountains, Nevada, the absence of ice-wedge phenomena and the paucity of large sorted circles suggests that either the snow cover exceeded 0.50 m over much of the range (Harris 1981a) or that the mean annual air temperature above 3,000 m probably did not drop much lower than -5°C. Smooth upland surfaces with sorted circles and stripes at 3,200-3,300 m in the middle of the range, which surely were as wind-swept during glaciations as they are now, tend to corroborate this estimate. Presence of most stone stripes on south- or west-facing slopes and their absence on north- and east-facing slopes probably reflects the thickness of winter snow cover as much as temperature. They do suggest, though, that temperatures on the slopes above the glaciers probably were no higher than about -3°C at 2,800 m in the north part of the range. Relict rock glaciers of the ice-cemented

FIGURE 5 Lobate rock glacier, Holocene, Schell Creek Mountains.

FIGURE 6 Active, inactive, and relict rock glaciers on Wheeler Peak, Snake Range.

FIGURE 7 Wheeler Peak, Snake Range, block slopes and block streams; active rock glacier shown in Figure 6 is below snowbank in cirque.

type are almost wholly in cirques that face between east and northwest. If these locations average 4°C colder than the mean annual air temperature at the same altitudes as observed in the Cordón del Plata, Argentina (Wayne 1981b), the 0° mean annual isotherm at 41°N latitude at the time they formed, probably 12,000-13,000 years ago, would have been about 2,600 m, approximately 5°C colder than the present mean annual temperature at that altitude.

Only relict rock glaciers, sorted stripes, and a few sorted circles in the Schell Creek Range provide reasonably reliable guides to the Pleistocene temperatures there. On the slopes of South Schell and Taft Peaks (latitude 39°20'N), rock glaciers reached 2,930 m, which suggests a mean annual air temperature of -1°C to -2°C, again about 5°C lower than the present calculated temperature of +4.3°C. A similar difference is suggested by the altitudes of relict cryogenic features on Wheeler Peak (latitude 39°N).

For comparison in the Cordón del Plata (latitude 33°S), patterned ground on wind-swept surfaces that protruded above the Vallecitos (=Wisconsinan) glaciers at 3,500 to more than 4,000 m are covered with large sorted circles, sorted and nonsorted stripes, boulder lobes, and trenches that suggest ice wedge development. Such features at and above 4,010 m in bouldery debris derived from quartzites suggest a mean annual air temperature over these surfaces of about -10°C or lower. This would be a reduction of at least 5°-6°C below the present calculated mean annual temperature of -4°C, a figure not significantly different from the 4.5°-5° lowering calculated for 2,500 m in the same region from the distribution of relict rock glaciers (Wayne 1981a).

The existence of Holocene rock glacier debris in the Ruby and Schell Creek Mountains and its presence well below the present active rock glacier on Wheeler Peak indicates that a significant reduction in temperature did take place in these mountains during Neoglaciation, probably with little change in precipitation. In the northern part of the Ruby Mountains older Neoglacial rock glaciers reached 3,000 m; in the same area, two rock glaciers were active during the later Neoglaciation at 3,050 m. These altitudes suggest a 2°-3°C reduction in mean air temperature during the two Neoglaciations.

On Wheeler Peak an earlier Neoglacial advance brought an active rock glacier to 3,260 m. During a somewhat later Holocene glaciation, a glacier left a small end moraine at 3,300 m. The Little Ice Age of the past few centuries brought the rock-glacier front to 3,360 m, just slightly beyond its present position. The temperature reduction on Wheeler Peak during the earliest Neoglaciation would have been about 2°C, during the Little Ice Age about 1.5°C, based on the position of the rock glacier fronts.

In the Cordón del Plata all three Neoglaciations seem to have accompanied about the same temperature reduction. Data from rock-glacier altitudes and the character and distribution of patterned ground suggest a mean annual air temperature on the order of -1.5° to -2.0°C at 3,300-3,500 m.

The use of cryogenic features provides a maximum figure for paleotemperatures. In this evaluation, temperatures above alpine glaciers were at least 5°-7°C lower than the present during the Wisconsinan

glaciations. These temperatures are relatively close to the 5°C figure that has been suggested by some authors.

ACKNOWLEDGEMENTS

The field work in Argentina that provided some of the data in this report was done in 1980 and 1983 while I was attached to the Instituto Argentino de Nivología y Glaciología in Mendoza, Argentina and was supported by NSF grants. I would like to thank Arturo E. Corte of IANIGLA for the opportunity to discuss some of the ideas, and Troy Péwé and R. F. Black for their comments on the manuscript. Naomi Wayne was my field assistant in both the Nevada and Mendoza investigations.

UNDERGROUND CAVITIES IN ICE-RICH FROZEN GROUND

Paul C. Weerdenburg¹ and Norbert R. Morgenstern²

¹ EBA Engineering Consultants Ltd., Edmonton, Alberta, Canada T5L 2M7

² Department of Civil Engineering, University of Alberta, Edmonton, Alberta, Canada T6G 2G7

An analytical study of closure behavior and stress changes surrounding unlined and lined circular openings in warm, ice-rich permafrost has been undertaken. The creep law of polycrystalline ice has been used to describe the constitutive behavior of fine-grained, ice-rich permafrost soils. The results show that shallow openings in warm permafrost experience very large strains above the crown of opening. Placement of a tunnel liner will reduce the tunnel closure to an insignificant level. A new analysis of the in situ deformation behavior of the Fox Tunnel near Fairbanks, Alaska, has shown that the flow law for polycrystalline ice does not yield an upper bound solution to the observed room closure measurements. However, it is argued that the in situ deformations resulted from creep and plastic yielding.

INTRODUCTION

Underground chambers have been used extensively for civilian and military purposes since very early in history. Military applications of underground space date back to Roman times. Traditionally, mining operations have made extensive use of underground space and will continue to do so in the future. The current world energy situation has brought about an increased awareness amongst the civilian population of the tremendous advantages of utilizing underground space as a means of conserving energy.

The U.S. Army Cold Regions Research and Engineering Laboratory (USA CRREL) has investigated the use of underground space in frozen ground as early as 1955. During the summers of 1955-1957, the Lower Tuto Tunnel was excavated into the Greenland Ice Cap at Camp Tuto, Greenland (Abel 1961). The objective of this tunnel was primarily to provide a research facility to study the deformation behavior of glacial ice and assess the feasibility of excavating tunnels and rooms in ice to utilize the space for storage of perishable food, military equipment, etc. With the experience gained from the Lower Tuto Tunnel, the Upper Tuto Tunnel was excavated the following two summers near the original tunnel as a prototype shelter to house a 25 man camp and related support facilities under ice. This facility was closed down during the summer of 1962 due to excessive deformations of the openings, attributed primarily to warming of the surrounding ice medium (Russel 1961).

During the summers of 1959 and 1960, a third tunnel was driven into cold frozen till near Camp Tuto, Greenland. Personnel of USA CRREL report that this tunnel is virtually the same size as it was when it was excavated.

The Fox Tunnel, near Fairbanks, Alaska, was excavated to evaluate the use of underground space in warm permafrost. During the winters of

1963-1965 USA CRREL excavated a near horizontal tunnel 100 m long into frozen, ice-rich Fairbanks silt. During the winter of 1968 to 1969, in a cooperative study with the U.S. Bureau of Mines (USBM), an inclined winze was excavated off of the main adit to gain access to the gold-bearing gravel deposit underlying the frozen silt. USA CRREL and the USBM excavated one room each at the end of the inclined winze. Each room had frozen gravel walls and the ceiling was ice-rich Fairbanks silt. In situ deformation studies carried out in conjunction with both phases of this project revealed that tunnel closure becomes excessive when the ambient air temperature in the tunnel is near the soil temperature of -1° to -2°C (Swinzow 1970).

CONSTITUTIVE BEHAVIOR OF ICE-RICH FROZEN SOIL

Ice is the most important component controlling the rate, time, and temperature dependent properties which characterize frozen soil. Ice can be present both as discrete segregated structures and more uniformly in the pore spaces of the soil mass.

The load-deformation behavior of ice-rich frozen soil is dominated by the presence of segregated ice. Laboratory evidence of Savigny (1980) shows deformations are localized along segregated ice in natural permafrost soils. Thus, it would seem appropriate to use the creep behavior of ice as an upper bound to the time dependent deformations in ice-rich frozen soil.

The constitutive equation for steady state creep of polycrystalline ice is most commonly represented empirically by a simple power law of the form

$$\dot{\epsilon} = A \sigma^n \quad (1)$$

where $\dot{\epsilon}$ denotes the strain rate, σ denotes the

stress and A and n are the experimentally derived creep modulus and creep stress exponent, respectively. The creep modulus is constant for a given ice type and temperature. Considerable experimental evidence is available to show that the power creep law represents the steady state creep data in the low to intermediate stress range (Sego 1980).

An extensive review of the secondary creep data was carried out by Morgenstern et al. (1980). Based on this review, the authors presented the values shown in Table 1 for the parameters A and n in the power law.

TABLE 1 Creep Parameters for Polycrystalline Ice

Temperature ($^{\circ}\text{C}$)	A ($\text{kPa}^{-3} \text{ yr}^{-1}$)	n
-1	4.5×10^{-8}	3.0
-2	2.0×10^{-8}	3.0
-5	1.0×10^{-8}	3.0
-10	5.6×10^{-9}	3.0

Creep data for undisturbed ice-rich permafrost tested at the stress and temperature range of interest in geotechnical practice are scarce. Roggensack (1977), McRoberts et al. (1978), and Savigny (1980) tested fine-grained ice-rich permafrost from the Mackenzie River valley. These data are shown in Figure 1. The flow law shown in Figure 1 is that for polycrystalline ice as proposed by Morgenstern et al. (1980). With a few exceptions, the

laboratory data fall within a narrow band at stresses exceeding 75 kPa. Thus, it can be concluded that the flow law for ice represents a reasonable upper bound to the constitutive behavior of fine-grained ice-rich permafrost.

FINITE ELEMENT CREEP ANALYSIS

The finite element method is now widely used in geomechanics to determine the stress and deformation states in a nonlinear viscous medium. An incremental, initial strain finite element procedure was adopted to solve steady state creep problems in frozen soil. Details of development of this procedure are given by Weerdenburg (1982).

The incremental procedure is based on Hoff's (1954) analog, which simply states that the stresses in a nonlinear viscous medium can be obtained directly by solving for the stresses in a nonlinear elastic body. The following assumptions are made in order to compute the increments of creep strain:

1. There is no volume change associated with creep strains.
2. For an isotropic material, the principal directions of strain rate and stress tensors coincide.
3. The creep rate is independent of any superimposed hydrostatic state of stress.
4. The generalization of the uniaxial creep laws to the multiaxial state of stress should recover the uniaxial relationship for the case of a uniaxial stress.

FIGURE 1 Steady-state creep data from ice-rich glaciolacustrine clay from various locations in the Mackenzie River Valley, N.W.T. (Savigny, 1980).

UNDERGROUND CIRCULAR OPENINGS IN PERMAFROST

Major design considerations of tunnels in frozen ground are stand-up time, change in diameter of the unlined opening with time, and change in pressure on a tunnel liner with time. The first two factors will influence the decision on whether or not to support the underground opening with a tunnel liner. The third factor will provide guidelines for dimensioning the tunnel liner. A limited parametric study of shallow circular tunnels in permafrost was carried out to study closure phenomena and the stress changes in the frozen soil surrounding the opening.

The first part of this study deals with the closure behavior of an unlined circular opening excavated at various depths in warm ice-rich permafrost. The height to diameter (H/D) ratios of the circular openings varied from 1.5 to 4.0. Warm ice-rich permafrost was chosen as the host soil medium as it would present an upper bound solution for the closure rates.

A homogeneous soil profile was assumed for all analyses. Material properties were assigned on the basis of data reported in the literature. The flow law chosen for the frozen soil used in this study was

$$\dot{\epsilon} = 2 \times 10^{-8} \sigma^3 \quad (2)$$

where the units for stress and strain rate are kPa and yr^{-1} , respectively. This flow law is identical to the flow law for ice at -2°C (Morgenstern et al. 1980).

A plot of the closure velocity versus depth of overburden for the crown, springline, and invert of the tunnel is shown in Figure 2. The depth of overburden in this figure is expressed nondimensionally as the H/D ratio. For all three points considered, the closure rate increases with the depth of overburden. Also, the downward movement of the crown is greater than the upward movement of the floor, creating a sag in the roof. Thus, the initial circular

FIGURE 2 Tunnel closure velocity versus depth of overburden.

opening undergoes a transition to an elliptical shape as the frozen soil creeps inward. At greater depths, this transition will be less pronounced because the relative change in overburden stress from the crown to invert will be smaller. Based on these preliminary results, it would appear that a circular opening located 9-10 diameters below the surface would deform axisymmetrically. This is somewhat deeper than a circular opening in an elastic soil or rock.

A vector plot depicting the magnitude and direction of velocity throughout the region analyzed for a tunnel at H/D = 2.0 is shown in Figure 3. The relative magnitude is given by the length of the vector. As expected, the frozen soil flows in toward the opening. The largest velocity components occur along the periphery of the tunnel wall. The transformed cross section is shown on a grossly exaggerated scale by the dashed line connecting the velocity vectors around the tunnel wall.

FIGURE 3 Velocity vectors for unlined tunnel at H/D = 2.0.

It was clear from the foregoing that shallow circular cavities located in warm, ice-rich permafrost would ultimately become unstable unless some mitigative measures were undertaken to arrest the deformations. The second part of this study dealt with the closure of a lined circular opening in permafrost. Only one tunnel located two diameters below the surface was analyzed. A 100 mm thick concrete liner placed around the periphery of the tunnel was considered.

The velocity vector diagram for the lined tunnel is shown in Figure 4. As shown in the

FIGURE 4 Velocity vectors for lined tunnel at $H/D = 2.0$.

figure, the liner plays a significant role in altering the velocity distribution in the frozen soil surrounding the opening. In the vicinity of the tunnel, the creeping frozen soil is deflected around the tunnel liner since the stiffness of the concrete is much greater than that of the frozen soil. The tunnel liner also serves to drastically reduce the downward velocity of the crown of the tunnel. In this case, the crown velocity is reduced by three orders of magnitude for the same tunnel with no liner present.

IN SITU CREEP AT THE FOX TUNNEL

In situ creep movements of the ice-rich Fairbanks silt were evaluated independently by Thompson and Sayles (1972) and Pettibone (1973).

Pettibone (1973) studied the in situ creep behavior of the USBM room at the Fox Tunnel. After 37 months, a total of 300 mm of floor to roof deformation was recorded. Vertical separation and expansion of the ice-rich silt between the ceiling and the 1.8 m depth into the roof accounted for 20% of the total room closure.

The vertical closure measurements recorded in the USA CRREL room are shown in Figure 5 (Thompson and Sayles 1972). The vertical closure rate increased rapidly during the first year of observations due to the general warming trend caused by installation of the insulated

FIGURE 5 Vertical closure of USA CRREL room in Fox Tunnel.

bulkheads. Following removal of the USBM bulkhead, the closure rate decreased as a consequence of cooler permafrost temperatures. The same general behavior was noted in the USBM room. The vertical closure rate continued to attenuate for the entire period that closure measurements were recorded. After 3 1/2 years of observations, 480 mm of vertical closure had taken place.

Thompson and Sayles (1972) reported the results of a finite element simulation of the closure of the USA CRREL room. Laboratory samples were obtained for uniaxial creep testing. The authors used a simple power law to predict the in situ behavior of the room for the first year of observations. They concluded that the form of the flow law predicted the in situ creep behavior quite well. However, the back-calculated flow law predicted a creep rate 3.3 times faster than had been established in the laboratory on the same frozen silt. A few comments can be made regarding the analysis carried out by Thompson and Sayles (1972).

A new analysis of the USA CRREL room has been carried out. The purpose of this simulation was to assess the validity of the simple power law for ice as an upper bound solution for the in situ deformations in the frozen Fairbanks silt.

The creep properties of the silt were assigned the values of pure ice at -2°C as given by Equation 2 (Morgenstern et al. 1980). The frozen gravel walls were assumed to behave elastically based on the fact that they were very dense in situ and retained grain-to-grain contact with no massive ice forms present (Sellman 1972).

The predicted vertical steady state velocity using the simple power law given by Equation 2 to model the creep behavior of the frozen silt was 1 mm/yr. In this case, the simple power law for ice does not represent a valid upper bound for the in situ creep behavior of the frozen silt. However, an examination of the vertical closure data presented in Figure 5 clearly shows that steady state conditions did not exist during the first year of observations as assumed by Thompson and Sayles (1972). It is entirely possible that the overall closure measurements that were recorded consisted of both plastic and creep flow. Plastic flow in this sense refers to time dependent failure of the frozen soil.

Excavation of the USA CRREL room has decreased the vertical stress at the ceiling from overburden to zero. This stress release is accompanied by a corresponding increase in the stresses in the adjoining soil mass above the gravel walls. Consider the two elements shown in Figure 6. The vertical stress in element A will be a small fraction of its initial value before excavation. The vertical stress in element B will have to increase to maintain equilibrium. Assume that the strength of frozen soil is given by a linear Mohr Coulomb failure envelope and the vertical stress decrease in element A is equal to the stress increase in element B. Plotting these stress increments on a simple vertical-horizontal principal stress

FIGURE 6 Stress paths for soil elements above an underground opening.

plot, as shown in Figure 6, shows that the stress release in element A could exceed the long term $\sigma_H > \sigma_V$ failure line. However, an equal stress increase in element B lies below the long term $\sigma_V > \sigma_H$ failure line. Although the actual stress paths followed by soil elements surrounding a rectangular opening are quite complex, this simplified approach illustrates the interaction between strength and deformation in frozen soil.

An additional factor contributing to the discrepancy between the in situ and the laboratory flow law is that closure instrumentation installed in the roof and floor could not discriminate between the vertical deformations in the gravel walls and the downward creep of the ice-rich silt. The strain rate measured in the laboratory on the frozen silt samples was independent of the vertical deformations occurring in the gravel walls.

CONCLUSIONS

The case histories of cavities in frozen ground reported in the literature, while limited in number, indicate that these underground cavities can be successfully completed. However, in situ deformation studies carried out to date indicate that deformations can become severe when a tunnel is excavated in warm, ice-rich permafrost.

A comprehensive review of the constitutive behavior of ice and ice-rich soil suggests that the creep law of polycrystalline ice constitutes a reasonable upper bound to the constitutive behavior of fine-grained, ice-rich permafrost soils.

The results of preliminary analytical study indicate that shallow openings in warm permafrost experience very large strains above the crown of the opening. Placement of a concrete liner after excavation will reduce the tunnel closure to an insignificant amount.

A reanalysis of the in situ deformation behavior of the USA CRREL room at the Fox Tunnel has shown that the flow law for polycrystalline ice did not yield an upper bound solution to the observed room closure measurements. More

comprehensive instrumentation is needed in the future to discriminate between the various deformation processes that affect closure of highly stressed underground cavities in frozen ground.

DIURNAL FREEZE-THAW FREQUENCIES IN THE HIGH LATITUDES:
A CLIMATOLOGICAL GUIDE

Ruth L. Wexler

U.S. Army Corps of Engineers
U. S. Army Engineer Topographic Laboratories
Fort Belvoir, Virginia 22060 USA

This study provides relatively simple climatological models for determining the incidence of frost days (minimum daily temperature $< 0^{\circ}\text{C}$), ice days (maximum daily temperature $< 0^{\circ}\text{C}$) and freeze-thaw days (minimum daily temperature $< 0^{\circ}\text{C}$, maximum daily temperature $> 0^{\circ}\text{C}$) throughout Alaska, E. Siberia, Iceland, and Greenland. Both area and station models yield estimates of the frequency of diurnal freeze-thaw cycles per month or year. The various models demonstrate the relationships between daily freezing conditions and the different temperature regimes. The results should improve understanding of periglacial activity and provide a means of predicting possible climatic effects on the construction of buildings, roads and airport runways.

INTRODUCTION

The impact of diurnal freeze-thaw cycles on soils, rocks, roadbeds, and construction materials is of much concern to the agriculturist, hydrologist, geologist, and transportation or construction engineer. As noted by Troll (1958), such alternation of freezing and thawing not only affects the particular size structure of the soil but also causes erosion, runoff, or flooding and reduces the bearing strength of the surface layer. The vulnerability of the ground depends, among other variables, on the amount of available moisture and whether the ground is bare or is covered with vegetation, ice, or snow.

The surface covering affects the albedo which in turn is largely responsible for local differences in extreme temperatures, that is the daily maximum and minimum, the determining factors of daily freeze-thaw. Daily freezing conditions may be defined as consisting of frost days (min $< 0^{\circ}\text{C}$), ice days (max $< 0^{\circ}\text{C}$), and freeze-thaw days (min $< 0^{\circ}\text{C}$, max $> 0^{\circ}\text{C}$). The inter-relationship among these three variables forms the basis of this study. The principal question is: What incidence of diurnal freeze-thaw cycles may be expected at a given site per given interval of time?

This paper presents information on daily freezing conditions in the permafrost and contiguous regions of Alaska, E. Siberia, Iceland, and Greenland. Also included are several German stations representing a range of elevations for the comparison of the effects of altitude with those of latitude. As in an earlier study by Wexler (1982), a number of guides are offered for estimating the respective frequencies of frost days, ice days, and freeze-thaw days per month or year for any given site from routine climatological parameters.

BACKGROUND

The geographical distribution of the annual number of diurnal freeze-thaw cycles has been

determined for various countries or sections: United States, Canada, Poland, Japan, the Arctic, Europe, and the U.S.S.R (Fraser 1959, Hastings 1961, Hershfield 1972, Pelko 1970, Russell 1943, Shitara 1970, Visher 1945, Wexler 1982, Williams 1964). Annual or monthly frequencies of frost days, ice days, and freeze-thaw days have been correlated respectively with mean daily minimum temperatures, mean daily maximum temperatures, and a combination of both (Fraser 1959, Hershfield 1972, Shitara 1970, Wexler 1982).

DATA

Frequencies of diurnal freeze-thaw cycles are not readily available. Many climatic summaries list frost days, but few list ice days. In the past information on freeze-thaw cycles has sometimes been simulated (Hastings 1961, Visher 1945). In this paper, all the analyses are based on actual observations of frost days and ice days, the data for which were obtained from a variety of sources, mainly: the U.S. Department of Commerce (1980), the Danske Meteorologiske Institute (1947-1965), and U.S. Air Force Environmental Technical Applications Center (1978). All the temperatures referred to in this paper were from standard weather shelters at 1.5 to 1.8 m above ground.

FROST DAYS AND ICE DAYS

For a network of stations in a given region observations were obtained of: The mean daily minimum temperature, N , the mean daily maximum temperature, M , the number of frost days, F , and the number of ice days, I , per month and year. From these observations, simple linear regression models were determined such that F may be derived from N and I may be derived from M for any site within the specified region per given interval of time. Figure 1 gives examples of these regression plots for annual data for Alaska, E. Siberia, Iceland, and Greenland. Figure 2 contains similar plots for monthly data for May, Greenland and April for the other areas. All of the days of the

month were usually below freezing if the mean maximum temperature was $< -6^{\circ}\text{C}$ and above freezing if the mean minimum temperature was $> 6^{\circ}\text{C}$. The corresponding regression equations are of the form:

$$F = a_1 + b_1 N \quad (1a)$$

and

$$I = a_2 + b_2 M \quad (1b)$$

The parameters a and b depend on the data: They serve as constants for any data set. Table 1 lists values of these constants for monthly and annual data for the above regions. The coefficient of determination, r^2 , for the various equations (implied in Table 1) ranged from .50 to .99 with few exceptions: .24 for February, Greenland and .36 for March, E. Siberia. (The value of r^2 indicates the quality of fit between F and N or I and M : 1.0 = excellent fit, 0 = no fit).

Stations were chosen in a given area so as to represent as large a range of temperature as possible. Each pair of equations as (1a) and (1b) is therefore applicable throughout the entire area, with only the parameters M and N changing from station to station.

The parameters (constants) a and b may vary a little with the period of record. If the computations are carried out for M and N in degrees Celsius (as for Table 1), then the value of a equals 160-185 days for the annual data or 12-18 days for the monthly data. In other words, $F(I)$ equals half the days per interval of time if the minimum (maximum) temperature is 0°C . An exception is for the annual number of frost days for Greenland, with $a = 227$. For the annual data, the absolute value of parameter b appears to decrease with continentality, as from 20 for Iceland, a maritime climate, to 6 for E. Siberia, a highly continental climate.

With respect to the monthly data, the value of a tends to be closest to 15 for the months of the transitional seasons, the spring or the fall, when diurnal freeze-thaw cycles are most frequent in this latitude (See Figure 3). Usually the colder the month the higher the value of a , the warmer the month the lower the value of a . Those months for which no constants are given in Table 1 are either too warm (no ice days or frost days) or too cold (all days are frost or ice), therefore no linear relationship. In the computations of the monthly data, the number of frost (ice) days were limited to $1 < F(I) < (n-1)$ where n = total number of days per month.

A comparison between the observed and the estimated annual numbers of frost days or of ice days for test stations is given in Table 2. Values of r^2 for the quality of fit between the observed and estimated frequencies were $>.8$ for each set of stations.

FREEZE-THAW DAYS

The number of freeze-thaw days, Z , per given interval of time, a parameter not available in climatic summaries, may be found by a variety of methods, as by direct counting (Williams 1964) or

by correlation with ΔT (Fraser 1959, Vischer 1945). In the case of just the crossover of the freezing level, as in this study, Z is simply the difference between the number of frost days and the number of ice days, or

$$Z = F - I \quad (2)$$

For each area under consideration, the individual equations for annual F and I were first obtained by means of the appropriate constants in Table 1. The annual Z may be expressed as follows:

$$\text{Alaska} \\ Z = 14M - 10N - 7 \quad (2a)$$

$$\text{E. Siberia} \\ Z = 6(M-N) + 16 \quad (2b)$$

$$\text{Iceland} \\ Z = 18M - 20N - 4 \quad (2c)$$

$$\text{Greenland} \\ Z = 12M - 5N + 59 \quad (2d)$$

A comparison between the observed and the estimated annual Z (Table 2) shows somewhat greater discrepancies than in the cases of F and I , the factors on which Z depends. Values of r^2 , which indicate the quality of fit between estimated Z and observed Z range from .60 to .76 compared to $>.90$ for F and I (except for Iceland for which r^2 was .84).

Equation (2b) implies that Z may be correlated directly with $(M-N)$ or ΔT for E. Siberia. Fraser (1959) found a similar relationship for Canada, although the cycles he investigated were for a larger temperature span, -2° to 1°C , rather than just across the freezing level.

STATION MODELS OF DIURNAL FREEZE-THAW CYCLES

Station models of percent days per month with diurnal freeze-thaw cycles from January to December are given for selected stations in Greenland, Alaska, Iceland, the U.S.S.R, and Germany (See Figure 3). For most of the high-latitude stations, especially those close to the Arctic Circle, the peak incidence of diurnal freeze-thaw cycles occurs during the transitional seasons of spring and fall. The stations are arranged so as to show a gradual change in pattern from an extremely cold climate as Barrow, Nord, or Polar Station where diurnal freeze-thaw cycles prevail only in summer to the relatively warm stations of Annette or Vladivostok, which have relatively long summers with no freezing and the peak frequencies of freeze-thaw cycles in the winter. The German Stations from Zugspitze (2962 m) to Munich (532 m) reflect the effect of altitude on the incidence of diurnal freeze-thaw cycles. The station model for Zugspitze is somewhat similar to that for Barrow (or Polar Station). The plots for the Icelandic stations resemble that of Fichtelberg (or Brocken). At Vladivostok, despite the low latitude, January and December are too cold for freeze-thaw, whereas in Iceland, freeze-thaw occurs all winter.

Another set of station models is shown in Figure 4. This time the abscissa is the mean monthly temperature, however, the ordinate is the same as that of Figure 3, namely the average percent days per month with freeze-thaw. In general, for a given station the daily freeze-thaw cycles per month tend to increase as the mean monthly temperature approaches 0° C. The frequencies per given temperature vary from one station to another. Nevertheless, certain of the models may sometimes serve several stations or groups of stations.

In particular each model shows the temperature limits for its freeze-thaw regime. These limits, as well as the peak amplitudes, are climate dependent.

Station models of this type have also been obtained for numerous other stations in the high and mid-latitudes. A few of these models, as well as an equation which approximates the manual plots in Figure 4, has been given previously (Wexler 1982). See Appendix for the equation. For a highly continental station, as Verkhoyansk (not shown), the freeze-thaw temperature regime extends

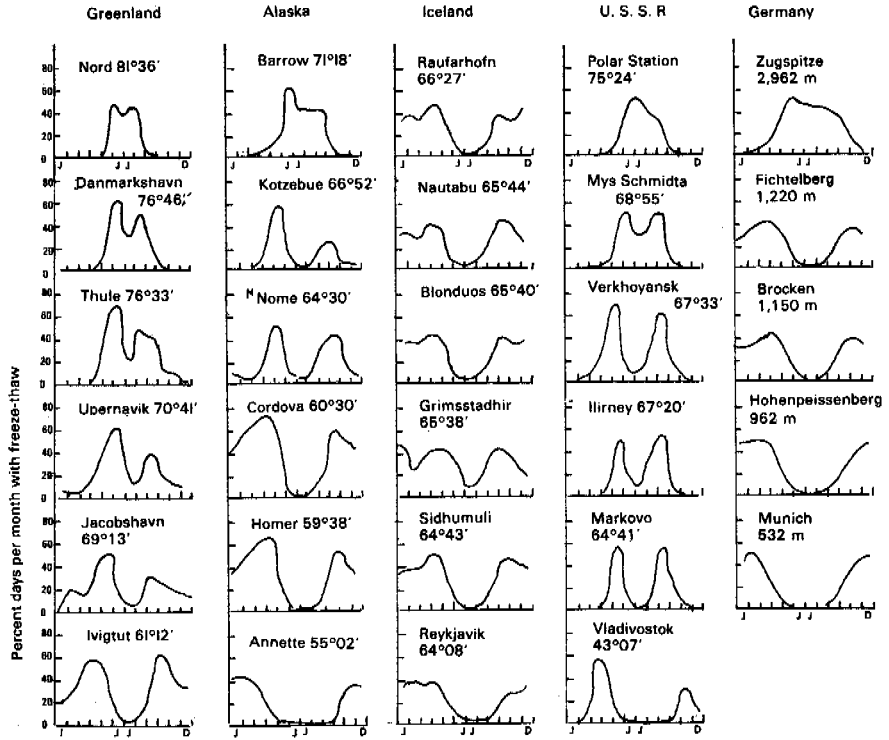

FIGURE 3 Percent days per month with freeze-thaw

FIGURE 4 Percent days per month with freeze-thaw vs. mean monthly temperature.

from about +16 to -16° C with an amplitude of about 68% at about 0° C. Most stations in Iceland have an amplitude of about 40% to 50% with a positive temperature range of about 10° C. Cold Bay, Kodiak, and Annette in Alaska have freeze-thaw regimes similar to stations in Iceland. On the other hand, interior stations in Alaska have much higher amplitudes, about 70% to 80% as Fairbanks, McGrath, and Gulkana, with temperature ranges from 12° C to -16° C. For a number of stations in Greenland the plots (not given) show much greater irregularities of pattern than for Iceland or Alaska, possibly because of the relatively short periods of records.

SUMMARY

Several mathematical and graphical models were presented for estimating the frequencies of frost days, ice days, and freeze-thaw days per month or year for stations in Alaska, E. Siberia, Iceland, and Greenland. Once linear regression equations are determined for the derivation of frost days and ice days, respectively, per given situation, these equations are then applicable to any site within the area, given only M and N for the site. The frequencies of diurnal freeze-thaw cycles then may be readily obtained from the difference between the frequencies of the frost days and the ice days.

Two types of station models were provided, the first the conventional annual cycle of monthly freeze-thaw and the second, the same data plotted per mean monthly temperature. The percent freeze-thaw for a given temperature varies from one station to another. Although the models tend to be distinctive, each depending on latitude (solar elevation), altitude, continentality, and local conditions nevertheless certain of the models may be used to represent groups of stations.

The study shows that diurnal freeze-thaw cycles may not be derived from mean temperatures alone: Essential parameters are the mean daily minimum and mean daily maximum temperatures. The latter yield definitive information concerning frost days, ice days, and freeze-thaw days. The results indicate that periglacial activity might be better correlated with the mean minimum and/or mean maximum daily temperatures per year or month rather than mean temperatures.

APPENDIX

An equation which roughly approximates the manual plots in Figure 4 is given by:

$$y = a \sin Q \quad (3)$$

where

$$y = \% \text{ days per month with freeze-thaw}$$

$$a = \text{amplitude of curve (peak \% monthly freeze-thaw)}$$

$$Q = 1.57 (T + b)/b$$

$$b = T_{y=a} - T_{y=0}$$

$$T_{y=a} = \text{temperature at peak \% (usually } 0^{\circ}\text{C)}$$

$$T_{y=0} = \text{temperature at which freeze-thaw is nil = cut-off temperature}$$

$$T = \text{mean monthly temperature } (^{\circ}\text{C)}$$

NOTE: If the peak % frequency is not at 0° C, let d = departure from 0° C and substitute T-d for T.

ROCK GLACIERS—PERMAFROST FEATURES OR GLACIAL RELICS?

W. Brian Whalley

Department of Geography, The Queen's University of Belfast,
Belfast, BT7 1NN, United Kingdom

The two main models of rock glacier composition, ice-rock mixture and glacier ice cores, are briefly examined. It is argued that there seems to be no evidence which suggests that talus can normally become a rock glacier just by the addition of ice. Talus exists at high slope angles but shows no signs of glacier-like movement. All that appears necessary for a rock glacier to form is relict glacier ice and sufficient debris cover to preserve the core for long periods. As they are such thin bodies of ice, they can flow only slowly; this is sufficient to explain their behavior and distribution. Although permafrost can be present in an area of rock glaciers and may prolong the existence of the ice core, it is not necessary for their formation.

INTRODUCTION

Rock glaciers have been phenomena of interest and controversy since they were described in the early part of this century. Despite much recent work (Washburn 1979), many aspects of rock glacier behavior, formation, and flow mechanisms are still unknown and the paper by Wahrhaftig and Cox (1959) still holds considerable sway, even though some of its conclusions have been questioned. There are problems because of the difficulties of examining rock glaciers in detail and much must be inferred from visual inspection. Tautologically, if it looks like a rock glacier then we may call it so, but qualification may be necessary if something specific is known, e.g., a glacier ice core. This paper is concerned mainly with valley or cirque floor rock glaciers (Outcalt and Benedict 1965) rather than the valley wall type, and the simple term 'rock glacier' alone will be used to identify them. This paper is not primarily concerned with flow mechanisms but discusses problems relating to the occurrence and preservation of ice in rock glaciers.

DISTRIBUTION OF ROCK GLACIERS

Rock glaciers are predominantly alpine phenomena; in Europe, many exist in the Alps (e.g. Barsch 1977, Barsch et al 1979, Haeberli 1975, 1978) although they appear to be very infrequent in Norway (Whalley 1976, Griffey and Whalley 1979). In Scandinavia difficulties in terminology have arisen with respect to "rock glaciers" and "ice-cored moraines" (Barsch 1971, Østrem 1971). In Sweden, transitional forms between the two exist (Whalley 1974) and in Iceland, several examples of rock glaciers have been found (Whalley 1974, Eyles 1978). The range of environments in which rock glaciers are found in North America is reviewed in Washburn (1979) and in White (1976) and of examples in South America by Corte (1976, 1978).

It is usually considered that rock glaciers indicate the presence of permafrost (Barsch et al 1979, Haeberli 1978). Thus,

The climatic snow line and the lower limit of active rock glaciers do not run parallel but diverge from oceanic to continental environments. The general conditions for the formation of rock glaciers are an adequate supply with coarse debris, a favourable topography, and last but not least a climate cold enough to produce alpine permafrost. (Höllerzmann 1980)

The work of Wahrhaftig and Cox (1959) is taken by some authors to be the definitive framework within which to study rock glaciers (Barsch 1971, 1977, Barsch 1978, White 1976). Thus in this interpretation the presence of an active rock glacier is a definite indicator of permafrost. To use the presence of rock glaciers in this way depends upon their having been formed from ice-rock mixtures (Barsch 1978). Some authors (e.g. Washburn 1979) acknowledge that there may be several types of rock glacier mechanics and basic structures to be found: an interstitial ice-rock mixture and a debris-covered remnant glacier (sandwich) are the two main models used.

W.B. Whalley (1974) has suggested that there are difficulties in accepting the mixture model on mechanical grounds. In essence, he argued that an ice-rock mixture has too high a 'yield strength' to flow plastically under the stresses which would be expected from their topography. Conversely, a very thin glacier ice core, protected from melting by overlying debris, would show flow velocities commensurate with those found for rock glaciers.

It is difficult to envisage valley floor rock glaciers being built up by filling the interstices of talus slopes with ice as some have suggested (Barsch 1969) Talus slopes, often bearing snow patches are usually quite distinct from active rock glaciers, which flow at right angles to them. There is a substantial difference in angle of the surface of these features; talus slopes are generally at 35° - 40° whilst the general rock glacier surface is rarely greater than 10°. Two notions arise from this. Why, if melting snow percolates into the talus slopes and then refreezes, does talus not form valley side rock glaciers? With an angle of twice (at least) that of the valley floor rock glacier, the shear stresses

in talus might be expected to allow the ice in the interstices of the mixture to flow. This rarely seems to be the case. Conversely, it is the rather low-angled rock glaciers which move. Thus the latter must develop a much lower basal shear stress than the talus slopes.

The assumption must be that rock glaciers can move because in fact they are still glaciers and possess thin ice cores which are protected from melting by accumulated debris. The ice core deforms according to the flow law for ice and actual rock glaciers show close agreement with predictions from the flow law (Whalley 1974). Although drilling (e.g. Barsch et al 1979) has found ice-rock mixtures this does not show that the whole thickness of the rock glacier is an ice-rock mixture. In the sandwich model, rock glaciers are viewed as being different from ordinary glaciers only in the amount of surface debris carried and, consequently, in their response to climatic changes. This last factor includes the mass balance of the original glacier and debris-induced modifications. There is a gradual transition between active glaciers, composed entirely of ice and with no debris cover, through glaciers with a heavy debris load to rock glaciers. The final stage is a stagnant rock glacier from which the once-present ice core has melted. This viewpoint is much simpler than the possible origins proposed by J.P. Johnson (1973) or P.G. Johnson (1980) as it supposes that substantially all the ice which is responsible for rock glacier flow is of true glacial origin. It is no longer a problem to explain the origin of the ice although the way in which the ice is preserved does need explanation.

FIGURE 1 Curves showing relations between ablation and debris cover for three glaciers at various latitudes.

PRESERVATION OF ICE CORES

Debris cover on an ice surface protects the ice below; the amount of protection depends mainly

upon climatic factors. Østrem (1959, 1964) and Loomis (1970) give what few data there are on this problem. Figure 1 shows their curves as well as one for Feeegletscher (Switzerland), which at 2,100 m lies well below any permafrost. Local climate and debris thickness are primarily responsible for the preservation of ice cores. If sufficient debris can accumulate over an ice core and ablation cut to a minimum then the core can be preserved for great lengths of time (Østrem 1959, 1964). Geothermal heat flow will, in the absence of permafrost, allow some ice to melt at the base of the core but this will be rather small, of the order of a few mm per year (Paterson 1981) and would probably not approach the amount of surface melting. Melting due to the frictional flow of ice is likely to be negligible because rock glacier flow rates are very low. There is a general lack of data at rock glacier sites to indicate the amount of melting although several authors have reported streams emerging from the snouts of rock glaciers (Corte 1978, Johnson 1981).

EFFECT OF DEBRIS ON GLACIERS

A debris cover suddenly imposed on the ablation area of a glacier reduces the ablation rate and, for a given glacier in a steady state, this means that the ablation area will no longer be effective in balancing the accumulation. The extension of a glacier to compensate for such an apparent loss of ablation area is seen in some glaciers in the Alps (Renaud 1964) as well as in more northerly latitudes (Bull and Marangunic 1968).

Debris falling in the accumulation area of a glacier ultimately emerges in the ablation area and may reduce ice ablation as just described. Snow input must greatly exceed any debris input so that an ice-rock mixture could not be formed in this way.

Debris accumulates at a glacier snout, producing a slow response of the glacier with respect to modified ablation rates. Any glacier extension will depend upon the climatic control of ablation rates as well as upon changes in accumulation and the debris thickness. If we consider a glacier which is losing mass (i.e., a negative ice mass balance) but whose snout is advancing due to an increase in debris cover, then a steady state may be achieved very rapidly. For an uncovered glacier there would be a continued retreat, dependent on the length of time during which the mass balance is negative. For two identical glaciers, both with the same negative net mass balance but one free from debris and the other heavily charged at the snout, the latter will keep its snout position very much longer than the clean glacier—entirely due to the reduction of snout ablation. In practice, there will be many variables operating over time; however, no comparisons of this type have been done. Generally, the more debris the lower downvalley the snout position will be. If ice discharge is restricted or debris supply very great then the behavior is modified and a rock glacier may form (Whalley 1976, Griffey and Whalley 1979).

There will come a time when the ice supply is totally cut off from the glacier ice below the debris due to the disparity of ablation rates.

Before this happens there will be a thinning of the exposed ice; this is the reason for the spoon-shaped hollow noted by many authors and is sometimes acknowledged as such (Potter 1972). In an extreme case, a sufficient cover of debris over a considerable glacier area could result in a glacier advance even though the glaciers in the area are generally retreating. Such a case is described by Michaud and Cailleux (1950) and is commonly seen in the rock glaciers in the Hindu Kush mountains (Whalley, unpublished data).

In many cases of glacier retreat the debris cover is too thin and the ice discharge too great to provide any reduction of the ablation rate in the ablation area; hence the thinning is rapid. However, if debris accumulation at the snout is substantial or the ice discharge is reduced then the effect of the debris on the glacier dynamics will become increasingly important. As long as there is contiguity between accumulation area ice and the debris-covered ice of the core, then the system will behave in a predictable way, very similar to a glacier with little or no debris (Griffey and Whalley 1979). If a glacier does get cut off from its accumulation area, then it may exist for a long time, dependent upon the thermal conditions, but will eventually decay (Whalley 1979, Griffey and Whalley 1979).

EFFECTS AT THE ROCK GLACIER SNOT

Active rock glaciers are usually so-called because of the fresh appearance of the debris at the snout, i.e., occasional rockfalls and an unstable surface inclined approximately at the resting angle of the material. If the snout is not fresh, then the rock glacier is usually considered to be inactive.

Yearly movements of the debris at the front of an active rock glacier represent, according to the interstitial ice model, the amount of debris discharging through the system. In a steady state ice-cored rock glacier this is also true but frontal movement is a function of both debris discharge and the amount of ablation of the ice core. If extra ice arrives at the snout (which then advances, due to a positive mass balance or reduction in ablation), then an exaggerated debris discharge would be calculated. Such an advance is a normal consequence of glacier movement. The exact relationship between ablation, the forward movement of the ice, and the debris quantity is uncertain without detailed measurements of ice core melting characteristics. It has been assumed (Barsch 1977) that the volume of a rock glacier represents the quantity of debris removed from cliffs above. However, this is only true if the debris-ice mixture model applies and it is not so if there is a glacier ice core. Similarly, calculation of annual debris discharge at an advancing snout would also seem to be in error if the interstitial-ice model is used. Reactivated rock glaciers (Wahrhaftig and Cox 1959) show fresh, steep, snouts though there may be no apparent movement of the rock glacier. Clearly, the appearance of the rock glacier front is not a good guide to what is happening to the system as a whole.

Figure 2 illustrates three possibilities of

frontal change with the glacier ice core model. In Figure 2a the ablation balances the ice income and the net position of the snout is static. At the very front however, surface debris does move from stable to unstable positions due to slight seasonal variation of position. If the ice flow is weak and the ice thin, then movement about the mean ice front position is small and the face ultimately may become relatively stable with very little movement of the surface debris.

In Figure 2b there is a decreasing ice input for a given climate and this gives a general surface lowering. However, debris is still added to the snout if the ice remains active. Decreasing surface velocity can still give a fresh snout appearance. Increasing debris thickness at the snout gives increased protection to the ice so that there may be a return to equilibrium and, ultimately, a low-angled and stable snout.

FIGURE 2 Changes at the fronts of rock glaciers with changing mass balances. See text for details.

In Figure 2c any lifting of the ice surface through a positive ice mass balance is most pronounced at the snout and the ice velocity increases. Debris dumping is accelerated but thins the protective debris layer relative to its volume; thus ice ablation increases. This ultimately gives increasing stability as debris covering the ice toe thickens again.

What these three basic regimes do not show is the complex way in which the nature of any individual rock glacier may alter due to changes in the ice mass balance or debris input. Which balance dominates depends upon factors such as debris supply and glacier length. For instance, a kinematic wave bringing down 'extra' ice will not carry a corresponding debris supply; conversely, a rockfall will produce a substantial debris increment.

A variety of situations exist relating the protective nature of a debris cover to the ice mass balance. There is considerable complexity of dynamics as well as topography for rock glaciers but it would appear that the sandwich model only needs changes in two basic parameters--debris and ice supplies--to accommodate them. We do not need to imply gross changes of climate for the formation of a rock glacier but rather adjustments between the two supplies.

THE ROLE OF PERMAFROST

The presence of permafrost could almost permanently protect an ice core. In such cases it is possible that the glacier ice core may move very slowly downhill under its own weight plus that of the overburden debris. It is possible that a variety of forms such as protalus lobes and the lobate rock glacier of Wahrhaftig and Cox (1959) could be formed in this way. The ice mass could be glacial (Brown 1925) or snowbank (Outcalt and Benedict 1965); it would merely have to be sufficiently thick to flow and be protected by a debris cover.

In W.F. Thompson's (1962) discussion of Balch ventilation, the idea of addition of ice to a glacier surface through covering debris is not proposed but there is no reason why melting snow on the surface of the debris should not melt, percolate through the rocks, freeze on top of the glacier ice and be preserved by the Balch mechanism. In this way it would be possible to build up debris encased in ice near the equilibrium line. Such superimposed ice would be very similar in origin to that found on polar glaciers (Müller 1962) and would act in the same way, lowering the equilibrium line to below the visible snow line. In the ablation area, melting of the true glacier ice below the debris/ice mantle would be further reduced as this "superimposed" ice is melted instead. This is one link with the interstitial ice hypothesis; various authors have reported an ice-rock mixture above glacier ice (Brown 1925, Outcalt and Benedict 1965). In the main hypothesis of the sandwich model this is merely an addition, possible where there are permafrost or near permafrost conditions, but it is not the main driving force of the rock glacier. If interstitial ice and rock debris are found on a rock glacier; the likelihood is that glacier ice exists below. In discussing the rock glaciers at Grubengletscher, Whalley (1979) has found and interprets a glacier ice core whilst Barsch et al (1979) have found interstitial ice. It is probable that this is an example of interstitial (superimposed) ice overlying a glacier ice core.

If the ablation area of a rock glacier-ice

glacier system is well-covered with debris, then even a very small debris-free accumulation area (and net accumulation) will be sufficient for ice replenishment, both conventionally and by superimposed ice within the rock debris.

CORRIE GLACIERS AND ROCK GLACIERS

Proponents of the interstitial ice model for rock glacier flow do not consider that the proximity of a true corrie glacier indicates a connection between the two, either at present or in the past. This idea seems untenable, not only because the mechanics demand a solid, though thin, ice layer which can remain there (due to its protective cover) but also because of the relationship of ice and debris mass balances.

For a given climatic regime, a rock glacier is most likely to form where the corrie glacier is small rather than large (Whalley 1974). The formation is due to the large amount of rock debris falling onto the ablation area in relation to the activity of the glacier in removing it. This effect can be seen in a comparison of the rock glaciers and corrie glaciers of the Colorado Front Range (Whalley 1974).

Rock glaciers in northern Iceland show close relations of corrie glaciers to the mass balances of debris and ice (Whalley 1974). The debris input from the disintegrating cliffs is sufficient to keep the glaciers covered, even though the ice discharge is high. In various examples examined by the author no superimposed ice was seen, although in one case glacier ice could be traced all the way from the edge of the debris covered zone to the snout. Although there is plentiful evidence of sporadic permafrost in Iceland (Priesnitz and Schunke 1978) there is no evidence related in any way to the rock glaciers found in the Akureyri region or to the example described by Eyles (1978). The rock glaciers descend to around 800 m, the only explanation being that they are intimately related to corrie glaciers and not to the presence of permafrost.

CONCLUSIONS

There is evidence for the existence of rock glaciers in many parts of the world; they may occur in regions of sporadic, discontinuous or continuous permafrost. This does not necessarily mean that there is any implicit connection between them. It has been argued that mean annual temperatures near zero may favor refreezing of snowmelt. This adds to the ice supply of ice-cored rock glaciers in a way analogous to superimposed ice found on many northern glaciers.

There is opportunity for rock glaciers to form directly from talus but this is rarely, if ever, the case. They can form (to give lobate or valley-side forms) where the debris supply is great and where it spills onto a small glacier, glacierette or large snowpatch (Whalley 1979). There is evidence that rock glaciers are closely related to corrie glaciers, even if the former have now ceased to exist. It is usually stated that the evidence for lack of glaciers (but presence of

periglacial conditions) in the Pleistocene is lack of moraines. Conversely, it can be argued that rock glaciers actually are the moraines and that this is what would be expected because of the close relationship between rock debris and ice mass balances in their formation. Terminal moraines, rock glaciers, and protalus ramparts are related forms, only differing in topography.

The complex and varied forms of rock glaciers are often assumed (e.g., Johnson 1974) to indicate the operation of a number of mechanisms. A much simpler explanation is achieved if the sandwich model, based upon glacier ice preservation, is accepted. Much still needs to be explained about rock glaciers and their relation to climate. It would appear that they are not good indicators of climatic conditions and may exist in their present form substantially unchanged for long periods. Just how long depends upon such factors as local climate (mean air temperature and radiation), debris cover thickness and any contiguity with an ice accumulation area. Thus they are also insensitive in their relationship to permafrost of whatever type. The presence of permafrost may help to preserve a rock glacier but does not cause it.

ACKNOWLEDGMENTS

I thank various people who have assisted with field work or discussion at various times: Peter Birkeland, Jack Ives, Gunnar Østrem, Helgi Björnsson, Malcolm Clark, Tony Escribano, and Nigel Griffey. Jim McGreevy and a reviewer made valuable suggestions about the paper.

COLD-MIX ASPHALT STABILIZATION IN COLD REGIONS

Antoni S.E. Wojcik¹, Peter M. Jarrett² and Anthony N.S. Beaty²

¹Construction Engineering Unit, CFB Winnipeg, Westwin, Manitoba, R2R 0T0, Canada

²Department of Civil Engineering, Royal Military College,
Kingston, Ontario, K7L 2W3, Canada

Problems arising with unbound aggregate runways in the northern environment are identified and arctic paving experience briefly reviewed. Following consideration of a range of possible stabilizing agents, cut-back bitumen was identified as being the most promising for conditions in the high arctic. A modified Marshall method of mix design for cold-mix stabilization of northern aggregates near to 0°C is described. Laboratory and field test results are presented and the effects, on ground temperature, of unbound, stabilized and white painted stabilized pavements are reported. It is concluded that cold-mix stabilization, at temperatures little above freezing, is feasible using the method described.

INTRODUCTION

All of Canada's major population centres are found close to its southern border. These are served by transportation links which run essentially along an east-west axis. However, the great land mass of Canada lies to the north of this populated region and extends almost to the North Pole. This vast area has a very low population but contains increasingly important mineral and energy reserves. The provision of amenities to the population, the development of the resources and the exercise of sovereignty can only be assured if a reliable transportation system exists throughout the region.

The principal means of transportation in the region is the aircraft. Unbound aggregate runways form by far the most common landing sites. These runways may, depending on the quality of local aggregate, suffer from the following problems during the warm season:

- rutting of the surface
- formation of dust clouds causing poor visibility and loss of fines
- flying stones with the potential to damage aircraft
- imperfect drainage due to deterioration of the profile

In view of the importance of such runways to the communities they serve, it would be desirable to develop a cost effective form of surface stabilization to alleviate these common problems. The stabilization methods must be applicable under the local climatic conditions and with the local aggregates.

ARCTIC PAVING EXPERIENCE

A number of runways in the North have successful, conventional, hot-mix asphalt pavements. These include Inuvik, Frobisher Bay, Whitehorse and also Thule in Greenland. One problem considered in design has to be the effect on the ground thermal regime of imposing a heat absorbing black surface. In Thule this problem

was avoided by painting the asphalt surface white to prevent thawing of unstable soils lying beneath the runway. However, for most small communities a full hot-mix asphalt pavement is not economically justifiable. One therefore turns to less demanding methods. Transport Canada is believed to have laid trial sections of cold-mix asphalt at Rankine Inlet to observe its effect on the thermal behaviour. No results have been published, however. The main street of Inuvik was successfully stabilized using a mix-in-place asphalt stabilization method. An MC250 cut back bitumen was used at between 5 and 6 percent by mass of aggregate. In this installation, insulation was placed beneath the pavement system where thaw-unstable soils were present. This case is the only major northern use of cold-mix stabilization known to the authors. One probable reason for this is the Asphalt Institute's (1977) guideline that cold-mix not be used below about 10°C.

In the work reported in this paper, various possibilities for stabilization in the Arctic region were considered and the specific case of a gravel runway at Canadian Forces Station Alert on Ellesmere Island was studied in detail. Full details of the work have been given by Wojcik (1982).

CHOICE OF STABILIZER

The stabilizers and dust palliatives considered in general were:

Fuel or Road Oils which can be used as short term dust palliatives but require frequent renewal as they have low residual bitumen after evaporation and may be washed out by rainfall.

Lime stabilization requires more fines than were present in the aggregate at the specific site considered, but also in general, the full development of the cementing action intrinsic to lime stabilization requires higher temperatures than prevail in the north.

The use of Portland cement to form soil-cement is feasible. This was shown by

construction of a small trial section at Alert. However, its long term durability is not known and fears have been expressed concerning maintenance difficulties should the hard, brittle, cement-stabilized material begin to break up under the thermal regime of the high arctic.

Lignosulphonates are chemical by-products of the pulp and paper industry that have been used as dust palliatives. They are water soluble and so are prone to leaching from the stabilized material. However, under the relatively dry conditions common in many arctic areas, this may not be a severe problem. Certainly laboratory and small scale field trials conducted during this project show this method to be of potential interest and worthy of further study.

Bituminous emulsions will work at low temperatures. This again was shown in a small scale field trial at Alert. However, bituminous emulsions break down if subject to freezing. Logistically, it is difficult to guarantee that the material would not be subjected to freezing during shipment to the north. This form of bitumen was therefore discounted.

Cut-back bitumen was considered to offer the most promise especially for the high arctic location under consideration. At the site the mean daily temperature is above freezing only during July and August and only in July is the mean minimum daily temperature above freezing. The construction season therefore lasts only about six weeks with the mean temperature between 0°C and 4°C. Further details of the climate and ground thermal regime have been given by Taylor et al. (1982) for that period. Because of these low temperatures, only low viscosity cutbacks were considered. The results presented from laboratory and field trials deal with a Gulf Oil RC-30 cutback and a Primer. The products are similar but have the following slight differences:

Property	Primer	RC-30
Kinematic Viscosity at 60°C, cs	26.2	33.0
Minimum Residue by volume, %	60.0	65.0
Solvent type	Gasoline	Heavy Reformate

MODIFIED MARSHALL MIX DESIGN

No widely accepted method is available for the design of cold-mix asphalt pavements. Lefebvre (1966) and Head (1974) used modifications of the Marshall method commonly used for hot-mix design. A similar approach was adopted for this study. Marshall samples were compacted using 75 hammer blows per face, then cured and tested in a cold room maintained at 4°C, Wojcik (1982). This temperature was selected to represent the mean daily temperature at Alert in July. The grading of the crushed rock aggregate used at Alert and in these mixes is given in Figure 1.

FIGURE 1 Typical grain size distribution for aggregate from CFS Alert crusher.

The design aircraft is the Lockheed Hercules transport, operating at a tire pressure in the range 0.55 to 0.69 MPa and having a maximum take-off mass of 70,400 kg. For design purposes, this aircraft falls within load classification group IV. Consideration of these characteristics and of values typically cited for hot-mix asphalt tested at 60°C led to the following target values for the cold-mix design:

Minimum stability	4000 N
Maximum flow	4 mm
Voids in the mineral aggregate	14%
Air voids	3-5%

From the results obtained with binder contents varying between 3 and 6 percent by weight of aggregate it appears that 5 percent binder content is optimal in meeting these design criteria. The following are the results at that percentage:

Property	RC-30	Primer
Bulk density (kg/m ³)	2330	2360
Air voids (%)	4.1	4.2
VMA (%)	12.2	12.3
Marshall stability (N) (3 day curing)	5900	5800
Marshall flow (mm)	5.3	4.0

Samples prepared over the same range of bitumen contents were also subjected to freeze-thaw cycling. Whilst no criteria are available with which to compare results certainly those samples with 4 percent or less were inadequately bound and showed signs of wear after 12 cycles.

LABORATORY TESTING PROGRAM

Having decided on an optimum mix, a laboratory testing program was instituted to study the effects of variation of the mixing and

compaction temperatures and to study the rate of curing. Sets of identical Marshall samples were prepared and compacted at temperatures of 0°C, 4°C and 10°C. They were weighed and then cured at 4°C for periods of up to sixty days. Periodically samples were reweighed and the Marshall test performed. Results of stability and solvent loss against curing time are shown in Figure 2 for the case of the Primer mixed at 4°C. These results

FIGURE 2 Solvent loss and Marshall stability versus curing time for Primer-aggregate specimens prepared at 4°C.

are typical of all series for both the binders used and show the expected parallel development of strength with solvent loss. In general the rate and extent of curing is slower than that experienced at higher temperatures but is still thought to be adequate to allow construction of a useable pavement. Mixing temperature did not markedly affect the results. Stabilities were perhaps 10 percent higher and mixing easier at 10°C compared to 0°C. Indeed at 0°C with the more viscous RC-30, hand mixing was difficult and some cases of incomplete coating were noted. No consistent variation in compacted density was obtained over the range of temperature investigated.

FIELD TRIALS

In the summer of 1980, a series of preliminary small trial sections 10 m long by 5 m were constructed on a road at Alert. These included Lignosol, soil cement, bituminous emulsion, fuel oil, chip seal and control sections. Mixing was achieved using a grader to turn windrows of aggregate on which the stabilizer had been sprayed and placed. From these trials and the results of the laboratory testing program, it was decided that cold mixing at low temperature was both possible and potentially a useful method of stabilization. Therefore in July 1981, a series

of larger test sections was constructed on the turning circle at the end of the runway in Alert.

In brief, an 8 cm thick pad of compacted crushed rock aggregate was laid over an area of approximately 20 m by 60 m. The aggregate was compacted at its optimum moisture content of 6 percent. Four lanes, each 3.8 m wide, were laid out on this pad using 5 cm by 10 cm timbers as dividers. Stabilized aggregate was then prepared using a Cedarapids pug mill with a 700 tonne per hour capacity. For the small trial sections constructed, this machine was operated for only brief periods at its slowest production rate. This fact, combined with problems in calibrating the bitumen flow rate and the limited quantity of bitumen available on site, led to mixes that were not proportioned exactly as originally intended. However, mixes were prepared over a wide range of bitumen contents. These mixes were then laid in the lanes on the compacted pad, screeded and raked flat using the timbers as a guide and compacted using a 9 tonne vibrating roller. The as-built sections with their various bitumen contents, as determined by bitumen extraction tests, are shown in Figure 3. The construction was carried out over a period of 3 days during which time the mean temperature was approximately 3.4°C. The aggregate temperature was between 0°C and 1°C.

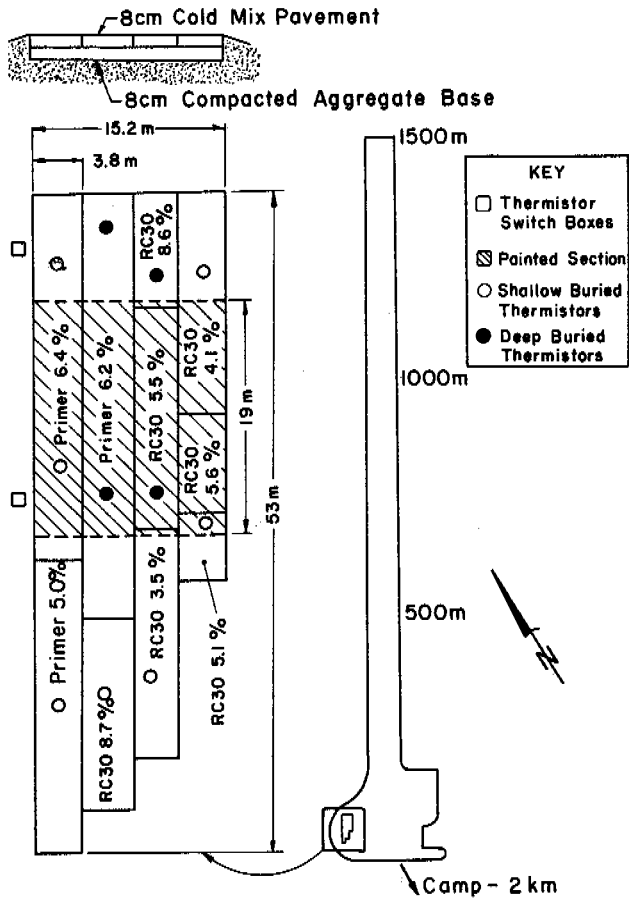

FIGURE 3 Layout of field trial sections as built.

The following construction details are of significance: The mixes looked good with an even distribution of the bitumen over the particles. Even the more viscous RC-30 mixed well. This was attributed to the fact that the pug mill imparts more energy to the mixing than could be achieved by hand in the laboratory. Compaction of all sections was monitored using a nuclear-density gauge and confirmatory sand-cone tests. Density was measured after each double pass of the roller. A comparison of the field densities after six roller passes and the laboratory densities from the Marshall test is given in Figure 4. This

FIGURE 4 Laboratory and field bulk densities for RC30 cutback-aggregate mixtures.

indicates that approximately 97 percent of laboratory compaction was achieved in the field. Vibration was observed to be of definite benefit. Bleeding occurred in the sections with high bitumen contents (8.7% and 8.6% RC-30, 6.4% Primer).

After compaction, field CBR tests were made on each section as a measure of the strength. It was realized that CBR is not a normal test for asphaltic materials, but under the circumstances it was the only test practically possible. The rate of strength gain with time was studied by periodically repeating the field CBR tests. Typical results for three of the RC-30 sections are shown in Figure 5. These results are felt to be representative. The scatter is attributed to variations in temperature of the surface with time and the size of aggregate compared to the CBR plunger as well as normal variation attributable to non-homogeneity. The trends shown were, however, consistent. The sections with a high bitumen content (8.6% and 8.7% RC-30) were very soft and clearly contained excessive bitumen. Also, they were not curing very rapidly. The low

FIGURE 5 Corrected field CBR values versus curing time for RC30 cutback-aggregate trial sections.

bitumen content specimens (3.5% and 4.1% RC-30) were the strongest, as they were in the laboratory. However, there was insufficient bitumen present in these sections to coat the particles fully. This affects the permeability of the stabilized material and in the long term its durability also. In September when the fifty day CBR measurements were made, ice crystals were observed within the fabric of these sections. The ice may have been a factor in the relatively high strength measured but would certainly also represent the first stage in a break down process. The sections with bitumen contents close to 5 percent represented the "design" condition. The degree of compaction achieved in the field was good and yet the strength values were rather lower than expected, with some early softness noticed in subjective judgment of the sections. From Figure 5, it is seen that the CBR was 30 percent after one day and about 45 percent after 4 days. The curing rate then slowed considerably. A correlation was attempted in the laboratory between Marshall Stability in Newtons and CBR. For stabilities between 4000 and 6500, the following relationship held with a correlation coefficient of 0.94:

$$\text{Marshall Stability} = 36.5 \text{ CBR} + 1925$$

For a CBR of 45 percent, by extrapolation this gives a stability of 3568 N which is rather less than the desired minimum and considerably less than the equivalent stability obtained in the laboratory. This may be due to a combination of a slower rate of curing in the field and variability between the field and laboratory methods of measuring CBR. This latter point is considered the most probable.

It was also decided to investigate the effect of the paving on the ground thermal regime. To provide a wider range of information, part of the paved area was painted white. "Deep" strings of thermistors were installed every 30 cm to depths of approximately 1.5 m. In addition, thermistors were placed within the stabilized layer and also in the compacted base course. "Shallow"

thermistors were placed only in the asphalt and base courses. The thermistor locations and the painted area are shown in Figure 3. An additional deep string of thermistors was placed at the edge of the runway.

Readings were taken from the time of construction until freeze-up in September. Figure 6, compiled from these results, shows the variation with time of the depth to the freezing plane. This indicates a significant increase in the depth of thaw beneath the black paved section

FIGURE 6 Depth of thaw under the unpaved runway, the unpaved pavement and the white painted pavement.

and a decreased depth of thaw beneath the white painted section as compared to that beneath the gravel runway which is grey-brown in colour. Comparison of the air temperature with that of the pavement surface showed that the temperature of the white painted section was close to or less than the air temperature whereas the black section was considerably warmer than air temperature for most of the time. It should be noted that these results represent only a portion of the thawing season and so should not be considered indicative of a full season's thaw depth.

CONCLUSIONS

1. It proved possible to mix, lay and compact cold-mix asphalt under arctic conditions with operational temperatures close to 0°C.
2. The modified Marshall method of mix design yielded a bitumen content which proved satisfactory in field construction and reliably predicted achieved field densities.
3. The overall results verified the viability of cut-back bitumen for construction of a stabilized pavement under arctic conditions. Further observations will be required to determine the long-term performance of the stabilized pavement.

BASIN WATER BALANCE IN A CONTINUOUS PERMAFROST ENVIRONMENT

Ming-ko Woo, Philip Marsh, and Peter Steer

Department of Geography, McMaster University, Hamilton, Ontario, Canada L8S 4K1

The hydrology of a basin in the continuous permafrost region of Canada was studied for 6 years to establish seasonal and annual water balances. Emphases were placed upon the spatial and temporal variations of snowmelt, rainfall, evaporation, streamflow and active layer storage capacity. Spring melt released considerable meltwater which could not be accommodated by a thinly thawed active layer. High runoff resulted. Evaporation was active concurrently but from the snow-free portion of the basin. Summer rainfall was often of low intensity. Storage capacity increased as the frost table receded and much of the rain could be held in the active layer to maintain evaporation and baseflow. Over the years, snowfall constituted about three-quarters of annual precipitation, about 80% of which was consistently removed by runoff. Annual evaporation was small and net change in storage for the 6 year period was also of low magnitude.

INTRODUCTION

The water balance for an arctic drainage basin is

$$M + R - E - Q = ds/dt, \quad (1)$$

where M is snow and ice melt, R is rainfall, E is evaporation, Q is runoff, and ds/dt is change in storage. Dingman (1973) regarded the water balance to be a fundamental environmental characterization of a geographic region. Yet, for the arctic, the paucity and the inaccuracy of the hydrometeorologic data render water balance computations difficult. One consequence is that most attempts were restricted to individual components of the water balance.

Another problem is the lack of spatially distributed information. Most studies made use of single point measurements to represent basin gains or losses. This is inadequate because topographic variations often cause uneven distribution of snow or rainfall. Similarly, evaporation determined for a station cannot be substituted for basin evaporation without accounting for the daily changing basin snow cover (Woo et al. 1981). Further, all water balance studies have ignored the presence of permafrost at shallow depths. A thinly thawed active layer provides limited storage capacity and encourages runoff (Woo and Steer 1982), and a deepening of the frost table consumes energy for thawing which otherwise is used to warm the ground or to increase evaporation.

This study recognizes the need to consider all the components of equation (1) in attempting a basin water balance; to deal with the areal variations of hydrometeorologic variables; and to continue the research over several years to ensure representativeness of results. Our objectives are therefore to establish the seasonal and annual water balance for a small basin in the High Arctic, and to relate the water balance to the hydrologic conditions of the continuous permafrost region.

STUDY AREA AND METHOD

The McMaster River basin (area 33 km²) was selected for this study because it is centrally located in the Canadian Arctic archipelago and is close to a weather station at Resolute (74°45'N, 94°50'W). The basin has a rolling topography, with elevation ranging between 85 and 200 m a.s.l. (Figure 1). The dominant surface materials are gravel and loam with only patches of tundra vegetation scattered over an otherwise barren landscape. The weather station reports a January mean minimum of -36°C and a mean July maximum of 7°C. Continuous permafrost is maintained, usually at 0.2-0.7 m below the ground surface. The snow cover lasts for about 9 months each year, and such hydrologic activities as evaporation and runoff are confined between late June and early September.

FIGURE 1 Topography of McMaster basin with contours at 50' intervals.

This study was carried out between 1976 and 1981. Emphases were placed upon the spatial variation of hydrometeorologic quantities in the basin. Extensive snow surveys were conducted in late winter (May or June) using a method described by Woo and Marsh (1978). In summer, a network of 5-15 gages was deployed to establish the spatial variation of rainfall. Results of these measurements were used to adjust the precipitation data reported by the Resolute weather station.

Snowmelt was determined at a central site using the energy balance approach (Woo et al. 1981). In extending the computation to other parts of the basin, corrections were made for temperature and vapor pressure differences (Brutsaert 1975). To obtain mean melt rate for the basin, n terrain units were first recognized, and the mean premelt snow storage held in each unit was determined by the late winter snow survey. When melt began, basin snowmelt (M) on day t is

$$M(t) = \sum_{i=1}^k m_i(t) a_i / \sum_{j=1}^n a_j, \quad k \leq n, \quad (2)$$

where k of the n units remains snow covered on day t , m_i is melt rate for terrain unit i calculated by the energy balance approach, a_i is the area occupied by unit i , and there were $n = 24$ units for McMaster basin. The amount of snow remaining at unit i was updated daily by

$$\begin{aligned} ps_i(t) &= ps_i(t-1) + p_i(t) - m_i(t), \\ ps_i(t) &\geq 0, \end{aligned} \quad (3)$$

where $ps_i(t)$ is the snow stored at unit i on day t , and $p_i(t)$ is new daily snowfall. When $ps_i = 0$, terrain unit i becomes snow free and the bare ground would be incremented by a_i .

Evaporation was computed using the Priestley and Taylor (1972) approach,

$$e = \alpha[\Delta/(\Delta + \gamma)](Q^* - Q_G)/L_v \rho_w, \quad (4)$$

where e is evaporation, Δ is the slope of the temperature-saturated vapor pressure curve, calculated as function of air temperature (Dilley 1968), γ is the psychrometric constant, Q^* is net radiation, Q_G is ground heat flux, L_v is the latent heat of vaporization, ρ_w is water density, and α is an empirical coefficient which varies with surface soil moisture (Marsh et al. 1981). Net radiation was measured with a Swissteco net radiometer. Ground heat flux was estimated by (Rouse 1982)

$$Q_G = \int_{z=0}^{z_0} c \frac{\partial T}{\partial t} dz + L_f \rho_w I \frac{\partial z_f}{\partial t}, \quad (5)$$

where z_0 is the depth at which the annual soil temperature amplitude equals zero, c is soil heat capacity, T is soil temperature, L_f is the latent heat of fusion, I is the fractional ice content, and z_f is the depth of the frost table. Field evidence showed that the heat that warms the ground (first term on the right-hand side) can be neglected because its magnitude is small compared with the heat required to thaw the active layer (second term). The thaw depth (z_f) τ days after ground thaw began, can be obtained as (Woo 1976).

$$z_f(\tau) = \beta \sqrt{\tau}, \quad (6)$$

where β is a coefficient, empirically found to be 0.1 for gravel soils in the Resolute area. Field observation showed that the soil pores immediately below the frost table were usually filled with infiltrated meltwater which subsequently refroze (Woo and Heron 1981). The ice content can therefore be approximated by the soil porosity (ϵ) which averages 0.37 for the study basin. Then,

$$Q_G \approx [z_f(\tau) - z_f(\tau-1)] L_f \rho_w \epsilon. \quad (7)$$

Evaporation occurs only in the snow-free areas, and daily evaporation for the basin (E) is

$$E(t) = \sum_{i=1}^m e_i(t) a_i / \sum_{j=1}^n a_j, \quad (8)$$

where m terrain units are snow free on day t .

Discharge was measured twice daily using the velocity-area method during spring when the channel was not yet stabilized (Woo and Sauriol 1980). When a stable channel was established, river stage was recorded by a Leopold-Stevens Type F recorder and the stage was converted into discharge using empirically derived rating curves.

RESULTS

Water Balance During Melt Period

Snow is unevenly distributed at the end of winter. Figure 2 gives an example of snow storage in McMaster basin at the end of May 1978. In a typical year, areas with little snow included hilltops and exposed flat areas, but topographic depressions such as valleys and gullies had considerable snow. Snowmelt often began in June and progressed quickly, fragmenting the snow cover where the pack was thin. Several processes then occurred simultaneously. The snow-covered areas yielded meltwater, while the bare ground experienced evaporation. The shallow thawed zone of the bare areas had little storage capacity, and the excess water moved rapidly downslope as surface flow (Woo and Steer 1982). Upon reaching the deep valley snowpacks, the bulk of the flow was absorbed as liquid water storage. It was when these deep packs were partly saturated that channels were initiated within, above, or below the snow barrier to convey the first streamflow (Woo and Sauriol 1980).

Being controlled by the above processes, the water balance provides a quantitative expression of the hydrologic conditions. Figure 3 is an example drawn from 1979. When the snow cover was extensive, meltwater was released from almost the entire basin and the weighted basin melt contribution was high. Gradually, a shrinking snow cover diminished the water supply, accompanied by increasing basin evaporation due to the enlarged bare area. The combined magnitude of snowmelt and the occasional rainfall, however, overwhelmed the evaporation loss.

Meltwater can be held in deep snowpacks or in the thawed zone of the active layer. On any day t after the initiation of melt, the amount of water storage (s_t) is

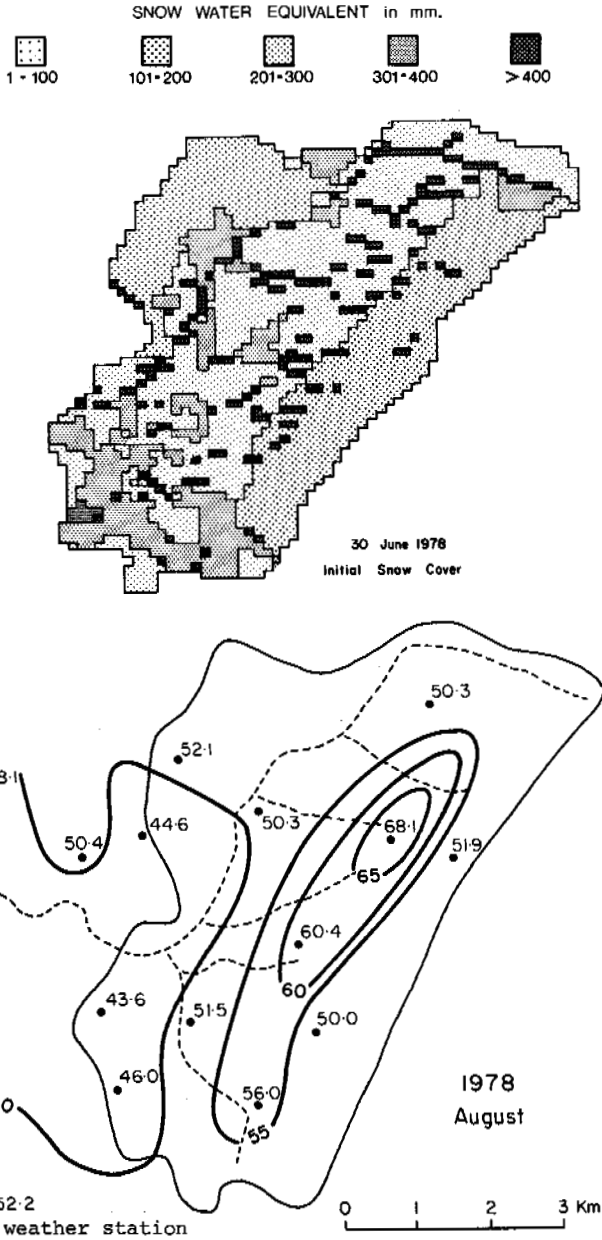

FIGURE 2 (Top) Snow distribution by terrain units immediately before snowmelt in 1978. (Bottom) Total rainfall in mm for August 1978.

FIGURE 3 Water balance of the snowmelt period, 1979.

$$S_t = \sum_{i=1}^t (M_i + R_i - Q_i - E_i), \quad (9)$$

where M , R , Q , E are daily melt, rainfall, runoff, and evaporation from the basin. The storage capacity of the active layer at any point in the basin on day t (SC_t) is

$$SC_t = z_f(t) \epsilon, \quad (10)$$

where z_f is depth of the frost table, obtained by equation (6), and ϵ is soil porosity. The mean basin storage capacity can be obtained by weighting against the fractional snow-free area in the basin. Figure 3 shows that in 1979, $S > SC$ until July 9, indicating that the excess water was probably stored in the snowpack. Field observation confirmed a gradual hydrostatic water level rise in the valley snowpack until flow began in channels carved through the snow (Figure 4). Once begun, streamflow removed the bulk of the storage. Simultaneously, the active layer storage capacity increased as the frost table receded. Surface flow ceased gradually as $SC > S$. The melt season ended with a depletion of the snow cover and a steady drying of the ground.

FIGURE 4 Initiation of streamflow in a snow-filled channel after the deep pack was saturated.

Summer Water Balance

Although snowfall can occur any time during the year, rainfall is more common in July and August. Most events are of low magnitude and sometimes cannot be measured by conventional means. Such trace rainfall was of importance in certain years (Woo and Steer 1979). Spatially, rainfall distribution varied from storm to storm. Orographic effect was not noticeable because of the low basin relief. Over the entire summer, mean rainfall for McMaster basin was often similar to the value recorded at the government weather station (Figure 2).

Continued thawing of the active layer increased its storage capacity which was able to absorb most of the low rainfall without yielding immediate runoff. Only occasional high rainfall produced significant increase in flow. An example of the summer water balance is given as Figure 5. After the

spring of 1978, the basin became snow free except along steep valley walls. Streamflow was low on most nonrainy days. Despite the extensive bare surfaces, evaporation was limited by low radiation energy for high latitudes and by the drying ground. The rainstorm of August 2-3 deposited 17 mm of rain, 14 mm of which was taken up by active layer storage. Most of the remaining rainwater went to streamflow. Unlike the melt season, such high flow was short lived and its magnitude was lower than the spring floods.

At the beginning of September, most of the storage was depleted by evaporation and by continuous low flow. Streambeds were often dry when winter arrived, offering little chance for ice formation. The low level of storage also prevented augeis formation. In this regard, rivers of the High Arctic behave differently from those of the sub-Arctic (e.g., Kane et al. 1973).

Annual Water Balance

The annual water balance computation considers the water year to span between the first significant snowfall in September (when the snow would remain for the winter), and the arrival of snowfall in the following September. In the 6 years of study, annual precipitation ranged from 120 - 273 mm (Table 1), about three-quarters of which was snowfall, suggesting a preponderant influence

TABLE 1 Water Balance of McMaster Basin (mm/yr.)

	Precipitation	Run-off	Evaporation	Storage Change
1975-1976	191	161	31	-1
1976-1977	120	155	31	-66
1977-1978	273	213	38	23

Mean	190	158	38	Total-34

FIGURE 5 Water balance before, during, and after a rainstorm, 1978.

of snowmelt upon the hydrologic cycle. Streamflow accounted for 80% of annual water loss, most of which was during the melt season. A high ratio of runoff to precipitation is typical of impermeable areas which, in our cases, is the permafrost. With considerable runoff, only a small amount is available for evaporation.

The active layer storage capacity was highly dynamic, being very limited during spring but increasing steadily as the bare areas thawed. From middle to late summer, active layer storage sustained evaporation and baseflow, and by September the residual storage was low. Water balance confirms that the year to year change in basin storage was usually less than 10% of precipitation (Table 1). An exception was 1977 which was a dry year with a large storage deficit. One possible reason for such a large deficit is an underestimation of precipitation due to many trace rainfall events (Woo and Steer 1979).

CONCLUSION

The major conclusions of this paper are

1. Spatial variation of hydrologic quantities plays a major role in the water balance of polar drainage basins. Of particular importance is the melt season when snowmelt and evaporation occur simultaneously but at different parts of the basin.

2. Snowfall constitutes a large portion of annual precipitation and most of the annual runoff is generated by snowmelt. Such hydrologic prominence of snow quantitatively verifies Church's (1974) conclusion that rivers such as the McMaster manifest a distinct arctic nival regime.

3. Hydrologic effect of permafrost is transmitted through the dynamic active layer storage capacity. A shallow active layer in spring enhances rapid runoff. As the frost table recedes, storage capacity increases and much of the summer rain can be stored to maintain evaporation and to sustain low discharge.

RELATIONSHIPS BETWEEN RUNOFF GENERATION
AND ACTIVE LAYER DEVELOPMENT NEAR
SCHEFFERVILLE, QUEBEC

Richard K. Wright
Department of Geography, McGill University
805 Shebrooke St. West, Montreal, Quebec
H3A 2K6 CANADA

The generation of runoff in areas underlain by permafrost is similar to that of temperate regions, but is distinguished by the seasonal changes in the extent, shape, and thickness of the areas generating runoff as well as the storage and transfer of small amounts of water by frost-related mechanisms. Studies conducted near Schefferville, Quebec have shown that these mechanisms can significantly alter the development of the active layer. The development of the active layer partially controls the distribution of saturated surfaces in a given catchment, and thus its hydrologic response to runoff-generating events. This phenomenon is similar to the variable-source area runoff generating mechanism of temperate regions, except that the ratio of stormflow to baseflow is also partially controlled by the depth and extent of the active layer. A detailed study of a small catchment at Schefferville has demonstrated that consideration of these effects can increase the precision of models of runoff-generation from such catchments.

INTRODUCTION

The movement of moisture within the active layer is an important component of both the moisture and thermal balances in northern regions. The rate of moisture movement through the active layer largely controls the distribution of saturated surfaces in a given catchment, which in turn, controls the rate at which runoff leaves the catchment. At the same time, the vertical and horizontal fluxes of moisture within the active layer transfer both sensible and latent heat, thereby influencing the rate and depth of thaw. There is therefore a degree of feedback between the rate of runoff generation and the rate of active layer development. This paper will present some observations of the processes of active layer development at Schefferville, and discuss the implications of those processes for modelling sub-arctic water balances.

The results presented in this paper are only a part of the information obtained in a study carried out near Schefferville, Quebec during the period 1976-1979. The primary goal of the project was the accurate representation of the water balance of a lichen tundra underlain by permafrost. In line with that project, some data were collected about the ground thermal regime. The results of the water balance investigations have been reported elsewhere (Wright 1981, 1982). This paper will present, in more detail, some observations of the development of the active layer and the generation of runoff.

ACTIVE LAYER DEVELOPMENT

The study's primary objective was accurate characterization of the water balance, but data about the ground thermal regime were required for the accurate estimation of the amount of suprapermafrost

groundwater. It was initially thought that point determinations of the depth of the active layer could be made from interpolation of the discrete temperature measurements along a thermocable while the areal estimates of the depth of the active layer could be achieved by applying a known relationship between maximum active layer depth and the distribution of vegetation at the surface (Nicholson 1978). Significant problems were encountered, however, due to the importance of latent energy transfer, which had been implicitly ignored in the estimation procedures.

The transfer of sensible and latent energy can result from moisture movement in either the liquid or gaseous phases. The transfer of sensible heat by water vapor is probably of little importance in cold regions, but the transfer of sensible heat by liquid water movement appears to be of considerable importance. Although it can be shown that the vertical transfer of sensible heat is of little moment, Lewis' (1977) study at Timmins 4 indicates that the lateral concentration into the very permeable wet-lines (areas of slight to moderate topographic depression and concentrated subsurface flow) of the latent and sensible heat associated with suprapermafrost groundwater can lead to active layers up to 10 m deep. Nicholson (1978) improved the accuracy of his model of permafrost distribution in the Schefferville area by adding a groundwater flow component.

The problem of adequately explaining the physics of latent heat transfer within a partially-frozen soil is one that has attracted considerable attention in recent years. Much of the attention has been focussed on accurately modeling the phenomenon in the laboratory and, while considerable success has been achieved (e.g., Jame and Norum 1980), it is not clear whether such models are applicable under the range of conditions normally found in the field.

One of the effects associated with latent energy transfer is the well-known "zero-curtain", where a significant portion of the freezing or thawing active layer assumes temperatures at the freezing point due to the large amount of latent energy involved in the fusion of water. The near-zero temperatures produced during the phase change of the soil water reflects conditions under which water exists in two phases. Under those conditions, it is difficult to accurately determine the thermal and hydraulic properties of the ground.

The relative changes in moisture content and phase over the depth of the active layer also influence the rate and depth of thaw. The magnitudes of the thermal conductivity and apparent specific heat will vary over the depth of the soil column according to changes in the composition and structure of the inorganic matrix, the amount and distribution of organic matter, and the proportions and distribution of frozen and unfrozen water within the soil column. Since the variation of soil moisture content is a function of both depth and time, the rate and depth of thaw is a function not only of the heat flux at the surface, but is also a function of the distribution and state of water within the active layer.

In general, models of active layer development (e.g. Nakano and Brown 1972, Smith 1975, McGaw et al 1978) have assumed that soil thermal properties are double-valued; i.e. one value would hold in the 'frozen' state and another value would hold in the 'thawed' state. The transition between the two states was presumed to be instantaneous, occurring when the soil temperature passed through the freezing point. The data collected in this study clearly demonstrates that heat transfer is not solely by conduction and that the active layer is not sharply demarcated into frozen and unfrozen zones.

THE FIELD AREA

The bulk of the results presented in this paper were collected near Schefferville, Quebec ($54^{\circ}51'N$, $67^{\circ}01'W$; 520 m a.s.l.). Located within the Labrador Trough in central Ungava, the area is composed largely of Proterozoic metamorphosed rocks (Figure 1). The region is characterized by broad, permafrost-free valleys and long, narrow ridges underlain by extensive permafrost. The valley bottoms are largely covered by spruce woodlands and lakes, while the ridgetops are dominantly lichen tundra. Mean annual air temperature at Timmins 4 is $-6.2^{\circ}C$. Mean annual precipitation at the Schefferville townsite (15 km SE of the main research site) is 785 mm, of which 407 mm falls as rain and the rest falls as snow (Barr and Wright 1981).

The main research site (Hematite, Figure 2) is at an altitude of 685 m a.s.l. The area is typical of lichen-heath tundra in central Ungava. The surface over 80% of the site is a 5-10 cm thick lichen mat (predominantly *Cladonia* and *Cladina* spp.) with scattered dwarf birch (*Betula glandulosa*). The remaining 20% of the surface is bare, frost-scarred ground, partially paved with frost-shattered debris. The bedrock, which is typically overlain by 1-2 m of very stony till, is weakly metamorphosed sediments. Permafrost underlies the entire site to a depth of at least 30 m. The annual depth of thaw ranges from 2.0 m under thick lichen mat to

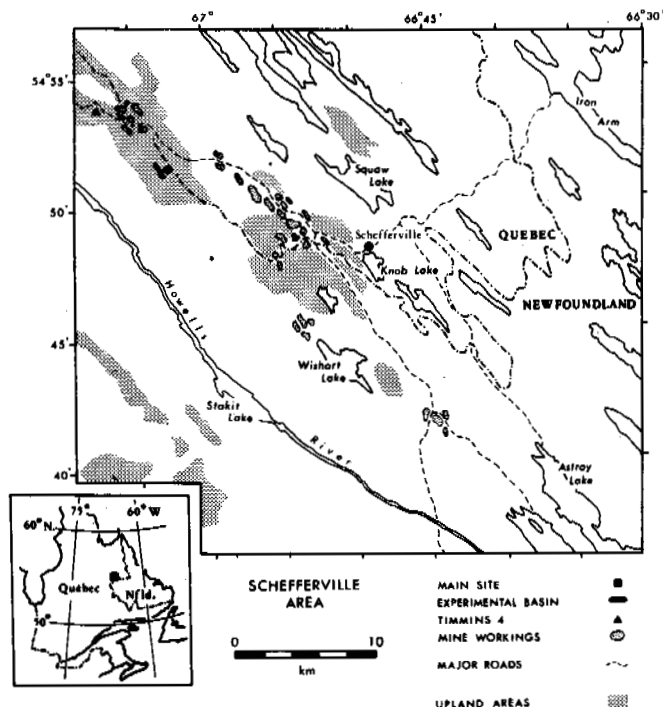

FIGURE 1 Location of Schefferville and the study sites.

3.0 m under bare surfaces. Two areas of special interest at Hematite are locations One and Two. Both are located in an area of lichen-heath tundra, but the surface of One is slightly convex and is stripped of vegetation. Location Two is relatively flat and has an undisturbed lichen mat.

Data were collected at the main site from December 1976 through August 1979, though the frequency of observation varied from daily during the summers of 1977 and 1978 to monthly or bimonthly during the winter. Intensive data collection was carried out from May through September in 1977 and 1978 as well as frequent observations during the freeze-up of 1977. Daily observations (during the thaw season) included air temperature and humidity at screen height, ground temperatures, incoming and net radiation, evapotranspiration, and rainfall (Wright 1981). In addition, soil moisture contents were monitored with a neutron moisture probe through the freeze-up of 1977 and the summer of 1978.

Observations at the main site in 1978 were paralleled by observations of the water budget of a small basin adjacent to the main site (Bazilchuk 1979). The basin is, like most of the Schefferville region, strongly controlled by the underlying geology. Permafrost is estimated to underlie approximately 80% of the basin, being absent beneath the lake and possibly the lower reaches of the creek. The distribution of vegetation in the basin is controlled by aspect, exposure, and drainage. Low-lying, often-saturated areas are dominated by birch-willow scrub while better sites are dominated by lichen-heath tundra.

RESULTS

Freeze-up

In the Schefferville region, when the surface of the mineral soil freezes, an essentially impermeable barrier is formed between the atmosphere and the active layer. The development of a well-defined zero-curtain was observed at all cables at Hematite in 1977. Zero-curtain temperatures observed during freeze-up ranged from -0.02°C to -0.08°C with the most frequently observed value being -0.06°C .

The magnitude of the freezing point depression increases as the solute content of the soil water increases and as the grain size of the matrix decreases. It can be shown that (in the active layer) the effect of solutes in the pore water is trivial, but it is difficult to accurately characterize the effect of a given grain size distribution. The values observed at Hematite are slightly lower than the values observed at Timmins 4 (Nicholson 1978), but the slight difference is probably due to instrumental error, though it may also be partially attributable to the deeper, finer-grained till cover at Hematite.

The unsaturated part of the active layer is usually at or near field capacity at the beginning of freeze-up because that period tends to be cool and moist in central Ungava. In addition, late season rainfall is usually augmented by the melting of an early snowpack and that may lead to a large soil moisture content as freeze-up commences. It seems

unlikely, however, that freeze-up could be completed with soil moistures in excess of field capacity unless the drainage of the soil were poor or non-existent. For example, the complete melting of a 15 cm snowpack and heavy rainfall (approximately 20 mm) in late October 1977 produced a saturated zone up to 2 m thick at Hematite, but, despite a relatively rapid freeze-up, the saturated zone quickly disappeared.

The reduction of the saturated zone during freeze-up is largely due to suprapermafrost groundwater flow, but there is also a minor amount of moisture transport from the lower part of the active layer towards the surface. The upwards transport result from the water potential gradient set up by the freezing process itself. The gradient is caused by the attenuation of the interfacial liquid films on the soil particles as the ice crystals forming within the pores abstract the less tightly-held soil water (Dirksen and Miller 1966). It follows that a finite amount of moisture transport should take place within a freezing soil; such transport has been detected in the laboratory (e.g. Hoekstra 1967, Jame and Norum 1980), but only limited field observations are available (e.g. Woo and Heron 1981).

Field data demonstrating these phenomena are shown in Figure 3, which depicts the moisture and temperature data collected at Hematite from November 1977 to February 1978. The precision of the temperature measurements is quite high ($\pm 0.03^{\circ}\text{C}$), but the interpolations between the discrete

FIGURE 3 Temperature and soil moisture profiles observed at Locations One and Two during freeze-up 1977. Dashed lines represent the temperature profile on the first date indicated while the solid line is for the second date indicated. The bars represent the change in soil moisture content between the two indicated dates.

temperature measurement points are approximate, particularly in the vicinity of the freezing front. The changes in moisture contents, though relatively small, show quite clearly that the moisture transport is correlated with changes in the ground thermal regime. The large transfers took place between 12 November and 5 December and between 12 and 29 December. Both of those periods were characterized by rapidly decreasing air and surface temperatures, leading to strong temperature gradients toward the surface.

The data clearly demonstrate that there is detectable moisture transport during freeze-up and that those changes are closely associated with the ground temperature field within the active layer. The changes in moisture content are presumably the result of the unsaturated flow induced by the increased soil matrix suction developed during the freezing process. However, attempts by the author to numerically model the presumed relationships between soil moisture contents and the temperature field have been unsatisfactory, primarily because of an inability to adequately characterize the properties of the active layer during the freezing process.

Thaw Season

It was initially thought that soon after the ground began to thaw there were three zones within the active layer that possessed significantly different thermal and hydraulic properties: unsaturated unfrozen, saturated unfrozen, and unsaturated frozen. The difference in thermal properties between the saturated and unsaturated unfrozen materials is probably not very large because of the generally low porosity of the till and bedrock in the Schefferville area, but the higher thermal conductivity and lower specific heat of the frozen ground should give it a significantly higher thermal diffusivity with respect to the unfrozen materials. It follows that the temperature wave should be strongly attenuated with depth, especially in the frozen material. That conclusion is based, however, on the assumption that the transfer of heat is solely by conduction and that there is no significant transfer of heat by moisture transport. The data collected at Hematite during June and July of 1978 clearly demonstrate that those assumptions are not warranted.

Although the phenomena indicating latent heat transfer were observed at all main thermistor cables

during 1977, 1978, and 1979, the following discussion is based on the data from Locations One and Two during 1978 since those sites and periods have the most complete data records.

Following the completion of freeze-up in 1977, soil moisture contents remained essentially constant until the following spring. Ground temperature patterns observed during the spring of 1978 were characterized by decreasing amplitude of the temperature wave with depth, indicating that heat transfer was primarily conductive.

In early June, however, when active layer depths were approximately 35 cm and completely saturated, abrupt and substantial increases in temperature were observed at Location Two. Those temperature increases coincided with increases in moisture content of the still-frozen part of the active layer. A week later, a very similar sequence of events was observed at Location One, when percolation from a thick saturated zone led to large moisture increases in the still-frozen ground and those moisture changes were coincident with sharp temperature increases in the still-frozen ground. The amount of percolated water was quite large, equivalent up to 30 mm of water at Location One. The magnitude of the temperature increase was not attenuated with depth, but was instead a function of the initial temperature with respect 0°C (Figure 4). The closer the initial temperature to the freezing point, the smaller was the temperature increase. This is attributed to the sharp increase in the apparent specific heat of frozen materials as the freezing point is approached (Williams 1967).

A related phenomenon was the existence of a zero-curtain throughout the thaw season. Its presence was indicated by a pause (at -0.02° to -0.08°C) in the passage of each temperature measurement point through the freezing point. The transition was frequently observed to coincide with the occurrence of a thick saturated zone in the thawed portion of the active layer. In periods when the saturated zone was thin or absent, the zero-curtain appeared to descend slowly. The zero-curtains were observed at every thermocable, although the duration of a particular temperature measurement point at the freezing point varied.

These phenomena indicate that there is significant penetration of suprapermafrost groundwater into the still-frozen parts of the active layer. When the amounts of water are large, the zero-curtain is well developed, but when the pore pressures at the thawing front are small or negative, only a very small amount of water penetrates the still-frozen material. Presumably, such percolation is self-limiting, since the penetration and re-freezing of the water would tend to reduce the effective permeability of the soil.

DISCUSSION

It is clear that heat transfer in at least some frozen soils is not solely by conduction and that the traditional view of the active layer is not always adequate; the transition from frozen ground to unfrozen is shown to be gradational in nature both thermally and hydraulically. It follows, then, that simple models of active layer development will not give accurate results unless latent heat transfer

Figure 4 (a) Temperature and soil moisture profiles observed at Location One during June 1978. (b) Temperature patterns through time at Location One during June 1978.

is somehow inhibited (e.g., the frozen material is effectively impermeable). Heat budget models based upon time-dependent heat storage will give adequate results only if the zero-curtain zone and the variation in moisture storage can be accurately approximated or if the time interval is sufficiently long that those effects can be neglected.

For example, in non-wetline areas (i.e. those areas that are little affected by suprapermafrost groundwater flow), there is a good correlation between the percentage of bare ground in a given area and the maximum active layer depth (Nicholson 1978), which indicates that conduction of surface heat is the dominant mode of heat transport over an entire thaw season. On the other hand, in the low-lying wetline areas the saturated zone tends to be much thicker, so the pore pressures at the thawing front are much higher than on adjacent slopes. The higher pore pressures, in conjunction with the higher permeabilities of the wetlines, leads to significant amounts of suprapermafrost groundwater percolating to relatively great depths within the still-frozen ground. The influence of latent heat transfer therefore extends well below the zone in which

conductive transfer is dominant and the magnitude of the latent heat transfer probably exceeds that of conduction. It is for these reasons that the active layer depths in the wetlines do not correspond to the vegetation distribution at the surface. Accurate prediction of active layer depths along the wetlines requires some measure of the magnitude of the latent heat transfer, either through a budget type of procedure (e.g., Lewis 1977, Wright 1981) or through actual knowledge of the pore pressure distribution within the wetline.

There are two main areas in which the development of the active layer can strongly influence the generation of runoff in subarctic areas. First and most important is in controlling the effective depth to which percolating water can penetrate. The depth of the effectively permeable portion of the active layer strongly controls the distribution of saturated surfaces within a given catchment and that, in turn, controls the rate at which runoff reaches the outlet of the catchment. Thus, the rate and depth of thaw in a given area can influence the response time of that area to a given runoff-generating event.

The second area in which development of the active layer affects the water balance is through the percolation of suprapermafrost groundwater into the still-frozen part of the active layer. As noted above, the amounts percolated at Location One equalled up to 30 mm of water. If the same processes take place along the wetlines, the amount of abstracted water could be quite significant. That such percolation does take place is indicated by the very deep wetlines themselves. Water stored in this fashion would presumably be released only when the depth of thaw had reached the depth of the percolation. Attempts to incorporate such an effect in subarctic water balance models have been partially successful (Wright 1982). Good correlation is achieved between observed and predicted runoff volumes, but few data are available on subsurface moisture storage over the course of a thaw season, so it is difficult to assess the realism of such a model.

CONCLUSION

The results presented here constitute strong qualitative evidence of the importance of latent heat transfer to the development of the active layer. It is clear that such effects can significantly affect the rate and depth of thaw and, indirectly, the rate of runoff generation. The rate and depth of thaw control the rate at which runoff is generated and, in turn, patterns of moisture flow and storage influence the thermal behavior of the ground.

These results represent only the first step in quantifying the thermal and hydrologic behavior of the active layer. The prime needs at this time are for a more detailed picture of the distribution of heat and moisture within a wetline over an entire thaw season and the development of a model which can adequately describe the three-dimensional flow of heat and moisture within a partially thawed active layer. It may well be that the present numerical models of these processes can be adapted to the far less homogeneous conditions of the field. That will certainly require a more complete description of the temperature and moisture distributions

within a wetline, a project which the author has recently begun in central Ungava.

A STUDY OF THERMAL CRACKS IN FROZEN GROUND

Xia Zhaojun

Department of Hydraulic Engineering, Northeast Agricultural College
Harbin, Heilongjiang, People's Republic of China

The formation of thermal cracks damages roads and hydraulic construction and causes seepage and other problems. Thermal cracks usually occur in early winter, when the snow cover is still thin and the surface temperature falls rapidly to -20°C or lower, and they may reach 1.5 m in depth and 10 to 16 cm in width. The particle composition, water content, temperature gradient, freezing depth, and freezing penetration rate of soil as well as the snow cover and vegetation all affect crack formation. Thermal cracks occur when the maximum contractional stress σ_{\max} reaches the ultimate tensile strength σ_0 of the soil. The distance between cracks is directly proportional to σ_0 and inversely proportional to the temperature gradient and linear contractional coefficient of frozen soil. The width of the crack is proportional to the distance between cracks and to the temperature gradient. The depth of the crack during one freeze-thaw cycle is proportional to the freezing depth, and is related to the minimum temperature and the temperature when the crack occurs. The main stresses can be determined and used to predict crack formation.

For small-scale hydraulic engineering facilities, such as pools and reservoirs, elevated canals and ditches, or embankments, frost cracks can be the cause of problems such as spring seepage, scouring, soil flows, and piping. This is especially obvious in the case of irrigation and drainage systems, at the level of ditch crossing or of culverts under elevated ditches, where the increase in contact plane reduces the cross-section area of the upper structure, the possibility of frost crack forming at the top of the lower structure increases and subsequent risks of leakage or even collapse also increase. Therefore, the study and analysis of frost cracks is necessary to help us acquire the theoretical and practical knowledge for predetermination, detection, and prevention. Only on this basis can concrete measures be developed, including selection of less-susceptible, environment-compatible building materials, control of pre-frost water content, and local thermal insulation to reduce thermal and mechanical frost-period factors. The objective of this research is therefore to lessen frost damage and to ensure the safe operation of civil structures under severe climatic conditions.

CHARACTERISTICS OF CRACK FORMATION

In the winter, under the influence of subzero temperatures, a portion of the water in the ground turns into ice, which causes an increase in volume and frost heave phenomena. After the completion of this phase-change, i.e. when the unfrozen ground has turned into frozen

ground, if the air temperature continues to fall, the ground will be affected by unhomogeneous contractional deformations and contractional stresses, which will be largest at the soil surface.

When surficial stresses are higher than the tensile strength of the frozen ground, the ground surface is pulled apart and cracks appear. We call such cracks "frost cracks", or "cracks", as they will be referred to in this paper.

The curve in Figure 1 shows the relationship between the contractional stresses in frozen ground and the depth of freezing. For ease of analysis and calculation, we can in a first step reduce this relationship to a primary straight-line function. The curve also shows that the distribution of the contractional stress as

FIGURE 1 Contractional stress distribution along depth.

a function of depth of freezing takes the form of a triangle with its apex down, the contractional stress being zero on the freezing plane in the ground and reaching its highest value at the ground surface.

In areas of seasonally frozen ground, frost cracks occur mostly in the beginning of winter, when the snow cover is thin and ground temperature falls rapidly to -20°C to -25°C . They can reach 1.5 m in depth, 10 to 16 cm in width, and they are wedge-shaped, with the opening wider than the bottom. They occur more frequently on roads and runways and around canals, dams, and embankments, whereas they are rarely found under thick snow covers.

In homogeneous ground, when the boundary conditions make frost penetration unidirectional in half space, intersecting frost cracks are usually at right or close-to-right angles. As the subzero temperatures keep falling, and the number, depth, and length of the cracks increases, and the soil surface might be hacked into blocks with irregular sides.

Cracks in seasonally frozen ground are not as frequent and their development, in terms of both size and continuity, is not as complete as in permanently frozen ground where, due to longer freezing cycles and greater temperature gradients, cracks appear in larger numbers, are deeper and wider, and form more developed networks. This is especially evident in mountainous areas where, in addition to vertical cracks, one can also observe horizontal, or slanting cracks; the intersection of these cracks often creates favourable conditions for avalanches and landslides, especially during melt-water runs in the spring. Even in flat terrain, however, frozen ground cracks can damage roads, highways, and airport runways, or to the points of connection with the ground of hydraulic engineering buildings, as well as to canals, dams, embankments, and buried pipelines.

FIGURE 2 Crack spacing and width calculations

CRACK SPACING, WIDTH, AND DEPTH CALCULATION

With the continuous falling of subzero temperatures, contractional stress increases in the superficial ground layer. When the main contractional stress reaches the unidirectional tensile strength limit $[\sigma^t]$ of the frozen ground, there is a possibility of cracking. When the former becomes higher than the latter, cracks must occur. After the cracks have been formed, due to the stress concentration as well as to the increase of the frost contact plane and its thermic effects, there is an acceleration of the directional development of the cracks both in depth and in width.

Crack Spacing Calculation

Let us assume an ideal strip of homogeneous ground elongated in the direction of the main stress, subjected to normal motion limitations by the friction between frozen and unfrozen soils, and with a cross-section equal to 1 unit. We sample a segment of minute length ds . When the temperature gradient reaches $\text{grad}(t)$, the contractional stress is σ and, in the whole strip, the accumulated contractional stress is:

$$\sigma_{\max} = \int_0^s \sigma \cdot ds = \sigma \cdot s \quad (1)$$

$$\sigma_{\max} = S \cdot E \cdot \alpha \cdot (h_c - \Delta h) \cdot \text{grad}(t) \quad (2)$$

where

$$\text{grad}(t) = \frac{\Delta t}{h_c} = \frac{t_2 - t_1}{h_c} \quad (3)$$

When $\sigma_{\max} > [\sigma^t]$, superficial ground breaks and cracks occur. Let us now take the critical state $\sigma_{\max} = [\sigma^t]$

From the above, we can deduce the basic formula to calculate the distance between two cracks;

$$[\sigma^t] = n \cdot S \cdot E \cdot \alpha \cdot (h_c - \Delta h) \cdot \text{grad}(t) \quad (4)$$

or

$$S = [\sigma^t] / n \cdot E \cdot \alpha \cdot (h_c - \Delta h) \cdot \text{grad}(t) \quad (5)$$

where s is the distance between two cracks;
 n is the modifying factor for soil type, water content, vegetation and snow cover. Though its value is

$n \leq 1$, assume a value $n = 1$ for rough calculations;
 α is the linear contraction factor of frozen soil;
 $[\sigma_c]$ is the unidirectional tensile strength limit of the frozen ground;
 S is the crack spacing
 $\text{grad}(t)$ is the temperature gradient.

We can also obtain;

$$S = \frac{1}{2} \cdot n \cdot E \cdot \alpha \cdot h_c^2 \cdot \text{grad}(t) / [\tau] \quad (6)$$

where h_c is the depth of the crack of frozen ground;
 $[\tau]$ is the shearing strength limit of the frozen ground.

Crack Width Calculation

By width, or width of opening, we designate the longest distance between the two sides of one frost crack measured at the surface. To any one crack, it is a function of the temperature gradient; if the temperature gradient is a constant, the crack width is a constant as well. When the distance between two cracks is known, the width of the opening can be obtained from the following formula:

$$\Delta L_{\max} = n \cdot L \cdot \text{grad}(t) \cdot (h_c - \Delta h) \cdot \alpha \quad (7)$$

where ΔL_{\max} is the maximum width at the ground surface;
 L is the distance between two cracks.

Crack Depth Calculation

In the winter, with the continuous decrease of subzero temperatures, there is also a continuous deepening of frost cracks

FIGURE 3 Crack depth calculation

FIGURE 4. Stresses acting on element.

and at a certain depth from ground surface, the temperature of the frozen ground layer keeps decreasing, which causes new tensile stresses. When this layer reaches the breaking temperature of the soil surface, it is subjected to the same cracking and thus the cracks keep developing in depth.

In order to study further the question of crack depth, we have first drawn a graph to show, for analytical purposes, the correlation between the average depth of the active layer calculated over years and temperature (Fig. 3).

In the case when such a graph is drawn for an area of seasonally frozen ground, we have first indicated on the graph the temperature of cracking $-t_c$, we have drawn a vertical line which meets at M the oblique linking point $-T$ to h_a . Therefore, the length of the line from $-t_c$ to M is the maximum depth of the crack. From Figure 3, we can obtain:

$$h_c = \frac{-T - (-t_c)}{-T} \times h_0 \quad (8)$$

where: h_c is the depth of the crack;
 $-T$ is the lowest temperature;
 $-t_c$ is the temperature at which cracks occur;
 h_0 is the depth of the winter frozen layer.

Since $h_0 = \sqrt{\frac{\lambda^+ \cdot t_F \cdot \tau}{\rho_l}} \quad (9)$

where λ^+ is the heat conduction coefficient of freezing ground;
 t_F is the temperature at which the ground surface freezes;
 τ is the longest frost

Q_L is the phase-change period;
is the phase-change temperature.

The above relationship can also be written

$$h_c = \frac{-T - (-t_c)}{-T} \cdot \sqrt{\frac{\lambda \cdot t_F \cdot \tau}{Q_L}} \quad (10)$$

To simplify, we can use $\xi = \frac{-t_c}{-T}$ and write the above formula as follows:

$$h_c = B \cdot (1 - \xi) \cdot h_0 \quad (11)$$

$$\text{where } \xi = \frac{-t_c}{-T} \quad (12)$$

B is the modifying coefficient for which we can assume a value $B = 1$ for rough calculations.

MECHANICAL ANALYSIS OF FROST CRACKS

The width, depth, and spacing of frost cracks are related to the intensity of thermal propagation, i.e. thermal currents intersecting isotherms at right angles. We take a small cubic sample unit at the ground surface, with its sides parallel to the thermal currents and to the isotherms. The stresses to which the sample unit is submitted during the process of ground surface freezing are shown in Figure 4.

These stresses vary according to the distance to the surface and to temperature as well as to soil conditions. In figure 4, we can also see that the stresses are oriented along two perpendicular axes. There are 2 groups of pulling stresses (σ_x and σ_y) and 2 groups of shearing stresses (τ_x and τ_y), with $\tau_x = \tau_y$.

In such conditions, stress intensity can be obtained by the method illustrated in Figure 5 (stress round calculation method). From Figure 5, we can obtain

$$\sigma_1 = \frac{\sigma_x + \sigma_y}{2} + \sqrt{\left(\frac{\sigma_x - \sigma_y}{2}\right)^2 + \tau_x^2} \quad (13)$$

$$\sigma_2 = \frac{\sigma_x + \sigma_y}{2} - \sqrt{\left(\frac{\sigma_x - \sigma_y}{2}\right)^2 + \tau_x^2} \quad (14)$$

The angle between the main stresses σ_1 and σ_2 is

$$\alpha = \frac{1}{2} \arctg \frac{2\tau}{\sigma_y - \sigma_x} \quad (15)$$

where σ_1 is the first main stress;
 σ_2 is the second main stress.

As to the value of σ_x and σ_y , it suffices to measure arbitrarily two perpendicular ground surface contractional stresses, calling one σ_x and the other σ_y (Usually the greater of the two is called σ_x and the lesser σ_y); then, by using the above method and formulas, calculate the position, orientation, and intensity of the maximum and minimum stresses. Then, by comparing the maximum stress thus obtained and the maximum tensile strength under the same temperature conditions, it is possible to determine whether or not a frost crack will occur and, further, to predict its direction and size.

Using the above stress-determination method, the following cases are usually encountered:

a. The measured values for the perpendicular stresses σ_x and σ_y are not equal. This is the most common case.

b. The measured values for σ_x and σ_y are equal; in that case, the value of the main stresses σ_1 and σ_2 is as follows:

$$\sigma_1 = \sigma_x + \tau_x \quad (16)$$

$$\sigma_2 = \sigma_x - \tau_x \quad (17)$$

c. In the two measured stresses, one is equal to zero, that is $\sigma_x = 0$ or $\sigma_y = 0$, but not the other; in that case,

FIGURE 5 Graphic analysis of the main stresses in frozen ground in homogeneous half-space conditions

σ_1 and σ_2 are determined as follows:

$$\sigma_1 = \frac{\sigma_x}{2} + \sqrt{\left(\frac{\sigma_x}{2}\right)^2 + \tau_x^2}$$

$$\sigma_2 = \frac{\sigma_x}{2} - \sqrt{\left(\frac{\sigma_x}{2}\right)^2 + \tau_x^2}$$

The angle between the main stresses σ_1 and σ_2 is

$$\alpha = \frac{1}{2} \arctg \frac{-2\tau}{\sigma_x}$$

As to the values σ_x and σ_y are equal, the angle between the main stresses σ_1 and σ_2 is

$$\alpha = \frac{1}{2} \arctg \frac{-2\tau}{\sigma_x - \sigma_x} = 45^\circ$$

It is also worth noticing that in the process of frost-induced contraction, when the main stresses reach or exceed the maximum limit of tensile strength of the frozen ground, the ground breaks and cracks appear. The cracks thus formed are perpendicular to the first main stress and cause a sudden release of the first main stress. At that time, the second main stress, perpendicular to the first, is still building: a substantial change then occurs and this second main stress becomes the first main stress and keeps growing until a crack perpendicular to it is formed. As the process is repeated, it leads gradually to the development of crack networks. Since the angle between the two main stresses is 90° , the cracks they cause also cut at right or close-to-right angles, the former conforming more to the theoretical model.

When the composition, water content, vegetation cover, and snow layer thickness of civil works such as roads, runways, elevated ditches and canals, or embankments present tangible differences with the surrounding terrain, and when their width-to-length ratio is very high or, under certain conditions, can be considered infinite, the first main stress σ_1 is extremely great, whereas the second main stress σ_2 is extremely small. In that case, one may consider the tensile strength as unidirectional. At the same time, the first main stress σ_1 is basically oriented along the length axis of these civil works and the frost cracks that occur are nearly all perpendicular to it.

FIGURE 6 The formation of frost networks. The numbers represent the orders of frost-crack formation.

CONCLUSION

For some small-scale projects of hydraulic engineering such as pools and reservoirs, elevated canals and ditches, or embankments, the thermal cracks of frozen ground are the major sources resulting soil current and piping in embankment in the spring, especially for the crossing projects of hydraulic engineering of agriculture.

The formation of frost cracks can be detrimental to construction projects in cold regions. In China, cases where construction workers neglected to take adequate protection measures against frost have been observed. The subsequent formation of cracks has resulted in fissures up to 3 cm wide in the ground floor and basement floors, necessitating major repairs. This is not only waste of time and capital, but has a detrimental effect on the building's life span; it can be avoided by a careful study of the frost crack susceptibility of the ground and materials and by taking appropriate preventive measures at the planning stage.

DEVELOPMENT OF PERIGLACIAL LANDFORMS IN THE NORTHERN MARGINAL REGION OF THE QINGHAI-XIZANG PLATEAU SINCE THE LATE PLEISTOCENE

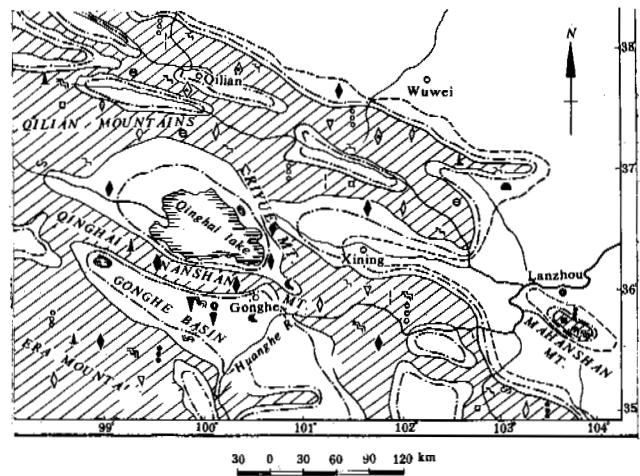

Xu Shuying, Zhang Weixin, Xu Defei, Xu Qizhi, and Shi Shengren

Department of Geology and Geography, Lanzhou University
People's Republic of China

Based on field investigations and C^{14} dating, there have been three cold periods since the Late Pleistocene: (1) the main Würm Glaciation, when the air temperature was about 7° to $8^{\circ}C$ lower than at present, and the lower limit of the periglacial belt was at 2200-2300 m a.s.l.; (2) the second stage of the Middle Holocene, when the air temperature was about $2.5^{\circ}C$ lower than at present, and the lower limit of the periglacial belt was at about 3300 m a.s.l.; and (3) the Neoglaciation at the end of the Middle Holocene, when the air temperature was about $2.7^{\circ}C$ lower than at present, and the lower limit of the periglacial belt was at about 3200 m a.s.l. Between these three cold periods, there were warm stages with air temperatures 1° - $2^{\circ}C$ higher than at present, and the periglacial lower limits were at about 3500 to 3900 m. During the cold periods, many periglacial phenomena were formed, namely frost-heave mounds, sand wedges, involutions, blockfields, spline cryoplanation terraces, and sorted and nonsorted polygons. The modern periglacial belt can be divided vertically into three zones: the zone of frozen weathering and of freeze-thaw denudation in the upper part, the zone of freeze-thaw creep and frost heaving in the middle, and the zone of frost heaving and heat thawing in the lower part.

The northeast marginal region of the Qinghai-Xizang plateau refers to the peripheral area bordering the northeast of the plateau. It covers the eastern part of Qinghai plateau, the eastern section of Qilian mountains and the western marginal region of Gansu Centre Basin, etc. (Fig. 1)

The northeast boundary of permafrost on the plateau crosses the northern hillside of Ela mountain at the eastern end of Kunlun mountain at elevation of 3,800-4,000 m. In this region, only Qilian mountains, western Qinling mountain and other areas of high altitude where permafrost develops belong to the contemporary periglacial belt. This region was the area of both altitude and latitude periglacial zones during the Quaternary Ice Age. Many former periglacial phenomena are left in the present-day non-periglacial belt. Some fossil periglacial features were formed under colder climatic conditions than currently experienced in the modern periglacial belt.

PERIGLACIAL LANDFORMS OF MAIN WÜRME
GLACIATION OF LATE PLEISTOCENE

The Würm glaciation of the late Pleistocene can be divided into two substages: early Würm glaciation and main Würm glaciation. The records of seafloor sediments and levels of the Yellow and East China Seas both prove that the climate of the main Würm glaciation was colder. During this glacial age, the snowline of the mountain areas dropped to about 1,500 to 1,700 m in the mountain areas around the Qinghai-Xizang plateau. The precipitation today is abundant, with 900-1,000 m in the general continental glacier areas, (Zheng Benxing et al., 1981). Field observations indicate that the snowline drop in Lenglongling mountain amounted to 800 m. Glaciation was extensive (Shi Yafeng et al., 1981). In the main Würm glaciation,

Fig. 1. The distribution of periglacial landforms Northeast marginal region of the Qinghai-Xizang plateau. 1. modern periglacial belt; 2. periglacial belt low limit of main Würm-glaciation; 3. periglacial belt low limit of neo-glaciation; 4. fossil pingos; 5. fossil blockfields; 6. fossil nivation hollows; 7. fossil ice wedges; 8. fossil involutions; 9. fossil patterned ground; 10. fossil tors; 11. fossil periglacial sand dunes; 12. fossil stone streams; 13. fossil freeze-thaw mud-flow terraces; 14. stone circles; 15. blockfield; 16. patterned ground; 17. heat-thawing hollows; 18. stone streams; 19. stone stripes; 20. nivation hollow and freeze-thaw debris cone; 21. involutions; 22. freeze-thaw mud-flow terraces.

the altitudes of fossil cirques on the northern slope of Nanshan mountain, Qinghai, was 3,800 to 3,900 m. This is 900 to 1,000 m lower than the calculated modern climatic snow line. Such lowering of the snow line is bound to bring about the lowering of the periglacial belt. As a result, wide areas remain of the main Würm glaciation in this region. Descriptions of the periglacial land forms of the Gonghe Basin and the foot hills of the Maomao and Mahan mountain since the main Würm glaciation are as follows.

The Gonghe Basin

The area below about 3,000 m in the basin is non-periglacial. Wang Jiyu et al (1979) reported involutions of late Pleistocene age at Taggemu in the centre of the basin. Recently we have found sand wedges on the surface of Tara 1, the high terrace of the Yellow River in the basin. The altitude there is 2,950 m. The sand wedges formed in layers of alluvial gravel with loess. The wedges are filled mainly with gravel. The enclosing material is 17,300±250 years B.P. proving that the wedges were the products of the main Würm glaciation.

In the Gonghe Basin, there are two different kinds of sand dunes of different ages. The older kind developed extensively on the Tamai terrace which is on the left bank of Qiabuqia river. This terrace was formed at approximately the same time as Tara 1. The base of the terrace consists of layer of river-lake facies, the Gonghe group, which was formed during the early-middle Pleistocene. It is covered with layers of alluvial gravel and loess. On top of the loess layer are older sand dunes whose tops have developed a fossil soil layer. C-14 dating of this layer is 6,180±80 years B.P. It is, therefore, the product of the high temperature period of the mid-Holocene. Based on this, the older sand dunes are inferred to be the result of periglacial wind action of the Würm glaciation. At that time, fossil sand dunes were formed in many other parts of the world, (Goudie 1981; Xu Shuying et al. 1982).

The Maomao Mountain Foot Hills

Maomao mountain, the eastern extension of Lenglongling mountain, is 3,949 m above sea level. The lower boundary of the periglacial belt is about 3,700 m above sea level. At the foot of the Maomao mountain is Songshantan, a faulted basin of Quaternary age. In the south is the Shihuigou brook, flowing south into the Zhuanglang river. Near Hongshanzui, two terraces of the brook are well developed. The second terrace is 10 to 15 m above the river level. Below this terrace is a gravel layer with horizontal bedding. The overlying layer of alluvial loess contains several thin humic, dark-gray layers. A thicker layer in between arches upward to form a buried fossil pingo whose horizontal length is 25 to 30 m. The height is about 5 m. The altitude there is 2,540 m, 1,460 m lower than the lower boundary of the contemporary periglacial belt. The layer over this deformation is 31,100±1,500 years B.P. This proves that the fossil pingo may have been formed during the main Würm glaciation.

Mahan Mountain

Mahan mountain, located on the southern part of the Lanzhou Basin, is 3,670 m above sea level. The mean annual air temperature at the summit is about -2°C. The extent of the present-day periglacial belt is small and periglacial processes are not well developed. According to temperature measurements there may be no permafrost present. The existing periglacial processes are mainly freeze-thaw weathering, thaw-freezing flow and frost heaving. Tors and blockfields found on the flat cryoplanation level at the summit, together with cryoplanation terraces and nivation hollows, are all fossil periglacial features. The blockfields in the summit area consist of large blocks 1 to 2 m in size, resulted from the frost shattering of gneissic granite. The necessary conditions are extreme cold and a long freeze-thaw period (Embleton 1975). If cracking caused by freezing is at its maximum at -22°C, this proves that the blockfields on top of Mahan mountain may not be the products of the present day climatic conditions. Also, they did not form during the Neoglacial age when the temperature was only -2°C to -3°C lower than today. The blocks are stable with their surface covered with mosses. Some blocks bear frost clefts and experience "frost-heaving action", both of which are probably the results of the modern periglacial climate. Cui Zhijiu (1981a) believes that the altitudes of the blockfields in various places of the Qinghai-Xizang Plateau are generally about 200 to 250 m lower than their contemporaneous snowlines. Thus it can be deduced that when the blockfields on Mahan mountain were formed the snowline should have been 3,800 to 3,850 m. During the main Würm glaciation, Lenglongling mountain, which is 2°C higher in latitude than Mahan mountain had a snowline of 3,600 m and the Qinghai Nanshan mountain, which is 0.5°C higher in latitude than Mahan mountain had a snowline of 3,800 to 3,900 m. Both snowlines agree with that suggested for the Mahan mountain when the blockfields were formed. Therefore it can be presumed that the blockfields on top of Mahan mountain also formed during the main Würm glaciation.

PERIGLACIAL LANDFORMS OF HOLOCENE PERIOD

The Holocene period underwent cold stages. During these cold stages the snowlines and the periglacial lower boundaries in China's western mountain areas lowered between 100 to 300 m. For example, the snowline of Lenglongling mountain was about 200 m lower than today's during the Neoglacial age. Though the periglacial zone in the region has reduced greatly, it was still larger than today's. Therefore many periglacial phenomena formed during the Holocene cold stages are still found in existing non-periglacial areas. Radiocarbon dating indicates two periods of cold stages during the Holocene. The periglacial phenomena formed during the cold stages can be found in the following areas.

The Gonghe Basin

The Shazhuyu River flows into the Dalianhai lake and forms a closed river system. Since the

lake level has lowered since the Holocene, and river-lake facies have emerged at the river mouth, groups of small sized sand wedges and involutions are found in the deposits at depths of 0.4 to 0.5 m beneath the ground surface. The enclosing deposits are light yellow and dark gray silt and clay. The wedges are filled with reddish clay and small gravels which are $7,750 \pm 90$ years old B.P. The involutions are 0.5 m to 0.8 m under the ground surface. Both the overlying and the underlying layers have very fine horizontal bedding. The involutions assume the form of gently symmetrical folded curves. According to the C-14 dating, the overlying and underlying layers are $7,090 \pm 185$ and $8,350 \pm 100$ B.P. years old each. This proves that the involutions were formed in the same period as the sand wedges.

Riyueshan Mountain and Qinghai Nanshan Mountain

Both mountain areas are over 4,000 m above sea level, with the lower boundary of the existing periglacial belt lying between 3,600 to 3,700 m above sea level. On the flat and gentle slope at the pass of Riyueshan mountain ($3,450$ m) there are extensive areas of non-sorted polygons, 1 to 2 m or 5 to 8 m in diameter. The clefts around the polygons have, however, been filled with post-glacial fine-grained mineral soil. Between 1.5 to 2.0 m under the ground surface is a paleo-soil layer, with rich humus. It is dated at $4,920 \pm 80$ years B.P. As the non-sorted polygons are over this soil layer, they were developed earlier. Therefore, they are the products of the Neoglacial age. On the gentle, flat summit level of 3,500 m a.s.l. in Qinghai Nanshan mountain where the Qinghai-Xizang Highway passes, there are frost heaving grassy mounds. Some are decaying. No waterlogged areas have been left but instead, grass meadows. 1.8 to 2.3 m under the ground surface is a well developed palaeo-soil layer of subalpine meadow type which is $3,590 \pm 90$ years old B.P. This proves that the frost heaving grassy mounds were formed during the Neoglacial age.

Qinghai Lake Basin

The level of the Qinghai Lake is 3,196 m above sea level, and the lake basin is generally no more than 3,400 m above sea level. The mean annual air temperature there is 0.9°C to 2.7°C . Though the basin belongs to the modern non-periglacial region, many fossil periglacial remains are found in the lakeshore areas. For example, the valleys near the lake-like Daotanghe, Buhaha, and Heimahe rivers have many non-sorted polygons. The polygons are usually 3 to 4 m in diameter. Besides the polygons there are also freeze-thaw mud-flow terraces and frost heaving grassy mounds in the valleys. Various signs indicate that they are all non-active.

Concentrated pyramid-shaped dunes are distributed on the east bank of the lake from mouth of Ganzihe river in the north to the foot of Manlong mountain in the south. On the watershed between the Datang and Langmahe rivers active dunes have formed over the old dunes which have been already covered by a layer of paleo-soil which is $3,960 \pm 100$ years old B.P. At present plants have begun

to grow sporadically on these new dunes, which shows that the stage of strong wind action has passed. Therefore, we think that new dunes formed during the Neoglacial age. The history of the Qinghai Lake indicates that during the middle and late Pleistocene the lake level progressively rose. It was not until the Holocene that the lake level began to drop, associated with uplift of the adjacent mountain areas and as the climate became arid. The wind action then began to erode the Holocene lake deposits. Hence the old dunes in Qinghai Lake basin should have been formed during the early cold stage of the Holocene and should be more than $3,960 \pm 100$ years old.

Mahanshan Mountain

In this mountain the blockfields, tors, and altiplanation platforms were formed during the main Würm glaciation. Other features such as snow-eroded hollows and terraces of freeze-thaw mud flows are the products of the Holocene cold stages. C-14 dating of a paleo-soil from 0.8 m under the ground surface shows it is $1,860 \pm 95$ years old. It is inferred that snow-eroded hollows may have formed during the Neoglacial age.

THE MODERN PERIGLACIAL BELT AND ITS VERTICAL ZONATION

Since the permafrost on the Qinghai-Xizang plateau is situated in the area of lower-middle altitude, the lower boundary of the permafrost is approximately the same as the mean annual air temperature, which is -2°C to -3°C . Accordingly, based on the -2° mean annual air temperature isotherm and using field data to amend, the distribution of modern periglacial belt is shown in Fig. 1. The zonation can be divided into three periglacial belts.

1. The upper belt. The mean annual temperature of part of Datong mountain within this belt is -4.5°C to -5°C and of Tuolai mountain -4.5°C to -8.2°C . The periglacial phenomena are mainly tors, altiplanation platforms, nivation hollows and freeze-thaw debris cones, blockfields, and polygons.
2. The middle belt. The mean annual temperature of the parts of Datong mountain and Tuolai mountain within this belt is -3.5°C to -4.5°C . The periglacial forms are chiefly terraces of freeze-thaw mud flows, tongue of mud flows and frost heaving mottled grounds.
3. The lower belt. The mean annual temperature here is -2°C to -3.5°C . There is comparatively weak frost heaving and freeze-thaw mud flow activity. There is also widespread solar thawing which produces sliding collapse and the formation of small ponds and marshy areas.

PERIGLACIAL HISTORY SINCE MAIN WÜRM GLACIATION

The great number of relic periglacial phenomena found in the northern region of the Qinghai-Xizang Plateau enable discussion of periglacial history of this region.

During the main Würm glaciation the most significant periglacial phenomena are relic frost

heaving mounds, relic sand wedges, and relic blockfields.

Washburn (1973) believes that pingos or frost heaved mounds, which indicate the existence of permafrost, develop in polar or subpolar areas where the mean annual air temperature is -2.2°C to -5.6°C . The mean annual air temperature of the areas in the permafrost belt on the Qinghai-Xizang Plateau where pingos extensively develop is -3°C to -5°C . (Wang Shaoling et al, 1981; An Zhongyuan et al, 1980) If we take the mean annual air temperature of -4°C as the necessary temperature under which the frost heaved mounds are able to form, then the difference between the main Würm and the present temperature is 7.5°C .

Another indicator showing the existence of formed permafrost are relic sand wedges. Pewe (1963) believes they exist where the mean annual air temperature is below -6°C to -8°C , while Washburn believes no less than -5°C . In view of the smaller size of the sand wedges in Gonghe Basin during the main Würm glaciation, and taking -5°C as the temperature indicator for their growth, we can see that the air temperature of the Gonghe Basin during the main Würm glaciation was 7°C lower than today's, and the lower periglacial boundary was about 2,400 m above sea level.

As said above, very cold climatic condition must have existed for the formation of the blockfields as found in Mahan mountain. On top of the present Tuolaishan and Zoulangnashan mountains which are 4,500 m above sea level and where the mean annual air temperature is about -5°C , no blockfields are formed with such great blocks as are found in Mahan mountain. In west Datan area of eastern Kunlun mountain, contemporary blockfields composed of blocks of 2 to 3 m in dimensions develop on mountain summit level at 4,950 to 5,000 m above sea level. In the Qomolangma area, they only form on summit levels over 5,800 to 6,000 m. Based on calculations, the mean annual air temperature in these areas is about -10°C . If we take -10°C as the air temperature condition under which the blocks were formed on Mahan mountain, then the amplitude between the main Würm and the present temperature is 8°C . Thus it is estimated that the lower boundary of the periglacial belt at that time was 2,220 m.

The periglacial development and environmental evolution of the Holocene can be divided into the following stages.

The Early Holocene Stage

This stage, 12,000 to 8,000 years ago, was the warm climatic stage at the beginning of the post-glacial age. In Gonghe Basin there are paleo-soil layers widely distributed 2 m under the ground surface of the footslope in front of Qinghai Nanshan mountain. Among them the soil buried near Qanbulu temple is 11,540±150 years B.P. At the place where the Shazhuyu River flows into Dalianhai lake, the top of the thick layer of lake facies which is 5 m above the lake surface is 8,350±100 years B.P. This indicates that during the early Holocene stage, Dalianhai lake experienced a period of high lake levels. The analysis of Holocene spore pollen in lake facies of the Qinghai Lake basin demonstrates that the woody plant pollen accounts for 48% of the total. In view of the large quantity of populus sp. and

salix sp., each of which accounts for 16% of the total pollen, and comparing their ecological environment with that of the present day populus and salix, it is calculated that the mean annual air temperature at that time was about 1°C higher than today. Therefore, the altitude of the lower boundary of the periglacial belt was 160 m higher than present day.

The Middle Holocene Stage

This stage which is 8,000 to 2,500 years ago can be further divided into the following stages:

1. The first cold stage. This stage, which is 8,000 to 7,000 years ago, is a cold fluctuating period. In Daxingan mountain (Xie Youyu et al) and Daihai lake, Inner Mongolia (Zhou Tingru et al) there are involutions which formed between 7 and 8 thousand years ago. Cui Zhijiu (1981b) reported relic pingos in the Kunlun mountain. In the Qinghai-Xizang region, the involutions and sand wedges near the mouth of the Shazhuyu River in the Gonghe Basin and the paleo-periglacial dunes in the Qinghai Lake basin were all produced during this stage. Since the involutions and sand wedges produced in the Gonghe basin are small, which suggests the climatic conditions were not severe, and since it is also possible that they were formed during a short period of time, their altitude of 2,860 m above sea level may not represent the lower boundary of the periglacial zone of the whole cold stage. Generally speaking, the periglacial dunes are in the external areas of the periglacial belt. Therefore, the altitude of 3,300 m above sea level is tolerance as the lower limit of the periglacial belt. During this cold stage, the temperature should have been about 2.5°C lower than today's, and altitude of the lower boundary 400 to 500 m lower than today's.

2. The high temperature stage. This stage which is 7,000 to 3,500 years ago is period of the middle Holocene when the climate was warm and humid. Peat formed during this stage. The water levels of lakes increased. Thick deposits of lake facies sediments were formed. For instance, the water level of Dalianhai lake in Gonghe Basin was over 10 m higher than today, and that of Qinghai Lake was at least 20 m higher than today. Spore-pollen shows that salix sp. still accounted for 5% of the total amount. The mean annual air temperature during this stage ought to have been about 1.8°C higher than today, and the lower boundary of the periglacial belt about 300 m higher than present day.

3. The second cold stage. This cold stage, which is 3,500 to 2,500 years ago, is also called the Neoglacial stage. The periglacial phenomena formed during this stage are widely distributed and of various types. The snow line value of Leng-longling mountain, which is the eastern part of Qilian mountain, drops about 200 m during this stage and temperature was accordingly about 1.2°C lower than today's. The lowest altitude of periglacial phenomena in the Qinghai Lake basin is 3,200 m a.s.l., the mean annual air temperature was 2.7°C lower and the lower boundary of the periglacial belt ought to have been 500 to 600 m lower than today's.

Judging from this, the Neoglacial age was the coldest stage in the Holocene.

The Late Holocene Stage

About 2,500 years ago the world came into the late Holocene stage where the climate was comparatively warm. With the rise of the lower boundary of the periglacial belt, paleo-soils again developed widely in the non-periglacial belt. The

C-14 dating of the paleo-soils in the nivation hollow on Diaoling, Mahan mountain shows that the soil was formed about 1,860±90 years ago. In order to make comparisons, Table 1 sums up the periglacial development and the changes in the altitudes of the lower boundary of the periglacial belt.

TABLE 1: The development of periglacial landforms and the altitude changes of periglacial belt in the northeastern region of Qinghai-Xizang Plateau since main Würm-glaciation.

Age	Events	Age of Formation (Years B.P)	Altitudes of periglacial boundary (m a.s.l.)	Temperature change	Elevation change of lower boundary of periglacial belt			
Holocene period	Late Holocene	Paleosoil on Diaoling of Mahanshan	1860±95	3,700-3,800				
		Middle Holocene	Neoglaciation	Frost heaving grassy mounds on Qinghai-Nanshan	3,590±90 after	3,200±	Dropped temperature about 2.7°C	Fell about 500-600 m
	Periglacial sand dunes on the east bank of Qinghai Lake			3,960±100 after

A PRELIMINARY STUDY OF THE DISTRIBUTION OF FROZEN GROUND IN CHINA

Xu Xiaozu and Wang Jiacheng

Lanzhou Institute of Glaciology and Cryopedology, Academia Sinica
People's Republic of China

Based on field data and statistical calculations, a distribution map of frozen ground in China has been compiled. It was found that the different types of frozen ground are located in different climatic zones. Permafrost is located mainly in the northern temperate zone, seasonally frozen ground in the middle and southern temperate zones, and intermittently frozen ground in subtropic areas. The values of mean annual air temperature at the lower or southern limit of permafrost depend on the differences between the annual mean ground temperature and the air temperature; these differences vary with districts because of the variation in solar radiation. The altitude of the lower limit of permafrost depends on four factors: latitude, the change rates of annual mean air temperature to latitude and altitude, and the difference between the annual mean ground temperature and the air temperature at that point. Differences of altitude between the snow line and the lower limit of permafrost vary with climatic districts: 1000-1500 m for arid districts, 500-1300 m for semi-arid districts, 250-1000 m for subhumid districts, and 0-400 m for humid districts.

Several papers have discussed the distribution of permafrost in China, but except for one (Zhou and Guo 1982), they deal with particular regions of China.

Based on data from field investigations and using statistical methods, a map of the distribution of frozen ground in China has been compiled at a scale of 1:4,000,000. From this work, it was found that the distribution of frozen ground in China is characterized by specific environmental factors.

HORIZONTAL DISTRIBUTION OF FROZEN GROUND

Frozen ground in China is classified into three types according to its duration, i.e. permafrost, seasonally frozen ground, and intermittently frozen ground. Permafrost can in turn be divided into two zones, a continuous and a discontinuous zone, according to the soil types on the ground surface.

In the continuous zone, permafrost occurs at the ground surface in all soil types, from fine-grained to coarse-grained soil. The area distribution of continuous permafrost is more than 50% in the Da-Xiao Hinggan Ling, northeast China, and more

than 70-80% in the high mountains and on the Qinghai-Xizang Plateau.

In the discontinuous zone, permafrost occurs only in peat or in wet fine-grained soil. The area percentage of permafrost in this zone is less extensive than in the continuous permafrost zone.

The criteria for classification of frozen ground are shown in Table 1.

Permafrost is mainly distributed on the Qinghai-Xizang Plateau, in the Pamirs, in the high mountains of western China, and in the Da-Xiao Hinggan Ling and on the tops of high mountains in northeast China, such as Dashi Shan, Changbai Shan, and the Zhangguangcai Ling.

The continuous permafrost zone of the Qinghai-Xizang Plateau can be divided into three subzones according to the continuity of the permafrost in horizontal distribution: a nearly continuous subzone from the northern slopes of the Kunlun Mountains to the southern slopes of the Tanggula Mountains; a wide-spread subzone on both sides of the valley of the Za'gya Zangbo River in Tibet; and a sporadic subzone from the south bank of the valley of the Yarlung Zangbo River to the Himalayas. The discontinuous permafrost zone is narrow in the north

TABLE 1 Classification of frozen ground.

Type	Limiting ground-surface temperatures (°C)	Minimum duration	Mean annual air temperature (°C)
Permafrost	Mean annual temperature < 0	≥ 2 yrs	Continuous -2.4 - -5
			Discontinuous -0.8 - -2
Seasonally frozen ground	Mean monthly minimum temperature < 0	≥ 1 month	8-14
Intermittently frozen ground	Extreme minimum temperature < 0	< 1 month	18.5-22

and wide in both the eastern and southern Qinghai-Xizang Plateau.

The discontinuous permafrost zone in the high mountains of western China is also very narrow, but it is widely distributed in the Da-Xiao Hinggan Ling mountains of northeast China, especially in Xiao Hinggan Ling.

The southern limit of seasonally frozen ground runs from Wakuhe (25°14'N, 97°52'E) northeast to Lianyun Harbour (34°30'N, 119°20'E). Seasonally frozen ground is also distributed on the tops of mountains, such as Dable Shan, Laiyang Shan, and Yu Shan.

The southern limit of intermittently frozen ground is nearly identical to the Tropic of Cancer. There is no frozen ground south of this line except on high mountains.

The area of each type of frozen ground in China is shown in Table 2. Frozen ground covers 98% of the total area of China, and permafrost covers approximately 20%.

The general distribution of frozen ground shows definite zonal patterns in latitude and altitude (Figure 1). From north to south, as latitude decreases, the type of frozen ground gradually changes from continuous permafrost to intermittently frozen ground. The pattern of this horizontal zonation is extremely clear in eastern China.

From north to south, as altitude decreases, the zonal structure of different types of frozen ground changes. First, there is a two-laminate structure with permafrost and seasonally frozen ground, as in the Tian Shan and the Altai Shan. Then, a three-laminate structure with permafrost and seasonally and intermittently frozen ground occurs, as in the Himalayas, followed by another three-laminate structure with seasonally and intermittently frozen ground and unfrozen ground, such as in the mountains of Taiwan. Finally, a two-laminate structure with intermittently frozen and unfrozen ground appears, as on Mt. Wuzhi on Hainan Island in the Gulf of Tonkin. This pattern of vertical zonation is readily apparent in the western region of China.

TABLE 2 Areal distribution of frozen ground.

Type	Area (10 ⁴ km ²)	Total area of China (%)
Permafrost	198.8	20.7
Seasonally frozen ground	521.7	54.3
Intermittently frozen ground	229.1	23.9

DISTRIBUTION OF FROZEN GROUND VS. ENVIRONMENTAL FACTORS

Climate

By comparing the distribution of frozen ground to the climate zones, we find that the different types of frozen zones are located in the different climatic zones, and the limits of the frozen ground classifications are nearly the same as the lines of climatic districts (Central Bureau of Climate 1979).

Permafrost is located mainly in the northern temperate zone and in the mountain regions of the middle temperate zone; seasonally frozen ground is found in the middle and southern temperate zones and in the mountain regions of the northern subtropics; intermittently frozen ground occurs in the subtropics and in the mountain regions of the northern tropics.

In Da-Xiao Hinggan Ling, continuous permafrost is located mainly in the humid region; discontinuous permafrost extends through the humid, subhumid, and subarid regions. Permafrost essentially appears in the subarid region of the Altai Shan, extends into the subarid and the arid regions of the Tian Shan, and is located in the arid regions of the Qilian Shan and the southern Qinghai-Xizang Plateau and the subhumid regions of the eastern Qinghai-Xizang Plateau.

Mean Annual Air Temperature

Information published both in China and abroad shows that the mean annual air temperature at the lower (southern) limit of permafrost differs from place to place. This is mainly due to differences in ground-surface temperature, which in turn are the result of differences in solar radiation (Figure 2).

The mean annual air temperature at the lower limit of permafrost in China and in similar areas of the world is shown in Table 3; we can see that the values for discontinuous permafrost in China are basically the same as those in other places, but are higher than in Gongbu Himalaya, in Nepal. This phenomenon can be explained by differences in total annual solar radiation. The mean annual air temperature at the lower limit of continuous permafrost in China is much higher than that of the continuous permafrost in arctic and subarctic regions, because in our classification the distribution of continuous permafrost does not take into account the influence of such factors as slope orientation, snow cover, and local heat resources.

From Figure 2, we can see that the mean annual values of total solar radiation around the world, including America, are within the range of the mean annual values of the western and eastern regions of

FIGURE 1 The laminated structure of types of frozen ground (after Gorbunov 1978).

FIGURE 2 Total solar radiation vs. latitude.

TABLE 3 Mean annual air temperature at the lower limit of permafrost, °C.

Region	Types of permafrost	
	Discontinuous	Continuous
Arctic or subarctic	-1.1	-8.3
Canada	0 - -1.0	
Rocky Mountains	-1.0	
Mt. Fujiyama (Japan)	-1.4 - -1.8	
Gongbu Himalaya (Nepal)	-2.8 - -3.4	
China	-0.8 - -2.0	-2.4 - -5.0

(Source: Brown and Péwé 1973).

TABLE 4 Total solar radiation vs. ground-surface temperature.

Station	Location			Soil type	T_a^1	Q^2	T_s^3
	Latitude	Longitude	Altitude				
Mangui	51°59'N	122°06'E	900 m	Peaty clay	-5.3	105	-4.3
Muli	38°15'N	99°12'E	4091.2 m	Peaty clay	-5.6	155	-3.7
Tumen	32°51'N	91°34'E	4930.5 m	Peaty clay	-5.2	195	-3.6

¹ T_a is the mean annual air temperature, °C.² Q is the total annual solar radiation, kcal/cm².³ T_s is the mean annual ground-surface temperature, °C.

China. Total solar radiation in western China increases with the decrease in latitude, so it is natural that the values in Gongbu Himalaya are higher than in western China.

The differences in total solar radiation result in differences in ground-surface temperature (Table 4). In general, where the mean annual value of total solar radiation is large, the ground-surface temperature is high. Simultaneously, where the mean annual ground-surface temperature is high, and given that all other conditions are the same, the mean annual air temperature must be low if frozen ground is to occur.

To sum up, the altitude of the lower limit of frozen ground depends on four factors: latitude, the ratios of mean annual air temperature to latitude and to altitude, and the difference between mean annual air temperature and ground-surface temperature (or the mean annual air temperature at the lower limit of frozen ground). This can be expressed by the empirical formula

$$H = (A - T - B_1 L) / B_2$$

where: H = the altitude of the lower limit of frozen ground, in units of 100 m

A = a constant, controlled by regional climatic conditions, in °C

L = the latitude, in °N

B_1 = the ratio of mean air temperature to latitude, in °C/°lat.

B_2 = the ratio of mean annual air temperature to altitude, in °C/100 m

Using this formula, we obtained the values for the lower altitude limit. The difference in the lower altitude limit between continuous and discontinuous permafrost ranges from 265 m to 600 m. The differences are approximately 300 m in arid mountain regions and 500 m in humid regions.

Snow Line Altitude

The difference between the lower altitude limit of discontinuous permafrost and the altitude of the snow line varies with climatic districts (Table 5). From arid regions to the subhumid, the altitude of the lower limit of discontinuous permafrost is lower than the altitude of the snow line, but in the humid regions this may be reversed.

The differences between the altitude of the snow line and the altitude of the lower limit of the discontinuous permafrost are as follows: 1000-1500 m for arid regions, 500-1300 m for subarid, 250-1000 m for subhumid, and 230-400 m for humid.

TABLE 5 Lower altitude limit of permafrost vs. the altitude of snow line.

Location	Latitude	Longitude	H _s ¹	H _p ²	ΔH ³	District
Lhunze	29°30'N	94°30'E	4800-5200	4850	-50-350	Humid

Tanggula Shan	33°06'	91°	5400-5500	4400	1000-1100	

¹ H_s is the altitude of the snow line, m.

² H_p is the lower altitude limit of the permafrost, m.

³ ΔH is the difference between H_s and H_p, m.

CONCLUSIONS

There are three types of frozen ground in China: permafrost, seasonally frozen ground, and intermittently frozen ground. Of these, seasonally frozen ground is the most common, as indicated by the percentage of area it covers.

The distribution of frozen ground in China follows horizontal and vertical patterns. From north to south, the types of frozen ground vary from permafrost to intermittently frozen ground, and the 2-3-3-2 laminate structures are observable.

The permafrost in the Da-Xiao Hinggan Ling has the characteristics of the high-latitude type, and latitude is the main factor controlling its distribution. In western China, permafrost has the characteristics of the alpine type, and altitude is the main factor controlling its distribution.

The distribution of frozen ground is closely related to environmental factors. The lower altitude limit of frozen ground depends on four factors: latitude, mean annual air temperature, and the ratios of mean annual air temperature to latitude and to altitude.

ACKNOWLEDGMENTS

We wish to express our gratitude to Professor Shi Yafeng, director of our institute, who directed this work, and to Prof. Zhou Youwu and Wu Zhiwan for their many helpful suggestions in the preparation of this paper.

DETERMINATION OF ARTIFICIAL UPPER LIMIT OF CULVERT FOUNDATION
IN PERMAFROST AREAS OF THE QINGHAI-XIZANG PLATEAU

Ye Bayou and Yang Hairong

Northwest Institute of the Chinese Academy of Railway Sciences
Lanzhou, People's Republic of China

In permafrost regions, the bearing capacity of foundation soil changes with periodic thawing and freezing. Many shallowly buried culvert foundations have been destroyed by uneven subsidence from thawing and frost heaving. The authors present a method for calculating the safe burial depth of culvert foundations and the approximate maximum thaw depth in accordance with specific features of the permafrost areas of the Qinghai-Xizang Plateau. This paper presents the calculation of maximum thawing depth, provided thawing of culvert foundation is permitted, and the design principle for keeping the ground beneath a culvert foundation in the unfrozen state. To simplify design, empirical formulas are recommended as reference as well. Comparing the calculated results with data from an experimental culvert in the Fenghou Mountains, the authors give the relation curve of the water-passing surface temperature of an experimental culvert vs. the ground surface and atmospheric temperatures of the local weather station.

The brooks and river valleys on the Qinghai-Xizang Plateau are generally 4,000-5,000 m above the sea level. The distribution of permafrost at small-sized river valleys is continuous horizontally and vertically, and the suprapermafrost table is about 2-3 m. The rainfall in this area reduces gradually from south to north. It is solid precipitation mainly. The precipitation concentrates from 6 to 9 months, among which precipitation in 7-8 months is about 50% of annual precipitation. So time for precipitation is short and strength is great. Thus, the flow in most of the culverts in this area is intermittent stream except for few culverts with constant stream during thawing.

Large numbers of the culverts built in this area before belong to the shallow-buried foundations. Many of them are subjected to failure of different degree. In order to determine correctly the burying depth of culvert foundation and the alternative depth of foundation soil, the law of artificial upper limit of foundations after the culverts built is mainly discussed in this paper.

CALCULATION OF THE MAXIMUM THAWING
DEPTH OF SOIL BENEATH FOUNDATION

Derivation of Equations

Under the effect of daily and seasonal variation of atmospheric temperature, ground surface temperature will fluctuate regularly. The simplest pattern of temperature fluctuation appears in the form of sine or cosine, i.e.

$$t_F = \bar{t}_F + A_F \cos\left(\frac{2\pi\tau}{T}\right) \quad (1)$$

where t_F and \bar{t}_F are the ground surface temperature and its average (in $^{\circ}\text{C}$), respectively; A_F is the amplitude of fluctuation of the ground surface temperature ($^{\circ}\text{C}$); τ is the time, in hours; T is the annual fluctuating cycle ($T = 8760$ hr).

As ground surface temperature varies sinusoidally or according to the law of cosine and without heat source in underground, the temperature at any given depth also varies in the same way. t_F in eq 1 can be substituted by t_x —temperature at depth x and the average temperature \bar{t} depth x can be assumed as a constant. Let $A_F = A_0$ and draw into temperature wave $\theta = t_x - \bar{t}$, we have, for the depth of perennial ground temperature, i.e. the depth not affected by temperature wave, the lower boundary condition $\theta(x = \infty, \tau) = t_x - \bar{t} = 0$. Then, by eq 1, the upper boundary condition will be:

$$\theta(x = 0, \tau) = A_0 \cos\left(\frac{2\pi}{T}\tau\right).$$

For ground surface under natural conditions, the distribution of initial temperature in ground layer factually does not affect on the temperature field of it, because radiation equilibrium and heat equilibrium act on it cyclically in an unlimited long period of time. Thus, it is clear, there isn't initial condition but boundary condition then. If the ground layer is uniform on nature of soil and thermal physical indexes do not vary with temperature, the differential equation for heat conducting is

$$\begin{cases} \frac{\partial \theta}{\partial \tau} = a \frac{\partial^2 \theta}{\partial x^2} \\ \theta(x = 0, \tau) = A_0 \cos\left(\frac{2\pi\tau}{T}\right) \\ \theta(x = \infty, \tau) = 0 \end{cases} \quad (2)$$

The specific solution of eq. 2 is:

$$\theta(x, \tau) = A_0 e^{-x\sqrt{\frac{\pi}{T a}}} \cos\left(\frac{2\pi}{T}\tau - x\sqrt{\frac{\pi}{T a}}\right)$$

while, if ground surface temperature varies sinusoidally, it becomes

$$\theta(x, \tau) = A_0 e^{-x\sqrt{\frac{\pi}{T a}}} \sin\left(\frac{2\pi}{T}\tau - x\sqrt{\frac{\pi}{T a}}\right)$$

Using the above equations to solve the necessary time τ_1 , taken for temperature of culvert foundation to get to 0°C and assuming the thickness of foundation is δ , we have:

$$\sin\left(\frac{2\pi}{T} \tau_1 - \delta\sqrt{\frac{\pi}{T a_2}}\right) = 0$$

Through simple calculation,

$$\tau_1 = \sqrt{\frac{T}{4\pi a_2}} \delta \quad (3)$$

where a_2 is the thermal coefficient of diffusivity of foundation material (m^2/hr); δ is the thickness of the foundation, including culvert pipe, in meters. If culvert pipe and foundation material differ, the thickness of the pipe shell must be converted into the thickness of the foundation material δ_1 . (λ_2/λ_1). Then the total thickness of foundation material will be

$$\delta = \delta_2 + \delta_1 \frac{\lambda_2}{\lambda_1} \quad (4)$$

where λ_1 and λ_2 are the thermal conductivities of pipe and foundation material respectively (see Figure 1).

Foundation soil begins to thaw after time τ_1 , which is within the thawing period, has elapsed. The thawed depth is calculated by Rukiyanov's (1963) equation:

$$h = \sqrt{\frac{2\lambda_1\theta_0}{\alpha_0 + \frac{1}{2}c_0\theta_0}} (\tau - \tau_1) + S^2 - S$$

where S is the equivalent thickness of surface layer. If the thermal conductivity of foundation material is λ_2 , according to the viewpoint of equivalent heat resistance the thickness of the first layer, foundation, can be converted into the equivalent thickness of the second layer, foundation soil, then $\delta(\lambda_1/\lambda_2)$. Substitute $S = \delta(\lambda_1/\lambda_2)$ along with eq. 3 into the above equation, we have the maximum thawed depth of foundation soil within the section of culvert body as:

$$h = \sqrt{\frac{2\lambda_1\theta_0}{\alpha_0 + \frac{1}{2}c_0\theta_0}} \left(\tau - \delta\sqrt{\frac{T}{4\pi a_2}}\right) + \left(\delta\frac{\lambda_1}{\lambda_2}\right)^2 - \delta\frac{\lambda_1}{\lambda_2} \quad (5)$$

where τ is the cumulative time in thawing period, hr; δ is the thickness of culvert foundation in meters, (calculated by eq. 4); θ_0 is the latent heat fusion of permafrost (kcal/m^3); λ_1, C_1 is the thermal conductivities of foundation soil beneath culvert foundation

FIGURE 1 Sketch of culvert foundation.

($\text{kcal}/\text{m}\cdot\text{hr}\cdot^{\circ}\text{C}$) and volume heat capacity (kcal/m^3) respectively; λ_2, a_2 are the thermal conductivity of foundation material of culvert ($\text{kcal}/\text{m}\cdot\text{hr}\cdot^{\circ}\text{C}$) and thermal coefficient of diffusivity respectively; θ_0 is the average positive ground surface temperature of water-passing surface of culvert ($^{\circ}\text{C}$).

In order to study the effects of the large-diameter culvert through the high filling of the soils on the foundation temperature field and the change of artificial upper limit, we built a concrete rectangle culvert of $2 \times 2.5 \text{ m}$ in the Mount Fenghuo region in Qinghai-Xizang Plateau. The topics developed with this testing project are blasting excavation of foundation pit and the construction technology of concrete foundation prefabricated unit of large size, etc. The culvert is 26.32 m long. The highest height of the filling soils above it is 6.0 m. The observation net of ground temperature, water temperature, atmospheric temperature inside it and ground surface temperature of water-passing surface is set up inside. The relative curves in Figures 2, 3, 6 are obtained through the information of continuous observation these years. The values adopted are the observed data from 5-9 months of annual thawing time. The value of every point in these figures is the average value of a month.

Since flowing surface water in Qinghai-Xizang Plateau mainly originates from solid-state falling water and thawed snow, the water temperatures are lower. Therefore, it is worth while to use the results of long-term observation data on the testing culvert at Mt. Fenghuo in this area, which is located in this region, for reference.

1. Temperature θ_0 of Culvert with Intermittent Stream

It is seen from Figure 2 that the temperature of the side wall of the body section of the test culvert at Mt. Fenghuo is slightly lower than local atmospheric temperature, on account of that there occasionally exists the influence by small amount of flow, it is, therefore, suggested that the mean value of average monthly positive temperature reported by local weather station be taken as θ_0 for calculating, supplemented by necessary safety coefficient according to particular conditions.

FIGURE 2 Relation between side wall temperature of testing culvert at Mt. Fenghuo and atmospheric temperature by local weather station.

TABLE 1 Various Calculating Indexes of Test Culvert at Mt. Fenghuo.

Locality	τ (hr)	Q_0 (kcal/m ³)	λ_1 (kcal/m.hr.°C)	C_1 (kcal/m.°C)	λ_2 (kcal/m.hr.°C)	a_2 (m ² /hr)
Opening No.4 (crushed stone concrete foundation)	3240	18816	1.38	630	1.1	2.75×10^{-3}
Opening No.5 (ceramsite concrete foundation)	3240	18816	1.38	630	0.5 (0.75)	1.5×10^{-3} (2.25×10^{-3})

2. Temperature Θ_0 of Culvert with Constant Stream

The ordinary flow area of the test culvert at Mt. Fenghuo is 0.25 m². According to the long-term observation data, we sorted out the mutual relation between temperature Θ_0 of water-passing surface of culvert body, atmospheric temperature reported by Mt. Fenghuo weather station, and ground temperature (Figure 3). In this article, the values of Θ_0 taken in calculating were all calculated by regression equation given by Figure 3 based on ground surface temperature provided by local weather station.

FIGURE 3 Relation between temperature of water-passing surface of culvert body, atmospheric temperature by local weather station and ground temperature.

Correlation between Calculated Results and Field Conditions

Given: A reinforced concrete rectangular culvert of 2 x 2.5 m² area in Mt. Fenghuo region of Qinghai-Xizang Plateau, the thickness of foundation of its body being $\delta_2 = 0.5$ m; Prefabricated crushed-stone concrete was used as the foundation of section from inlet to center line of the culvert; Prefabricated ceramsite concrete was used as the foundation of section from center line of the culvert to outlet. All of the culvert pipes were made of reinforced concrete, the thickness of its shell $\delta_1 = 0.23$ m and the thermal conductivity $\lambda_1 = 1.33$ kcal/m.hr.°C.

The contrast between results calculated and those tested is shown in Table 2. One thing to be mentioned here is that water movement after setting up the culvert and variation of thermal conductivity of ceramsite concrete after its being buried were not taken into account. On condition that the thermal conductivity of ceramsite concrete is increased by 50%, the corresponding results calculated can be found in Tables 1 to 3 in parentheses.

TABLE 2 Comparison between Calculated Thawed Depth and Measured Depth*.

Year	Temperature (°C)		Opening No. 4		Opening No. 5	
	Surface temperature by local weather station	Temperature of water-passing surface of culvert	Thaw depth calculated (m)	Thaw depth measured (m)	Thaw depth calculated (m)	Thaw depth measured (m)
1978	7.44	4.86	1.49	1.40	1.23, (1.37)	1.40
1979	7.34	4.76	1.48	1.25	1.21, (1.36)	1.25
1980	6.79	4.18	1.41	1.20	1.17, (1.30)	1.30
1981	7.38	4.80	1.49	1.60	1.23, (1.37)	1.50

* Measured values from spots of measuring hole by means of insertion (measuring distance = 0.5 m). The value of the thawing depth includes the thickness of the culvert foundation and pipe.

TABLE 3 Comparison of Calculated Depth of Foundation and That of Living Example, Keeping Foundation Ground Frozen.

Foundation	year	Temperature of water-passing surface of inlet and outlet, θ_0 ($^{\circ}\text{C}$)	Necessary burial depth of foundation calculated (m)	0°C Position in foundation measured (m)	Volume heat capacity of foundation material, rC_2 (kcal/m^3)

	1981	5.38	1.96	1.88	
Culvert outlet	1980	4.52	1.06, (1.49)	1.25	334
	1981	4.91	1.12, (1.58)	1.55	

CALCULATION OF CULVERT FOUNDATION THICKNESS NEEDED TO KEEP FOUNDATION SOIL FROZEN

While building a culvert in a permafrost area, the subsoil beneath the foundation of culvert body may thaw to a certain extent, provided it is refilled with coarse granular soil or other effective measures are adopted. The soil at the foundation of inlets, outlets, the wing wall, and the foundation beneath the culvert itself must be kept in a frozen state. Under such conditions, theory of energy equilibrium is used to derive equations for calculating the necessary thickness of foundation.

Derivation of Equation

a. According to the observed data of ground temperatures and strata beneath the culvert, it is assumed that the temperature within the seasonally thawing layer is distributed in a straight line, while that within permafrost layer is roughly expressed by eq. 6.

$$\theta = \theta_d \cdot \text{erf}\left(\frac{x - \delta}{2\sqrt{a_1 \tau}}\right) \quad (6)$$

where θ_d is the perennial ground temperature, which is unaffected by temperature fluctuation; a_1 is the thermal coefficient of diffusivity

FIGURE 4 Sketch of ground temperature curve in thawing period.

of foundation soil. The other symbols are the same as above. The ground temperature curve during the thawing period is shown in Figure 4.

b. The temperature within the thawing layer can be considered to be distributed in a straight line. From the similar triangles in Figure 4, we see that

$$\frac{\theta_0 - \theta_x}{\theta_x - \theta_\delta} = \frac{x}{\delta - x}$$

By this the temperature at a given depth of foundation is solved as:

$$\theta_x = \theta_0 - \frac{\theta_0 - \theta_\delta}{\delta} x \quad (7)$$

Equation 7 suits the first group of boundary conditions, when $x = 0, \theta = \theta_0; x = \delta, \theta = \theta_\delta$; where θ_δ is the temperature of the foundation bottom. In the light of Fourier's theorem, the heat gained by culvert foundation of unit length under the condition of temperature difference $= \theta_0 - \theta_\delta$ can be obtained by eq. 7 as:

$$Q_1 = \int \tau = -\lambda_2 \frac{\partial \theta}{\partial x} \Big|_{x=\delta} \cdot \tau = \frac{\lambda_2}{\delta} (\theta_0 - \theta_\delta) \tau$$

To prevent the foundation soil beneath the culvert foundation from thawing, the foundation bottom temperature θ_δ must be 0°C , thus the above statement becomes:

FIGURE 5 Heat consumed in temperature rise of culvert foundation.

$$Q_1 = \frac{\lambda_2}{\delta} \theta_o \tau \tag{8}$$

c. The heat consumed in raising the temperature of the foundation material is equivalent to the product of the area of the triangle in Figure 5 by the volume heat capacity of the material, rC_2 :

$$Q_2 = \frac{1}{2} \theta_o \delta \gamma c_2 \tag{9}$$

d. According to Fourier's theorem, the quantity of heat flow leaving from foundation bottom and getting into the surface of the frozen area is calculated by eq. 6 as:

$$q = -\lambda_1 \frac{\partial \theta}{\partial x} \Big|_{x=\delta} = \frac{-\lambda_1 \theta_d}{\sqrt{\pi a_1 \tau}}$$

It is seen from the above equation that heat flow q is a function of time τ , and if we substitute the negative value of perennial ground temperature of permafrost layer into the equation and change its sign, the total heat from thawing area to frozen area in the whole course of thawing, i.e. in a successive period of τ hours will be:

$$Q_3 = \int_0^\tau q d\tau = \int_0^\tau \frac{\lambda_1 \theta_d}{\sqrt{\pi a_1 \tau}} d\tau = \frac{2\lambda_1 \theta_d}{\sqrt{\pi a_1}} \sqrt{\tau} \tag{10}$$

e. In the light of Law of Conservation of energy and on account of lateral dissipation of foundation, we have $KQ_1 = Q_2 + Q_3$, where K is a revision coefficient. Based on the field investigation, it is suggested that when λ_1 (of foundation material as crushed stone concrete) = 1.1, K be 0.7; or $\lambda_1 \approx 0.5$ (as ceramsite concrete), K be 0.8. Thus we have

$$K \frac{\lambda_2}{\delta} \theta_o \tau = \frac{1}{2} \theta_o c_2 \delta \gamma + \frac{2\lambda_1 \theta_d}{\sqrt{\pi a_1}} \sqrt{\tau}$$

Noticing $a_2 = \lambda_2 / rC$ and rearranging the above equation, we get the formula to calculate depth of culvert foundation:

$$\delta = \sqrt{\frac{2\theta_o^2 \lambda_2^2 k + 4\lambda_1^2 \theta_d^2}{\pi a_1} - \frac{2\lambda_1 \theta_d}{\sqrt{\pi a_1}}} \sqrt{\tau} \tag{11}$$

where the symbols have the same physical meanings as stated above except for λ_1 and a_1 , which have to be the thermal conductivity and thermal coefficient of diffusivity of foundation soil within the range from foundation bottom downward up to depth of annual change zone of ground temperature. For layered foundation soil composed of different media, the method of weighted average is used to calculate the average of λ_1 and a_1 .

Determination of Temperature θ_o of Water-passing Surface of Culvert Inlet and Outlet

Little information has been accumulated so far for making a quantitative evaluation of a culvert with intermittent water flow. However, the temperature of the inlet and outlet foundation may be only a bit higher than the atmospheric temperature, since they are only slightly

FIGURE 6 Relation between temperature of water-passing surface of inlet (1) and outlet (2) of Mt. Fenghuo testing culvert and ground surface temperature provided by local weather station.

affected by sunshine. As for culverts of constant flow, regression equation of mutual relation between temperature of water-passing surface of inlet and outlet and that of ground surface reported by local weather station has been obtained, referring to the data observed at Mt. Fenghuo test culvert (Figure 6). This equation is used as reference for designing projects in the Qinghai-Xizang Plateau permafrost area.

Comparison between calculated results and data measured given in the above example of Mt. Fenghuo testing culvert, the foundation of its inlet and outlet are composed of crushed stone concrete and ceramsite concrete respectively both 3 m deep. The perennial ground temperature θ_o at the spot where the culvert is located is -3.20°C (Note: Its positive value is taken while substituted into the equation); the thermal conductivity and thermal coefficient of diffusivity of the foundation soil (the layer downward up to depth of annual change zone of ground temperature are $\lambda_1 (= 1.19)$ and $a_1 (= 2.66 \times 10^{-3})$ respectively; the other calculating indexes are listed in Table 1. The results calculated are presented in Table 3, in which the temperature (θ_o) of water-passing surface of culvert inlet and outlet were calculated by regression formula on the basis of the ground surface temperature by local weather station. The successive thawing periods were all the same, i.e. $\tau = 3240$ hr.

EMPIRICAL FORMULA

Determination of the Formula

Based on the analysis of weather data in permafrost area along with consulting information abroad, it is found that thawing depth of foundation soil is proportional to the square root of the positive cumulative temperature of local atmosphere or ground surface temperature, and the thawing depth curves of ground of different thermal conductivities in the same region almost tend to be a group of parallel lines; again, thawing depth of foundation soil is dependent on the specific yield as well as the dimension of opening of culvert. Thus the experience formula is written in the form of

$$h = K \lambda \sqrt{\Sigma \tau \tau} \tag{12}$$

where h is the thawed depth beneath culvert (m), including the thickness of culvert pipe, foundation depth as well as thawed depth of foundation soil underlying; λ is the thermal conductivity (kcal/m. hr. °C). The weighted average of culvert pipe, foundation and foundation soil is taken in calculating; $\sum T \tau$ is the thawing index of air temperature (°C day), namely, the sum of product of average positive temperature each month times number of days of the month. It is best to take the 10-year average thawing index of air temperature by local or neighboring weather station; K is an experience coefficient concerning the diameter of culvert inversely calculated in accordance with the measured data of culverts of different apertures (Table 4).

TABLE 4 K Values of Different Culvert Apertures.

Aperture of Culvert (m)	2.0	1.0	0.75
Experience Coefficient K	0.075	0.050	0.040

A test was made for comparing the calculated maximum thawing depth of foundation soil of Mt. Fenghuo test culvert by using the 5-year (1976-

1980) average thawing index of air temperature provided by Mt. Fenghuo weather station with the measured data, which resulted in a relative error of 15%. As for the existing culverts, only the data of thawing depth of foundation sides were present, however, the calculated results basically tallied with the variation of thawing depth of culvert sides measured. For instance, the thawed depths measured in 1977 on the side of Mt. Fenghuo Pass Highway Culvert and Wudaoliang Highway Culvert were 0.2 m and 0.16 m deeper than that measured in 1976 respectively, the error being no more than 4% compared with the variation amplitude of thawing depth calculated (Table 5).

In Table 5 the numerator values are the thawed depth calculated in accordance with the temperatures measured in testing boring at culvert side while the denominators are those calculated based on the annual thawing indexes of air temperature in the same years.

Use of equations if foundation soil is kept frozen. To design a culvert keeping foundation soil beneath its body foundation in frozen state,

TABLE 5 Measured and Calculated Thawing Depth.

Locality		No. of opening (m)	Annual thaw depth					Calculated value by 5-year average thawing index of air temperature
			1976	1977	1978**	1979	1980	
Mt. Fenghuo Test culverts	2.0 diam.	4	1.52	1.63	1.40	1.25	1.20	1.78*
		5	1.22	1.68	1.40	1.25	1.30	
Mt. Fenghuo pass highway culvert	1.0 diam.		0.98/ 1.00	1.18/ 1.24				
Wudaoliang highway culvert	0.75 diam.		0.85/ 0.85	1.01/ 1.00				
Qingshuikou highway culvert	1.0 diam.		0.92*/ 1.00					

* Obtained by means of experience coefficient of culvert having same apertures.

** A new temperature-testing boring set up in 1978.

TABLE 6 Results Calculated by eqs. 12, 13, and 14.

Year	Concrete foundation		Potter granule concrete foundation		Concrete foundation		Potter granule concrete foundation	
	Conversion formula	Empirical formula (12)	Conversion formula	Empirical formula(12)	Conversion formula	Empirical formula (12)	Conversion formula	Empirical formula(12)
1976	1.38	1.30	0.91	0.70				
1977	1.82	1.60	1.23	0.78				
1978	1.89	1.64	1.29	0.80	1.51	1.52	1.29	0.70
1979	1.63	1.47	1.08	0.70				
1980	1.70	1.52	1.14	0.74				

we still use eq. 12 to calculate the necessary foundation thickness, at the moment the value of λ is the thermal conductivity of foundation material substituted into eq. 12. Since the foundation thicknesses of the culverts along Qinghai-Xizang Highway are generally not greater than 0.5 m, there is not sufficient practical information for verification. Here the Sahuniach (1958) converting Formula is used to present a collateral evidence, i.e.

$$h_3 = h_2 \sqrt{\frac{a_3}{a_2}} = h_2 \sqrt{\frac{\lambda_3 C_2 \gamma_2}{\lambda_2 C_3 \gamma_3}} \quad (13)$$

where h_2 is the thawing depth of foundation soil, in meter; h_3 is the thickness of foundation material converted from thawing depth of foundation soil, in meter; a_2 , C_2 , r_2 are the thermal coefficient of diffusivity (m^2/hr), specific heat ($kcal/kg \cdot ^\circ C$) and unit weight (kg/m^3) of foundation soil respectively; a_3 , C_3 , r_3 are the thermal coefficient of diffusivity (m^2/hr), specific heat ($kcal/kg \cdot ^\circ C$) and unit weight (kg/m^3) of foundation material respectively.

This total thickness of foundation after being converted by Sahuniach formula (1958) is

$$h = h_1 + h_3 \quad (14)$$

where h_1 is the predetermined foundation thickness.

The results calculated by eqs. 12, 13, and 14 are listed in Table 6 for comparison. The value from the empirical formula in Table 6 is derived from eq. 12, while the value from the conversion formula is derived from eqs. 13 and 14. The

left hand numbers in the table are calculated results based on the thawing index of the air temperature each year, while those on the right are based on 5-year average thawing index of air temperature and the maximum measured thawing depth.

CONCLUSION

The permafrost area in Qinghai-Xizang Plateau is the source of the Yangzi River basin, where the river system is very developed. The culverts of road engineering built in this area are more and the engineering quantities is large. So it is important to study the change law of thawing depth after the culverts built and to determine correctly the burying depth of culvert foundation and alternative thickness of foundation soil.

In this paper, the thawing depth and the burying thickness of foundation calculated by equations are zero ($^\circ C$) places in the center line of transverse section of culvert.

Equation 5 is considered by one dimension, not corrected. Time that the temperature of foundation bottom needs to reach $^\circ C$ is determined by attenuation equation of temperature. Thus, the calculating error increases with the increase of foundation thickness. The equation is only used to calculate the maximum thawing depth beneath the culvert body. It can't determine the shape of thawing circle.

In addition to that, the effect during temperature fluctuating is not considered in the equations given in this paper. So, these equations should be used according to the actual condition.

A REVIEW OF CRYOGENIC STRUCTURE AND TEXTURE IN FINE-GRAINED ROCKS AND SOILS

E. D. Yerшов, Yu. P. Lebedenko, O. M. Yazynin, Ye. M. Chuvilin,
V. N. Sokolov, V. V. Rogov, and V. V. Kondakov

Geology Department
Moscow State University, USSR

The paper presents the results of investigations into the mechanics and laws governing the formation of cryogenic structure and texture in soils during freezing or thawing. A number of thermophysical, physico-chemical and physico-mechanical processes were studied theoretically and experimentally using a range of modern techniques. In the light of the results obtained, conditions for the formation and development of segregated ice layers and for the creation of various cryogenic textures were examined. A system of classifying cryogenic textures is proposed, which is unique in its potential to explain the formation of various types of cryogenic textures within a standard framework based on the major classification parameters and conditions of segregated ice formation. The paper considers peculiarities in the formation of cryogenic structure as observed both in laboratory experiments and in the field. A close relationship is demonstrated between the structural parameters, their degree of variability, and the intensity of the processes accompanying the freezing and thawing of unconsolidated rocks. The peculiar microstructure of naturally frozen unconsolidated rocks of various origins is described. The proposed classification system of cryogenic structures takes into account the type of ice cement, the pattern of bonds between the structural elements, and the nature of the areas of contact.

MECHANISM OF CRYOGENIC TEXTURE FORMATION

Cryogenic structure and texture formation in fine-grained rocks and soils is due to complex thermophysical, physico-chemical and physico-mechanical processes which essentially transform the composition, structure, and properties of freezing, thawing and frozen soils. As shown earlier (Yeršov, 1977; Yeršov et al., 1978), to determine the mechanism and kinetics of segregated ice formation (in other words, the conditions for cryogenic texture formation) one must know the relationship between heat exchange and water migration in freezing and thawing ground (i.e., the thermal conditions for cryogenic texture formation).

It is also necessary to consider the physico-mechanical environment in which segregated ice layers appear and grow. Cryogenic texture formation is impossible if the essential thermal conditions of coupled flows of heat and water within the frozen and thawed parts of the freezing or thawing soil are not present. In particular, segregated ice layers are formed in freezing fine-grained soils at the cost of migrating water whenever the amount of heat withdrawn exceeds that of heat emitted at the phase transition of water segregated during freezing. The thermal conditions vital to cryogenic texture formation, nevertheless, do not include all the physico-chemical and physico-mechanical processes occurring in freezing and thawing fine-grained soils (namely, shrinkage, swelling-heaving, structurization, appearance of zones with high structural strength, etc.). Thermal conditions alone fail to show the location and

nucleation point of ice layers with different orientation (for instance, parallel or perpendicular to the freezing front). The conditions sufficient for revealing the generation and growth of segregated ice layers are the physico-mechanical conditions under which cryogenic textures are formed, since they determine when the local strength of the soil is exceeded and microlayers of ice come into being.

The mechanism of forming ice microlayers can be generally described as follows. When a fine-grained soil is freezing, the thawed part is dehydrated owing to water migration to the frozen part and undergoes a process of structural formation and shrinkage resulting in new structural units of soil. Zones of concentrated strain evolve along the boundaries of these structural units. Within such zones the soil water is under tension (less than atmospheric pressure) compared to other sites of the soil. Owing to the pressure gradient, water migrates to the zones of concentrated strain. When these zones appear in the freezing portion of the soil, the shrinkage strain sharply increases (Yeršov, 1979), and the swelling-heaving strains caused by water migration and by ice crystallization in the freezing area become intensive. Local cohesion of the soil is broken along the zone of concentrated strain, and the water contained there passes into an unstressed state (i.e. its total thermodynamic potential increases stepwise) and the water rapidly transforms into ice. Microlayers of ice emerge in a definite region of the freezing soil, becoming most highly developed near the border at which the shrinkage and swelling-heaving strains change their directions. This region is

the negative temperature range (-0.2°C to -0.4°C).

Conditions for specific features of the emergence of segregated ice layers parallel and perpendicular to the freezing front and the kinetics of their evolution have been described in detail (Yershov, 1977, 1979; Yershov et al., 1978). It was shown that ice layers parallel to the freezing front result from cleavage (or displacement) stresses (P_{cl}) which are due to the variously directed strains affecting the dehydrating and the swelling (heaving) parts of the rock. Taking into account the disjoining pressure of fine water films (P_d^f), one can determine the region of soil where ice layers parallel to the freezing front may appear. To this end, the relationship ($P_{cl} + P_d^f$) and the local cohesion of the soil (shear strength P_{coh}^{sh}) are used together with the value of actual pressure (P_{act}) of the overlying soil sequence:

$$P_{cl} + P_d^f > P_{coh}^{sh} + P_{act} \quad (1)$$

The region of further growing ice layers may be identified by means of a similar relationship:

$$P_{cl} + P_{coh}^{sh} > P_{coh}^{s-i} + P_{act} \quad (2)$$

where P_{coh}^{s-i} is the cohesion of ice layers and frozen soil ($P_{coh}^{s-i} < P_{coh}^{sh}$).

Vertical segregated ice layers are related to the developing tensile stresses (normal stresses, P_n) specified by the difference between the shrinkage stresses and stresses of swelling-heaving ($P_{sw-heav}$). The area of P_n is the one below the border at which the shrinkage and swelling-heaving stresses change their directions. This area embraces some part of the freezing horizon and the unfrozen part of the soil. The regions where vertical microlayers of ice can originate and grow further can be found by the following relationships:

$$P_{shr} - P_{sw-heav} > P_{coh}^{tens} + P_{act} \quad (3)$$

$$P_{shr} - P_{sw-heav} > P_{coh}^{s-i} + P_{act} \quad (4)$$

where P_{coh}^{tens} is the local tensile strength of the rock ($P_{coh}^{s-i} < P_{coh}^{tens}$). It should be noted that regarding the appearance and growth of vertical ice layers (unlike horizontal ones) the disjoining effect of fine water films is neglected, since water migration to vertical zones of concentrated strains is chiefly due to the gradient of P_n inasmuch as the horizontal isothermal plane has no temperature gradient providing a gradient of P_d^f .

CLASSIFICATION SCHEME FOR CRYOGENIC TEXTURES

The formation of cryogenic textures is determined by a great number of interrelated processes which can be divided into thermophysical, mass exchange, physico-chemical, and physico-mechanical processes. However, cryogenic textures of certain types can form only under specific conditions. These include the following conditions: the lithological features of rocks; conditions providing for

water migration to the frozen region of freezing and thawing fine-grained soils (thermophysical and mass exchange conditions); conditions determining the appearance of migratory-segregated ice interbedding parallel or perpendicular to the front of freezing or thawing (physico-mechanical conditions); and finally, conditions specifying the incidence and thickness of layers. The thermophysical and physico-mechanical conditions for formation of cryogenic textures have been described above. As to the incidence of ice layers in fine-grained soils of homogeneous composition, structure, and properties, the case for ice interbedding parallel and perpendicular to the freezing or thawing front is determined by gradients of cleavage and normal strains, respectively, according to the following relationships:

$$l_{par} = f\left(\frac{I}{\text{grad. } P_{cl}}\right) \quad (5)$$

$$l_{perp} = f\left(\frac{I}{\text{grad. } P_n}\right) \quad (6)$$

where l is the distance between the interbeds of segregated ice. The thickness of segregated ice layers (h) is found from the relationship

$$h = f\left(\frac{I \cdot \Delta X}{V}\right), \quad (7)$$

where I is the density of water flow migrating to ice interbeds, V is the freezing rate, and ΔX is the vertical thickness of the region where horizontal or vertical segregated ice layers can develop.

The above notions on cryogenic texturization have been used to base a classification scheme for cryogenic textures in terms of their emergence and development conditions (Yershov, 1977, 1979).

Among streaky textures, classes are determined according to specific geological and genetic features of friable deposits and their lithology. Fine-grained soils of heterogenic composition, structure, constitution, and properties give rise to a class of inherited cryogenic textures, whereas homogeneous soils develop a class of superimposed cryogenic textures. In the first case, the pattern of cryogenic textures depends on the lithological-facial features of the freezing or thawing friable deposits. The genetic systematization of the second class of soils involves the thermophysical, physico-chemical, and physico-mechanical processes occurring in the specific geological and geographical environment.

A class of bulky cryogenic textures typical of soils with a broad gradation (from coarse to fine-grained) is formed when the physico-mechanical conditions are not satisfied (I,3). This class includes interstitial and basal-solid types of cryogenic textures which can be formed both with and without water migration.

Finally, cryogenic textures of contact and film-solid types develop when the thermophysical and physico-mechanical conditions for segregated ice layer formation are not satisfied.

The types of streaky superimposed cryogenic textures (for homogeneous materials) are determined by physico-mechanical conditions under which ice

layers are formed parallel or perpendicular to the front of freezing (or thawing). Versions of such conditions specify the variety of existing types of cryotextures within a particular class (porphyry-like, incompletely and completely developed layered and reticulate cryotextures).

Heterogeneous fine-grained soils may reveal combined physico-mechanical conditions similar to those which are found in the case of superimposed segregated textures. However, such conditions are usually also satisfied for the various inhomogeneities, providing for the origination and evolution of inherited ice layers. Considering the effect of inhomogeneities on the thermophysical, mass exchange, physico-chemical, and physico-mechanical processes, three types of inherited cryogenic textures can be identified. Textures of defective strength evolve in friable deposits of homogeneous composition which have zones of displacement, bearing, overmoistening, thinning, etc. Such zones determine the configuration of ice layers confined within soils of defective strength. Contact-stressed cryotextures reveal ice layers confined to contacts of fine-grained soils with different composition, structure, constitution, and properties. When ice layers are formed, the soil ruptures most easily along the contacts of heterogeneous layers, because the thermophysical, mass exchange, physico-chemical, and physico-mechanical processes in each of them differ. And, finally, there are cryogenic textures where the configuration of ice layers depends on the disposition, geometry, and material composition of foreign inclusions such as pebble, boulders, peat lenses, etc., within the heterogeneous fine-grained soil.

The classification scheme specified for each type of cryogenic texture the incidence and thickness of ice layers. To this end, relationships 5, 6, and 7 are used. The scheme is unique because it provides a uniform basis for explaining the formation of various types of cryotextures in freezing and thawing fine-grained soils by using the principal classification parameters of the segregated ice separation. It therefore becomes possible to assess quantitatively the great variety of geological and geographical factors of the environment.

CRYOGENIC STRUCTURIZATION

In laboratory experiments, intense water exchange and ice layer formation in freezing soils were induced by maintaining temperature conditions close to the natural ones (the cooling surface temperature was -6°C to 12°C). Water exchange was excluded through rapid acceleration of freezing at very low freeze-through temperatures (-30°C to -60°C). Such conditions are known to fix water as ice in situ (without obvious migration) and to yield massive cryotextures. The technique helps to identify the effect of mass transfer on structurization and also to assess the changes in the structure in relation to different factors. In the investigation of cryogenic structurization, such parameters were considered as the size and quantitative ratio of structural elements (organic-mineral particles and aggregates, ice inclusions, and pores), their shape and interrelation in clay soils of different composition and properties under

diverse conditions of freezing-thawing. These investigations yielded the following results.

When water-saturated soils are freezing such that water transfer from the unfrozen to the freezing region is intense, the mineral skeleton of the unfrozen part becomes dehydrated and shrunken irrespective of the rate of water inflow to the soil samples (with or without aquifers). The highest degree of dehydration (and of shrinkage) was observed in soils in which the water exchange was most intensive. Studies based on a micro-aggregate analysis have shown that the porosity of soils undergoes important changes largely in the region of highest dehydration and intensive shrinking strains, i.e. at the boundary of freezing. In unfrozen regions lying rather far from the freezing boundary the porosity does not change much. It is common for microaggregate compositions in the dehydrated unfrozen region of soils for the fraction of coarse dust and fine sand to increase while that of fine dust (and, more rarely, of clay particles) decreases.

The reduction in porosity owing to aggregation and coagulation of fine-grained materials results from the dehydration of the mineral skeleton. As the films of bound water around the particles become thinner and more desiccated, the particles draw closer and their interaction increases, i.e. their structural bonds become stronger. Within the freezing and frozen horizons, the growing aggregation levels off as the aggregates undergo destruction caused by crystallization and temperature stresses. In an electron-microscopic analysis the traces of ruptured primary particles and aggregates can be easily discerned by their distinct broken contours and the abundance of fine-grained material along the boundaries of the elements.

Low temperature freezing of fine-grained soils (without water exchange) mainly disperses structural elements. Such dispersion is particularly characteristic of grounds with high freezing rate and rapid water-ice phase transitions. In these cases we regard the temperature-crystallization destruction as the principal mechanism of structural disintegration. The porosity of low-temperature soils rises also during their thawing.

MICROSTRUCTURE OF NATURAL FROZEN FINE-GRAINED SOILS

Microstructure of freezing soils with different initial porosities is characterized by an increasing size of aggregate and a decreasing porosity of soil with ice-cement. This effect is most obvious in clays. Enlargement of aggregates in loams and sandy loams is weaker because water exchange is lower and shrinkage is less intense. In clay soils, the mineral composition determines the water exchange and ice formation during freezing, as well as the morphology of the cryogenic structure. The peat content of fine-grained soils proportionally contributes to the enlargement of ice inclusions. Organic-mineral material in freezing grounds yields large, shapeless aggregates (up to several mm in size). Freezing soils with organic material develop basal forms of ice-cement.

The effect of chemical composition on micro-structurization is manifested primarily with

salinity. Low soil salinization with monovalent cations ($10^1 - 10^2\%$) practically gives no aggregation, providing for homogeneous microstructurization of soils and diminishing the size of ice-cement inclusions. Higher soil salinity enhances aggregation because the salts crySTALLIZING from the freezing solutions cement the soil particles. Multivalent cations (especially Fe^{3+}) augment the aggregation of particles in the mineral skeleton and enlarge the inclusions of ice-cement inasmuch as water migration and interactions of structural elements increase.

CLASSIFICATION SCHEME OF CRYOGENIC STRUCTURES

The specific microstructural features of freezing, thawing, and frozen soils discussed in this paper testify to the great range of variously combined parameters of cryogenic structures. In view of this, it is hardly possible today to offer a scheme to rank cryogenic structures with regard to all features indicative of frozen soils. Nevertheless, it is feasible to provide a classification reflecting the principal structural parameters typical for groups of cryostructures. Among such characteristics are the type of ice-cement, and the pattern of bonds between structural elements and their contacts (Figure 1). In terms of the ice-cement type, cryostructures are specified in accordance with the total water content of the rock. Higher water contents alter the type of ice-cement, which can be epitaxial-pellicular, cuff-like, pellicular, interstitial, or basal.

Epitaxial-pellicular ice-cement is formed when the water content is lower than maximum hygroscopicity ($W < W_{m.h.}$); cuff-like ice-cement evolves with $W > W_{m.h.}$, and pellicular ice-cement develops when the water content causes capillary breakage ($W'_{c.b.}$). Interstitial ice-cement appears when the pores become completely filled with ground moisture, while with W exceeding the water content of swelling (W_{sw}), basal ice-cement is formed. Systematization of cryostructures in terms of the bonds between their structural elements is based on the content of unfrozen water determining the coherence and, indirectly, the force interactions of structural elements separated by water films of diverse thickness. It is also possible that at very low temperatures the bound water completely freezes, forming ice contacts. If so, ice-aggregating contacts transform into ice-epitaxial, and ice-coagulating ones—into highly epitaxial contacts.

The classification parameters discussed above rank various groups of cryogenic structures, including microtextures of fine-grained soils.

In terms of their contacts, cryogenic structures are systematized according to the distance between interacting structural elements and the state of contacts of water layers. Groups of contacts in frozen soils can be identified as water-free, water, ice, and water-ice contacts (Figure 2). Water-free contacts exist in over-dense soils where the particles of the mineral skeleton directly contact one another (the phase type of contact), and also in heavily salinized fine-grained soils in which the particles are cemented with various salts (the crystallizing type of contact). The group of water contacts includes

aggregating and coagulating ones. In the case of aggregating contacts, the particles are separated by weakly bound water; in the case of coagulating contacts the water is strongly bound.

With bound water partially freezing out, the above contacts transform into water-ice ones, both of ice-aggregating and ice-coagulating type. Stabilization of the mineral skeleton during freezing of bound water of different categories (from weakly to strongly bound) depends on the character of the ice-cement bonds. In terms of soil temperature, which determines the unfrozen water content, the following types of cryogenic structures can be defined: (a) the weakly bound ones observed at temperatures from $0^\circ C$ to the freezing point of weakly bound water (t_1) when the unfrozen water content exceeds the maximum molecular water capacity ($W_{m.m.w.c.}$); (b) the bound structures found within the range from t_1 to the freezing point of strongly bound water (t_2) when $W_{unfr.}$ is less than W_{mmwc} but greater than the water content of maximum hygroscopicity W_{mh} ; and (c) the strongly bound structures developing at t_2 and lower temperatures, with $W_{unfr.}$ being less than or equal to W_{mh} .

WATER REDISTRIBUTION MEASUREMENTS IN PARTIALLY FROZEN SOIL
BY X-RAY TECHNIQUE

Kiyoshi Yoneyama, Takeshi Ishizaki and Nobuaki Nishio

R & D Institute, Tokyo Gas Co., Ltd., Tokyo, Japan

ABSTRACT

This paper reports the results of water redistribution measurements in partially frozen soils under overburden pressure. The authors developed an experimental apparatus using X-ray technique to measure the water flow both in the unfrozen and frozen part of a freezing saturated soil under overburden pressure. The experimental method consists of taking X-ray photographs of the sample in which small lead shots are embedded, determining the location of small circular images of lead shots on the film and measuring the dilatations or the consolidations in each part of the sample by comparing them with those of subsequent films. During the experiment the temperatures of end plates were held constant. After the experiment was started, a large ice lens was formed around the center of the sample. Ice segregation was also observed in the region that was colder than the center of the sample. The amount of dilatations due to ice segregation was measured quantitatively with displacements of lead shots. The consolidation of the unfrozen part was observed. And the water flow both in the unfrozen and in the frozen part was calculated.

INTRODUCTION

Several models for frost heave have been proposed to describe water flow, heat flow, and ice segregation in freezing soils. A theory of coupled heat and water flow in freezing unsaturated soils without overburden pressure was proposed by Harlan (1973) and Taylor and Luthin (1976). Experiments along these lines of soil moisture movement were carried out by Dirksen and Miller (1976) using the gravimetric method and by Hoekstra (1966), Jame and Norm (1976), and Fukuda et al. (1980) using the gamma ray technique. These experimental results verified the validity of the coupled model for the frost heave phenomenon.

On the other hand, in designing Liquefied natural gas in-ground storage tanks and performing artificial ground freezing, saturated soils under overburden pressure must be taken into account. Theoretical studies of freezing soils under this condition have been carried out by Hopke (1980), Gilpin (1980), and Takashi (1982). Experimental research of water movement in freezing soils, including the frozen part, has been performed by Mageau and Morgenstern (1980) using the gravimetric method and by Loch and Kay (1978) using the gamma ray technique. However, only few such experiments have been made.

The present authors developed an experimental apparatus using X-ray technique to measure the water flow both in the unfrozen part and in the frozen part of a freezing saturated soil under overburden pressure. The X-ray technique permits us to observe the dilatation in the frozen part of the sample with a high accuracy. Consequently, experimental results obtained by using the X-ray technique might provide useful data to improve the theoretical researches for frost heaving of saturated soils under overburden pressure.

EXPERIMENTAL METHOD

Experimental Apparatus

The complete test configuration is given in Figure 1. The soil sample is contained in a plexi-glass cylinder with a wall thickness of 2 cm and an inside diameter of 12.5 cm. The temperature of the end plates is controlled by a thermoelectric cooling control system. The drainage tube from the upper end plate is connected to a volume change indicator which measures the water inflow and outflow from the soil sample. A dial gauge is set on the upper end plate to measure the total frost

Figure 1 Experimental apparatus

Figure 2 X-ray instrument

heave amount. Copper-constantan thermocouples are located at 1-cm intervals along the column to determine the soil temperature profile. The load can be applied to the sample through the top piston to the maximum capacity of 4 t. The soil container is covered with thermal insulation, to prevent radial heat exchange between the sample and air, and is placed in a room with a constant temperature of $+1^{\circ}\text{C}$. A schematic diagram of the sample and X-ray apparatus is shown in Figure 2. Small lead shots (diameter $D = 2$ mm) were embedded in the sample at intervals of about 5 mm in two vertical rows on a single plane. Lead shots for position reference are located on the outside of the sample. The sample is located between the X-ray source and the X-ray film holder. The X-ray source is positioned at the elevation of the growing ice lens to avoid parallax errors.

X-ray Film Reader

An X-ray film reader is used to determine accurately the location of small circular images of lead shot. A schematic diagram of the apparatus is shown in Figure 3. The apparatus is composed of a 45 x 45 cm film carriage, a two-axis D.C. motor drive system, a projection system, and a C.C.D. (charge coupled device) light intensity measuring system. An X-ray film is placed between two optically flat glass plates. The camera has 1,500 pieces of C.C.D., which is a semiconductor to transfer the light intensity into an electric

Figure 3 X-ray film reader

Figure 4 Properties of silty loam

signal. The accurate center of the image is determined by its light intensity profiles. Thus the accurate coordinates of lead shot images are measured. The accuracy of reading is 30 microns. A detailed explanation of the apparatus is given by Takagi et al. (1983).

Test Procedure

A silty loam was used in this experiment. The various properties of the soil are summarized in Figure 4. The frost heave test was performed in the following sequence. First the test sample was saturated with pure water. Lead shots were embedded in a sample in the manner mentioned above. The sample was then consolidated to the desired applied load. After the sample preparation was finished, the lower side plate was cooled down, and the sample was frozen from the bottom upward. During the experiment, both end plates were held at a constant temperature. X-ray photographs of the sample were taken at initially set time intervals. These photos were obtained using an X-ray tube with a source current of 5 mA at 195 kV and an exposure time of 2 min. The expansion in the frozen part of the sample was measured by reading accurate coordinates of lead shot images and by comparing them with those of subsequent films. Data from the thermocouples, the volume change indicator, and the dial gauge were collected periodically by a digital data acquisition system.

Figure 5 Total heave and heave by water intake

TEST RESULTS AND DISCUSSION

Total Heave and Heave by Water Intake

Three experiments (Test 1, Test 2, Test 3) were carried out with the sample in normally consolidated condition. The overburden pressures were 0.1, 0.5, 1 MPa; the initial sample heights were 94, 86, 104 mm; and the durations were 300, 550, 500 hours for Test 1, Test 2 and Test 3, respectively. The temperatures of the upper and the lower plate were maintained at +5°C and -5°C, respectively. Figure 5 shows both changes of the total heave amount and the heave amount by water intake as a function of time. As the applied load was increased, the rate of water migration into the sample decreased. The rates of the total heave coincide with the rates of the heave by water intake after about 24 hours from the start of the run. This coincidence is due to the completion of in situ water freezing by frost penetration in about 24 hours. This was confirmed by X-ray photos and the temperature profiles of the sample.

Temperature Change in Sample

The soil temperature changes for Test 2 are shown in Figure 6. As porous metal plates with a thickness of 5 mm are attached to both ends of the sample, the temperatures of both sample ends are a little different from those of the cooling plates. The measured temperatures of the upper and the lower end of the sample were +4.7°C and -4.7°C, respectively. The temperature profile established a semisteady state after about 24 hours from the start. However, the soil temperature decreased gradually and was shown to change after 500 hours.

Figure 6 Temperature changes (P = 0.5 MPa)

Displacements in Sample

Displacements of lead shot in the sample for Test 2 are shown in Figure 7. The curves indicated as -1°C, -2°C, -3°C, and -4°C show the displacements of lead shot where the average temperatures are the indicated values. The temperatures at the locations of the lead shot decreased by about 0.2°C between 24 and 500 hours from the start. The U.P. curve shows the displacements of lead shot in the unfrozen part. The line with dots shows the total heave amount. This is consistent with the displacements in the unfrozen part. In the frozen

Figure 7 Displacements in sample versus elapsed time (P = 0.5 MPa)

part, greater displacements took place in the warmer layer than in the colder layer. The segregation speed of the large ice lens that formed in the center of the sample decreased with time. However, the segregation rates of the small ice lenses that formed in the region colder than that in which the large ice lens had formed did not decrease in the same way, and were almost constant throughout the duration of this experiment.

X-ray Films and Other Data

X-ray photos, temperature profiles, displacements of lead shots, and dilatations between lead shots for Test 2 are shown in Figure 8. A, B, C, and D show the results after 24, 96, 315, and 502 hours from the start, respectively. A1 shows a print of the X-ray film of the sample after 24 hours from the start. The dots in the sample are the images of the embedded lead shot. The dots on the outside of the sample show the images of lead shot used as reference points. The horizontal white band in the middle of the sample indicates the image of the segregated ice lens. The thickness of the ice lens increased gradually. The thicknesses of the ice lens for A1, B1, C1, and D1 are 0.6, 3.0, 5.3, and 6.1 mm, respectively. In C1 (315 hours) the other ice lens images can be seen at the distances of 15 and 35 mm from the bottom of the sample. These ice lenses are seen to have increased their thicknesses to D1 (502 hours).

A2, B2, C2, and D2 show the temperature profiles at each elapsed time. The dashed line shows the temperature profiles after 24 hours from the start. The horizontal line shows the location of the upper side of the large ice lens. According to the modified Clausius-Clapeyron equation, ice lenses are considered to segregate at or below -0.45°C when the overburden pressure is 0.5 MPa (Hoekstra, 1969). The vertical line shows -0.45°C. The temperature of the upper side of the large ice lens determined from the temperature profile is close to the expected value.

A3, B3, C3 and D3 show the displacements of lead shot at each elapsed time. The dashed line shows the displacements of lead shot from the start to 24 hours. The dots show the displacements of the upper end plate measured by the dial gauge. And it is noticed that the upper part of the large ice

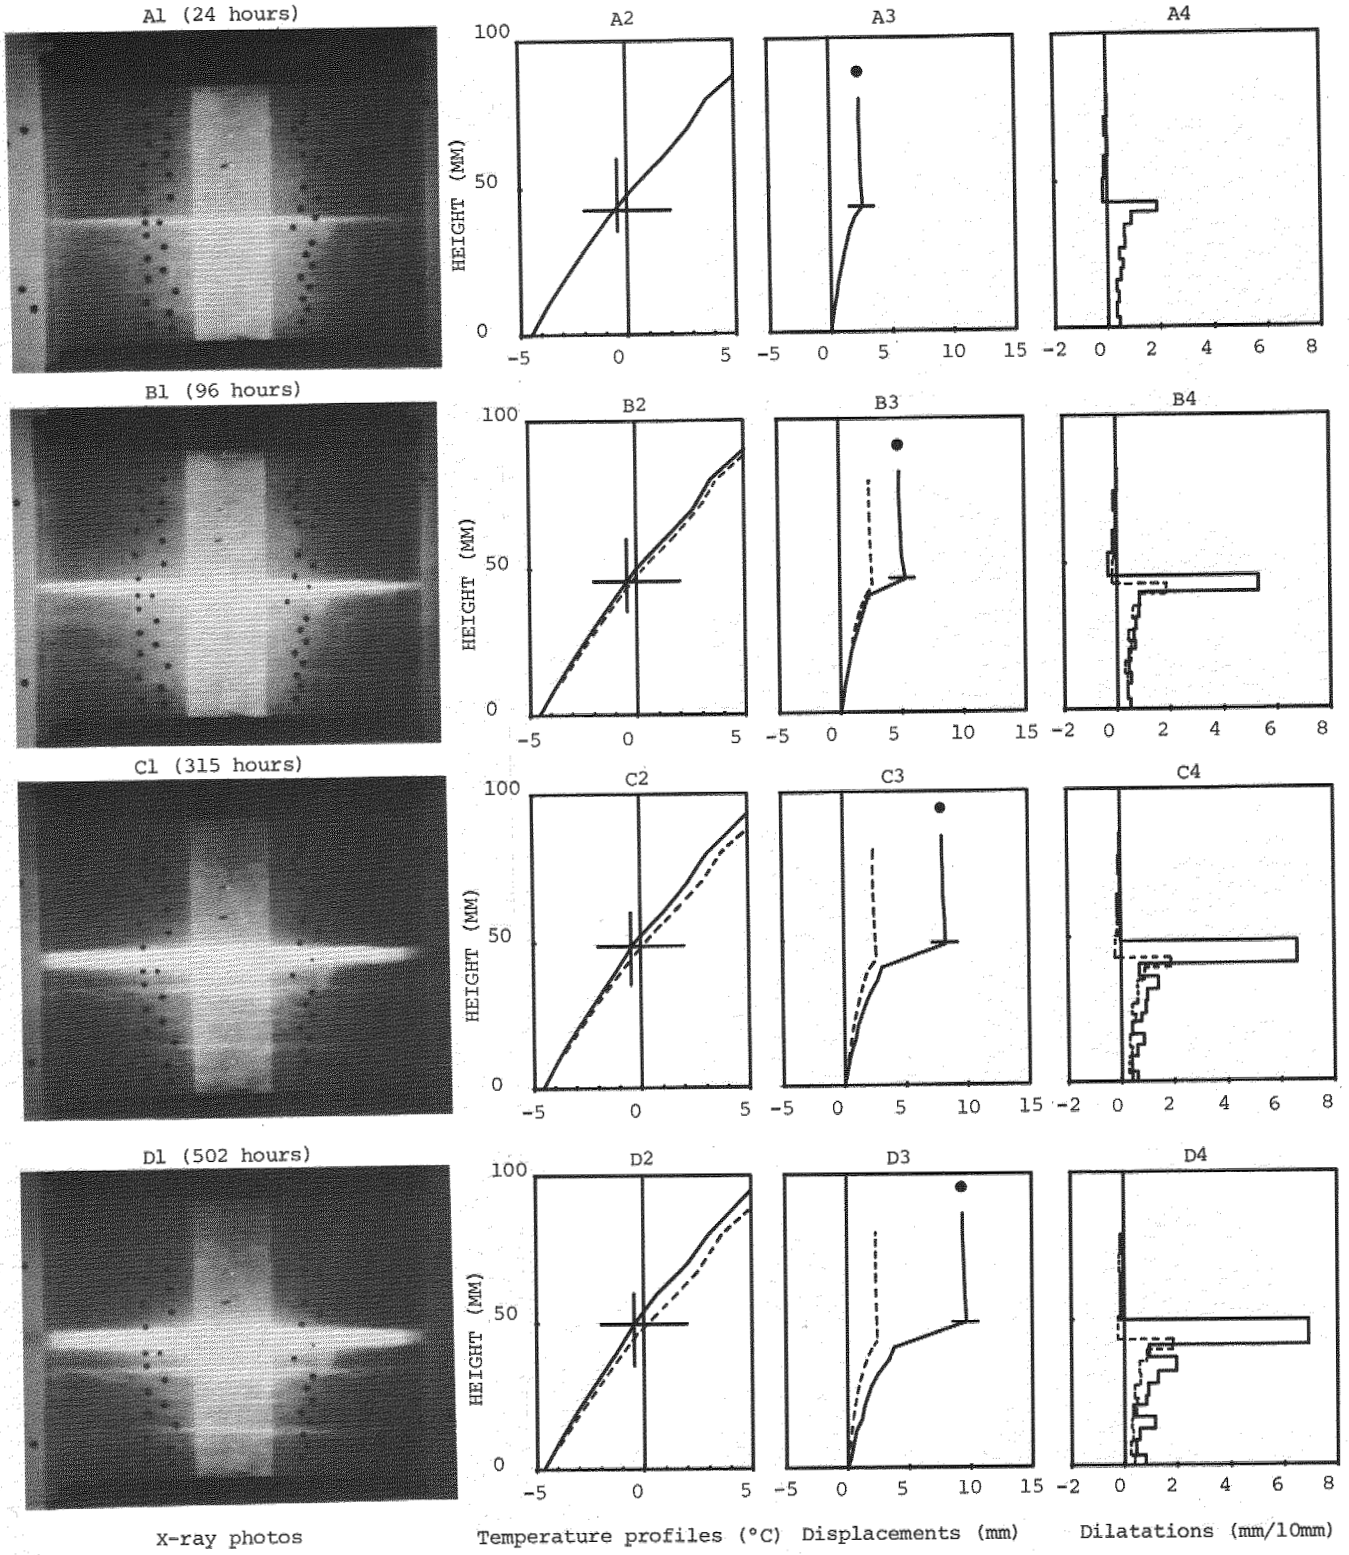

Figure 8 X-ray photos and other data ($P = 0.5 \text{ MPa}$)

lens displaced more than the part near the warm end. This means that the unfrozen part has consolidated after the experiment was started.

A4, B4, C4, and D4 show the dilatations between lead shots at each elapsed time. As the distance between lead shots is different in each location, the amount of dilatation was normalized so that the distance between every lead shot is 10 mm. The dashed line shows the dilatations between lead shots from the start to 24 hours. The area between the solid line and the dashed line shows the dilatation of the sample after 24 hours. Large dilatation is shown at the distances of 15 and 35 mm from the bottom, as well as in the center of the sample (C4, D4). This corresponds to the ice segregation in each location which is shown in the X-ray films (C1, D1).

Consolidation due to Soil Freezing

Figure 9 shows the displacement change with various lapses of time for Test 1. The dots show the displacements at the warm end measured by the dial gauge. The horizontal line shows the location of the upper side of the large ice lens. The unfrozen part of the sample has consolidated greatly since the start of this experiment. Line TH shows the displacement of lead shot after the sample was thawed. Figure 10 shows the displacement change for Test 2. In the unfrozen part, the consolidation can also be seen. However, its amount is smaller than that for Test 1. The amount of the thaw consolidation is also small.

Figure 9 Displacements in sample (P = 0.1 MPa)

Water Flow Rate in Sample

Figure 11 shows the relationship between the water flow rate and the temperature in the sample. As the temperature profile both in the unfrozen part and in the frozen part is almost linear, the horizontal line (the temperature axis) can also be considered to represent its location. F1 shows the average flow rate between 96 and 192 hours, and F2 shows that between 407 and 502 hours. The flow rates in the unfrozen part for F1 and F2 are 1.8×10^{-3} and 7.6×10^{-4} cm/h, respectively. These values are consistent with the measured water

Figure 10 Displacements in sample (P = 0.5 MPa)

intake rates. The flow rate changes abruptly at the location of the large ice lens. Although the flow rate in the unfrozen part for F2 reduced to 40% of that for F1, the flow rate in the frozen part for F2 did not reduce in the same way. This tendency can also be seen in Figure 7. The flow rate for F2 also changes greatly at the locations of -1.5°C and -3.5°C . This is caused by the segregated ice lens at each location as shown in Figure 8.

CONCLUSIONS

The water movement and the ice segregations were observed by using a recently devised X-ray technique. The experiments were performed for a saturated soil sample under overburden pressure. Ice lens segregation was observed in the region that was colder than the center of the sample where the large ice lens had formed. The dilatation in the frozen part due to ice segregation was measured quantitatively by the precise determination of the locations of lead shot images on X-ray films (Figure 7 and Figure 8). The consolidation of the unfrozen part due to soil freezing was observed

Figure 11 Water flow rate in sample (P = 0.5 MPa)

(Figure 9 and Figure 10). The water flow both in the unfrozen and in the frozen part was calculated (Figure 11). This frost heave apparatus using X-ray technique is found to provide various data on saturated soils under overburden pressure, and these data will be used to develop the theoretical studies of the frost heave phenomenon.

ACKNOWLEDGMENT

The authors wish to thank S. Kinoshita and M. Fukuda of the Institute of Low Temperature Science for their valuable suggestions.

CONDITIONS OF PERMAFROST FORMATION IN THE ZONE
OF THE BAIKAL-AMUR RAILWAY

S. I. Zabolotnik

Permafrost Institute, Siberian Branch,
Academy of Sciences, Yakutsk, USSR

On the basis of statistical analysis of data derived from many years of observations conducted at 170 weather stations in the region, quantitative relations between the basic environmental parameters were obtained. They enable us to explain the formation of taliks in the western and eastern fringes of the zone and also the extreme low temperatures (down to -7 to -12°C) and the extreme thickness (700-1300 m) of the permafrost in the alpine areas of the Udokan and Kodar ranges. It was established that continuous permafrost occurs in the regions where the mean annual air temperature is lower than -7°C . In those parts of the zone where the mean annual temperature falls between -3 and -7°C , either seasonally frozen ground or permafrost occurs. As a rule, no permafrost forms in regions where the mean annual air temperature is above -3°C .

The Baikal-Amur Railway stretches more than 3.5 thousand kilometers, from the Taishet station of the main Trans-Siberian Railway in the west to the Pacific coast in the east. It crosses vast regions of southern Siberia and the Far East—regions of complex relief including flat country as well as ranges of mountains of different altitude and degree of distribution.

Numerous investigations carried out along the railway itself and in territories adjacent to it (Bibliografiya ... 1978, Bibliografiya ... 1982) have shown that the permafrost regime of the region is extremely complex. The majority of the region is dominated by continuous permafrost, whose temperature varies between values close to 0°C to -10°C and below while its thickness ranges, respectively, from several meters to 500 m and more. At the same time, in the extreme west and in the eastern part of the Baikal-Amur Railway the permafrost exhibits a discontinuous or island-shaped nature while in the Amur River valley to the south of Komsomolsk, it occurs only in the form of individual islands or as short-term permafrost (The Baikal-Amur Railway, 1979).

Such a wide range of variation of the permafrost zone characteristics is largely due to the climatic peculiarities both of the entire region and of its parts in isolation. In order to reveal these peculiarities an analysis was made of many years of observations from all weather stations located within the railway zone—a belt up to 200-250 km across, extending eastward from 101°EL along the Baikal-Amur Railway. At the beginning of construction work on the railway, nearly 170 weather stations were operative within this zone, including about 30 stations in the immediate vicinity of the railway (Directories on Climate in the USSR, v. 22-25, 1966).

This number of weather stations is obviously insufficient to provide a detailed understanding of all parts of such a diverse region. Statistical methods do, however, help to reveal both the general trends in particular climatic parameters

and their correlation with one another.

In analyzing correlations between individual quantities, it was assumed that the relationship was linear and obeyed the equation:

$$y = ax + b \quad (1)$$

where the regression coefficients a and b were determined with a least-squares technique (Smirnov and Dunin-Barkovsky 1959 and Fisher 1958).

One of the principal factors that determines the degree of severity of climate and indicates the possibility that permafrost is present, is the annual average air temperature. In assessing this factor in different parts of the region, we must recall that the Baikal-Amur Railway passes mainly in the latitude direction so that the zone of the Baikal-Amur Railway, stretching from west to east by more than 40°L , lies completely within 48 and 58°NL .

The analysis of the dependence of the annual average air temperature (t_a) on longitude of the site (ϕ) shows that it is substantially different for the western and eastern parts of the railway (Figure 1), and the natural demarcation line between these parts occurs at the eastern spurs of the Stanovoi upland.

The railway, moving eastward from Taishet, crosses first the northern part of the Lena-Angara plateau and the near-Baikal depression where the terrain varies between 200 and 400 m above sea level. Then it enters the area of mountain formations of the Stanovoi upland, gradually rising up to 800-1300 m altitude. Naturally, in such conditions the mean annual air temperature steadily decreases in this direction to 120°EL (see Figure 1, line 1). The dependence of the air temperature on longitude of the site in this part of the zone is described by the relation:

$$t_a = 0.34\phi + 31.79. \quad (2)$$

The lowest air temperatures are observed in the

eastern part of the Stanovoi upland within high-altitude (from 1000 to 1500 m ASL) valleys and hollows of the Yankan, Kalarsky, Udokan and Kodar ridges (Directory ..., v. 23, 1966), whose several tops reach 2000-3000 m above sea level.

The eastern part of the railway leaves the Stanovoi upland and crosses the southern spurs of the Stanovoi Ridge, the Upper-Zeya and Amur-Zeya plains, and the Turan, Bureys and Badzhalsky Ridges before arriving in Komsomolsk-on-Amur. Finally, it surmounts the northern spurs of the Sikhote-Alin to approach the Pacific. It is easy to see that in this direction, except for some local parts, a steady decrease of elevation is experienced, down to sea level. As one moves eastward, the annual average air temperature continuously increases (see Figure 1, line 2) with the longitude-dependence of temperature being described by the relation

$$t_a = 0.28\phi - 40.61. \quad (3)$$

The considerable range of air temperature fluctuations ($\pm 4^\circ\text{C}$) is a function of latitude and true altitude (Zabolotnik 1978).

On considering the fluctuations of the annual air temperature within the entire zone of the Baikal-Amur Railway, it is apparent that owing to the specific features of the relief, the air temperature on the average decreases by 3.4°C from west to east with every 10 degrees of longitude along the Bratsk-Udokan stretch while on the contrary that along the Udokan-Sovetskaya Gavan stretch increases by 2.8°C for each 10 degrees of longitude.

The relationships of annual average air temperature fluctuations within the region are mainly due to the different conditions of the formation of wintertime (subzero) temperatures.

The summertime average (above-zero) air temperatures (t_s) vary between 9 and 13°C throughout the Baikal-Amur Railway, with rare exceptions. On the average, the summertime air temperature ranges from 10.5°C in the region of Bratsk to 11.6°C in the region of Komsomolsk-on-Amur (Figure 2, line 3) and its relationship to the longitude of the site is described by the relation:

$$t_s = 0.03\phi + 7.47. \quad (4)$$

Such a minor variation of the summertime air temperature (0.3°C by every 10 degrees of longitude) cannot, of course, have substantial influence upon the formation of an annual air temperature and indicates the relative homogeneity of the summertime conditions of the entire zone of the Baikal-Amur Railway.

A completely different picture presents itself in the distribution within the railway zone of average wintertime air temperatures (t_w). Their dependence on longitude of the site is practically similar to the one for the air temperature and is expressed through the following relationships: for the western part of the zone (see Figure 2, line 4):

$$t_w = -0.34\phi + 19.09 \quad (5)$$

while for the eastern part (see Figure 2, line 5):

$$t_w = 0.27\phi - 53.32 \quad (6)$$

The calculation of dependences (4-6) neglected the data from weather stations situated in the immediate vicinity (up to 50 km) of the Tatar Strait coast, where the influence of the Pacific is far larger than elsewhere. That influence is expressed in a substantial decrease (to 8.5 to 9°C) of average summertime temperatures and in an abrupt increase (up to -9 to -10°C) of average wintertime temperatures (see Figure 2).

The fluctuation of annual average air temperatures within the zone of the Baikal-Amur Railway, predominantly in the subzero range (from -2 to -10°C), indicates the severity of the climatic conditions of the region. However, the subzero air temperature, in itself, is not yet a necessary condition for the formation of permafrost. It is known, for example, that there are taliks even near the Chulman settlement where the annual average air temperature is -9.4°C (Directory ..., v. 24, 1966). The permafrost forms only in areas with a subzero annual average temperature of the ground surface, that is below snow and plant covers.

The warming effect of a snow cover on underlying earth materials is fairly well known (The Foundations of Geocryology, 1959, Dostovalov and Kudryavtsev, 1967, General Geocryology, 1974, 1978, Geocryology, 1981), but determining the magnitude of this effect for a specific area presents a problem. The difficulty arises due to substantial snow cover variation (by 10 to 13 cm), even within one area, depending on a variety of local factors (open or wind-protected site, field, forest, etc.) as well as yearly variations. Therefore, it can be determined only quite roughly.

Within the zone of the Baikal-Amur Railway the winter-average thickness of the snow cover, inferred from 10-day data obtained at weather stations (Directory ..., v. 22-25, 1968) varies between 7 and 45 cm, with maximum thicknesses observed at the western and eastern ends of the zone (Figure 3).

The dependence of snow cover thickness (Z , cm) on longitude of the site is described by the following relationships: in the western part (see Figure 3, line 6)

$$Z = -0.96\phi + 127.56, \quad (7)$$

in the eastern part (see Figure 3, line 7)

$$Z = 0.89\phi - 91.61. \quad (8)$$

Consequently, the snow thickness, on the average, decreases by one cm in the western part of the Baikal-Amur Railway zone for every degree of longitude while that in the eastern part, on the contrary, increases by about the same value.

Of interest are the simultaneous decreases of both annual average air temperature and snow cover thickness in the middle part of the region. Such a combination of natural factors is highly favorable for the development of the lowest temperatures of the ground surface and therefore for the formation of permafrost of large thickness. It is, therefore, not unusual that we have observed within the high-altitude part of the Udokan and Kodar Ridges the lowest temperatures (as low as -7 to -12°C) and the largest thickness (700 to 1300 m) of permafrost in the entire zone of the Baikal-Amur Railway (Nekrosov, Zabolotnik, et al., 1967).

It is possible to determine a particular effect of the snow cover thickness on the underlying ground thickness, using stationary measurements of ground and air temperatures and snow cover thickness. In the Baikal-Amur Railway zone, of the nearly 170 weather stations discussed herein, such measurements are being carried on only at 26 stations. The measurements from these stations indicate that while protecting grounds from the wintertime cooling-down, the snow cover increases the annual average temperature of ground surface by 3 to 7°C. Analysis of the relationship between the difference of annual average temperatures of ground surface and air and the snow cover thickness shows that depending on the amplitude of fluctuations of annual temperatures and snow density the snow cover's warming effect for average wintertime thicknesses of 10, 20 and 30 cm is, respectively, 2.5 to 4.5°C, 4.5 to 8°C and 6.5 to 11.5°C.

Such a large effect of the snow cover on the formation of ground surface temperature can lead, in some areas where snow accumulates constantly or when very snowy years are experienced, to the formation of talik zones at very low air temperatures.

The determination of specific values of the warming effect of the snow cover makes it possible, using air temperatures nearly always obtainable on the basis of the data from the nearest station, to infer the range of ground surface temperature fluctuation. Therefore, prior to conducting field investigations, it is possible to establish the likelihood of the existence of talik zones or masses and islands of permafrost as well as to evaluate their thickness.

Similar information can be obtained using the data from the weather stations which take systematic measurements of ground temperature together with air temperature. Although the number of such weather stations is currently small (31 stations within the zone under consideration), the correlation between annual average air temperatures (t_a) and ground surface temperatures ($t_{g.s.}$), expressible through the relation:

$$t_{g.s.} = 0.77t_a + 4.05, \quad (9)$$

reveals some features of the formation of the ground temperature condition.

According to relation 9, the ground surface temperature, with some time delay, increases with increasing air temperature. On the average, it reaches 4°C at an air temperature equal to 0°C and becomes subzero only when the air temperature is below -5.2°C (Figure 4, line 8). However, due to the great inhomogeneity of the natural conditions in different areas of such a vast region, the same surface temperature is able to form at air temperatures varying within $\pm 2^\circ\text{C}$ (Figure 4, lines 9 and 10). Therefore, at the present stage of studies it appears possible to determine only the air temperature ranges at which the conditions are favorable for the formation of either seasonally frozen soils or permafrost.

Analysis of the relationship between the temperatures of air and ground surface shows that at an annual average air temperature below -7°C, the ground surface temperature within the Baikal-Amur Railway zone is practically always below zero.

Consequently, in the areas of the zone having such an air temperature, there must be continuous permafrost.

As mentioned previously, the annual average air temperatures in the region are able to reach -10°C and lower values. In such conditions, the annual average temperature of the ground surface will vary between -3 and -8°C and the thickness of permafrost will be 150-400 m at the mean gradient of 20 grad/km. In extreme conditions, there are much lower temperatures and permafrost thicknesses in excess of 2 to 3 times.

When the annual average air temperature varies from -3 to -7°C and the region is dominated by areas with such temperatures, either seasonally frozen grounds or permafrost form, depending on the relationship of some regional factors, because the ground surface temperature is able to vary from +3 to -3°C. The permafrost thickness (at the same gradient) can be quite different, from 1 or 2 to 150 m.

In regions where the annual average air temperature is above -3°C, generally no permafrost is present because the ground surface temperature here is above zero (see Figure 4). Exceptions to this are areas, occupied by "mari" (swampy sparse larch forests interrupted by hummocky bogs), in which owing to the cooling effect of moss-peat cover, reaching 2°C and more (Balobaev, Zabolotnik, et al., 1979), mainly thin (of up to 50 m) permafrost zones with annual average ground temperatures of about -2°C occur.

A MATHEMATICAL MODEL FOR THE VISCOPLASTIC DEFORMATION
OF FROZEN SOILS

Yu. K. Zaretskiy¹ and A. G. Shchobolev²

¹Scientific Research Center of Hydroproject Institute, Moscow, USSR

²Civil Engineering Institute, Moscow, USSR

A rheological model for frozen soil and ice, based on a theory of viscoplastic hardening, is suggested. The critical equations take the form of non-holonomic incremental relationships and describe the behavior of frozen ground and ice with time both in pre-limiting and limiting states. The model is formulated in such a way that no special experimental work is required to derive its parameters. Design parameters may be determined from triaxial compression tests. The results of numerical calculations of the behavior of frozen soils under triaxial compression are presented for various loading trajectories and for cases involving both decaying and progressive creep. The predicted soil behavior agrees well with experimental data. Results of applying the proposed model for solving the boundary problem using the finite elements method are also presented.

Frozen soils show pronounced rheological properties resulting from the presence of ice layers and massive frozen water in their composition. Deformability of frozen soils may be described in terms of viscoplastic hardening theory based on the following assumptions.

For an elastic viscoplastic medium the strain tensor may be represented as

$$\epsilon_{ij} = \epsilon_{ij}^e + \epsilon_{ij}^{vp}$$

where ϵ_{ij}^e and ϵ_{ij}^{vp} are the components of elastic and viscoplastic strain tensors, respectively.

Following Naghdi and Murch (1963) we assume the existence of a piecewise smooth instantaneous loading surface which may be described by the following relationship,

$$f_o^{(\tau)} = f_o^{(\tau)}(\hat{\sigma}_{ij}, \epsilon_{ij}^{vp}, \chi_i, k_i, T) = 0, \quad \tau = 1, 2 \dots (1)$$

where $\hat{\sigma}_{ij}$ are the components of active stress tensor, $\hat{\sigma}_{ij} = \sigma_{ij} - \tau_{ij}$, σ_{ij} are the components of the applied stresses, τ_{ij} are the components of internal stresses, $\tau_{ij} = f(\epsilon_{ij}^{vp}, \dot{\epsilon}_{ij}^{vp})$ at $\dot{\epsilon}_{ij}^{vp} = 0$, $\tau_{ij} = 0$, ϵ_{ij}^{vp} are the components of viscoplastic strains, χ_i are the hardening parameters, T is the frozen soil temperature, k_i are the material constants, $\dot{\epsilon}_{ij}^{vp}$ is the velocity of viscoplastic strains,

$$\dot{\epsilon}^{vp} = \frac{d\epsilon_{ij}^{vp}}{dt}$$

Region of elastic behavior of the medium corresponds to negative values of instantaneous loading surface

$$f_o^{(\tau)} < 0 \quad (2)$$

For the stabilized state (with zero viscoplastic strain velocity) the instantaneous loading

surface coincides with the stabilized surface $f_s^{(\tau)} = 0$ which corresponds to the loading surface introduced in plastic hardening theory. The equation of the stabilized surface has the form

$$f_s^{(\tau)} = f_s^{(\tau)}(\sigma_{ij}, \epsilon_{ij}^{vp}, \chi_i, k_i, T) = 0 \quad (3)$$

Some features of accumulation mechanism of viscoplastic strains accounted for by introduction of the instantaneous loading surface may be illustrated by a simple mechanical model (Figure 1). It is obvious that the strain of the mechanical model is equal to a sum of elastic, e^e , and viscoplastic, e^{vp} , components. The applied stress σ is distributed between viscous and plastic elements, respectively. The stress in the plastic element will be called "active," $\hat{\sigma}$, while the stress in the viscoplastic element will be called "internal," τ . It is clear that the plastic element's deformation is due to the magnitude of active stress $\hat{\sigma}$, rather than total stress σ . In the general case, the process of plastic strains' accumulation is described by the instantaneous loading surface, which depends on the active stress tensor. The internal stress tensor takes account of a delay in accumulation of plastic strains with respect to the moment in time of applying the stress. In general, this tensor depends on the value of viscoplastic strains and on their velocity.

The instantaneous loading surfaces have the following geometric interpretation (Figure 2). The stabilized surface I-I corresponds to the stressed state M_I on the plane of invariants $\sigma_1 \div \sigma$. Under repeated loading by a vector $M_I M_2$ the surface I-I finally occupies the position II-II, provided the deformation process is stabilized. If the equation of instantaneous loading surface is written in terms of active stresses, the loading point position in different time moments is determined by vectors $M_I M_2, M_{II} M_2, \dots$. The components of these vectors depend on the velocity of viscoplastic strains and they are equal to $\hat{\sigma}_{ij} = \sigma_{ij} - \tau_{ij}$. Instantaneous

loading surfaces II-II, II"-II",... pass through the loading points M_2M_2'' ,... In the stabilized state, when $\tau_{ij} = 0$, the loading point coincides with the point M_2 , while the instantaneous surface coincides with the stabilized surface II-II. If the instantaneous surface is written in terms of applied stresses, the point M_2 is passed through by instantaneous loading surfaces I-I, I"-I" (at different moments in time), the position of which depends on viscoplastic strain velocity. It can be easily seen that the surfaces I-I, I"-I",... are parallel to the surfaces II-II, II"-II",...

It should be noted that an experimenter who would like to check the associative law, would come to the conclusion that the vector of plastic strain increment at the loading point (M_2) changes its direction, so the point may be classified as singular.

Let us introduce criteria of unloading, loading and neutral loading for the piecewise smooth instantaneous loading surface $f_0 = 0$ (Lvlev and Bykovtsev 1971, Zaretskiy and Lombardo 1982). In accordance with equation 3 the material is assumed to be elastic, $f_0^{(t)} < 0$ inside the instantaneous surface.

The unloading process occurs if the active stress velocity is such that both viscoplastic strain velocity and increments of parameters $d\chi_i$ are equal to zero*: $\dot{\epsilon}_{ij}^{vp} = 0$, $d\chi_i = 0$

$$f_0^{(m)} = 0, \dot{f}_0^{(m)} \equiv \frac{\partial f_0^{(m)}}{\partial \hat{\sigma}_{ij}} \dot{\hat{\sigma}}_{ij} = \frac{\partial f_0^{(m)}}{\partial \sigma_{ij}} (\dot{\sigma}_{ij} - \dot{\tau}_{ij}) < 0, \quad f_0^{(j)} < 0, \quad (4)$$

where m and j are different and enumerate all the values of indices r.

Under neutral loading the active stress velocity is such that the end of the vector $\hat{\sigma}_{ij}$ remains at the instantaneous loading surface. In this case $\dot{\epsilon}_{ij}^{vp} = 0$, $d\chi_i = 0$, $f_0^{(m)} = 0$,

$$\dot{f}_0^{(m)} \equiv \frac{\partial f_0^{(m)}}{\partial \hat{\sigma}_{ij}} \dot{\hat{\sigma}}_{ij} = \frac{\partial f_0^{(m)}}{\partial \sigma_{ij}} (\dot{\sigma}_{ij} - \dot{\tau}_{ij}) = 0 \quad (5)$$

where m does not enumerate all the values of indices r, since the unloading process may take place for some regular parts of the surface.

Under the loading process the active stress velocity is such that the following relations hold:

$$\dot{\epsilon}_{ij}^{vp} \neq 0, d\chi_i \neq 0, f_0^{(m)} = 0,$$

$$\dot{f}_0^{(m)} = \frac{\partial f_0^{(m)}}{\partial \hat{\sigma}_{ij}} \dot{\hat{\sigma}}_{ij} + \frac{\partial f_0^{(m)}}{\partial \epsilon_{ij}^{vp}} \dot{\epsilon}_{ij}^{vp} + \frac{\partial f_0^{(m)}}{\partial \epsilon_{ij}^{vp}} + \frac{\partial f_0^{(m)}}{\partial \chi_i} \dot{\chi}_i = 0,$$

$$\dot{f}_0^{(m)} = \frac{\partial f_0^{(m)}}{\partial \hat{\sigma}_{ij}} \dot{\hat{\sigma}}_{ij} = \frac{\partial f_0^{(m)}}{\partial \sigma_{ij}} (\dot{\sigma}_{ij} - \dot{\tau}_{ij}) = 0 \quad (6)$$

* Since $\frac{\partial \hat{\sigma}_{ij}}{\partial \sigma_{ij}} = 1$ and τ_{ij} is independent of σ_{ij} we may write:

$$\frac{\partial f_0^{(m)}}{\partial \hat{\sigma}_{ij}} \dot{\hat{\sigma}}_{ij} = \frac{\partial f_0^{(m)}}{\partial \sigma_{ij}} (\dot{\sigma}_{ij} - \dot{\tau}_{ij}).$$

where m does not enumerate all the values of indices r, since unloading or neutral loading processes may take place for some parts of the surface.

It may be shown that Mizes's maximal principle is valid within the framework of viscoplastic hardening theory (Zaretskiy and Lombardo 1982). The principle states that any given parameters ϵ_{ij}^{vp} , χ_i and any given value of strain velocity components $\dot{\epsilon}_{ij}^{vp}$, the inequality

$$\hat{\sigma}_{ij} \dot{\epsilon}_{ij}^{vp} > \hat{\sigma}_{ij}^* \dot{\epsilon}_{ij}^{vp} \quad (7)$$

takes place, where $\hat{\sigma}_{ij}$ are the active stresses, corresponding to the given value ϵ_{ij}^{vp} , $\hat{\sigma}_{ij}^*$ are the components of any possible stressed state which satisfies the condition $f_0(\hat{\sigma}_{ij}^*, \dots) < 0$.

Equation 7 may be written in another form:

$$(\sigma_{ij} - \tau_{ij}) \dot{\epsilon}_{ij}^{vp} \geq (\sigma_{ij}^* - \tau_{ij}) \dot{\epsilon}_{ij}^{vp} \quad (8)$$

or

$$\sigma_{ij} \dot{\epsilon}_{ij}^{vp} \geq \sigma_{ij}^* \dot{\epsilon}_{ij}^{vp} \quad (9)$$

It immediately follows the validity of associated law of flow in spaces of both active and applied stresses. Thus we may write:

$$\dot{\epsilon}_{ij}^{vp} = \dot{h} \frac{\partial f_0}{\partial \hat{\sigma}_{ij}} = \dot{h} \frac{\partial f_0}{\partial \sigma_{ij}} \left(\frac{\partial \hat{\sigma}_{ij}}{\partial \sigma_{ij}} = 1 \right) \quad (10)$$

For piecewise smooth instantaneous loading surface it follows from generalized Koiter's law that

$$\dot{\epsilon}_{ij}^{vp} = \sum_i \dot{h}^{(i)} \frac{\partial f_0}{\partial \hat{\sigma}_{ij}} = \sum_i \dot{h}^{(i)} \frac{\partial f_0^{(i)}}{\partial \sigma_{ij}}; \left(\frac{\partial \hat{\sigma}_{ij}}{\partial \sigma_{ij}} = 1 \right) \quad (11)$$

A procedure of experimental determining the time domain of recoverable strains, i.e. of determining the position of instantaneous loading surface, was presented in detail by Zaretskiy and Lombardo (1982).

Within the framework of viscoplastic hardening Zaretskiy (1980) formulated master equations describing transient creep of unfrozen soils. On the basis of these equations, he solved the stability problem of a dam made of soil materials.

While describing the rheological behavior of ice and frozen soil, it is sometimes necessary to consider both transient and progressive characters of strains' evolution in time.

Based on a stochastic approach Zaretskiy and Lombardo (1982) suggested an equation of instantaneous loading surface describing the process of ice deformation and destruction. This equation may be written in a modified way as follows:

$$f^0 = \sigma_i - \sigma_{i(t)}^* \Phi(\epsilon_{ij}^{vp}) - \frac{m}{\psi(t)} \ln \left(1 + \frac{\dot{\epsilon}_{ij}^{vp}}{\dot{\epsilon}_{ij}^*} \right) = 0 \quad (12)$$

where σ_i is the applied stress intensity and $\sigma_i^*(t)$ is the long-term strength of soil. In the case where the long-term strength curves are similar $\sigma_i^*(t)$ may be approximated by the function

$$\sigma_i^*(t) = \sigma_i^*(\infty) \left(1 + \frac{\partial \sigma_i^*}{\psi(t)}\right) \text{ which depends on the sum of main stresses } \sigma_i(\infty) = c(\infty) + \sigma \tau g \phi(\infty), \psi(t) = t^\delta,$$

$\delta < 1$. If there is no similarity, the long-term strength values are to be introduced into computational program in table form and found for each value of t and σ by linear interpolation. In equation 12 $\Phi(\epsilon_i^{VP})$ is the hardening function,

$$\Phi(\epsilon_i^{VP}) = \frac{\epsilon_i^{VP}}{A + B \cdot \epsilon_i^{VP}}, \text{ A and B are parameters which}$$

depend on average stress; $\Phi(\epsilon_i^{VP}) < 1$ after reaching the long-term strength limit the hardening function becomes $\Phi(\epsilon_i^{VP}) \equiv 1$; $\dot{\epsilon}_i^*$ is the minimal velocity of viscoplastic strains, which characterizes the transition into the limiting state

$\dot{\epsilon}_i^* = \frac{1}{\eta} \dot{\psi}(t)$; t is the internal time, which corresponds to real time in case of active loading process, and to the time of viscoplastic deformation of the material in case of unloading process.

The equation of instantaneous surface includes time-dependence explicitly. This is due to the chosen form of the function, describing the long-term strength of ice, and not to a disadvantage of viscoplastic hardening theory. Zaretskiy and Chumichev (1980) suggested a condition of the long-term strength which does not depend on time explicitly. Although mathematical difficulties have not permitted realization of the condition in practical calculations until recently, the solving of this problem has already begun.

The model of ice proposed describes its deformability in both pre-limiting and limiting states. The volume creep flows due to the hydrostatic compression not being taken into account, the behavior of ice inside the instantaneous surface is assumed to be elastic.

A comparison of theoretical prediction of the ice creep with experimental data was presented by Zaretskiy and Chumichev (1980) for the case of one-dimensional compression of a sample. The model of ice formulated makes it possible to take into account the influence of loading regime on the ice deformability. Figure 3a shows loading diagrams of a sample under one-dimensional compression, while Figure 3b shows creep curves calculated on the basis of the model proposed. It is important to note that decrease of stresses does not always lead to unloading (curve 4). This is due to the fact that equation 4 of the unloading process is written for active stresses rather than applied stresses. Therefore, the unloading process will occur provided the applied stress vector finds itself inside instantaneous loading surface, which in this case coincides with the stabilized surface. The instantaneous surface changes its position in time, therefore equal decrease of stresses σ_1 occurring in various time moments may lead to unloading (curve 3) and may not (curve 4).

Based on the model of ice formulated, Groshev and

Chumichev (1982) solved the problem of the ice field pressure on stationary supports.

To describe the frozen soil deformability under isothermal conditions the piecewise smooth instantaneous loading surface is used (Zaretskiy and Lombardo 1982, Shchobolev 1982). An analytic expression for regular parts has the form:

$$f_o^{(1)} = \sigma - \sigma^*, f_o^{(2)} = \sigma_i - \sigma_i(t) \Phi(\epsilon_i^{VP}) - \frac{1}{\psi(t)} \ln \left(1 + \frac{\dot{\epsilon}_i^{VP}}{\dot{\epsilon}_i^*}\right); f_o^{(3)} = \sigma - p \quad (13)$$

where σ^* is the strength limit with respect to tension; the other notation is the same as in equation 12.

Volumetric strain of the frozen soil may be represented as

$$\epsilon_v^{VP} = \epsilon_v^{VP(o)} + \epsilon_v^{VP(i)} \quad (14)$$

where $\epsilon_v^{VP(o)}$ is the volumetric strain, caused by hydrostatic pressure, and $\epsilon_v^{VP(i)}$ is the volumetric strain, caused by tangential stress intensity. Volumetric strain of frozen soil, which is determined by hydrostatic pressure and by tangential stress intensity in pre-limiting state is usually small, so for the sake of simplicity it may be neglected.

The function P depends on the ratio $\epsilon_i^{VP}/\epsilon_v^{VP}$ and on the tangential stress intensity σ_i . Zaretskiy and Gorodetskii (1975) found that the dilatant part of volumetric strain and shear strain intensity develop in synchronism, their ratio being independent of time. This condition may be written mathematically as

$$\frac{\epsilon_i^{VP}}{\epsilon_v^{VP(i)}} = \beta(\sigma) \cdot \sigma_i; \sigma_i \leq \sigma_i^*(\infty) \quad (15)$$

$$\frac{\epsilon_i^{VP}}{\epsilon_v^{VP(i)}} = \beta(\sigma) \cdot \sigma_i^*(\infty); \sigma_i \geq \sigma_i^*(\infty)$$

Neglecting volumetric strains caused by tangential stress intensity at $\sigma_i < \sigma_i^*(\infty)$, we may write the function P as follows:

$$P = \frac{\epsilon_i^{VP}/\epsilon_v^{VP(i)} - C_1}{C_2} \quad (16)$$

where C_1 and C_2 are the material parameters, which depend on σ . The model parameters can be determined by means of soil tests under triaxial. For the model to be used it is necessary to determine:

- the long-term strength curve $\sigma_i^*(t) = \sigma_i(\infty) \left(1 + \frac{\partial \sigma_i^*}{\psi(t)}\right)$ with the account of the dependence $\sigma_i(\infty) = f(\sigma)$;

- the hardening function $\Phi(\varepsilon_i^{VP})$ based on stabilized values of viscoplastic strains at $\sigma_i < \sigma_i^*(t)$;
- the function $p(\varepsilon_i^{VP}, \varepsilon_v^{VP(i)})$ and the minimal velocity of viscoplastic strains ε_i^{VP} ;
- the value σ and moduli of elasticity G^e and k^e .

A picture of the instantaneous loading surface for a frozen soil is shown in Figure 4. Figure 5 shows a comparison of computational results obtained using the model presented, with experimental data (Gorodetskii 1975) of frozen soil tests at the deviatoric stress path.

Thus, the master equations proposed for a frozen soil have non-holonomic incremental character. The model enables one to describe the soil behavior in both prelimiting and limiting states with account of the loading path. The model does not require special investigations for determining its parameters. The design parameters may be found from triaxial compression tests by means of triaxial apparatus.

The model formulated served as a basis for solving the evolution problem of strength and deformability of a frozen retaining structure by means of the finite elements method. The solving algorithm was constructed on the basis of the initial strains' method (Zienkiewicz 1975), while separation of strains into elastic and viscoplastic components was done by a procedure suggested by Zaretskiy and Lombardo (1982).

The computational diagram is shown in Figure 6 for a case of shaft sinking by 2 m stopes. Fixation of the top end section by means of tubing was assumed to be rigid. The calculations were made for Callovian silty sandy loam, the pressure on the frozen retaining structure was assumed to be distributed uniformly and to be equal to 5.0 MPa which corresponds to the rock pressure at the depth about 500 m. The bottom was assumed to be completely frozen and locked in position. The soil temperature beyond the cross-section of the frozen retaining structure was taken constant and equal to 50°F.

Figure 7 shows the profile of the frozen soil pressure on the tubing for time moments $t=15$ minutes and $t=6$ hours. Figure 8 shows bending of the shaft walls for the same time moments.

The maximal displacement of walls of the frozen retaining structure may be found in terms of an analytic solution (Vyalov, Zaretskiy and Gorodetskii 1981) by a formula

$$\frac{B}{a} = \left[1 + \frac{(1-m)}{\bar{A}} (1-\xi) \left(\frac{h}{a}\right)^{1+m} \left(\frac{a}{u_a}\right)^m \right]^{-\frac{1}{1-m}} \quad (17)$$

where the following values of parameters for Callovian silty sandy loam are to be used at temperature 50°F: $m = 0.27$; $t_p = 6$ hours,

$\bar{A}(t_p) = 3^{-\frac{1+m}{2}} A(t_p)$, $A(t_p) = 6.4$ MPa, $\xi = 0$ or 0.1 depending on fixation degree of the computational cylinder's tops. The results of calculations by the equation 17 mean that the frozen retaining

structure's displacement at the time moment $t = 6$ hours varies from 12 cm to 8 cm, while the corresponding observed result is 9 cm. Thus the results obtained are in good agreement with analytic solutions.

Further improvements of the approach, which is directed to a description of viscoplastic behavior of soils, require detailed theoretical developments and more experimental investigations of rheological behavior of soil under conditions of complex stressed states for various loading paths and regimes.

This paper presents the results of both an experimental and analytical research program undertaken to develop design criteria for air duct systems. These systems have been used in Alaska as a method of preventing degradation of permafrost beneath highway embankments. An experimental duct was assembled and instrumented to determine the relationship between air flow rates and temperature difference, heat transfer rates, air duct length, stack heights, etc. A finite element computer model has also been used to investigate the placement of the air duct under the roadway. Optimum placement of the air ducts would allow sufficient winter cooling of the ground so that degradation of the underlying permafrost would not occur during the summer thawing season. Thermal profiles resulting from the finite element simulations showing the effects of air duct placement are presented. From the data presented in this paper, the design engineer should find it easier to design air duct systems for roadway stabilization in permafrost areas.

INTRODUCTION

The existence of permafrost in northern Canada and Alaska has required roadway designers to pay special attention to the thermal regime of the ground. In the past, many highway projects have employed varying thicknesses of gravel fill, or in some cases foam board type insulation with gravel fill to thermally protect the underlying frozen ground.

The purpose of using gravel fill or using insulation with gravel fill is to maintain the active layer within the non-frost-susceptible fill material. Generally, the thickness of the fill required to thermally protect the underlying permafrost increases as the mean annual soil surface temperature approaches 0°C. The thickness of the fill can be reduced by the use of foam plastic board insulation. Another source for structural degradation of the roadway is the embankment rotation due to thaw settlement. In many cases, even though the active layer is maintained in the fill material below the central portion of the roadway, the sloping of the fill material to smaller thicknesses out to the toe of the roadway section allows this region to experience thermal degradation of the original permafrost. This degradation can be further accentuated by the insulating effect of drifted or plowed snow over the roadway sideslopes which prevents the complete freeze-back of the active layer leaving a talic. The thaw settlement which results due to these effects usually shows up as lateral cracking on the wearing surface of the roadway.

A potential solution to this problem is the use of naturally ventilated air ducts placed in berm at the toe of the road, Figure 1. Air duct systems have also been used to stabilize foundations under

buildings and tanks, Sanger (1969) and Nixon (1978). These ducts are usually .25 m to .5m diameter corrugated metal pipe (culvert) with a short sloping or vertical inlet section leading to a long horizontal section placed in the problem zone connected to a vertical outlet section or stack. Cold air flows in the inlet, is heated by the ground surrounding the buried horizontal section and then flows out the vertical stack. Flow in the duct system is maintained by the "chimney" or "stack" effect. The warm air in the vertical outlet stack being less dense is buoyed upward by the cold ambient air establishing flow. Flow is maintained as long as the air is heated by the ground, i.e. the ground temperature exceeds the ambient air temperature.

During the summer when the ambient air temperature is higher than the ground temperature, flow ceases as the cold air now inside the culvert remains trapped there because of its greater density. So, theoretically, the air duct ventilation system is a totally passive device, extracting thermal energy from the ground during the winter accelerating the freeze-back time and then becoming dormant or inoperative during the summer months when thawing from the surface occurs. Wintertime winds will increase the cooling effect (by increased air flow) especially if the inlet and outlet sections have been designed to take advantage of the prevailing wind direction. However, summertime winds can have a detrimental effect if they are allowed to cause flow through the buried ducts.

This paper discusses an analytical and experimental study which has investigated the parameters that affect the performance of air duct systems.

ANALYSIS

A schematic diagram of an air duct system is shown in Figure 1. The static pressure difference, ΔP_s , created by the stack effect is:

$$\Delta P_s = g(\rho_i - \rho_o)h \approx (ghP_a/R) \left[(1/T_i) - (1/T_o) \right] \quad [1]$$

For the stack shown, if no heating occurs in the inlet section and no cooling occurs in the outlet section, then h is the stack height and ΔP_s can be calculated using equation [1]. A larger temperature difference between the cold and warm air or a longer (taller) stack will increase the stack effect pressure difference resulting in a greater air flow. This stack effect pressure difference is balanced by the velocity pressure $P_v = \rho V^2/2$ and the frictional pressure drop, ΔP_f

$$\Delta P_f = \frac{\rho f L_e V^2}{2D} \quad [2]$$

The Darcy-Weisbach friction factor, f , is determined based on the Reynolds number of the flow within the duct and the relative roughness of the duct. The sum of the velocity pressure and frictional pressure loss is equal to the stack effect pressure difference. Substituting the equations for ΔP_f , P_v and ΔP_s into the above expression and rearranging yields an expression for the average velocity

$$V = \left\{ [4gh/(1+fL_e/D)] [(T_o - T_i)/(T_o + T_i)] \right\}^{1/2} \quad [3]$$

The friction factor must be known in order to use equation [3] to calculate the velocity. Therefore, an iterative method of solution is necessary. It is recommended that a trial value of the friction factor of .07 be used to arrive at a first approximation to the velocity. An improved value of the friction factor can be determined from Figure 2 once the Reynolds number has been calculated. This iterative process is continued until the desired accuracy is achieved.

If an annular ring of frozen ground of radius R exists around the buried air duct, then the quasi-steady state heat transfer rate is

$$Q_c = \frac{(T_f - T_a)}{\frac{1}{h_c \pi D L} + \frac{\ln(2R/D)}{2\pi k l}} \quad [4]$$

The heat transfer rate given above is set equal to the thermal energy liberated in the freezing process

$$Q_c = 2\pi R L \rho_i \frac{dR}{dt} \quad [5]$$

Equating equations [5] and [6], rearranging and integrating, yields the following relationship:

Figure 1. Field Installation of Air Duct

$$F.I. = L \left[\frac{R^2 - (D/2)^2}{2} \left(\frac{2}{h_c D} - \frac{1}{2k} \right) + \frac{R^2 \ln(2R/D)}{2k} \right] \quad [6]$$

This solution neglects the sensible energy changes in the ground and as a result overpredicts the size of the frozen annulus for a given F.I. An improved approximation for the freeze radius to account for the non-steady temperature distribution and specific heat effects is given by Harlan and Nixon (1978) as

$$R' = R(1 - .12Ste)^{1/2} \quad [7]$$

where R is the initial approximation for freeze radius given by equation [6] and R' is the solution of increased accuracy. The Stefan number is defined as the ratio of sensible to latent heat or

$$Ste = C_t T_a / L \quad [8]$$

FIELD INSTALLATION

In 1973 a research project was initiated under the Highway Planning and Research Program of the Federal Highway Administration to study the benefits of several alternate embankment designs in controlling permafrost thaw under embankment slopes. Insulation, toe berms and air duct sections were constructed in 1974 at Bonanza Creek, approximately 40 kilometers west of Fairbanks on the Parks Highway.

The roadway embankment was constructed over undisturbed muskeg, underlain by ice-rich silt containing segregated ice. The permafrost temperature was measured to be between -3°C and -1°C .

Twenty centimeter diameter galvanized corrugated metal pipe ducts were installed. The inlet ends were placed above the maximum snow cover. The 15 to 30 meter long buried sections were sloped slightly upward toward the 3 meter stack. The conclusions of this study were reported by Esch (1978).

Air ducts in combination with insulation proved to provide maximum protection against thaw. Air ducts without insulation provided significantly less protection. However, after studying the temperatures along the duct, Esch concluded that the ducts were too long to provide efficient cooling along their entire length. This claim can be substantiated by Figure 3. As the air flows toward the outlet, its temperature approaches the ground temperature. Near the outlet of the duct, the temperature differential is quite small resulting in negligible cooling of the surrounding soil. It appears that this duct should have been about 10 meters shorter.

Heat flow can be estimated using the equation for cylindrical heat flow

$$Q = \frac{T_o - T_d}{\ln(2R/D)/2\pi k} \quad [9]$$

The soil density at the site is approximately 1600 kg/m³ with a 15% moisture content by weight and a thermal conductivity of 1.5 W/m °C. Using the pipe radius as 0.10 m and the outside soil radius of 0.40 m, the heat flow per unit length at any point along the duct can then be calculated. The heat transfer rate along the pipe for January 1980 is plotted in Figure 4. The total energy transferred can be calculated by integrating the heat transfer rate per unit length over the entire length of air duct or,

$$Q_t = \int Q \, dx = 381.1 \, W \quad [10]$$

Combining the First Law of Thermodynamics and the mass flow rate relationship yields

$$V = Q_t / A \rho c_p \Delta T \quad [11]$$

Using the thermal properties of air at 0°C and the Q_t value above, gives the air speed in the duct as

$$V = 0.33 \, \text{m/s}$$

Field measurements have indicated approximately 0.3 m/s air speed at ΔT of 30°C.

COMPUTER MODELING

An air duct system was modeled on the University of Alaska Computer Network (UACN) Honeywell Computer using the DOW Chemical Model, "Finite Element Heat Conduction Program", Wang (1979). The model is designed to solve a two dimensional heat conduction problem, assuming there is no temperature gradient in the third direction. The boundary temperature may be either fixed or time-varying. Each node point can be either a heat source or a heat sink.

The program further assumes that the phase change occurs between 0°C and -1°C. Latent and

Figure 3. Ground Temperature at Bonanza Creek, January 1980.

Figure 4. Heat Flow from Duct, January 1980.

sensible heats have been combined for this region to yield an apparent specific heat. (Most fine grained soils exhibit some subcooling in the freeze-thaw process as well as latent heat liberated over a temperature range due to unfrozen water content). The thermal conductivity of the soil can be varied in the x and y directions. Here it was assumed uniform for the same soil type but varied from layer to layer.

The air duct system in the embankment is shown in Figure 5. The embankment is comprised of three layers with the duct placed at the surface of the original ground. The properties of each layer are indicated on Figure 5. A 0.6 meter snow cover was placed on the embankment slopes and the berm between October 1 and April 15 of each year. The pavement surface was left bare throughout the year. The surface temperature was modeled by the cosine function:

$$T_s = \bar{T}_s - T_v \cos(wt - w\phi) \quad [12]$$

The following values were used;

$$\bar{T}_s = -3^\circ\text{C}, T_v = 20^\circ\text{C}, \text{ and } \phi = 10 \text{ days.}$$

An initial run was made without the ducts to determine the effect of the embankment on the underlying permafrost. As might be expected, degradation of the permafrost was noted beneath the shoulder. This would be evidenced on the pavement surface as a longitudinal cracking. Additional runs were made with the air duct using

Figure 5. Finite Element Simulation in August.

a convective heat transfer coefficient of 9.7W/m²-°C for the pipe and an air temperature equal to outdoor ambient. As seen in Figure 5, the duct raised the 0°C isotherm into the embankment, thereby preserving the permafrost.

It should be noted that the computer model provides an upper bound to the field installation. The duct in the model was larger and placed more effectively under the embankment. Ideally, the duct should be placed far enough under the embankment to prevent the degradation of permafrost beneath the shoulder material.

EXPERIMENTAL SYSTEM

An experimental facility was constructed during 1982 in order to augment field data obtained at Bonanza Creek. The experimental facility, Figure 6, consisted of an above ground convection duct, an adjustable electric heating circuit, and data acquisition system. Helicallly corrugated metal culvert 30 cm in diameter (60 cm plate and 7 x 1.5 cm corrugations) was used for construction of the duct. The horizontal section was 12.5 meters in length with a one meter vertical inlet section and a vertical outlet stack of variable length. Heat input was accomplished via copper clad heating tape wrapped in the corrugations on the outside of the duct. Three separate heating circuits spanning the horizontal section of the duct were employed (see Figure 6). In order to reduce heat transfer directly to the outside air and allow a stable duct temperature to be maintained, 5 cm of fiberglass insulation were wrapped around the outside of the horizontal section covering both the duct and heating tapes. Each of the tapes was powered by a "Variac" variable transformer and monitored by an individual power transducer. This allowed for flexibility not only in overall heat input but also in the heating profile along the duct.

Thermocouples were used to measure both air temperatures within the duct, and temperatures of the duct surface. Temperature and heat input data was collected with a Hewlett-Packard 3054A data acquisition system interfaced with the power transducers and temperature probes.

Headloss-flowrate tests were run on a 12.5 m horizontal section of the 30 cm diameter duct. Pressure drop data at flowrates covering Reynolds numbers from 7,000 to 30,000 were recorded. Darcy-Weisbach friction factors were calculated from the

Figure 6. Schematic of Experimental Duct.

data and the results have been plotted in Figure 2. Data from tests conducted with water in 30 cm diameter helical culverts by Silberman (1970) is also shown in this figure.

A series of tests were conducted as outlined in Table 1.

Table 1 - Experimental Tests--Duct Configurations

Test	Stack Height (m)	Description
1	2.10	no insulation on stack, no weather caps.
2	3.35	no insulation on stack, no weather caps.
3	4.60	no insulation on stack, no weather caps.
4	3.35	no insulation on stack, weather caps installed.
5	3.35	insulated stack, no weather caps.

Each of the experiments was run for six twenty-four hour periods at different power input levels. Temperatures and power inputs were scanned and recorded hourly during each period.

Reduction of the recorded data was accomplished by inspecting it for periods of stable operation. Usually a stable outside air temperature resulted in stable duct operation although this was not always the case, particularly during windy weather. In general, one twenty-four hour period resulted in three or four usable scans.

The amount of thermal energy absorbed by the air inside the duct was calculated by subtracting the heat lost through the insulation directly to the outside air from the total heat input recorded by the data logger. The value for the thermal resistance of the insulating layer covering the heat tapes and duct was obtained by heating the duct with airtight, insulating covers at the inlet and outlet. In this situation all power input by the heat tapes must escape through the insulating layer. Consequently, a thermal resistance value can be calculated simply by noting the heat input and the temperature drop across the layer. Once this resistance is known it is possible to calculate the amount of heat being absorbed by air flowing through the duct as described above. This value can then be used in conjunction with various temperatures throughout the duct to calculate the mass flow rate of duct air, Reynolds number, and the convection heat transfer coefficient as shown below:

$$h_c = Q_{air}/A_s (T_d - T_a) \quad [13]$$

$$m = Q_{air}/(c_p \Delta T)$$

$$Re = mD/A\mu$$

Finally the experimental results were presented as plots of m versus Q_{air} and h_c versus Reynolds number.

Experimental results presented here were obtained during winter of 1981/1982 on the University of Alaska Fairbanks campus. Outside air temperatures ranged from -5°C to -43°C . The heating circuits were adjusted to deliver a uniform heat flux along the entire horizontal section of the duct. Initial experimentation was hampered by difficulty in establishing proper air flow in the duct. By introducing a 1.5% slope to the horizontal section with the outlet at the high end this problem was eliminated.

As expected, a taller stack results in a larger draft head which in turn produces larger mass flow rates, Figure 7. Figure 8 shows that insulating the outlet stack with 5 cm of paper faced fiberglass has a detrimental effect on duct operation and is backed-up, at least in part, by observations conducted at Bonanza Creek. Figure 9 is a plot of h_c versus Re with data from all five experiments^C included. Theoretical h_c values calculated using the Reynolds analogy relating fluid friction and heat transfer are in good agreement with Figure 9. Results obtained for duct operation with weather caps on the inlet and outlet openings reveal reductions in mass flow rates of up to 20%. The weather caps used in this experiment were of the inverted cone type with a 15 cm gap between the cone and duct opening. This effect will vary depending on the geometry of the cap installation; therefore, results have not been presented graphically. Finally, stack efficiencies have been calculated by dividing the theoretical velocity given in [3] by the observed velocities. An average efficiency of 86% was obtained with a standard deviation of 3.5%.

Contrary to what was expected, insulating the outlet stack did not improve duct performance by maintaining a higher air temperature in the stack and thereby increasing the draft head. A possible explanation is that when no insulation is present on the outlet stack the stack itself will have a relatively low temperature, consequently the air film on the inside surface will be at a lower temperature and therefore lower viscosity. On the other hand, with insulation on the outside of the stack, a higher surface temperature results in a more viscous air film on the inside surface of the stack. Therefore, insulating the stack results in higher frictional losses in the stack which may be substantial enough to overshadow the increases in the draft head.

DESIGN PROCEDURE

A design procedure can be developed based on the information presented in this paper. If a talik of radius R' needs to be frozen back, then equations [6] and [7] can be used to determine the required freezing index. Figure 9 would be used to choose a convective heat transfer coefficient.

Figure 7. Effect of Stack Height.

Figure 8. Effect of Stack Insulation.

Figure 9. Convective Heat Transfer Coefficient.

If this freezing index was less than the air freezing index for the site then a dual air duct system should be considered. Next, the maximum permissible temperature leaving the stack can be calculated by dividing the freezing index from equation [6] by the length of the freezing season. The total energy removed from the ground can be estimated by determining the heat transferred in freezing and sensibly cooling a talik of radius R' . The average heat removal rate is found by dividing the total energy removed by the length of the freezing season. Then the average air speed in the duct can be calculated by equation [11]. The equivalent length of air duct is then calculated using equation [3] with the appropriate friction factor taken from Figure 2 and the stack height assumed. Finally, the length of the buried section is calculated by subtracting the inlet length, outlet length, and fitting losses from the equivalent length.

CONCLUSIONS

An analysis of an air duct system has been presented. The weak points in this analysis were lack of data on friction factors and heat transfer coefficients for air flow in the helical ducts and the stack efficiency. This data has been determined from the experimental program and presented. The finite element analysis was used to determine the optimum location for air duct systems which is centered in the expected talik. Finally, a design procedure has been outlined which can be used to estimate system size.

 ϕ = lag time, days
 ρ = density of air, kg/m³
 μ = dynamic viscosity, kg/m-s
 A = cross-sectioned area of duct, m²
 A_s = area of heated duct surface, m²
 c_p = specific heat of air, kJ/kg-k
 C_t = volumetric specific heat, kJ/m³-k
 D = inside duct diameter, m
 f = Darcy-Weisback friction factor
 FI = freezing index, °C-day
 g = gravitational acceleration, m/s²
 h = effective height of stack, m
 h_c = convective heat transfer, W/m²-k coefficient, W/m²-°C
 i = cold air
 k = soil thermal conductivity, W/m-°C
 l = length, m
 L = volumetric latent heat kJ/m³
 L_e = equivalent length of duct, m
 m = mass flow rate, kg/s
 o = warm air
 P = pressure, N/m²
 P_a = average pressure between warm and cold air
 ΔP_f = frictional pressure drop, N/m²
 ΔP_s = stack effect pressure difference, N/m²
 P_v = velocity pressure, N/m²
 Q = heat flow/unit length, W/m
 Q_c = total heat flow, W
 R^c = radius of frozen annulus, m
 \bar{R} = gas constant, J/kg-k
 Re = Reynolds number
 Ste = Stefan number
 t = time, s
 T_a = temperature of air in duct, °C
 \bar{T}_a = average temperature of air in heated section of the duct, °C
 T_d = average temperature of heated duct surface, °C
 T_f = temperature at the freezing point, °C
 T_o = temperature 0.3 m from duct surface
 T_s = ground surface temperature, °C
 \bar{T}_s = mean annual ground surface temperature
 T_v = seasonal temperature variation
 ΔT = change in temperature of air flowing through duct
 V = average air velocity, m/s
 w = $2\pi/365$

PRELIMINARY EXPERIMENTAL STUDY OF WATER MIGRATION AT THE ICE/SOIL INTERFACE

Zhang Jinsheng and Fu Rong

Lanzhou Institute of Glaciology and Cryopedology, Academia Sinica
People's Republic of China

On the basis of the theory of adsorption and Darcy's law, and by using the contact method, samples of Qinghai-Xizhang red clay and Lanzhou yellow silt were tested to determine their individual amounts of unfrozen water and the hydraulic conductivity and diffusivity in unsaturated soil (without ice in soil at negative temperature). The results show the following regularities: The amount of unfrozen water increases with time and approaches a certain constant value; different soils have different adsorption rates and different processing curves. At high temperatures, the adsorption rate is high, and the unfrozen water content is also large, while the rate of curvature approaching the final value is smoother. At low temperatures, the final value of unfrozen water is also smaller. During the entire process, diffusivity is not constant, but is a function of water content. The accuracy of the results depends on the interval of measurement used in the experiment.

Owing to the existence of a certain surface energy on the surface of soil mineral constituents, a certain amount of water molecules can be adsorbed on it and a water film with considerable thickness may be formed. Under negative temperature, such water film coexists with ice crystals in frozen soil, and is called unfrozen water.

The surface energy of ice is directly affected by temperature, and it has a constant value under a given temperature. Thus when ice crystals and soil particles coexist, no matter how much the total water content may be, there should be a corresponding amount of existing unfrozen water, which depends upon the surface energy of ice. Hence, the quantity of unfrozen water relates to temperature directly.

According to the adsorption theory, when different substances come into contact, the instability of thermodynamics induced by surface energy kept on the soils surfaces will cause molecular interchange at its boundary faces (Watanabe 1973). The larger the surface area, the greater such instability. So under the same temperature conditions, the sum of unfrozen water in soil of fine particles is generally a little larger. Therefore, when perfectly dry soil comes into contact with ice, a part of the water molecules will be adsorbed on the surfaces of soil particles in the forms of sublimation and direct removal. The increase of adsorbed water amount is a function of soil surface energy and temperature. To a specific soil, the amount of adsorbed water is just the amount of unfrozen water, and the

final amount of adsorbed water is only a function of temperature.

From this principle, the adsorptive nature of soil may be utilized to determine the quantity of unfrozen water in soil and the parameters of water movement in unsaturated soil.

METHOD

The tested soil is in the form of a slab, thoroughly dried under constant temperature and fixed pressure and put into mutual contact with ice or ice-rich frozen soil. To guarantee good contact, the contact surface should be smoothed beforehand. It would be all right to measure the increments of water content in the soil at regular intervals. This method is called the Contact Method. The sample weight lightened on the test process will cause error for the result, the error will prior correct before data processing.

According to the adsorption principle, the amount of adsorbed water with time obeys the following law (de Boer 1953):

$$G_t = G_\infty (1 - e^{-k_d \cdot t}) \quad (1)$$

where t is time; G_t is the adsorbed amount (in weight) at time t ; G_∞ is the adsorbed amount theoretically only reached after an indefinitely long time; k_d is a constant which, related to ambient conditions (temperature, pressure, etc.) and contact circumstances, soil surface area and permeability, and viscosity of water.

We have used the red clay of Qinghai-

TABLE 1 Basic Indexes for Two Kinds of Soils.

Kind of soil	Specific weight	Liquid limit	Plastic limit	Specific surface area (%)	Salt content (%)
Red clay of Qinghai-Xizang	2.76	22.0	15.0	31.8	0.08
Yellow silt of Lanzhou	2.70	19.9	13.6	41.9	0.194

TABLE 2 Particle Diameter Analyses for Two Kinds of Soils.

Kind of soil	Percentage of various particle sizes (diam in mm)							
	1-0.5	0.5-0.25	0.25-0.1	0.1-0.05	0.05-0.01	0.01-0.005	0.005-0.002	0.002
Red clay of Qinghai-Xizang	2.70	2.02	5.00	1.68	26.30	11.59	17.41	33.30
Yellow silt of Lanzhou		0.15	1.92	17.84	51.89	6.10	5.29	16.81

Xizang and yellow silt of Lanzhou as the examples to determine separately their individual amounts of unfrozen water and water movement parameters in unsaturated soil. The basic indexes of various kinds of soils are shown in Table 1 and Table 2.

RESULTS

Experimental results show that the amount of unfrozen water increases with time and approaches a certain constant value. Figure 1 shows the change in weights of unfrozen water at -3.0°C of the samples. To the same kind of soil, under different temperatures, the curve showing the process of change in amount of unfrozen water is different. Figure 2 shows

FIGURE 1 Changes of unfrozen water weights at -3 degree centigrade of two kinds of soil.

the process of change in amount of Qinghai-Xizang red clay at three different temperatures.

From these two figures, it is not difficult to see that different soils have different adsorption rates and different processing curves. The shapes of various curves are different too. For the same kind of soil, under high temperature, the adsorption rate is high, and the final value of unfrozen water content is also big. Meanwhile the rate of increase approaching the final value is smaller. Under low temperatures, rapidly approach-

FIGURE 2 Changes of unfrozen water contents of the Red Clay of Qinghai-Xizang under three kinds of low temperatures.

FIGURE 3 Unfrozen water contents and temperatures of two kinds of soil.

ing its terminal, the final value of unfrozen water is smaller too.

Figure 3 shows the relation between unfrozen water contents and temperatures of two kinds of soils from tested results obtained by the contact method (Zhang Jinsheng and Fu Rong, 1983).

EQUATION OF WATER MIGRATION

Moisture moves and its flux can be expressed in the same form of Darcy's law.

$$q_x = -K(\theta) \frac{\partial \psi}{\partial x} \tag{2}$$

where $K(\theta)$ is unsaturated water conductivity and varies with the water content; θ is volumetric water content and ψ is the soil water potential. If the unsaturated condition is described by Darcy's law of diffusive equation, we can obtain

$$q_x = -D(\theta) \frac{\partial \theta}{\partial x} \tag{3}$$

and

$$\frac{\partial \theta}{\partial t} = \frac{\partial}{\partial x} (-D(\theta) \frac{\partial \theta}{\partial x}) \tag{4}$$

where $D(\theta)$ is diffusivity of unsaturated water soil; t is time; and $D(\theta) = K(\theta)/C$, C is specific water capacity, and

$$C = \frac{\partial \theta}{\partial \psi}$$

The diffusivity $D(\theta)$ changes with time. If ignoring the change of diffusivity between the two measuring times of water weight in sample, we can obtain

$$\frac{\partial \theta}{\partial t} = D(\theta) \frac{\partial^2 \theta}{\partial x^2}$$

$$t = 0, \theta = 0 \tag{5}$$

$$t = \infty, x = 0, \theta = \theta_\infty$$

$$t = \infty, x = H, \frac{\partial \theta}{\partial x} = 0$$

where θ_∞ is the volumetric unfrozen water content of the sample under certain temperature; H is half of the sample length. If $\bar{t} = D \cdot t / H^2$, $\bar{x} = x / H$, then eq 6 can be rewritten as follows:

$$\frac{\partial \theta}{\partial \bar{t}} = \frac{\partial^2 \theta}{\partial \bar{x}^2}$$

$$\theta(\bar{x}, 0) = 0 \tag{6}$$

$$\theta(0, \bar{t}) = \theta_\infty$$

$$\left. \frac{\partial \theta}{\partial \bar{x}} \right|_{\bar{x} = 1} = 0$$

Using Laplace transform, eq 6 converted as

$$\frac{\partial^2 \bar{\theta}}{\partial \bar{x}^2} = P \bar{\theta} \tag{7}$$

$$\bar{\theta}(0, P) = \frac{\theta_\infty}{P} \tag{8}$$

$$\left. \frac{d\bar{\theta}}{d\bar{x}} \right|_{\bar{x} = 1} = 0 \tag{9}$$

and the solution can be obtained

$$\theta = \frac{\text{ch}(1-\bar{x}) \cdot p}{\text{ch } p} \cdot \frac{\theta_\infty}{P}$$

After the Laplace inversion, we obtain

$$\theta = \theta_\infty \left[1 - \frac{4}{\pi} \sum_{k=1,3,5,\dots} \frac{\sin \frac{k\pi}{2}}{k} e^{-(\frac{k\pi}{2})^2 \cdot \bar{t}} \right]$$

so

$$\frac{\partial \theta}{\partial \bar{x}} = -2\theta_\infty \sum_{k=1,3,5,\dots} \cos(\frac{k\pi}{2} \bar{x}) e^{-(\frac{k\pi}{2})^2 \cdot \bar{t}}$$

so

$$\left. \frac{\partial \theta}{\partial \bar{x}} \right|_{\bar{x} = 0} = -2\theta_\infty \sum_{k=1,3,5,\dots} e^{-(\frac{k\pi}{2})^2 \cdot \bar{t}} \tag{10}$$

Illustrated installation of sample in Figure 4. If A is the contact area of ice-soil, then eq 3 can be rewritten as

FIGURE 4 X axis and sample.

follows:

$$Q = -A \frac{D(\theta)}{H} \left(\frac{\partial \theta}{\partial x} \right) \Big|_{\bar{x} = 0} \quad (11)$$

where Q is the quantity of water migration in the sample. Hence, the water weight in the sample at time t is

$$G_t = \int_0^t Q \cdot dt \quad (12)$$

Substitute eq 10 and 11 into eq 12, we have

$$G_t = \int_0^t \frac{A D \theta_{\infty}}{H} \sum_{k=1,3,5,\dots}^{\infty} 2e^{-(\frac{k\pi}{2})^2 \cdot \bar{t}} dt$$

so

$$G_t = \int_0^{\bar{t}} \frac{A D \theta_{\infty}}{H} \frac{H^2}{D} \sum_{k=1,3,5,\dots}^{\infty} 2e^{-(\frac{k\pi}{2})^2 \cdot \bar{t}} dt$$

The resulting equation can be written as

$$G_t = G_{\infty} \left(1 - \sum_{k=1,3,5,\dots}^{\infty} \frac{8}{\pi^2} \frac{e^{-(\frac{k\pi}{2})^2 \cdot \frac{t \cdot D}{H^2}}}{K^2} \right) \quad (13)$$

As converges rapidly, we take k=1, and

$$\ln(G_{\infty} - G_t) = \ln\left(\frac{8G_{\infty}}{\pi^2}\right) - \frac{\pi^2}{4} \frac{t \cdot D}{H^2} \quad (14)$$

after transformed the unit of time and became as

$$D(\theta) = \frac{96H^2}{\pi^2 t} \ln \frac{\frac{8}{\pi^2} G_{\infty}}{G_{\infty} - G_t} \quad (\text{cm}^2/\text{day}) \quad (15)$$

Using a pressure membrane extract instrumentation, we can determine the relation between soil water potential and volumetric water content. As a result, the soil-water characteristic curves can be determined. Consequently, the conductivity K is reckoned (Xie Shenchuan 1982).

Some outcomes of experiments for diffusivities are shown in Figure 5, and part of the numerical value of D and K are shown in Table 3.

In fact, the diffusivity is not a constant during the entire process, but a function of water content. Eq 15 is an approximate equation, the accuracy of results depends on the interval of measurement in experiments. In addition, the length of the sample cannot be excessively large.

CONCLUSION

The contact method used to determine unfrozen water content in frozen soil is a simple technique, but the period of experiment is comparatively long.

With the help of moisture-time relationship, we can obtain the conductivity

FIGURE 5 Diffusivities of two kinds unsaturated soils and volumetric water contents.

TABLE 3 Diffusivity D (cm²/day) and Conductivity K (X10⁴ mm/day) of Unsaturated Water Soil.

Soil type	Temperature (°C)	Volumetric water content (cm ³ H ₂ O/cm ³ soil)

LONG-TERM RESISTANCE OF ANCHORS IN PERMAFROST

Zhang Luxing and Ding Jingkang

Northwest Institute of the Chinese Academy of Railway Sciences
Lanzhou, People's Republic of China

Pull-out tests on reinforced concrete anchors with a nominal diameter of 10 cm were conducted at field research stations on the Qinghai-Xizang Plateau to investigate the long-term resistance of anchors in permafrost. Based on analysis of the load-displacement behavior of the anchors tested, the authors present the concept of gradually advancing failure of the adfreeze strength between the anchors and their surrounding soils. The authors consider that there exists an "effective length" for anchors in permafrost, which may be of great significance in the study of piles and anchors in permafrost. Test results show that the ultimate resistance of permafrost anchors depends primarily upon the length and diameter of the anchors; soil temperature, composition, and moisture; and the loading rate. From tests it was found that the displacement rate of an anchor in permafrost can be expressed by $\dot{\gamma} = K(\tau - \tau_{\infty})^n$, where τ_{∞} is the long-term resistance of anchors in permafrost.

In order to build the light anchor retaining wall in permafrost areas, we made the long-term resistant test of anchors in Qinghai-Xizang Plateau in 1979. The reinforced concrete anchors prefabricated from 5 to 22 cm diameter and from 50 to 250 cm long were used in the test. The 72 anchors were tested in all.

The anchors were set up by following:

Inserting the anchors in the holes drilled of 15-32 cm diameter, then backfilling the cracks with the saturated middle-coarse sand.

We were testing with method of constant loading rate and constant load. The loads were loaded by screw block. The displacement was measured by dial indicator.

ANALYSIS OF THE TEST RESULTS

The Stress Distribution of Anchors Under External Load

Buried in permafrost, the anchors were back-filled with saturated sand and frozen into place by the surrounding permafrost. The load acting on the anchor is transferred to the sand and permafrost. Figure 1 shows the radial distribution of stress in the anchor system when under axial load and Figure 2 gives the distribution of stress on shearing surface of anchor system along depth. It is seen from Figure 1 that stress decreases rapidly in radial direction with increase in distance from anchor center and becomes zero at a distance of 25-45 cm from the center. From Figure 2 (test on No. 42 anchor of 10 cm diameter), we see that, when the load is comparatively small, the shearing stress as acting on shearing surface are a maximum in the upper part, attenuating rapidly with increasing depth, and becomes zero at certain depth. It appears that, under the maximum load, the shape is approximately trapezoidal. Such a

redistribution of stress indicates that the adfreeze strength in the upper part of the shearing surface has already been destroyed, attaining the maximum value before the load on the anchor reached its maximum. As the maximum load is attained, the adfreeze strength of the lower part of shearing surface reaches its maximum while that of the upper part remains at some residual value.

Figure 3 gives a load-time-deflection curve of No. 42 anchor obtained under gradually applied loads. It is seen from that the creep curves under 11,000 kg and 12,000 kg loads appear in the shape of stair, which is different from the others. This kind of creep curve is a reflection of gradually advancing failure of the anchor.

The "Effective Length" and "Conversion Effective Length" of Anchor

It is shown from gradually advancing failure that there exists an "effective length" of anchor arm in permafrost, which refers to the transmitting depth of the shearing strength at certain spot of shearing surface of anchor system when it attains the ultimate long-term adfreeze strength (see Figure 4). The effective length of anchor remains constant provided its diameter, ground temperature, and medium remain unchanged, i.e. the resistant forces of the anchor are irrelevant to its overall length in cases where the latter is longer than the "effective length".

However, it is shown by experiment that adfreeze strength can be divided into two parts, peak and residual. After failure, there still exists the action of the latter between the anchor and the backfill sand, as indicated by the

Figure 1. The radial distribution of stress in anchor system in permafrost. (Calculating by finite element. $P = 2,000$ kg, anchor of 10 cm diameter, backfill of 7 cm thickness.)

Figure 2. The distribution of stress on the boundary surface between anchor and filled sand along depth.

Figure 3. Stair-shaped creep curve of anchor arm system.

FIGURE 4 The sketch of effective length and conversion effective length of anchor.

FIGURE 5 The conversion curve of the conversion effective length of anchor arm

dotted line in Figure 4. Therefore, the total resistant forces rise correspondingly as the anchor length increases and the "conversion effective length" can be used on account of the action of residual adfreeze strength.

The action of the residual adfreeze strength increases with increase of anchor length. As a result, the "conversion effective length" increases as anchor length increase.

The "conversion effective length" can be calculated by the following:

1. Set the value of conversion ultimate long-term adfreeze strength on the basis of the average ground temperature around the anchoring section of anchor;

2. Calculate the theoretical ultimate long-term resistant force under such conditions by multiplying the above value by the frozen surface area of the anchor;

3. Plot the above obtained values on a diagram of the ultimate long-term resistant forces of anchor versus the anchoring lengths to achieve the conversion curve of anchor length (Figure 5);

4. On Figure 5 draw a straight line parallel to the horizontal axis from the tested curve to the theoretical curve, which intersects the latter at a point and the projection of the point on the abscissa is the value of the required conversion effective length of anchor.

The values of conversion effective length of anchor h_c obtained by the above method are listed in Table 1.

The ratio of conversion effective length of anchor to the actual anchor length is called the conversion coefficient of anchor length. It decreases with increasing anchor length (Table 1). Within the range of anchor lengths tested from

TABLE 1 Conversion Coefficient of Anchorarm Length

Anchor	Length of Anchoring part* (cm)	Average ground temperature (°C)	Tested ultimate long-term resistant force (kg)	Calculated ultimate long-term resistant force (kg)	Conversion effective length h_L (cm)	Conversion coefficient of anchorarm length $K_L = h_L/h$
33	50	-2.30	2504	2295	50	1.00
34	100	-2.50	5000	4762	100	1.00
35	150	-2.55	6974	7416	140	0.93
36	200	-2.74	8485	10684	172	0.86
37	250	-2.25	9995	13716	190	0.76

* Diameter of all anchors is 10 cm

FIGURE 6 Relation between the ultimate long-term resistant force of anchorarm and anchoring length.

100 to 250 cm, the relation between the two is considered to be linear and is expressed by the following equation.

$$K_L = 1.168 - 0.001665 h \quad (1)$$

where K_L is the conversion coefficient of anchor length; h is the actual anchoring length of anchor in permafrost.

The conversion effective length of the anchor, h_L is calculated by the following equation:

$$h_L = K_L h = 1.168h - 0.001665 h^2 \quad (2)$$

where K and h are as defined in equation 1.

Ultimate Resistant Force of Anchor vs Its Actual Anchoring Length

When the diameter of anchor, the constituents of medium around anchor, water content, and temperature are kept constant and the loading rate is uniform, the ultimate resistant force of the anchor is a function of anchor length, i.e. it

increases with the increase of anchoring length (Figure 6) and gradually approaches a maximum value---the maximum loading value determined by the yield strength of the reinforcing rod of anchor. The relation is expressed by the following equation:

$$P = \sigma A(1 - e^{-Kh}) \quad (3)$$

where P is the ultimate resistant force of anchor, kg; σ is the yield stress of reinforcing rod, cm^2 ; A is the cross-section of reinforcing rod, cm^2 ; h is the anchoring length of anchor, cm; and K is a testing parameter. $K=0.00698$ when $A=3.8 \text{ cm}^2$ and the diameter of the concrete anchor equals 10 cm.

It is seen from Figure 6 and equation 3 that to increase resistance force by increasing the anchor length is rational only within a limited range, i.e. when the anchor length exceeds a certain length, there is only a small increase in resistant force.

The nonlinear relation between resistant force and anchor length is directly related to the gradually advancing failure to the adfreeze strength in the upper reaches of the anchor. Since the effective length of anchor is constant provided ground temperatures, medium conditions, and the diameter of the anchor remains unchanged. An increase in anchor length is only beneficial to utilize a greater section of the anchor having residual strength.

Ultimate Resistant Force vs Diameter of anchor

The ultimate resistant force of anchor vs. the increase in anchor diameter, appearing in hyperbolic curve, is shown in Figure 7.

However, since the increase of anchor diameter is accompanied by the increase of rigidity, the decrease of effective length of anchor, under the same ground temperature and medium conditions, will bring about a decrease in the adfreeze stress distribution pattern with depth

FIGURE 7 Ultimate long-term resistant force vs. diameter of anchors.

. Group A (No. 10-18 anchors),
 * Group B (No. 19-27 anchors).
 The length of all anchors is 100 cm.
 The temperature is from -0.9°C to -1.3 °C.

FIGURE 8 The sketch of effective length vs diameter of anchor.

FIGURE 9 Conversion ultimate long-term adfreeze strength vs diameter of anchor

TABLE 2 Coefficient of Effective Diameter

Anchor diameter	Conversion ultimate long-term adfreeze strength	Coefficient of effective diameter K _d
5	0.92	1.44
8	0.71	1.11
10	0.64	1.00
12	0.59	0.92
14	0.55	0.86
16	0.52	0.82
18	0.51	0.80
20	0.50	0.78

(Figure 8). Therefore, the increase in anchor diameter will result in the weakening of conversion ultimate long-term adfreeze strength (Figure 9)*.

The effect of anchor diameter on the conversion ultimate long-term adfreeze strength can be expressed in terms of the coefficient of effective diameter. The so-called coefficient of effective diameter is the ratio of the conversion ultimate long-term adfreeze strength obtained in accordance with different diameters of anchor to that based on a fixed diameter of 10 cm, represented by K_d.

$$K_d = \frac{\tau_d}{\tau_{10}} \tag{4}$$

where τ_d is the conversion ultimate long-term adfreeze strength of anchor of diameter, d, in cm; τ_{10} is the conversion ultimate long-term adfreeze strength of anchor of 10 cm diameter.

The coefficient of effective diameter decreases with increase of the diameter (Table 2), which is expressed by equation 5.

$$K_d = K_{d0} + \frac{a}{D} - \frac{b}{D^2} \tag{5}$$

where D is the diameter of anchor, in cm; K_{d0}, a, b is the testing parameters. K_{d0} = 0.5457, a = 4.6125, b = -0.7023 for reinforced concrete anchor buried in frozen sand.

Ultimate Resistant Force of Anchor vs Temperature

When the diameter of the anchor, backfill, and water content remain constant, the ultimate resistant force increases linearly with a de-

* Conversion ultimate long-term adfreeze strength is equal to the ultimate resistant force of anchor divided by the frozen area of anchor.

FIGURE 10 Relation between ultimate resistant force of anchor arm versus temperature

FIGURE 11 Damage creep critical strain versus temperature

FIGURE 12 Damage creep critical strain versus loading rate

FIGURE 13 Damage creep critical strain versus anchoring length of anchor

crease in medium temperature (Figure 10). The relation between the conversion ultimate long-term adfreeze strength and temperature can be expressed by a linear equation, as:

$$\tau = A + m t \quad (6)$$

where τ is the conversion ultimate long-term adfreeze strength, kg/cm²; A is the testing parameter, kg/cm²; m is the testing parameter, kg/cm², Deg.; t is the absolute value of negative temperature, Deg.. For mediums of saturation sand the following values of testing parameters can be used:

$$A = 0.06 \text{ kg/cm}^2; \quad m = 0.56 \text{ kg/cm}^2, \text{ Deg.}$$

Equation 6 can be used to evaluate the conversion ultimate long-term adfreeze strength of saturation sand with reinforced concrete anchor 10 cm in diameter and 100 cm in length at different temperatures.

The Attenuation Creep Critical Displacement and Damage Creep Critical Displacement of Anchor System in Permafrost

Field tests show that when the creep displacement of anchor in permafrost under the action of an external load reaches a certain value, the displacement of the anchor becomes uniform with time. This value is called the attenuation creep critical displacement of anchor system. When the anchor system comes to uniform

flow and creep displacement reaches another maximum value, a transit of anchor from uniform flow to advancing flow begins. The latter maximum value is called the damage creep critical displacement of anchor system.

According to the results of experiments, the attenuation creep critical displacement of reinforced concrete anchor buried in saturation sand at temperature of -1.85 to -2.8°C, is about 2 to 4 mm.

The damage creep critical strain versus temperature is shown in Figure 11, which increases with a decrease in temperature and is approximately linear.

Damage creep critical strain limit, increase with increasing loading rates, as shown in Figure 12.

In addition to the above mentioned factors, damage creep critical strain also is relevant to the anchoring length of anchor, i.e. increases with an increase of anchor length, as shown in Figure 13.

To sum up, the damage creep critical displacement of anchors is a specific feature relative to the anchor system, but its variation is very complicated, since it is influenced by a number of factors. It tends to be a constant, however, provided temperature, testing method, anchor length, and medium conditions remain unchanged.

CONCLUSION

1. The failure of the adfreeze strength of anchors in permafrost takes place gradually along the frozen boundary surface between the anchor and backfill. After failure of the adfreeze strength, there still exists the residual adfreeze strength at the boundary surface.

2. The resistant force of anchor is the function of the length, diameter of anchor, temperature, water content of medium and acting time of load. It increases with increase of anchor length and diameter. When the anchor length exceeds a certain length, there is only a small increase in resistant force.

3. There exists an "effective length" of the anchors in permafrost, which is influenced by

the anchor diameter, temperature and constituents of medium and so on. In the calculations of resistant force of anchor, we can only consider it.

4. The attenuation creep critical displacement and damage creep critical displacement of anchor system are a specific feature relative to it. When the displacement of anchor is less than damage creep critical displacement, the failure of anchor will not take place under the action of an external load.

A STUDY OF THE CALCULATION OF FROST HEAVING

Zhang Shixiang and Zhu Qiang

Water Conservancy Department of Gansu Province,
Lanzhou, People's Republic of China

In recent years, numerous irrigation canals lined with concrete and masonry slabs have been built in regions of seasonally frozen ground in Gansu, China. Many of them, however, have been damaged by the heaving action of frozen soil. So it is of great importance to find a practical way to determine frozen depth and frost heave under various conditions. Frost heaving is known to be a comprehensive process of heat conduction and moisture migration. The authors describe the moisture migration process by the theory of unsaturated soil water movement, developed since the 1950's, and an improvement over the taxonomic method prevalent in the past study of soil water. A stepwise calculation method for one-dimensional frost penetration and heaving is derived by simplifying the boundary conditions of heat and moisture transport and temperature distribution. This method provides not only the maximum frozen depth and frost heave, but also describes the freezing process and the heaving ratio along the frozen depth. Analytical formulas for deeply and shallowly seated ground water levels are presented with illustrating examples.

INTRODUCTION

In recent years, numerous irrigation canals lined with concrete and masonry slabs have been built in seasonal frost regions of Gansu, China. However, many of them were damaged or partially damaged by the heaving action of the frozen soil. So it is of great importance to find a practical way to determine the frozen depth and frost heave under various conditions. Since the 1970's the numerical method for simulating the heat and water transfer and heaving processes have been developed by many investigators (Harlan, 1973; Guymon and Luthin, 1974; Taylor and Luthin, 1978; Jame and Norum, 1980). From the practical viewpoint, however, because of the complexity of this method, it has not been applied extensively to the design of large-scale canal constructions. In addition, many of the current analytical methods for predicting frost heave only deal with heat and mass transfer processes separately and cannot meet the various soil and ground water conditions.

This paper describes the moisture migration process and sets up its equation by the theory of water movement in unsaturated soil. To obtain a calculation method that will be simple enough for practical engineering use and to be able to reflect the various temperature and moisture conditions of soil during freezing, we will first make some simplifications to the boundary conditions of the heat and moisture transport equations as well as temperature distribution in the frozen soil. An analytical formula using a stepwise calculation method can be derived by solving these equations simultaneously.

WATER MIGRATION

According to the theory of unsaturated soil water movement (Hiller, 1971), the soil water potential is composed of the matric potential ψ_m ,

pressure potential ψ_p , gravitational potential ψ_g , temperature potential ψ_T , osmotic potential ψ_{os} , i.e.

$$\psi = \psi_m + \psi_p + \psi_g + \psi_T + \psi_{os}$$

Hereinafter, the study is limited only to the matric and gravitational potential. The moisture flux can be expressed as the same form of Darcy's law:

$$q = -K(\psi_m) \cdot \nabla \psi \quad (1)$$

where $K(\psi_m)$ is unsaturated water conductivity and varies with the water content.

During freezing, the water migration occurs mainly in the unfrozen zone. According to the experimental and simulated results presented by Taylor and Luthin (1978), Jame and Norum (1980), water movement in the frozen zone is insignificant. In the unfrozen zone, the occurrence of both water migration and frost heave depend on whether the potential in the unfrozen soil below the freezing front is greater than ψ_0 , the potential at the freezing front. Because the initial water content for frost heaving, w_0 , is a content below which neither frost heaving nor water migration will take place, ψ_0 may be regarded as the potential corresponding to w_0 . In turn, we can determine ψ_0 by w_0 from the characteristic curve of soil water. On the basis of the experimental work of Wu et al. (1981), w_0 is about $0.84 w_p$, where w_p is the plastic limit of water content.

In this paper, only a one-dimensional case will be studied. If the soil water potential is taken as that of a unit weight, we have:

$$q = -K(\psi_m) \left(\frac{\partial m}{\partial x} + 1 \right) \quad (2)$$

$$\frac{\partial w}{\partial t} = \frac{\partial}{\partial x} (D(w) \frac{\partial w}{\partial x}) + \frac{\partial K(w)}{\partial x} \quad (3)$$

where x is the vertical coordinate, positive downward, $D(w)$ is the diffusivity of unsaturated soil water, a function of water content.

1. In the case of deeply seated ground water, the soil is relatively dry and gravitational potential can be neglected as compared with matric potential, then equation 3 can be rewritten as follows:

$$\frac{\partial w}{\partial t} = \frac{\partial}{\partial x} (D(w) \frac{\partial w}{\partial x}) \quad (4)$$

Assuming that soil is semi-infinity, the initial water content and diffusivity are uniform along the depth and are equal to w_B and D , respectively. Where D is the weighted mean value of $D(w)$. According to Crank (1956), for a drying process, D can be expressed as:

$$D = \frac{1.85}{(w_B - w_0)^{1.85}} \int_{w_0}^{w_B} D(w) (w - w_0)^{0.85} dw \quad (5)$$

In addition, as shown before, the water content at freezing front is w_0 , thus the boundary and initial conditions can be written as:

$$w(t, h) = w_0, w(t, \infty) = w_B, t > 0$$

$$w(0, x) = w_B, x > h$$

where h is the frozen depth. Then the analytical solution of equation 4 is:

$$w(t, x) = w_0 + (w_B - w_0) \operatorname{erf} \left(\frac{x-h}{2\sqrt{Dt}} \right) \quad (6)$$

The water migration flux toward the freezing front is:

$$q = (w_B - w_0) \sqrt{\frac{D}{\pi t}} \quad (7)$$

2. In the case of shallowly seated ground water, the freezing process is divided into a number of time steps. Water movement can be approximately considered as a steady flow for each step. In equation 2, substitute soil water tension S for $(-\psi_m)$, after rearranging, this gives:

$$x = \int_0^S \frac{dS}{1 + q/K(S)} \quad (8)$$

At the present time, the theoretical relation between $K(S)$ and S has not yet been found. In general, they are related by an empirical formula derived from experimental data taking the following form:

$$K = \frac{K_s}{CS^m + 1}$$

where K_s is the saturated water conductivity and C and m are constants. When $m=1, 1.5, 2, 3, 4$, the analytical solution of equation 8 can be derived. For example, if $m=2$, we have:

$$\frac{K_s}{\sqrt{Cq(K_s + q)}} t_g^{-1} (S \sqrt{\frac{Cq}{K_s + q}}) = x \quad (9)$$

At the freezing front, $x = H-h$, $S = S_0$, where H is the depth of the ground water table, and we can obtain an implicit equation for the water flux:

$$h = H - \frac{K_s}{\sqrt{Cq(K_s + q)}} t_g^{-1} (S_0 \sqrt{\frac{Cq}{K_s + q}}) \quad (10)$$

HEAT CONDUCTION

The heat conduction equations during freezing are as follows:

$$\frac{\partial u_f}{\partial t} = a_f \frac{\partial^2 u_f}{\partial x^2}, h > x > 0, t > 0 \quad (11)$$

$$\frac{\partial u_T}{\partial t} = a_T \frac{\partial^2 u_T}{\partial x^2}, x > h, t > 0 \quad (12)$$

Assuming the freezing temperature of soil is zero, then at the phase changing point we have:

$$u_f(h, t) = u_T(h, t) = 0 \quad (13)$$

$$\lambda_f \frac{\partial u_f}{\partial x} \Big|_{x=h} - \lambda_T \frac{\partial u_T}{\partial x} \Big|_{x=h} = 333\gamma(q + (w - w_0) \frac{dh}{dt}) \quad (14)$$

where u is the temperature, λ is the heat conductivity, a is the thermodiffusivity, γ is the specific weight of water, and the subscripts f and T are for the frozen and thawed zones, respectively. The unit of latent heat is taken as J/g.

For practical purposes, it would be better to find an approximate solution for equations 11 to 14. First, the temperature increment in the period Δt is assumed to be linearly distributed along the depth. During the steady frost penetration period, the error caused by this assumption is an infinitesimal of higher order. Then we can obtain:

$$\Delta u_f = u_0 - \frac{\Delta u_0 - \Delta u_f'}{h} x \quad (15)$$

where Δu_0 , $\Delta u_f'$ is the temperature increment in the period Δt at the surface ($x=0$) and the frozen depth ($x=h$), respectively (see Figure 1).

FIGURE 1 Sketch of Δu along the depth.

DEEPLY SEATED GROUND WATER TABLE

If we rewrite the left side of equation 11 in a differential form and substitute equation 15 into it, we have:

$$a_f \frac{\partial^2 u_f}{\partial x^2} = \frac{\partial u_f}{\partial t} = \frac{\Delta u_o}{\Delta t} - \frac{\Delta u_o - \Delta u_f'}{h \Delta t} x$$

Integrate the above equation over x with the boundary conditions: $x=0$, $u_f = u_o$; $x=h$, $u_f = 0$. After rearranging, we have:

$$u_f = \frac{-(\Delta u_o - \Delta u_f')}{6a_f h \Delta t} x^3 - \frac{\Delta u_o}{2a_f \Delta t} x^2 - \left(\frac{u_o}{h} + \frac{2\Delta u_o + \Delta u_f'}{6a_f \Delta t} h \right) x + u_o \quad (16)$$

$$\frac{\partial u_f}{\partial x} \Big|_{x=h} = \frac{h\Delta u_o + 2u_o \Delta h}{6a_f \Delta t + 2h\Delta h} - \frac{u_o}{h} \quad (17)$$

In the unfrozen zone, the initial condition: $u_T(x, 0) = u_a$, $x > h$, is assumed and it should be noted that the temperature at the upper boundary, i.e. the freezing point, drops to zero. We can obtain the solution of equation 12 as:

$$u_T(x, t) = u_a \operatorname{erf} \left(\frac{x-h}{2\sqrt{a_T t}} \right) \quad (18)$$

$$\frac{\partial u_T}{\partial x} \Big|_{x=h} = \frac{u_a}{\sqrt{\pi a_T t}} \quad (19)$$

where u_a is the mean temperature of soil before freezing.

Substituting equations 7 and 17 which are for the deeply seated ground water table, or 10 and 19, which are for the shallowly seated ground water table, into equation 14, we then obtain the expression of dh/dt . Furthermore, the unfrozen water still exists in the negative temperature, mainly in the range of 0°C to -5°C . To consider the effect on frost penetration precisely is difficult for an analytical solution. According to the result of numerical method (Nixon et al., 1973), we can regard the latent heat is to be suddenly released at temperature zero without a significant error to the freezing process. So we can modify the second term $(w-w_o)$ in the right parentheses of equation 14 with $(w-w_{-5})$, where w_{-5} is the unfrozen water content at -5°C . Thus the basic formula can be expressed as follows:

$$\lambda_T \left(\frac{h\Delta u_o + 2u_o \Delta h}{6a_f \Delta t + 2h\Delta h} - \frac{u_o}{h} \right) \Delta t = 333\gamma((w-w_{-5})\Delta h + q\Delta t) + \lambda_T \frac{u_a \Delta t}{\sqrt{\pi a_T t}} \quad (20)$$

Substituting q determined by equation 7 into equation 20 gives:

$$\lambda_f \left(\frac{h\Delta u_o + 2u_o \Delta h}{6a_f \Delta t + 2h\Delta h} - \frac{u_o}{h} \right) \Delta t = 333\gamma(w_B - w_{-5})\Delta h + (w_B - w_o) \sqrt{\frac{D}{\pi t} \Delta t} + \lambda_T \frac{u_a}{\sqrt{\pi a_T t}}$$

This is a quadratic equation. After rearranging, we get the solution of Δh :

$$\Delta h = \left(\frac{1}{2} \lambda_f h \Delta u_o - 3a_f (333\gamma(w_B - w_o) \sqrt{\frac{D}{\pi t}} + \frac{\lambda_T u_a}{\sqrt{\pi a_T t}} + \frac{\lambda_f u_o}{h}) \right) / 1000\gamma a_f (w_B - w_{-5}) \quad (21)$$

When u_o is constant, equation 21 can be integrated to yield h as follows:

$$h = \left(\sqrt{\frac{-2\lambda_f u_o}{333\gamma(w_B - w_{-5})}} - \frac{333\gamma(w_B - w_o) \sqrt{D} + \lambda_T u_a / \sqrt{a_T}}{594(w_B - w_{-5})} \right) \sqrt{t} \quad (22)$$

If the latent heat of migrating water and the heat conducting toward the freezing front from the unfrozen zone are neglected (the second term in the parentheses), and the unfrozen water is assumed to be non-existent, then the well-known Stefan's formula can be derived from the above equation:

$$h = \sqrt{\frac{-2\lambda_f u_o t}{333\gamma w_B}}$$

We can see that Stefan's formula is a particular form of equation 22 under special condition.

When u_o changes with time, we must divide the freezing period into a number of intervals. The increment of frozen depth in a certain period can be calculated from the frozen depth at the end of the last period. Water migration flux in the various period can be defined by equation 7, and the frost heave is:

$$\Delta H_h = 0.09(w_B - w_{-5})\Delta h + 1.09 \sqrt{\frac{D}{\pi t}} (w_B - w_o) \Delta t \quad (23)$$

where ΔH_h is the heave value in the various period. In general, the first term may be neglected.

Example 1. At a given locality, the ground water is deeply seated and the soil is silty loam:

$$\lambda_T = 0.0105 \text{ J/cm} \cdot \text{s} \cdot ^\circ\text{C}, \quad \lambda_f = 0.0151 \text{ J/cm} \cdot \text{s} \cdot ^\circ\text{C},$$

$$a_T = 3.82 \times 10^{-3} \text{ cm}^2/\text{s}, \quad a_f = 7.41 \times 10^{-3} \text{ cm}^2/\text{s},$$

$$w_B - w_o = 0.13, \quad w_B - w_{-5} = 0.26,$$

FIGURE 2 Frozen depth and frost heave versus time and heave ratio distribution for the deeply seated ground water.

$$D = 1.16 \times 10^{-4} \text{ cm}^2/\text{s}, \quad u_a = 8.2^\circ\text{C}.$$

$$K_s = 1.16 \times 10^{-5} \text{ cm/s}, \quad c = 2.5 \times 10^{-3} \text{ cm}^{-2},$$

$$m = 2, \quad S_0 = 370 \text{ cm}.$$

The surface temperature changing with time is shown in Figure 2.

The time step is taken as 5 days, and the results are shown in Figure 2.

We can see that in the case of deeply seated ground water, the variation between results from equation 21 and Stefan's formula is insignificant. Moreover, the frost heave ratio in the upper zone is greater than in the lower zone; this conclusion can fit many observed data in situ (Zhu, 1980).

SHALLOWLY SEATED GROUND WATER

Under this condition, equation 20 should be modified. As shown in Figure 3, when frost penetration increases from h to $h + \Delta h$, the original water content that has changed phase is the shaded area between curve 1-1 and 2-2, so the first term of the right side of equation 20 should be re-written as:

FIGURE 3 Sketch illustrating the phase change of the original water.

$$333\gamma \left(\frac{2}{3}w_s + \frac{1}{3}w_0 - w_{-5} \right) \Delta h + q\Delta t$$

where w_s is the saturated water content. Then we can get the solution of Δh under this condition:

$$\Delta h = \frac{\frac{1}{2}\lambda_f h \Delta u_0 - 3a_f \Delta t \left(333\gamma q + \sqrt{\frac{\lambda T u_a}{\pi a T}} + \frac{\lambda_f u_0}{h} \right)}{1000\gamma a_f \left(\left(\frac{2}{3}w_s + \frac{1}{3}w_0 \right) - w_{-5} \right)} \quad (24)$$

The water flux q can be defined by a relation curve between q and h drawn from the implicit equation 10.

Example 2. The ground water table is 120 cm below the surface.

$$w_s = 0.51, \quad w_0 = 0.24, \quad w_{-5} = 0.11,$$

The other conditions are the same as in example 1. The results are shown in Figure 4. We can see that the frozen depth is much less and the frost heave is much greater than that under the deeply seated ground water condition. The result indicates that adopting Stefan's formula in this case may cause a great error. The heave ratio in the upper zone is much less than in the lower. This conclusion fits well with the field experiment and has an important effect on the perfect selection of the anti-heave measure in engineering (Zhu, 1980).

THE PERIGLACIAL ENVIRONMENT OF THE LATE PLEISTOCENE
ALONG THE QINGHAI-XIZANG HIGHWAY

Zhang Weixin, Xu Shuying, Xu Qizhi, and Shi Shengren

Department of Geology and Geography, Lanzhou University
People's Republic of China

There are several kinds of periglacial phenomena on the Qinghai-Xizang Plateau. Polygon and wedge-shaped casts 1 to 50 m in diameter were formed during the last glacial period, and the involutions buried at depths of 3 to 11 m may have been formed during the Neoglaciation. Based on C^{14} dating, pollen analysis, and periglacial phenomena, the paleogeographic environment during the Late Pleistocene can be reconstructed. About 35,000 years ago, the Qinghai He Basin and other high plains in southern Qinghai were an interperiglacial environment, and carbonate nodules were formed in lake deposits; the upper parts of the Kunlun and Tanggula Shan were periglacial environments. From 26,000 to 14,000 year ago, the mean annual air temperature was about -7° to $-8^{\circ}C$. No carbonate nodules developed in the lake basins, but large polygons and sand wedges were formed on terraces along some rivers, and glaciers continued to grow in the high mountains. The lower limit of the periglacial belt in the northern part of the Qinghai-Xizang Plateau descended to 3200-3400 m a.s.l. From 14,000 to 12,000 years ago, the climate was still rather cold, as indicated by undecayed buried plants.

As is well-known, the Qinghai-Xizang plateau is an area of strong uplift of altitude since the Quaternary period (Li Jijun et al, 1979). According to the data which have obtained, from geologic (Wen Shixuan 1981), geomorphic (Zheng Benxing et al, 1981), and paleontologic (Kong Zhaochen et al, 1981), and many other evidences demonstrate that the altitude of the plateau during the late Pleistocene was generally more than 4,000 m a.s.l., and the mountain areas were higher, usually more than 5,000 m. This high-altitude topography of the plateau first brought about a drop of the temperature with the rise of the plateau surface. Along with the coming of the cold climate of the late Pleistocene on a global scale, a superimposed cold happened on the plateau. The combination of the two kinds of cold put the plateau surface into a periglacial environment of long duration. This has been proved by a series of periglacial phenomena, ancient and existing, biologic and non-biologic, recently found on the south Qinghai plateau.

During the 4 summers from 1974-1977, we all worked along the Qinghai-Xizang Highway, and paid, to a certain degree, attention to a series of periglacial phenomena there. Later we made reports on some of them (Zhang Weixin 1979a; 1979b; 1982). It is based on these reports, on the date of the assemblages of spore pollen in the deposit of 20 m deep drilling hole, and absolute C-14 dating that makes this special discussion on several changes in the environment of south Qinghai plateau during the late Pleistocene. According to these data the paleogeographical environment in this area has been reconstructed.

Qingshui River area is located near the 68 rd station of Qinghai-Xizang Highway. To the north are Kunlun Shan and to its south the Tanggula Range; both mountains are more than 5,500 m a.s.l.

and about 60 and 400 km away from the area respectively. To the east and west is the hinterland of southern Qinghai plateau. During the Quaternary period, this area was a structure fault basin. The deposit of the Quaternary is over 200 m thick. At present there remains a small lake to the southeast of this area, and the former river bed from the southern slope of Kunlun Shan down to the lake basin is indistinct.

This area, has mean air temperature in January is $-17.3^{\circ}C$, in July of $5.4^{\circ}C$; the mean annual temperature is $-5.5^{\circ}C$, and for more than seven months in the year it is under $0^{\circ}C$. The annual precipitation there is 267 mm.

PERIGLACIAL REMAINS OF
THE LATE PLEISTOCENE

Up to now, the periglacial phenomena of the late Pleistocene we found in the area on the plateau south of Qinghai and north of Xizang, and the periglacial remains are great in variety, of type, scale, and content.

Polygon and Wedge-Shaped Casts

During Würm glaciation period large polygons were widely formed on the plateau (Zhang Weixin; Xu Shuying et al, 1981; Zhang Linyung 1981). The biggest of slopes of these developed on the southern and northern slopes of the Tanggula Range and on the banks of the valleys of some big rivers. They were usually more than 50 m in diameter. There are some of sand wedges in various shapes extensively distributed under the terraces surface, the biggest being over 3 m broad at the upper and 1.8 m deep. C-14 dating of the silt in the wedges is 24,000 to 15,000 years old (Gao Dongxin 1979; Zhang Weixin 1983). Therefore,

the sand wedge is the product of the main Würm-glaciation.

Involution

This is the best preserved form of former and modern periglacial on the plateau surface. In 1976 we found in 20 m by drilling hole under the ground surface 6-11 m many well-developed ground ice layers and marlud interbeddings, which are in form of involution. In the southern part of the Tanggula Range, there is also well-developed involution 2 m under the ground surface of the place east side of the highway near Liangdahe. The brown humic soil under the ground surface is 545-60 years old by its C-14 dating, which shows that the involution was formed during the Neoglaciation period.

Stair Surface on Slopes

During our research on the southern part of the Tanggula Range, we found a kind of well-developed bedrock stair surface on the mountain slopes between Ando Xian (county) and Nagqu Xian (Heihe county). It is different from the river-eroded bedrock terraces. The landform is distributed on the convex slopes at 4,500 to 4,800 m a.s.l. The rock step surface slant slightly forward. They are mostly covered with a thin layer of slope debris, and with angle of block rocks are accumulated before the tread surface, but at another place the bedrock are exposed, at the back border of the tread the bedrock becomes steeper only a little higher. Upwards from there the slope becomes gentle and its surface is covered with a thin layer of soil, and the ground surface is covered with a high cold of meadow. This kind of landform is nonactive under the present cold climatic condition. This landform is quite similar to the cryoplanation terrace developed in the periglacial environment of high latitude areas reported by Pévé et al (1981) and Reger et al (1976). It might have developed during the cold stage of the late Pleistocene. Landforms with such features have also been found in Qinlian Shan areas and on the southern slopes of Mt. Datong and Mt. Longlongling, which are distributed at piedmont, 4,000 to 4,200 m a.s.l.

FEATURES OF THE PALEOECOGRAPHIC ENVIRONMENT

From that 20 m hole in the Qingshui River area, the following assemblages of spore pollen are found in the layer of 18 to 20.25 m deep: Leptogramma, Pinus, Picea, Abies, Cedrus, Tsuga, Larix, Ephedra, Gramineae, Allium, Alnus, Quercus, Ulmus, Chenopodium, Nitraria, and Compositae. According to the analysis of their biological character and their required ecological geographic conditions, these plants are not likely to grow in the same natural geographic region. Because of it is different of biological feature of the different plants and of ecologic geographical condition, which their required. So the proper explanation for this is that they were distributed in the areas from plateau surface of warm and dry environment to mountains of

FIGURE 1. Paleolandscape belts. 1) Lake basin, 2) Gravel-Gobi steppe, 3) Broadleaf trees, 4) Broadleaf-coniferous, 5) Alpine meadow and periglacial belt, 6) Alpine snowline.

warm-cool and humid climatic conditions, similar to the natural landscape from Gansu corridor to Qilianshan area today. The spore-pollen of some of the plants probably have carried down by flowing water from Kunlunshan and accumulated in basin. According to their biologic features, these landscape belt may be divided as follows: the lake basin belt of Qingshui River; the belt of aquatic and wet plants on the banks; the belt of gravel-gobi steppe before mountains; the belt of broad leaf trees on low mountains and in valleys; the belt of broad leaf trees mingled with coniferous trees in mountain areas; the alpine meadow and periglacial belt; the alpine snow-ice belt (Figure 1).

The Lake Basin Belt

The lake basin of the Qingshui River is a fault basin of Cenozoic Era, the Quaternary deposit being over 200 m thick. The unearthed stratum from the 20 m hole is a set of deposits of river-lake facies formed during the late Pleistocene. The deposit features and the spore pollen in the deposits show that the environmental conditions were different from the interperiglacial climates on the plateau surface to the periglacial climates on the mountains.

The Belt of Gravel-Gobi Steppe before the Mountains

As a result of the new tectonic movement, the altitude of Kunlun Shan uplift very high, the great alluvial fans were distributed before the southern foot of Kunlun Shan. Because of the severity of the ecological environmental conditions, there are some drought-enduring plants, such as Ephedra, Nitraria, and Compositae growing there. This shows that the climatic condition then was warm-dry, similar to the natural landscape at the southern border of Qaidam basin at the northern foot of the Kunlun Shan.

The Broadleaf Trees Belt of Low Mountains and Valleys

This belt is distributed mainly in the areas of low mountains and valleys at the southern foot of Kunlun Shan. As the environment of

plants vary with an increase in altitude and landform scattered broadleaf trees of warmth-resisting and drought-enduring types such as Ulmus, Alnus, Betula, and a few Cupressus etc. grow on the sunny slopes of drier growing condition of low mountains and valleys.

Broadleaf-Coniferous Belt in Mountain Areas

The belt is distributed on the slopes at higher altitudes, the lower of which the climate becomes temperate cool and the atmospheric humidity increases. The plants which can grow in such environment are Betula, Quercus, Larix, Tsuga, and Cedrus. At the upper part of this belt the climate becomes cooler and the humidity greater; therefore, the number of trees of coniferous genus increases. At the place where the altitude still higher instead of Picea and Abies gradually.

Alpine Meadow and Periglacial Belt

This belt is above the forest belt, with a mean annual air temperature below 0°C. Alpine meadow takes the place of the needle-leaved forests. Up to the upper part of the mountain areas is periglacial environment where various periglacial processes and phenomena have developed.

Alpine Snow and Ice Belt

This belt is distributed on top of mountain areas of still higher altitude where all kinds of glaciers and glacial landforms have developed.

DISCUSSION

Characteristics and Evolutionary History of the Deposit of River and Lake Facies

According to the features of the deposit from that 20 m deep hole in Qingshui River, the assemblages of spore pollen and the absolute age by C-14 dating in it, this deposit can be divided into three layers.

The lower layer is between 11.78 to 20.25 m under the ground surface. The upper section of it, which is between 11.78 to 14 m, is of marlmud with a few ice crystals in it. The colour at the top of this part is dark-gray, which changes gradually into black at the lower part. Probably because of the influences of ground water, the record of this part is in melted form with a comparatively great content of carbonate nodules. The lower section of it, which is between 14 to 20.25 m, is of blue gray and light gray marlmud with coarse sand and limestone pebbles in it. This shows that the lake at the time when this part was formed still had rivers flowing into it. C-14 dating of the blue gray marlmud layer from 14 to 14.7 m under the ground surface shows that it is $34,700 \pm 2,800$ years old (Figure 2).

The middle layer, which lies 4.32 to 11.78 m under the ground surface, is composed of interlayers of gray-white and blue-gray marlmud and a yellow green one with a few pebbles and coarse sand layers in it, and the underground ice which is 5 to 7 cm thick being well-developed in it. Its frost deformation structure (involution) is

- Relics of leaves & roots of plants
- Ground ice & involution
- Carbonate nodules
- Sand & peaty soil
- Sample points

FIGURE 2. Geologic profile from drill record of Qingshui River Basin.

very clear. Down from there, it gradually turns into a marlmud and sand layer which contains carbonate nodules. In the part from 9.37 to 11.78 m in this layer the carbonate nodule is $26,200 \pm 890$ years old by its C-14 dating.

The upper layer, 1 to 4.32 m under the ground surface is, at the upper part, composed of sheets of brown roots and leaves of plants mixed with a little amount of sand and clay, and, at the lower part, a layer of blue-gray ooze mixed with sheets of medium-size and fine sands as well as with humic sheets of half-rotten leaves and roots of plants. Still lower it turns into an interlayer of sand and ice. The blue-gray ooze layer, which is 2.73 to 2.90 m under ground surface is $14,250 \pm 160$ years ago, and the ooze layer, which is 1.57 to 2.52 m under the ground surface, is $12,950 \pm 290$ years old by C-14 dating.

The Quaternary deposit in the lake basin discussed above and the features of spore pollen in it reflect that the lake basin of the Qingshui River area of the late Pleistocene underwent three stages.

The early stage was the period when all the deposit of the lower layer were formed and the spore pollen of plants in it was accumulated. According to C-14 dating of the blue-gray marlud between 14 to 14.7 m, this period is 35,000 years ago. This sedimentary material of Kunlun Shan col-basin from 40 to 20 m of drilling hole (upwards) under the ground surface is a layer of fine and coarse sand at the lower part, and a layer of subclay at the upper part. The spore pollen of plants in this part contains *Ephedra*, *Artemisia*, and *Chenopodiaceae*, whose composition is similar to the landscape of the southern part of Gansu Corridor. This part also shows that the environmental condition is semiarid steppe (Tang Lingyu et al, 1979). Thus it can be seen that the deposit in the lake basin was formed from 35,000 years ago when the environment was semiarid down to the climate at that time became very dry, the lake getting less water, and the amount of evaporation being great. The lake water therefore became concentrated and became rich in carbonate. As a result, deposit of marl containing large amount of carbonate was formed. The spore pollen of coniferous and broadleaf trees in this layer was probably carried down by flood from warm-cool mountain areas nearby. On the whole, this stage demonstrates the environmental features of the interglacial period.

The middle layer of the deposit in the lake basin was formed during this period. The lower section of it is composed of marlud and sand with a few carbonate nodules. Upwards the layer turns gradually into the upper part of marlud of grayish white, bluish gray, and yellowish green, in which sheets of coarse sand are mingled. This upper section is empty of carbonate nodules. The environmental condition reflected is warm and dry climatic condition evolving into cold climatic condition, the evaporation being lessened, and the chemical process weakened. From then on, it came into one cold periglacial environment, i.e. the Würm glaciation period.

The part formed during the late stage was the upper layer of the deposit. Its lower part is of ooze layer, which turns upwards into ooze of bluish gray which is mixed up with medium-sized sand sheets and gray ooze sheets containing half-rotten roots and leaves of plants. The upper part is a layer containing well-preserved brown roots and leaves of plants, with a little sand in the roots. The ooze layer of bluish gray, 2.73 to 2.9 m under the ground surface, is 14,250 ± 160 years old by its C-14 dating, and the sandy ooze layer, 1.57 to 2.52 m under the ground surface, is 12,950 ± 290 years old by its C-14 dating. These show that the water supply to the lake was lessened and the lake became shallow while the air temperature was still cold. The roots and leaves of aquatic plants growing on the lake bank accumulated without decomposition. Therefore this must have been at the stage of the Würm glaciation.

The analysis of the deposit from that hole in Qingshui River lake basin and the biological

features of the spore pollen in it shows that during the early stage, about 35,000 years ago, the environmental condition in which the deposit in Qingshui River was formed is a landscape of warm and dry steppe in areas of plateau; and a landscape of cool, humid forest steppe in low mountain areas changing gradually towards cold periglacial and glacial landscapes in top of the high mountains.

About 26,000 to 14,000 years ago, the climate grew very cold with the coming by degrees of the Würm glaciation. In this period, the lake deposit changed from marlud containing carbonate nodules of the early stage into marlud without any content of carbonate nodules. Glaciers developed throughout the Kunlun Shan and Tanggula Range, and polygons and river-bank sand wedges developed widely on the terraces of valleys and the plains.

About 14,000 to 12,000 years ago, owing to the plateau surface uplift by new tectonic movement, the altitude is increased, the cold of the Würm glaciation in the plateau area continued. As a result, the roots and leaves of aquatic plants accumulating 1.5 m under the ground surface of the lake basin and were not able to decompose. The cold periglacial environment lasted until the early Holocene. During the mid-Holocene period of high temperature, the temperature on the plateau increased slightly; it dropped again during the late Holocene. Therefore, the periglacial environment has been preserved until now.

Northern Lower Boundary of Periglacial Belt on Qinghai Plateau during Late Pleistocene

The highest peak in the Tanggula Range is 6,000 to 6,500 m a. s. l. The average height of the range is about 5,800 m. The modern snowline at 5,000 to 5,400 m, while the fossil cirques are at 5,000 to 5,200 m. The average height of fossil cirque is about 5,100 m. But the amount of uplift of plateau surface in Holocene is about 800 to 900 m, deduct this number from 5,100 m, then the height of fossil forms is about 4,300 to 4,200 m. The Fenghuo Shan area in the northern part of Tanggula Range is 4,600 m high, with a mean annual air temperature of -6.6°C today. Calculated according to the rate of the progressive decrease of 0.5°C per hundred metre, the mean annual air temperature near the existing snowline of the Tanggula Range is about -10°C to -11°C. The value is the temperature of fossil cirques formed. Accordingly it is deduced that the northern lower boundary of the paleo-periglacial environment in the plateau south of Qinghai was about 2,100 to 2,200 m during Würm glaciation.

Kunlun Shan is approximately 6,000 m a.s.l. at the central part and 5,600 to 5,800 m on an average. The height of the modern snowline at 5,200 to 5,400 m and 5,300 m on an average. The fossil cirques were at 4,800 to 5,200 m during the Würm glaciation, the average height at about 5,000 m. But the amount of uplift of plateau surface in Holocene is about 800 to 900 m, the number is deduct from 5,000 m, then the fossil cirques at 4,300 to 4,100 m.

Xidatan, the fault valley, in the northern

part of Kunlun Shan is 4,200 m a.s.l., and the modern mean annual air temperature is about -3°C . Calculated according to the rate of the progressive decrease of temperature mentioned above the mean annual air temperature near the modern snowline of Kunlun Shan is -9°C to -10°C , the temperature value is similar to that near the fossil snowline to some extent. Hence, it is inferred that the lower boundary of the periglacial belt on the northern slope of Kunlun Shan was 2,100 to 2,300 m during the Würm glaciation. This height is in accordance with that of the lower boundary of the northern part of the periglacial belt of Tanggula Range, which is deduced from the lower boundary of the fossil cirques on it. This height is lower than that of Nachitai.

Nachitai, which is at the central reaches of Kunlun River, is 3,500 m a.s.l. On the southern bank of Kunlun River in this area, a layer of involution is found on the first terrace. The plant roots and the stems underlying the layer are 4,900 \pm 100 years old by its C-14 dating (Fan Ronghe 1982), which demonstrates that the layer was formed during the Neoglacial Age. Similarly, such well developed structure was also found on the second terrace, which was possibly formed earlier, and is perhaps the product of Würm glaciation. The altitude at which the periglacial remains in this area lie fully proves that the northern lower boundary of the periglacial belt of Würm glaciation once reached the height of 2,100 to 2,300 m.

As is stated above, the involution layer in Liangdahe area took shape in the Neoglacial Age. The mean annual air temperature today is about -3°C there. According to this value, it is proved that the mean annual air temperature under which the involution layer on the first and second terraces were formed was no higher than -5°C . However, the mean annual air temperature is about $+0.5^{\circ}\text{C}$ in Nachitai. Thus we can see that the mean annual air temperature of Nachitai during Würm glaciation was 3°C to 3.5°C lower than today, meanwhile, the mean annual air temperature was between -8°C to -9°C on the plateau surface south of Qinghai and north of Xizang of 4,500 m during Würm glaciation. Therefore large polygons of over 50 m in diameter and the sand wedges developed under them were formed on the southern slope of Tanggula Range as well as on the western bank of the Tongtian River, on the northern bank of the Tuotuo River, on the river terraces of Fenghuo Shan area, all of which are to the north of Tanggula Range.

CONCLUSIONS

1. The fossil periglacial remains and the modern periglacial phenomena formed under the periglacial environment of the Würm glaciation and the Holocene are widely distributed on the plateau surface and mountains.

2. The hinterland area on the plateau of southern Qinghai was a warm and interglacial environment about 35,000 years ago when glaciers and amphitheater terrain was left in the areas of Tanggula Range and Kunlun Shan, and about 26,000 to 14,000 years ago, great polygons with sand wedges under the periglacial environment widely developed on the terraces of all the big rivers, and about 14,000 to 12,000 years ago, the peri-

glacial environment on the plateau surface is the lasted of Würm glaciation.

3. The northern lower boundary of the periglacial belt on the plateau was 2,100 to 2,300 m during Würm glaciation.

CALCULATING THE THAWED DEPTH BENEATH HEATED BUILDINGS IN PERMAFROST REGIONS

Zhao Yunlong and Wang Jianfu

Scientific and Technical Institute of Qiqihar Railway Bureau
Qiqihar, Heilongjiang Province, People's Republic of China

Determining the maximum thawed depth beneath the foundation of a heated building in the permafrost region is an important subject in engineering cryopedology. It is directly related to the materials, depth, and type of foundation. Based on the formula suggested by Ding Dewen, the authors have developed a new formula for calculating the thawed depth in the midpoint of the building span, which represents the maximum thawed depth. In this formula, the following factors have been taken into account: the effect of the thermal resistance of the floor, the thermal current under the ground, and modifications corresponding to the transition from two-dimensional calculation, as well as empirical coefficients for calculating the thawed depth beneath wall foundations. At the end of the paper, there is a nomograph for determining the thawed depth. The difference between the calculated and observed values of thaw depth is less than 8%.

INTRODUCTION

In the permafrost region, the foundation of a heated building is built on the perennially frozen soil. Because of the heating inside the building, the ground beneath it thaws gradually and the intensity of this thawing process becomes weaker as time goes on until equilibrium is reached. The limiting surface designating this equilibrium expands in summer, Figure 1, and contracts in winter Figure 2, within a certain range.

If the foundation of a heated building is designed improperly, the thawing of the frozen ground may cause sinking and deformation of the building due to differential settlement between various parts of the building having exceeded a certain limit. These excessive nonuniform settlements are caused by the decrease of bearing strength of the foundation base. The bearing capacity of the soil varies due to the thawing of the perennially frozen ground in which the foundation is built. This is one of the important subjects in engineering cryopedology.

The conditions for thermal equilibrium at the boundary surface of phase transformation are used and the generalized Green's formula is

FIGURE 1 In summer.

FIGURE 2 In winter.

often employed in establishing integral differential equations, using potential equations instead of thermal conduction equations. Almost all the equations for calculating the thawed depth include transcendental functions and it is difficult to consider the effect of the thermal resistance of floor and that of the heat flow under ground. Therefore, it is a major problem to find a numerical solution directly from analysis.

Taking into account the effect of the thermal resistance of floor and the heat flow under ground, a new approximate formula for calculating the thawed depth at the mid-point of the building has been derived, using the method of iteration and the formula suggested by Ding Dewen (1978).

In this formula, modifications corresponding to the transition from two-dimensional to three-dimensional calculation have been taken into account and empirical coefficients have been used in calculating the thawed depth beneath the wall foundations. The difference between calculated and observed values is less than 8%.

In this article, nomographs for practical use are constructed simplifying the laborious process of manual calculation, so the thawed depth can be found directly from the nomograph. Thereby the basis for designing the foundation of heated building in permafrost region is given.

THAWING OF THE GROUND BENEATH HEATED BUILDINGS

If a heated building is constructed on permafrost, heat is transmitted downward which thaws the frozen ground. The intensity of thawing decreases gradually with time and depth, until a state of relative equilibrium is reached. After that, the thawed depth of the ground at this

FIGURE 3 The range of thawing

FIGURE 4 The geometry for the problem

site will vary with the season within a certain range as shown in Figure 3, if there are no unusual changes in such conditions as room temperature, thermal conductivity of the ground, thickness of the floor, etc.

In the summer, the frozen soil below the earth's surface outside the building (active layer) has already thawed and linked up with the thaw bowl inside the building, thus the boundary surface of equilibrium takes an open shape as shown in Figure 1, and the thawed depth of the ground has reached its maximum value.

In winter, the thawed soil below the earth's surface outside the building freezes again, and the thawed depth inside the building draws back due to the horizontal loss of energy. Thus the boundary of equilibrium takes a closed shape as shown in Figure 2, when the thawed depth has reached its minimum value. Although the thawed depth in winter is different from that in summer, under ordinary conditions the difference is not great during a year. In very rare instance this difference has reached several tens of centimeters. The amount of this variation fluctuates within a certain range as shown in Figure 3, and this fluctuation is basically steady.

BASIC THEORY

The geometry for the problem is shown in Figure 4. The basic assumptions are as follows:

1. The soil is homogeneous. If the soil is heterogeneous, it should be made homogeneous by a weighted average.
2. The temperature field is quasi-steady. At any given time τ the temperature distribution as a function of the space variables will satisfy the potential equation. Thus, we would substitute potential equation for the thermal conduction equation.

According to the above-mentioned assumption. The functions $t_r(X, Z, \tau)$, $t_n(X, Z, \tau)$ for the temperature distributions of the thawed and frozen regions satisfy the potential equations.

$$\Delta t_r = 0 \quad (X, Z) \in G_r \quad (1)$$

$$\Delta t_n = 0 \quad (X, Z) \in G_n \quad (2)$$

The general cases are shown in Figure 4. The upper-boundary condition are:

$$t_r|_{z=0} = f_r(X, \tau), \quad X \in \Gamma_r, \quad \Gamma_r: Z=0, X_1(\tau) < X < X_2(\tau) \quad (3)$$

$$t_n|_{z=0} = f_n(X, \tau), \quad X \in \Gamma_n, \quad \Gamma_n: Z=0, X > X_2(\tau), X < X_1(\tau) \quad (4)$$

When X_1 and X_2 approach infinity, the upper-boundary function is

$$t_r|_{z=0} = f_r(X, \tau), \quad X \in \Gamma_r, \quad \Gamma_r: Z=0 \quad -\infty < X < +\infty$$

On the interface of the phase, namely, on the $Z=h(X, \tau)$ temperature and heat flux equality exist.

$$t_r|_{z=h(X, \tau)} = t_n|_{z=h(X, \tau)} = t_0 \quad (5)$$

$$\therefore \lambda_r \frac{\partial t_r}{\partial n} = \lambda_n \frac{\partial t_n}{\partial n}$$

Where $\frac{\partial t}{\partial n}$ is the derivative along the normal. In the layer of frozen soil in the natural condition, the heat flow is $q = \lambda_n g$.

Where g is the gradient of the temperature in the permafrost layer.

Now, define the converted temperature t_x

$$t_x = \frac{\lambda_n}{\lambda_r} t \quad (7)$$

With the bounded solutions $t_r(X, Z, \tau)$ and $t_n(X, Z, \tau)$ of equations (1)~(7) solve the unknown interface $Z=h(X, \tau)$ by Green's function and the generalized Green's formula.

Take Green's function

$$g'(x, x_0, Z, Z_0) = \frac{1}{4\pi} \ln \frac{(x-x_0)^2 + (Z+Z_0)^2}{(x-x_0)^2 + (Z-Z_0)^2} \quad (8)$$

It is easy to know that the g' is to satisfy

$$\Delta g' = -\delta(x-x_0)(Z-Z_0) \quad (9)$$

$t_r(X, Z, \tau)$ and $g'(X, X_0, Z, Z_0)$ are used in the generalized Green's formula within the G_r and can be written as follows

$$\oint_{\Gamma_r} (g' \frac{\partial t_r}{\partial n_r} - t_r \frac{\partial g'}{\partial n_r}) d\Gamma_r = \iint_{G_r} (g' \Delta t_r - t_r \Delta g') dG_r \quad (10)$$

Thereupon, when the surface temperature $f(x)$ and $Z_0 = h(X_0)$ are known, the solution of equation (1) can be written as:

$$(t_r) = \frac{1}{\pi} \int_{-\infty}^{+\infty} f(X) \frac{h(X_0) dX}{(X-X_0)^2 + h^2(X_0)} \quad (11)$$

FIGURE 5 Equivalent layer

Considering the boundary condition we split the integral to obtain:

$$(t_\tau) = \frac{1}{\pi} \int_{x_1}^{x_2} f_\tau(x) \frac{h(x_0) dx}{(x-x_0)^2 + h^2(x_0)} + \frac{1}{\pi} \int_{-\infty}^{x_1} \frac{\lambda_M f_{M1}(x) h(x_0) dx}{\lambda_T f_{M1}(x) (x-x_0)^2 + h^2(x_0)} + \frac{1}{\pi} \int_{x_2}^{+\infty} \frac{\lambda_M f_{M2}(x) h(x_0) dx}{\lambda_T f_{M2}(x) (x-x_0)^2 + h^2(x_0)} = 0 \quad (12)$$

Solving the equation of implicit function of $Z_0=h(X_0)$, we can get the shape of the stable thawed bowl.

In equation (12), considering the mean annual temperature value $f(X)$ at the different locality X on the ground surface, we take $X_1=-a; X_2=+a$ (as a is the span of the building), $f_\tau = \text{constant}$ (the indoor mean annual temperature), f_{M1} and f_{M2} are also constants (the outdoor surface mean annual temperature), when both sides are the same, namely, $f_{M1} = f_{M2} = f_M$.

Substituting them into equation (12), we get

$$\frac{\lambda_M \cdot f_{M1} + f_{M2}}{\lambda_T} + \frac{1}{\pi} \left[\left(f_\tau - \frac{\lambda_M}{\lambda_T} f_{M1} \right) t_g^{-1} \frac{a + X_0}{h} + \left(f_\tau - \frac{\lambda_M}{\lambda_T} f_{M2} \right) t_g^{-1} \frac{a - X_0}{h} \right] = 0 \quad (13)$$

When the maximum thawed depth is at the centre (as $X_0=0$) of the span of the building, equation (13) can be written as:

$$H = a \cdot \text{ctg} \left[\frac{\pi}{2} \frac{F}{F - f_\tau} \right] \quad (14)$$

where

$$F = \frac{\lambda_M \cdot f_{M1} + f_{M2}}{\lambda_T}$$

The equation (14) had been obtained by Ding Dewin and Lunardini.

When considering the indoor floor, a layer of insulation exists as shown in Figure 5.

δ is thickness of layer of the floor of the building, λ_δ is thermal conductivity and the coordinates are also shown in Figure 5.

In this problem, when $Z=0$, the mean annual temperature values ranging from $-T < Z < +T$ have been chosen, then, it can be calculated by equation (14).

Under stable condition, one-level approximate is made. Suppose that, the distribution of temperature T in the center line by sectional linearity is expressed by

$$t_\tau \Big|_{Z=0} = \begin{cases} A_\delta \cdot Z + T_\delta & (\delta \geq Z \geq 0); \\ A_T \cdot Z + T_T & (0 \geq Z \geq -H_S). \end{cases} \quad (15)$$

$$(16)$$

Determination of $A_\delta, A_T, T_\delta, T_T$ from the following group of the linear equation

$$A_\delta \cdot \delta + T_\delta = f_\tau \quad (17)$$

$$A_T \cdot (-H_S) + T_T = 0 \quad (18)$$

$T_\delta = T_T$ (the temperature is equal on the contact surface $Z=0$);

$\lambda_S A_S = \lambda_T A_T$ (the heat flow is equal on the contact surface).

Thus, to solve equations (15)-(18) we obtain:

$$T_\delta = T_T = \frac{H_S \cdot f_\tau}{H_S + \frac{\lambda_T}{\lambda_S} \delta} = f_\tau - \frac{f_\tau \cdot S}{H_S + S} \quad (19)$$

$$S = \frac{\lambda_T}{\lambda_S} \delta \quad (\text{Thickness of equivalent layer}).$$

Therefore, the formula of the maximum thawed depth at the centre of clear span of the building can be rewritten as a transcendental equation

$$H_S = a \cdot \text{ctg} \left[\frac{\pi}{2} \frac{F}{F - f_\tau + \frac{f_\tau \cdot S}{H_S + S}} \right] \quad (20)$$

Thus, the numerical solution is solved by the method of successive approximation. This method of approximate solution of algebraic equation is given that, as follows

$$\text{take } \frac{f_\tau}{F - f_\tau} \cdot \frac{S}{H_S + S} = D \quad (21)$$

D is a small parameter of dimensionless equation (20) can be written as

$$H_S = a \cdot \text{ctg} \left[\frac{\pi}{2} \cdot \frac{F}{F - f_\tau} \cdot \frac{1}{1 + D} \right] \approx a \cdot \text{ctg} \left[\frac{\pi}{2} \cdot \frac{F}{F - f_\tau} \cdot (1 - S) \right] \quad (22)$$

Solving the above equation we obtain

$$H_S = \frac{1}{2} \left[H - S + \sqrt{(H + S)^2 + \frac{2\pi F f_\tau S}{(F - f_\tau)^2} (H^2 + a^2)} \right] \quad (23)$$

On this basis, considering simultaneously the heat flow q under the ground, namely, adding the converted value $G H_S = \frac{\lambda_M}{\lambda_T} g H_S$ to the equation (20), it can be rewritten as

$$H_q = a \cdot \text{ctg} \left[\frac{\pi}{2} \frac{(F + G \cdot H_S)(H_S + S)}{(F - f_\tau)(H_S + S) + f_\tau \cdot H_S} \right] \quad (24)$$

when it is transmitted from two-dimension to three-dimension, the coefficient K of rectification should be multiplied to it, then, we can get the value of H_M

$$H_M = k \cdot H_G \quad (25)$$

CALCULATION OF THE MAXIMUM THAWED DEPTH OF THE GROUND

The point of maximum thawed depth of ground beneath the building in the permafrost region is mostly located near the mid-point of the span of building or slightly deviated from this position to that of the heat source. So that the thawed depth at the mid-point of the span of building can be used in calculation instead of the maximum thawed depth, and the maximum difference between these two values does not exceed 2%.

The formula for calculating the maximum thawed depth of ground is given as follows:

$$H_m = k \cdot H_g$$

In which H_m is the maximum thawed depth of ground, in m; H_g is the thawed depth of ground when considering the effect of the thermal resistance of floor and the heat flow under ground; (as the values of F, G, S, a, f_T etc. are known, the value of H_g can be found directly from the nomograph), in m.

When consulting the nomograph to find the value of H_g the meanings of the symbols shown in the nomograph are:

F is the converted value of the annual mean surface of ground temperature outdoors, °C, is equal to

$$F = \frac{\lambda_m}{\lambda_T} f_m \quad \text{or} \quad \frac{\lambda_m}{\lambda_T} \cdot \frac{f_m + f_{m_2}}{2}$$

f_m, f_{m_1}, f_{m_2} is annual mean surface of ground temperature outdoors, °C; f_T is annual mean atmospheric temperature indoors, °C;

λ_m, λ_T is thermal conductivity of frozen soil and of the thawed soil (kcal/m, °C,h); G is the converted value of temperature gradient of the frozen layer $G = \frac{\lambda_m}{\lambda_T} g$ (g is the value of temperature gradient of the frozen layer and it is a negative value, ordinarily taken as 0.01~0.02); S is the equivalent thickness in meters (m) of the heat insulation layer;

$$S = \lambda_T R_n = \lambda_T \left(\frac{1}{\alpha} + \frac{\delta_1}{\lambda_1} + \dots + \frac{\delta_n}{\lambda_n} \right) \quad (26)$$

where α is coefficient of heat emission, 7.5 is adopted; δ_i is thickness (m) of the material of the i -th layer; λ_i is thermal conductivity (kcal/m, °C,h) of the material of the i -th layer; δ_n is thickness (m) of the material of the n -th layer; λ_n is thermal conductivity (kcal/m, °C,h) of the material of the n -th layer; a is the half of clear span of the building (m); K is the coefficient considering the effect of the ratio of the length and width of building on the thawed depth in the mid-point, see TABLE 1.

CALCULATION OF THAWED DEPTH BENEATH WALL FOUNDATION

The formula for calculating the thawed depth H_a beneath wall foundation is given as follows:

$$H_a = K_a \cdot H_m \quad (27)$$

where H_m is the maximum thawed depth of the ground (m); K_a is the coefficient considering the effect of orientation of the building.

TABLE 2 Determining the value of K_a

The location of K_a	The value of K_a under condition listed below		
	R=0.30	R=0.60	R=1.00
K_{a_1}	0.80	0.70	0.65
K_{a_2}	0.70	0.65	0.60
K_{a_3}	0.55	0.50	0.50
K_{a_4}	0.65	0.65	0.60
K_{a_7}	0.60	0.60	0.60
K_{a_6}	0.70	0.70	0.70

where

$$R = \frac{\lambda_m f_m}{\lambda_T f_T}$$

In which the meanings of the symbols a are the same as that in formula (25).

EXAMPLE

Now, a building of region of Mangui is made by way of example .

1. Clear length and clear width of the building are 4.6 m and 27.6 m.
2. The geological conditions of engineering are as follows (See TABLE 3)
3. Other values

f_T is 17 °C; f_m is -5.5 °C; $\lambda_T = 1.2$ kcal/m °C h; $\lambda_m = 1.29$ kcal/m °C h; g is 0.02 °C/m; $a = 2.3$ m $L = 13.8$ m.

$$\frac{L}{a} = \frac{13.8}{2.3} = 6.00, K = 0.955$$

FIGURE 6 The location of K_a .

4. Conversion values

$$F = \frac{\lambda_M}{\lambda_\tau} f_M = 1.075 \times (-5.5) = -5.913 \text{ } ^\circ\text{C} ;$$

$$G = \frac{\lambda_M}{\lambda_\tau} g = 1.075 \times (-0.02) = -0.022 \text{ } ^\circ\text{C}/\text{m} ;$$

$$\frac{F}{F-f_\tau} = \frac{-5.913}{-5.913-17} = 0.258$$

5. Thermal resistance of the floor is with brick laid on flat, the thickness is 0.06 m, the λ_f = 0.70 kcal/m·°C·h.

$$R_n = \frac{1}{\alpha} + \frac{\delta_i}{\lambda_i} = \frac{1}{7.5} + \frac{0.06}{0.70} = 0.219$$

$$S = \lambda_\tau R_n = 1.2 \times 0.219 = 0.263 \text{ m}$$

The values of $\frac{F}{F-f_\tau}$, a, S, G are known, the value of H_q can be found directly from the nomograph. H_q = 5.11 m.

H_M = K·H_q = 0.955 × 5.11 = 4.87 m.
H_M is 4.87 m and observed value is 5.0 m, the difference between the calculated and observed value is 2.6%.

FIGURE 7 Nomograph of calculations

CALCULATION OF THE THICKNESS OF INDOOR FLOOR (THE THERMAL INSULATION LAYER)

To design the indoor floor for heat insulation is used to control unthaw or a little thaw of perennially frozen soil beneath heated building, so that, the heat insulating layer must be calculated according to thermodynamics. In general, according to H converted to the heat insulating layer by various formulas. In this paper the following formula is submitted for reference of calculation.

Under the stable condition, one-level approximation is made, according to equations (15)~(18) and the condition at $Z = 0$, $T_s = T_r$,

$\lambda_s A_s = \lambda_r A_r$ solve the group of equations when the frozen foundation is unthawed, namely, $H_m = 0$

$$\text{we obtain } S = \frac{\lambda_s f_r}{\lambda_r A_r} \quad (28)$$

When the frozen foundation is thawed admittedly for H namely, $H_m = H$,

$$\text{we obtain } S = \frac{\lambda_s f_r}{\lambda_r A_r} - \frac{\lambda_s H}{\lambda_r} \quad (29)$$

where A_s and A_r is the gradient of temperature of equivalent layer of indoor floor and the foundation of thawed soil ($^{\circ}\text{C}/\text{m}$);

λ_s and λ_r is the thermal conductivity of the equivalent layer of indoor floor and the foundation of thawed soil ($\text{kcal}/\text{m}, ^{\circ}\text{C}, \text{h}$);

S is thickness of equivalent layer (m);

f_r is the mean annual indoor temperature ($^{\circ}\text{C}$).

SOME FEATURES OF PERMAFROST IN CHINA

Zhou Youwu and Guo Dongxin

Lanzhou Institute of Glaciology and Cryopedology, Academia Sinica
People's Republic of China

The permafrost that underlies 2,150,000 km² of China can be divided into two broad categories: high-latitude permafrost and high-altitude (alpine) permafrost. High-latitude permafrost is found in the northeast, and its distribution and characteristics depend chiefly upon latitudinal zonation. The mean annual ground temperature increases by 0.5°-1°C/1°N, and permafrost varies in thickness from 5-20 m in the south to 50-100 m at the northernmost limit. High-altitude (alpine) permafrost occurs in the high mountains and plateaus of western China and is vertically zoned. The mean annual ground temperature varies from -0.1° to -2.5°C at the lower limit to -4° or -5°C at the higher limit. Correspondingly, the permafrost increases in thickness with elevation. Alpine permafrost also shows latitudinal variation, however. As the latitude increases, the lower limit of the alpine permafrost descends with a variable of about 150-200 m/1°N. The latitudinal and vertical zonation of permafrost distribution may be modified by a zonal factor. On the Qinghai-Xizang Plateau, some taliks are the result of geothermal anomalies and surface and ground water; and in northeast China, temperature inversions in winter, together with the swampy process, makes for well-developed permafrost in the valleys rather than on the higher crests. Horizontal ground-ice layers are widely developed on north-facing slopes and in well-vegetated intermontane swampy depressions, especially in fine-grained soils. In coarse-grained sediments, there is cemented and cemented-segregated ground ice. In perennially frozen bedrock, there is some vein-shaped ground ice in cracks.

Regional investigation on permafrost in China began in the early 1950's. With the national economy developing and with the specific institutions being set up, systematic scientific explorations have been carried out since 1960 in the vast permafrost regions, including the Da-Xiao Hinggan Ling of Northeast China, along the Qinghai-Xizang Highway, Qilian Shan, and Tian Shan and Altay Shan of West China.

DISTRIBUTION, TEMPERATURE, AND THICKNESS OF FROZEN GROUND

Permafrost underlies 2,150,000 km² or 22.3% of the territory of China. The total area of perennially and seasonally frozen ground (the depth is over 0.5 m) occupies 68.6%. Generally, permafrost in China can be divided into two broad categories: permafrost in high latitudes and permafrost in high altitudes (Fig.1).

The permafrost region in northeastern China is part of the southmost zone of the Eurasian continental high latitude permafrost area. The distribution of permafrost depends on latitudinal zonation. The mean annual ground temperature rises southward. Generally, with a 1° decrease in latitude, the mean annual air temperature and the mean annual ground temperature will increase 1°C and 0.5°C, respectively. To the south, the continuity of permafrost goes from predominantly continuous to island permafrost. Permafrost

thickness varies from 50 to 100 m in the northmost part, to 5 to 20 m at the south limit (Table 1, Guo 1981).

The southern limit of permafrost is between 46.6 and 49.4° N; the mean annual air temperature in the middle section is 0°C; at the western section, between 0°C and -1°C; and at the eastern section the air temperature is between 0°C and +1°C. In mountains to the south of this limit, such as the Huangganglian Shan, Changbai Shan, Wutai Shan and Taibai Shan, alpine permafrost occurs.

In West China, permafrost occurs in high mountains, such as the Qilian Shan, Tian Shan, and Altay Shan. With rising elevation, the permafrost temperature at the depth of zero amplitude varies from -0.1°C at the lower limit to -2.5° or -4-5°C at the higher; correspondingly, permafrost varies in thickness from several meters to 100 to 200 m or more (Table 2). For instance, in the Reshui Region of the Qilian Shan, with an elevation increase of 100 m, the ground temperature decreases 0.6°C and the permafrost thickness increases 14 to 21 m. The temperature gradient at an elevation of 2,700 to 3,000 m in the Tian Shan is the same as in the Reshui region; however, the thickness increases as much as 31 m/100 m. The lower limit of alpine permafrost ranges from 2,200 m in the north (Altay Shan) to 3,700 m in the south (Qilian Shan).

The Qinghai-Xizang Plateau has the highest and largest permafrost region in

* from unpublished reports.

the low-middle latitudes of the world. Generally, this plateau inclines south-eastward topographically, and the precipitation and air temperature become lower northward.

Along the Qinghai-Xizang Highway, which traverses the plateau from north to south, the lower limit of isolated permafrost in the Kunlun Shan in the north is at 4150 to 4200 m. As the elevation increases per 100 m, the ground temperature decreases 0.6 to 1.0°C. Above 4350 m continuous permafrost occurs. The lower limit of isolated permafrost rises southward and coincides approximately with the -2 to -3°C isotherm of mean annual air temperature. In the

continuous permafrost regions, at an elevation of 4500 to 4900 m, the mean annual ground temperature ranges from zero to -3.5°C. The maximum thickness measured is 128.1 m. (Zhou 1965; Cui and Zhou 1980; Zhou and Guo 1982; Tong 1965, 1981; Wang et al. 1979).

In most of the alpine permafrost regions the lower limit of permafrost on south-facing slopes is higher than on north-facing slopes. However, the Himalaya Shan are an exception. According to calculations based on meteorological data and glacial ice temperature (Shen 1975; Xie and Wang 1975), it could be estimated that the lower limit of permafrost on north-

facing slopes is at about 5100 to 5300 m, and is 300 to 400 m higher than on south slopes (Fujii 1980). This can be explained by the fact that the north slope is much drier than the south.

As mentioned above, the altitude in the mountains and plateau of West China is a decisive factor for permafrost development and conservation there; however, latitude also has an important effect on alpine permafrost (Fig. 2).

1. The snow line and the lower limit of alpine permafrost have a close relationship to latitude. With the increase in latitude, the elevation of the lower limit of the snowline and permafrost becomes lower. From the north to the south, the lower limit rises 3000 m.

2. The lower limit of permafrost in the west at a given latitude is 1150 to 1300 m higher than in the east.

3. The variation in lower limit of permafrost is 150 m/1° of latitude in the high mountains both in the east and west.

4. Snowline is usually higher than the lower limit of permafrost; the difference between them is 1000 to 1100 m.

In the Qinghai-Xizang Plateau, the permafrost temperature rises 0.5 to 1.0°C per 100 to 200 km southward; correspondingly, the thickness decreases 10 to 20 m for 100 to 200 km.

Because of the combination of the vertical zonation and latitudinal variation, the permafrost distribution in this plateau is very complex.

INFLUENCE OF REGIONAL FACTORS ON PERMAFROST

The latitudinal and vertical zonation mentioned above is modified by intrazonal factors, including geologic structure, neotectonic movement, thermal regime, drainage, lithological characteristics, relief, vegetation and local climatic conditions.

The main geologic structure line stretches W-E in the Qinghai-Xizang Plateau; the secondary structure line is N-S, stretching with several fold-fault zones or rotating layers that are connected with the pressure-twisted faults. Such a tectonic pattern has important effects on permafrost development.

First, there are many geothermal anomalies at the intersection of two structure groups, forming cool springs, hot springs, gas fountain springs, and the structure-geothermal taliks. The cool springs, though their temperature is only 1 to 4° or 7°C, can make the permafrost warmer and thinner, and even form thawed channels, such as those seen at the Xidatan, Budongquan (Unfrozen Spring) of the Kunlun Shan. From the Kaixin Ling to the Amdo, a 260 km section along the Qinghai-Xizang Highway, there are many hot springs with temperatures of +20 to +30°C, or even +70 to +80°C, and a series of structure-geothermal taliks.

Second, the tectonic pattern determines the skeleton of the landform and controls the development of the hydrological system. The geothermal background, together with the thermal action of surface water, makes a 1.5 to 2.0 km wide talik in Buqu River Valley. There are complete taliks found under the Tuotuo River and Tongtain River, 1000 and 4000 m wide, respectively. Under and surrounding the lakes on faults, such as the Yaxing-cuo Lake and Basicuo Lake, there are structure-lacustrine taliks with diameters from several hundred meters up to 2-3 km.

Third, tectonic movement controls the landform differentiation and the depositional condition, which affect permafrost development. For example, the neotectonic movement in the Kunlun Shan and Tanggula Shan is rather strong, so the Xidatan and Wenquan Basins are filled with coarse-grained sediments; but in the middle of this plateau, the rising and sagging movement during the Neocene and Quaternary periods is rather weak; therefore, a series of fault-basins were filled with fine-grained sediments. Correspondingly, the latter was a more favorable condition for the development of permafrost and ground ice.

Lithological characteristics, marsh formation, and slope orientation all have a close relationship to permafrost development. When the other conditions are similar, the mean annual ground temperature of perennially frozen clay and sandy clay is usually 1 to 3°C lower than that of bedrock or gravels. The existence of a coal layer raises the ground temperature and geothermal gradient. According to the temperature measurement in wells, the geothermal gradient in permafrost of West China is 1.5-2.0°C/100 m, in general; however, under the influence of a coal layer, the gradient increases 4 to 5°C/100 m. The marsh and moss cover can promote the development of permafrost, especially in those places where the temperature is near 0°C. In the Da Hinggan Ling, the temperature in a marshland is 1 to 2°C lower than in other kinds of landscapes. Therefore, near the southern limit of the permafrost zone, the marshland could be considered as the indicator of isolated permafrost. On the other hand, in those places with a mean annual ground temperature near 0°C and with a zero geothermal gradient, permafrost is very unstable; therefore, clearing of land results in the increase of ground temperature and lowering of the permafrost table. Moreover, even in Region I of Da Hinggan Ling, which is far from the southern limit, permafrost is regenerating due to the interference of mankind; this is indicated by the fact that the temperature-depth curves with a negative gradient have been found there.

The lithological characteristics and water content have an important effect on the seasonal freezing/thawing process, making them vary in large range within a short distance. Generally, the maximum freezing depth ranges from 2 to 8 m, and the thawing depth is 1-4 m in unconsolidated Quaternary sediments, 8-10 m in bedrock. The seasonal layer is able to link up with the permafrost, however, near the lower/south limit of permafrost, or at those places with the supra-permafrost water unfrozen in winter, the permafrost will not connect with the seasonally thawing layer.

Difference of slope orientation and steepness could make the alpine permafrost distribution unsymmetrical. For instance, in Tian Shan, the lower limit of permafrost on south-facing slopes is 400 m higher than on north-facing slope (Qiu and Zhang 1981). In the Qilian Shan, there is a 210 m difference between north and south (Guo Pengfei 1983), and in the Qinghai-Xizang Plateau, the temperature difference between north-facing and south-facing slopes is 1.7 to 2.4°C, and the difference in permafrost thickness is 50 to 70 m. Also, ground ice development conditions vary on different slopes. For example, in the Fenghuo Shan Region, it has been found that at the lower part of north-facing slopes the ice layer is as

thick as 2 to 5 m, while on the south-facing slopes with the same elevation, only a few discontinuous thin ice lenses occur (Wang Jiacheng et al. 1979).

The winter temperature inversion covers a considerable area of Northeast China, from Heilong Jiang in the north to Nenjiang and Hailar in the south; this has an obvious effect on the development of permafrost. Moreover, the marshland at the bottom of the valley is usually covered by moss, peat, or other well-developed vegetation; the combination of inversion and marshland makes the permafrost develop well at the lowland of a valley but not at the top of hills. For example, in the Amur region (Dai Jingbo, 1982), at the bottom of a valley, the mean annual ground temperature is as low as -4.2°C; at the lower part of a gentle slope, -1.7°C; on the north-facing steep slope, -0.1°C, and at the foot of a steep south-facing slope, +1.0°C. Usually, the ground temperature in lowlands is 1 to 2°C (max. 4 to 5°C) lower than that at a high divide.

GROUND ICE

Ground ice is widespread in the permafrost and has a close relation to relief, lithological characteristics and moisture supply.

1. On gentle north-facing slopes and in intermontane marsh depressions with well-developed vegetation, horizontal ice layers are usually well-developed, especially in clayey soil or peat with high water content. It is known that the upper surface of an ice layer is always parallel to the ground surface and approximately coincides with the permafrost table. The depth of the ice layers ranges from 0.9 m to 3.0 m in the Qinghai-Xizang Plateau, and from 0.3 to 1.5 m in the Da Hinggan Ling.

The horizontal ice layers can be divided into three types, according to their thickness: thin, from several millimeters to several centimetres; thick, several tens of cm; and the thickest, up to 6 to 7 m thick, distributed within the depth of zero amplitude of annual ground temperature, belonging to cemented-segregated ice.

There are two kinds of pingo ice: intrusive and segregated ice. In the famous huge pingo in the Pass Basin of the Kunlun Shan, there are four ice layers at the following depths: 1.3 to 14.6 m; 26.3 to 29.1 m; 30.0 to 34.9 m; and 42.1 - 43.0 m. The first one contains a little amount of silt, but the silt content becomes smaller with increasing depth. Between the thick ice layers, there is vein-structure permafrost composed of sandy clay, clayey sand, and fine sand, of which the ice content by volume is 50 to 70%.

2. In coarse-grained sediments, such as moraine, alluvial-pluvial gravels, and eluvial debris, the ground ice usually be-

REFERENCES

longs to cemented and cemented-segregated types, forming conglomerated cryogenetic permafrost.

3. In perennially frozen bedrock, there is some vein-shaped ground ice filling in the cracks.

It has been pointed out that in Galaya of Da Hinggan Ling, the ice veins reach the depth of 54 m; the largest one is 20 cm wide. Besides, the ice layer/veins develop along the original stratification or weathered cracks, forming the reticulated structure of permafrost.

Up to now, no ice wedges have been found in China. However, on the Qinghai-Xizang Plateau, on the second-order terrace of the Beilu, Tuotuo, Tongtian and Buqu Rivers, there are many sand wedges, from several tens of centimeters up to 2 to 4 m deep. According to the C^{14} dating, these may be the traces of ice wedges formed in late Pleistocene time (Guo 1979).

SUMMARY

1. Permafrost in China can be divided into two broad categories: permafrost in high latitudes and in high altitudes. The former is in northeast China and depends chiefly on latitudinal zonation; the latter occurs in the high mountains and plateaus in west China, and is vertically zoned.

2. A series of azonal factors play important roles in the development of frozen soils; among them, temperature inversion in winter and peat promote permafrost development in lowlands of the Northeast; geologic and hydrogeologic factors result in many kinds of taliks in the Qinghai-Xizang Plateau.

3. Most of the alpine permafrost in China belongs to the continental type, because the lower limit of permafrost is generally 800 to 1000 m lower than the local snowline; however, permafrost occurring on the south-facing slopes of the eastern section of Himalaya Shan, in southeastern Xizang, and in the Hengduan Shan belongs to maritime, with the lower limit near or higher than the local snowline.

4. Permafrost in the Northeast has a southern limit coinciding with the -1 to $+1^{\circ}C$ isotherm and extends to latitude $46.6^{\circ}N$. The lower limit of permafrost on Qinghai-Xizang Plateau coincides with the -2 to $-3^{\circ}C$ isotherm.

5. By comparing the thickness and ground temperature of permafrost in the Northeast with that on the Qinghai-Xizang Plateau, it is known that the permafrost on the latter is more stable.

STABILIZATION OF HIGHWAY SUBGRADE IN PLATEAU PERMAFROST REGION OF CHINA

Zhu Xuewen, Chen Guojing, and Zhang Binta

Highway and Transportation Research Institute, Ministry of Communication
People's Republic of China

According to the permafrost, engineering, and geological conditions, the permafrost regions on the Qinghai-Xizang Plateau can be divided into four categories: (I) poor in ice, with thaw-settlement coefficient of frozen soil A less than 5%; (II) with a moderate ice content, and A is 5-10%; (III) rich in ice, and A is 10-40%; (IV) with a massive ice layer beneath the permafrost table, and A > 40%. In applying these classifications to highway construction, the authors find that in Category I, no special techniques are needed to deal with frost damage. In Category II, cutting is generally avoided, but when it is unavoidable, the side slope should be gentle and the strength of the subgrade should be ensured. In categories III and IV, no cutting is allowed, since the natural ground surface should not be disturbed within 10 m of the roadside; the height of the embankment should not be lower than the critical value. Based on observation and calculation, a minimum thickness of embankment is recommended: for category I, the height of the road has no relation to permafrost and frost action. For category II, the height of embankment is 0.8-1.2 m; for category III, 0.9-1.5 m; and for category IV, 1.1-1.7 m, depending on what kind of fill material is to be used.

Permafrost regions in China are scattered in the northern part of the Major and Minor Xinggan Ling, the Qinghai-Xizang Plateau, and the alpine areas of western China. The permafrost grounds discussed in this article are those located in the Kunlun Shan and the plateau to its south with an altitude higher than 4200 m above sea level.

The climate of this region is cruel. In the thin air at high altitude, the oxygen content is only about one half of that at sea level. The annual mean air temperature is -2° - -7° C, and the frozen season is as long as 7 - 8 months a year. Even in the warm season (July and August), negative temperatures often occur at night.

The presence of permafrost and the severe climate cause a series of problems to the construction of asphalt pavement. It is necessary to find out the proper depths of embankment of the preservation of permafrost and the measures for prevention against frost action. According to the investigations taken in 1973-1980, several recommendations were made for the design of subgrade under an asphalt pavement.

GEOLOGICAL REGIONALIZATION OF HIGHWAY CONSTRUCTION AND PERMAFROST PROTECTION

The Qinghai - Xizang Plateau Permafrost Region belongs to one of the general highway natural regions of China. It may be divided into two subregions: continuous permafrost and discontinuous (sporadic) permafrost.

The continuous permafrost subregion that lies in the north of the plateau can be classified into three conditions: high mountains, low mountains and rolling hills, and level land in the valley (valley plain and terrace), according to their topographic and geomorphologic features.

With regard to the regional engineering geological conditions, those of the valley plain zones are the best, and there are thawing zones along big rivers. In the zones of low mountains and rolling hills, top soils are finer, moisture contents are higher, thawing and freezing actions are much more intensive, underground ice is more developed, and marsh lands are often found at the flat ridge or in depressions among mountains. All these phenomena make the engineering geological conditions most unfavorable. In the high mountain zones, the situation lies between the other two. But when the route is passing over the mountain ridge where the undulation of the terrain is flatter, the geological conditions are similar to that of the zones of low mountains and rolling hills.

The discontinuous (sporadic) permafrost subregion is on the south of Tangula Shan. The main unfavorable geologic phenomenon is marshy lands, and the route through it should be avoided whenever possible.

Underground ice is abundant in the plateau permafrost region. The engineering properties of frozen soils after thawing are substantially different according to their moisture content. Thus, the classification of frozen soil in highway engineering in the permafrost area depends upon the total water content of the frozen soil and its coefficient of settlement in thawing. The depth of the active layer, types and ice content (or the total water content) of the frozen soils must be defined by boring, and for design and construction purposes, roads are generally divided into sections according to the total water content of the frozen soils within the depth of 1 meter from the upper boundary of the permafrost horizon. The classification of the road sections is shown in Table I, and the appropriate requirements for the

preservation of the frozen state of the permafrost are also proposed. (1) For the cut sections and/or the sections where the hydrological and geological conditions are unfavorable, detailed geologic survey and special design must be taken.

MINIMUM DEPTHS OF EMBANKMENTS FOR ASPHALT PAVEMENTS

Solar radiation in the plateau permafrost region is much stronger than in the high latitude region. In the case of asphalt pavement, because of the higher adsorbing capacity of road surface from sunlight, the surface temperature of pavement and the accumulated heat in the road bed beneath it will be higher and more than that of the gravel pavement.

Thus, the thaw penetration will be deeper, and thaw settlement will also occur, if no appropriate preservation measures to the frozen state of permafrost were employed.

Practice shows that the settlement of the road bed caused by paving with black top can be prevented by raising the height of the embankment. However, under difficult conditions due to severe climate, raising the height of embankment from borrow on plateau would be very expensive.

Different thicknesses of embankment had been built at the altitudes of 4500-4600 m above sea level near 35°N in 1973-1976 to find out what is the proper thickness required. The data obtained from observation indicate that the thaw penetration of the active layer sank into the shape of a "disk" after the asphalt surface is placed (Fig. 1). For fillings with silty and clayey soil, an actual sinking of 39-43 cm has resulted (h, in Fig. 1) for loam or sandy soils; it is about 1.2 times of the mentioned value. The pavement on top of the embankment having 1.2 m thick at the section of category IV (see Table 1) still kept in good condition for nine years, although there was some light but uniform settlement. For the section of category I and II, the embankment with 0.8 m thick will be enough.

Two observation sites were also established near the experimental road sections in 1973 and 1977. The difference between the gravel and the asphalt pavements were observed. Surface temperatures were measured by glass surface temperature gauges used by the meteorological station 3 times a day for 2 years (1979-1980). The data at

FIGURE 1 Variation of upper boundary of permafrost horizon after the construction of embankment and asphalt pavement. H, height of embankment; h, deepened thawing penetration after paving asphalt pavement.

— upper boundary of permafrost horizon.
1, natural; 2, after the construction of embankment; 3, after paving asphalt pavement.

the depth of 5 cm (just beneath the asphalt pavement) were used.

The data of our observation and the meteorological stations show that there is a good correlation between the air thawing index and surface thawing index of the sandy gravel ground. This correlation is shown in Fig. 2, and can be expressed as equation 1.

$$N_g = \frac{I_s - a}{I_a} = 0.850 + 984I_a^{-1} \quad (1)$$

Where N_g is the N-factor of gravel ground; I_a is the air thawing index, in $^{\circ}\text{C}\cdot\text{days}$; $I_s - a$ is the surface thawing index of sandy gravel ground, in $^{\circ}\text{C}\cdot\text{days}$.

From 1, the surface thawing index of sandy gravel for various areas of this region can be calculated according to the long term air temperature data, and the N-factor is much greater than in high latitude areas.

The ratio of the surface thawing index I_s of gravel pavement against sandy gravel ground is 0.98 obtained from observation, and is considered to be the same, while the I_s of asphalt pavement against gravel pavement is 1.26 - 1.38. There will be a little difference between the years of observation and different filling heights. But these values are very close to those obtained from Alaska and the USSR. (3,5)

By these correlations and taking into account the effect of temperature variation during the service life of the pavement, the design surface thawing index of asphalt pavement can be defined. The results are shown in Table 2.

FIGURE 2 N - factor of natural sandy gravel ground verse the air thawing index in plateau permafrost region.

TABLE 1 Classification of road sections according to the preservation requirements

Category of road section	Conditions of frozen soil at the upper boundary		Preservation requirements
	Ice content	Thaw-settlement coef. $A\%$	
I	Low	5	Design and construction according to common seasonally frozen region
II	Moderate	5-10	Cutting is generally avoided. When unavoidable, side slope should be gentle and measures be taken to ensure the strength of the subgrade. Distance between borrow pit and the foot of the side slope should be not less than 5 m.
III	Rich	10-40	Height of embankment should meet the preservation requirement. Generally no cutting is allowed, measures should be taken to ensure the stability of the subbase and the side slope if cutting is unavoidable. Principally, natural ground surface within 10 m at the road side should not be disturbed. Distance of borrow pit should be at least 10m apart from the foot of the side slope, depth of excavation should not be greater than 80% of thaw penetration of local permafrost soil.
IV	Ice strata with soil inclusion	>40	Principally, cutting is not allowed. Height of embankment should meet the preservation requirements. Natural ground surface within 10m at the road side should not be disturbed. Earth borrowing from the road side should be avoided when possible, otherwise the borrow pit should be located as given above. For intercepting surface water retaining dikes are preferable to intercepting ditches. Side ditches along road side should be avoided.

TABLE 2 The design surface thawing index of asphalt pavement

Site No.	I	II
Latitude	35° 17' N	33° 57' N
Altitude(m)	4612	4533
Annual mean air temperature C°	-5.7	-4.3
Mean air thawing index (C°-days)	465	744
Surface thawing index of asphalt Pavement (C°- days)	2240	2484

Thus, the effect of an asphalt pavement on the top of gravel pavement can be estimated by equation 2.

$$h = \sqrt{\frac{48K}{L}} \left(\sqrt{I_{s-a}} - \sqrt{I_{s-g}} \right) \quad (2)$$

where h is the depth of thaw penetration deepened by paving asphalt pavement, in m; I_{s-a} and I_{s-g} are the surface thawing index of asphalt and gravel pavements respectively, in C°-days; K is the coefficient of thermal conductivity, in kcal/m.hr, C°; L is the latent heat of the soil, in kcal/m³.

It is found that (for homogeneous soil system):

1. For fine grained soils, the variation of the value of h is not significant for a same soil type

TABLE 3. Critical thickness of embankment in the plateau permafrost region (m)

Material for filling	Subgrade soils	Silty, clayey, and sandy soils	Coarse sand, sandy gravel, gravel, and stony soils
Local soils		0.8-0.9	1.0-1.2
Sandy gravel		1.1-1.2	1.0-1.2

having the moisture content and density changed within a conventional range. They range from 43 to 52 cm for silty and clayey soils, and from 56 to 66 cm for sandy soils, but somewhat deeper for coarse grained soils that range from 66 to 102 cm.

2. Although there exists a difference in the mean air thawing index between site I and site II, the surface thawing indexes of asphalt pavement are essentially the same.

Because the temperature conditions of site I and site II can be approximately considered as the margin cases of the plateau between the Tanggula Shan and Kunlun Shan, the critical thickness of embankment for preservation of permafrost in this area may be evaluated.

For the case of layered systems, the problems can be solved with the method used by Sanger (1973).

Figures shown in Table 3 had been developed using the data from the road investigation and observation sites (2). Results had been justified that it is applicable for conventional local cases.

Different factors of safety are adopted for different categories of road section. The minimum depths of embankment suggested to prevent thermo-thawing damages are shown in Table 4.

The pavement may be considered as a part of the preservation layer, and the proper thickness will be determined by the soil engineer in the field. For sections where the hydrological and geological conditions are very unfavourable, special design should be taken.

The annual rainfall of the southeast part of this region is 400-600 mm, but decreases to 200 mm from south to north, and decreases to less than 100 mm from east to west. The warm season is short and the temperature is low. Therefore, the soil forming process is very slow. These factors make the soil of the active layer usually coarse in size and moderate in moisture (less than liquid limit, and a large part of it ranged from 0.7-0.8 of the liquid limit). It is possible to build the embankment with local soils and drop the cost of construction. As the heat conductivity of local soils is less than that of gravel, the thickness of embankment may be thinner. But in this case, proper gradation must be kept in mind.

FROST HEAVE, FROST BOILS AND THEIR PREVENTIVE AND REMEDIAL MEASURES

In this region, sand, gravel, and sandy soil predominate. Investigation revealed that only very small amounts of accumulated water occurred in sandy subgrade soil with medium water content during freezing. Therefore, the stability of the subgrade will generally not be affected. While in subgrade

FIGURE 3 Soil moisture aggregation during the freezing period in plateau permafrost region. (a) natural ground, without external water supply to the system during freezing period; (b) embankment filling with silty soil on the grassland; case 1, without external water supply to the road system, case 2, external water came from the accumulating water in the borrowing pit.

with silty soil, the accumulated water during freezing is apparent.

It was also revealed in the investigation that without external water supply to the system, the moisture content of the entire active layer of soils remains essentially unchanged during the freezing period, and the upper and lower parts of the layer collected the water, while the moisture of the central part decreases. (Fig. 3a) The water aggregating phenomenon varies as the structural types of subgrade and pavement change, but their basic pattern is similar to that of the natural ground (Fig. 3 b case 1).

In the presence of external water supply, it can be seen that the moisture content of the whole subgrade soil increases (Fig. 3 b, case 2). The amount of frost heave is evidently dependent on the ground water level or the level of the accumulated water along the road side before or during the freezing period. Maximum frost heave up to 131 mm has been observed on highways in this region. Hence preventive and remedial measures must be taken.

Measures for the prevention and remedy of frost heave and frost boils currently adopted include improvement of the drainage system, raising the height of the embankment, and provision of a sand gravel bedding course.

Sand gravel bedding course has an obvious drying affect on its underlying base soil. It can not only serve as a part of the pavement structure, but also improve the performance of the subgrade, so that it has been widely adopted. The thickness of such bedding course should not be less than 20 cm, preferably extending right through the whole width of the cross-section.

When the accumulated water along the road side is difficult to drain or ground water effects still exist in winter times, for the sake of pro-

TABLE 4 Minimum thickness of stabilizing course for prevention of freezing damages (for silt and silty clay)

Height of embankment (m)		Minimum thickness of stabilizing course (cm)	
Above road side level	Above ground water level before freezing	For asphalt concrete	For other types of asphalt pavements
1.4-1.6	2.0-2.2	60	45
1.1-1.4	1.7-2.0	70	50
0.8-1.1	1.4-1.7	80	60

tection from frost heave the total thickness of the whole pavement structure, including the sand gravel bedding course, should not be less than the values listed in the Table 4.

CONCLUSION

The stability of highway subgrade is an essential problem in the construction of asphalt pavement in the plateau permafrost region. For the prevention of thawing settlement and frost action, proper depths of embankment is needed. Practice has been shown that it is possible to build the embankment with local soils of moderate moisture content. The minimum depths of embankment recommended for road sections according to the preservation requirements as well as the measures for

preventing frost heave, may be a feasible and economical approach for our country. Because of the insufficient experience for the construction of asphalt pavement in this area, further study will be needed.

ACKNOWLEDGEMENT

Information referred to in this article was presented by the Qing-Zang Plateau Highway Research Section. The authors wish to acknowledge all the researchers, engineers, and workers of the section. We also wish to acknowledge the organizations and individuals who gave much help in our investigation.

CREEP BEHAVIOR OF FROZEN SILT UNDER CONSTANT UNIAXIAL STRESS

Zhu Yuanlin¹ and D. L. Carbee²

¹Lanzhou Institute of Glaciology and Cryopedology, Academia Sinica
People's Republic of China

²U.S. Army Cold Regions Research and Engineering Laboratory
Hanover, New Hampshire 03755 USA

A series of unconfined compression creep tests was conducted on remolded, saturated frozen Fairbanks silt at constant-stress (σ) and constant-temperature conditions. It was found that a sudden change occurred in the slope of $\log \dot{\epsilon}$ vs. $1/\sigma$ curves at almost the same minimum strain rate (about 10^{-6} s^{-1}) for various test temperatures. Therefore, the authors suggest that the creep of frozen soil be classified into two types: short-term creep and long-term creep. Different constitutive and strength-loss equations are presented for each type of creep. The criterion of creep failure of frozen soil is considered to have the general form of $\dot{\epsilon} \times t_m^n = \epsilon_f$, where n is a material constant dependent only upon water content, ϵ_f is the failure strain, and t_m is the time to failure in minutes. On the basis of Assur's creep model (1980) and this criterion, a creep equation was derived that can describe the entire process of creep of frozen soil.

The design of stable structures on permafrost or in artificially frozen ground requires an understanding of the strength and deformation characteristics of frozen soils. The creep of frozen soil is a complicated physicomaterial process governed by various factors such as applied load, temperature, and material properties (such as composition, ice content, and texture).

The main external factors that influence the creep response of frozen soil are stress and temperature. To evaluate these influences quantitatively so as to predict the process of creep deformation and strength-loss of frozen soil, this investigation was performed under various stress levels and at various temperatures varying from -0.5 to -10°C . Three soil densities were used to investigate the influence of density on creep behavior, but this paper deals primarily with the data obtained from tests on the specimens with a dry density of from 1.16 to 1.24 g/cm^3 (correspondingly, with a water content of 40.0% to 44.8%). The complete results will be included in a CRREL report entitled "Creep and Strength Behavior of Frozen Silt in Uniaxial Compression," which is now in process.

EXPERIMENT

Test Material

The material used in this investigation was a remolded silt from the USACRREL experimental permafrost tunnel at Fox, near Fairbanks, Alaska. The physical property indicators are as follows: plastic limit of 34.16% , liquid limit of 38.4% , organic content of 5.49% , and a specific gravity of 2.68 . The silt is classified as ML with approximately 94% passing the #200 mesh sieve and 17% finer than 0.01 mm .

Test Specimens

Each soil specimen was compacted in uniform-density layers, vacuum-saturated, and quick-frozen unidirectionally in an open system. The frozen specimens were 7 cm (2.75 in.) in diameter and end-machined to 15.24 cm (6 in.) long.

Test Method

The unconfined compression creep tests were performed using the constant-stress creep test apparatus designed by Sayles (1968). It allows the applied load to increase proportionally to the increase in the deformation of specimens so that the test (true) stresses can remain constant during test.

RESULTS AND DISCUSSION

$\dot{\epsilon}_m - \sigma$ Relationship and Constitutive Equations

As reported by many researchers (Assur 1980, Mellor and Cole 1982, Martin et al. 1981, etc.), we consider that creep failure occurs when the creep rate reaches its minimum value $\dot{\epsilon}_m$. The time to the minimum rate is defined as the time to failure t_m , and the strain at the minimum is the creep failure strain ϵ_f .

Experiment indicates that for a particular material the minimum strain rates are closely related to temperature and stress. In Figure 1 the minimum rates $\dot{\epsilon}_m$ are plotted against stresses σ in logarithm for the material tested at various temperatures. They are obviously not straight lines, but a family of similar curves. It is especially interesting to note that they suddenly increase their slopes at a certain minimum rate as stresses

FIGURE 1 Plot of $\dot{\epsilon}_m$ vs. σ in logarithm.

FIGURE 2 Plot of $\log \dot{\epsilon}_m$ vs. $1/\sigma$.

decrease. This feature can be seen more clearly by plotting $\log \dot{\epsilon}_m$ vs. $1/\sigma$ as shown in Figure 2. In this graph a family of bilinear curves is obtained, and they all deflect at almost the same minimum strain rate (about 10^{-6} s^{-1}). This implies that there is a critical creep rate, $\dot{\epsilon}_c$, that may be considered the minimum rate for distinguishing between two fundamental types of creep of frozen

soil. The authors therefore suggest that the creep of frozen soil be classified into short-term creep, which has minimum strain rates greater than $\dot{\epsilon}_c$, and long-term creep, which has minimum strain rates less than $\dot{\epsilon}_c$.

Based on Figure 2, the constitutive equation can be well described by the following exponential equations. For short-term creep,

$$\dot{\epsilon}_m = \dot{\epsilon}_* \exp\left[-k\left(\frac{1}{\sigma} - \frac{1}{\sigma_*}\right)\right] \quad (1)$$

where $\dot{\epsilon}_*$ and σ_* are material constants independent of temperatures. By linear regression and standard deviation analysis, we obtain $\dot{\epsilon}_* = 8.84 \times 10^{-3} \text{ s}^{-1}$ and $\sigma_* = 71.4 \text{ kg/cm}^2$. The parameter k reflects the influence of temperature and can be determined by $k = 53.1 \theta^{0.72}$ with $-0.5 \geq -\theta \geq -2^\circ\text{C}$, and $k = 42.4 \theta^{1.02}$ with $-2 \geq -\theta \geq -10^\circ\text{C}$, where θ is the absolute value of temperature, in $^\circ\text{C}$.

For long-term creep,

$$\dot{\epsilon}_m = \dot{\epsilon}_c \exp\left[-k'\left(\frac{1}{\sigma} - \frac{1}{\sigma_c}\right)\right] \quad (2)$$

where $\dot{\epsilon}_c$ is the critical creep rate, equal to 10^{-6} s^{-1} for the material tested, and σ_c is the critical creep strength in kg/cm^2 , which corresponds to the stresses under which $\dot{\epsilon}_m = \dot{\epsilon}_c$. It varies with the temperature: $\sigma_c = 5.2 \theta^{0.78}$. The parameter k' also varies with temperature: $k' = 125.7 \theta^{1.10}$.

To explain this phenomenon, the authors propose that these two types of creep underlie different deformation mechanisms: short-term creep is controlled by dislocation creep, while long-term creep is controlled by glide creep (Zhu and Carbee, in press).

t_m - σ Relationship and Long-Term Strength

Figure 3 presents the plot of $\log t_m$ vs. $1/\sigma$ curves for the tested material at various test temperatures. These curves show a similar pattern to that shown in Figure 2, and can be well described by, for short-term creep,

$$t_m = t_* \exp\left[k_1\left(\frac{1}{\sigma} - \frac{1}{\sigma_*}\right)\right] \quad (3)$$

and for long-term creep,

$$t_m = t_c \exp\left[k_1'\left(\frac{1}{\sigma} - \frac{1}{\sigma_c}\right)\right] \quad (4)$$

where t_* and t_c are material constants independent of temperature. For the material tested, $t_* = 0.19 \text{ min}$ and $t_c = 912 \text{ min}$. k_1 and k_1' are a function of temperature:

$$k_1 = 49.7 \theta^{0.75} \quad \text{with } -0.5 \geq -\theta \geq -3^\circ\text{C}$$

$$k_1 = 30.7 \theta^{1.18} \quad \text{with } -3 \geq -\theta \geq -10^\circ\text{C}, \quad \text{and}$$

$$k_1' = 117 \theta^{1.1} \quad \text{with } -0.5 \geq -\theta \geq -10^\circ\text{C}$$

FIGURE 3 Plot of $\log t_m$ vs. $1/\sigma$.

FIGURE 4 Comparison of the predicted strength-time curves with test data.

By the definition of creep failure, the creep stress σ in Equations 3 and 4 is the ultimate strength of the frozen soil (denoted as σ_{ult}) at the time of load action (t) equal to t_m . Then, from Equations 3 and 4 we derived the following strength-loss equations, for $t < t_c$:

$$\sigma_{ult} = \frac{k_1 \sigma_*}{\sigma_* \ln(t/t_*) + k_1} \quad (5)$$

and for $t \geq t_c$:

$$\sigma_{ult} = \sigma_c \frac{k_1' \sigma_c}{\ln(t/t_c) + k_1'} \quad (6)$$

which can be used to predict the ultimate strength of frozen soil at any given time.

The curves predicted by Equations 5 and 6 and the data points are compared in Figure 4, showing a very good agreement.

It is clear that one should adopt different equations to evaluate ultimate strength according to the duration of loading. For the prediction of long-term strength, Equation 6 should be used.

Following the usual criterion, if we take the 100-year strength as the ultimate long-term strength (σ_{lt}), then from Equation 6 we have the following relation for frozen Fairbanks silt:

$$\sigma_{lt} = 3.49 \theta^{0.87} \quad (7)$$

where σ_{lt} is in kg/cm^2 and θ is in $^\circ\text{C}$.

The values of σ_{lt} predicted in this investigation are very close to those predicted for remolded frozen Hanover silt by Sayles (1974), but higher than those for undisturbed frozen silt reported by McRoberts et al. (1978).

$\dot{\epsilon}_m - t_m$ Relationship

Figure 5 shows a set of $\log \dot{\epsilon}$ vs. $\log t$ curves for the tested material under various stresses at -5°C . It is clear that all minimum points F in this figure distribute very close to a straight line. This means that there is a definite relationship between the minimum strain rate $\dot{\epsilon}_m$ and the time to failure t_m . Figure 6, which shows all of the minimum points for all test temperatures, indicates that this relationship is not influenced by temperature, and can be described by a simple power-law equation:

$$\dot{\epsilon}_m = c t_m^{-n} \quad (8)$$

where n is a constant dependent only upon water content, and c depends upon the water content and the unit of time (if $n \neq 1$). The values of n and c , with the unit of time in minutes for different water content groups, are given in Table 1. We note that the value of n for ice-rich frozen soil is very close to that of polycrystalline ice (Mellor and Cole 1982).

FIGURE 5 A set of $\log \dot{\epsilon}$ vs. $\log t$ curves under various stresses at -5°C .

Creep Failure Strain and Failure Criterion

Creep failure strain ϵ_f as a function of minimum strain rate $\dot{\epsilon}_m$ for different water-content groups is plotted in Figures 7 and 8, respectively. Clearly, it is substantially governed by the water content of the frozen soil: the higher the water content, the less the failure strain. It is interesting to note that for high (Figure 7a) and medium (Figure 8) water content, the creep failure strain is nearly independent of the strain rate and temperature, while for low water content (Figure 7b), it depends upon the strain rate: it decreases slightly with decreasing strain rate within each $\dot{\epsilon}_m$ range of the two types of creep discussed in this paper, and significantly decreases as $\dot{\epsilon}_m < 10^{-6} \text{ s}^{-1}$. Again, this evidence supports the viewpoint that the two types of creep are controlled by different deformation mechanisms. The average values of ϵ_f for high and medium water-content groups, together with that of the low water-content group for short-term creep, are given in Table 2.

FIGURE 7 Failure strain as a function of minimum strain rate at -2°C for (a) $w = 49.6-50.8\%$ and (b) $w = 30.9-32.3\%$.

FIGURE 8 Failure strain as a function of minimum strain rate for $w = 40-44.8\%$ at various temperatures.

TABLE 2 Averaged values of ϵ_f for tested material at different water contents.

Water content (%)	ϵ_f
49.6-50.8	0.0117
40.0-44.8	0.0870
30.9-32.3	0.1760

Comparing the values of failure strain with those of coefficient c in Equation 8, we can see that they are very close to each other. Thus, from Equation 8 we have the following creep failure criterion:

$$\dot{\epsilon}_m \times t_m^n = \epsilon_f \tag{9}$$

where t is in minutes, and $\dot{\epsilon}$ is in min^{-1} .

Evidently, the criterion $\dot{\epsilon}_m \times t_m = \epsilon_f$, which was proposed by Ladanyi (1972) and Assur (1980), is a particular case ($n=1$) or an approximate form of criterion 9.

Creep Model and Prediction of Creep Strain

To predict the creep deformation of frozen soils, a number of models have been proposed by different investigators. It is worth noting that a similar creep model was recently proposed, from different perspectives, by Assur (1980), Fish (1980),

FIGURE 9 Comparison between the predicted and test creep curves for short-term creep.

FIGURE 10 Comparison between the predicted and test creep curves for (a) $\sigma = 22 \text{ kg/cm}^2$, $\theta = -7^\circ\text{C}$ and (b) $\sigma = 7.7 \text{ kg/cm}^2$, $\theta = -2^\circ\text{C}$.

and Ting (1981), that can describe the entire process of creep of frozen soils. Among them, Assur's model is the simplest one. It is based upon physical reasoning in a differential equation with the resulting integral:

$$\dot{\epsilon}(t) = \frac{\dot{\epsilon}_m}{e} \left(\frac{t}{t_m}\right)^\beta e^{\beta t/t_m} \quad (10)$$

We found that the values of β were not directly related to temperature, but were closely related to stress. They can be expressed in terms of t_m as follows for short-term creep:

$$\beta = 0.33 \quad \text{when} \quad t_m < 30 \text{ min}$$

$$\beta = 0.23 t_m^{0.11} \quad \text{when} \quad t_m \geq 30 \text{ min}$$

The curves predicted by Equation 10 and the test data are compared in Figure 5. It is clear that Equation 10 can well describe the creep process for short-term creep, but does not describe the process as well for long-term creep. It is difficult to determine β in Equation 10 for long-term

creep. The authors suggest that, as a first approximation for long-term creep, one determines the value of β by fitting Equation 10 to the test data within the primary creep stage. From our test data, β has an average value of 0.6.

Integrating Equation 10 and taking into consideration Equation 9 and instantaneous strain ϵ_0 , we derived the following creep equation:

$$\epsilon(t) = \epsilon_0 + \frac{\epsilon_f}{e^\beta} \frac{t_m^{1-\beta}}{t^{1-\beta}} e^{\beta t/t_m} \left[\frac{1}{1-\beta} - \frac{\beta t/t_m}{(1-\beta)(2-\beta)} + \frac{(\beta t/t_m)^2}{(1-\beta)(2-\beta)(3-\beta)} - \dots \right] \quad (11)$$

where t_m is determined by Equations 3 and 4.

Comparing the predicted curves with the test data, we can see that Equation 11 can well predict the entire process of short-term creep (Figure 9). It does not predict long-term creep as well (see Figure 10), but as a first approximation it is still applicable for predicting the long-term creep deformation of frozen soil.

CONCLUSIONS

It can be concluded from this investigation that:

1. According to applied stress levels, the creep of frozen soil can be classified into two types: long-term creep and short-term creep. Each obeys different constitutive equations and stress relaxation equations.
2. The 100-year strength of remolded, saturated, frozen Fairbanks silt with a water content of from 40% to 44.8% can be determined by $\sigma_{1t} = 3.49 \theta^{0.87}$, where θ is the absolute temperature in $^\circ\text{C}$ and σ_{1t} is in kg/cm^2 .
3. For a certain type of failure mode, the creep failure strain of frozen soil is almost stress- and temperature-independent, but it is closely related to ice content.
4. The creep failure criterion of frozen soil takes the general form of $\dot{\epsilon}_m \times t_m^n = \epsilon_f$, where n depends only upon water content and t_m is in minutes.
5. Equation 11 can be used to predict adequately the entire process of short-term creep, and can also provide a rough estimation of creep deformation for long-term creep.

ACKNOWLEDGMENTS

This study was sponsored by the U.S. Army Corps of Engineers at the Cold Regions Research and Engineering Laboratory. The senior author expresses his appreciation to CRREL for providing the facilities to conduct this study. The authors are grateful to the CRREL staff for their help, especially to F. H. Sayles, Dr. A. Assur, and W. F. Quinn for their instructive discussions.

UNDERGROUND UTILIDORS AT BARROW, ALASKA: A TWO-YEAR HISTORY

Winston L. Zirjacks¹ and C.T. Hwang²

¹Frank Moolin & Associates, Anchorage, Alaska, U.S.A.

²EBA Engineering Consultants Ltd., Edmonton, Alberta, Canada

The City of Barrow has no areawide piped water or sewerage facilities. Water is pumped from the upper portion of the Isatkoak Lagoon to the treatment facilities. Treated water is then hauled to residences via private carriers. Many residents haul ice from clean water sources south of town. Sewage wastes are collected at residences in holding tanks or plastic bags, then trucked to a landfill. The North Slope Borough is improving these conditions by installing piped sewerage and water facilities in an underground utilidor system. Due to the unprecedented size of this project and the compatibility of a heated utilidor buried in ice-rich permafrost, an instrumented test section was built and operated in ice-rich soil. The objectives are to verify thermal modeling used in the design and to investigate the interaction between a heated utilidor and the surrounding permafrost. This paper presents and evaluates the data thus far obtained.

Barrow, Alaska, located on the Arctic Coastal Plain, is the northernmost community in the United States, with a population of approximately 3,800. The town is a modern arctic Eskimo community serving as the governmental center for the large North Slope Borough (Figure 1). Whaling and game hunting still constitute a major portion of the subsistence of the town's inhabitants.

The City of Barrow has not had areawide piped water or sewerage facilities in the past. Water is pumped from the upper portion of the Isatkoak Lagoon to treatment facilities in Barrow. The treated water is then hauled to residences via private carriers, and many residents haul ice from clean water sources south of the town for potable water uses. Sewage wastes are collected at residences in holding tanks or plastic bags then transferred to a "honey bucket" truck for deposition at the landfill at the South Salt Lagoon.

The North Slope Borough is improving these conditions by installing piped sewerage and water facilities in an underground utilidor system. Due to the unprecedented nature of this project, in terms of constructability and the compatibility of a heated utilidor buried in ice-rich permafrost, an instrumented test section was constructed and operated in ice-rich soil in order to verify thermal modeling used in the design and to investigate the interaction between a heated utilidor and the surrounding permafrost (Cerutti et al, 1982).

This paper presents and evaluates the data obtained from the test section during the last two years.

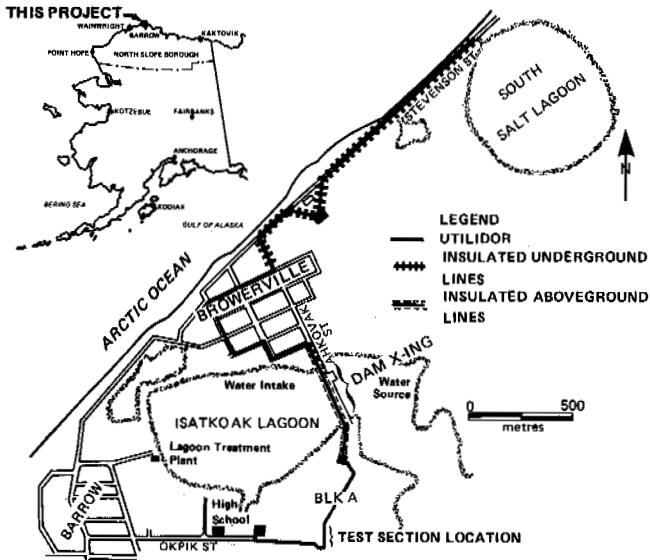

Figure 1 Location map.

Permafrost underlies the entire Arctic Coastal Plain. The bottom of the permafrost zone in the Barrow area lies 300 - 400 m below the surface. Polygonal or patterned ground is common in the area. The permafrost consists of ice-rich silt and contains numerous ice wedges and other ice inclusions (Black 1964). The area is characterized by typical arctic tundra growth of moss and sedges. The active layer of seasonal freezing and thawing is approximately 0.5 m in the undisturbed areas and varies in the disturbed areas in a manner proportional to any gravel fill that has been placed over the tundra.

UTILIDOR DESIGN

The utilidor is constructed with 5 cm x 15 cm Douglas fir lumber placed with the wide side of the boards against one another. Wheel loads as well as soil overburden and structure dead loads were considered in the design. The utilidor sections are 3 m long and contain six steel tie rods. The utilidor is designed to contain water, sewerage, electrical, cable TV, and telephone transmission systems. The interior will be kept above freezing with heated, circulating water, and space is provided for human access for maintenance (Figure 2).

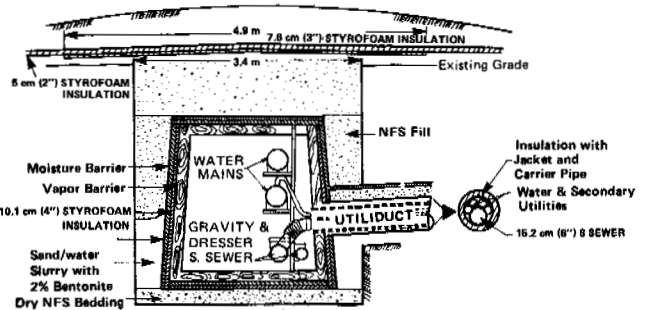

Figure 2 Typical utilidor section.

The exterior of the utilidor is covered with an impermeable vapor barrier, which is covered with 100 mm (4 in.) of insulation. The vapor barrier is designed to eliminate damage due to frost formation within the insulation layers and to also contain warm water within the utilidor from leaks or line breaks. An impermeable moisture barrier is then placed over the utilidor insulation to direct small amounts of free moisture away from the warming front created by the utilidor. Access to the utilidor is through prefabricated metal manholes.

Service to residences from the utilidor mains will be via utiliducts consisting of preinsulated polyethylene pipe. Water services will be circulated to residences with small circulating pumps located within the utilidor. All sewage wastes will ultimately be deposited in a facultative facility located in the South Salt Lagoon (Figure 1).

After the utilidor structure is installed, a slurry consisting of sand, water, and bentonite (2%) is placed to the midheight of the utilidor, and compacted dried gravel is placed above the slurry to the surface. A similar method is used for the utiliduct installation.

THERMAL DESIGN

The compatibility of a buried utilities system with the surrounding permafrost is of utmost importance in the design of the system. Sensitivity of the ice-rich permafrost to thermal degradation requires intensive engineering analyses as well as stringent construction procedures to ensure that the ground thermal regime around the utilities system remains stable. Design considerations are: (1) frost heave, thaw settlement, and buoyancy problems as a result of seasonal freezing and thawing of the surrounding soils and/or underground ice wedges; (2) structural integrity in response to the freeze/thaw mechanism; (3) possible groundwater seepage effects on the thermal regime; (4) possible freezing of the utility pipes within the utilidor or utiliduct during shutdown or maintenance periods; and (5) the influence on the ground thermal regime of neighboring structures, roadways, etc.

The EBA geothermal model (Hwang 1976) was used to perform extensive thermal analyses with respect to: (1) the insulation configuration of the utility structures; (2) the effect of burial depth; (3) soil stratigraphy, such as areas of ice-rich versus low-ice-content soils; (4) freezing point depression due to groundwater salinity; and (5) upset weather conditions, such as two successive "warm" years following construction and their long-term effect on the ground thermal regime. The warm-year simulation uses the maximum monthly air temperatures of the Barrow climatic data, while the normal year uses mean air temperature values.

Input parameters to the geothermal model are: (1) Barrow meteorological data, which include air temperature, wind velocity, snow depth, shortwave radiation, and evapotranspiration at the ground surface; (2) thermal properties of the soils; and (3) utilidor temperatures.

The design criteria considered are: (1) soil/fill around the structure should stay permanently frozen as to prevent seasonal freeze/thaw action and (2) half or more of the utilidor and utiliduct should lie below the maximum depth of penetration of the -1.1°C (30°F) isotherm to account for possible freezing point depression due to soil salinity.

TEST SECTION

To evaluate construction techniques and verify the thermal design parameters, part of the utilidor located in Block A (Figure 1) was isolated and instrumented as a test section in May 1981. This section was heated to the design interior operating temperature of 4°C to 9°C.

The instrumentation consisted of pressure cells, piezometers, and thermistor strings installed at various locations around the utilidor (Figures 3 and 4). Interior vertical and horizontal displacements were measured with extensometers at three locations.

Figure 3 Test section plan.

Figure 4 Thermistor string location.

The test section was constructed in an undisturbed tundra area, which contains 45 - 60 cm (1.5 - 2 ft.) of organic rich silt (tundra) overlying massive ice and ice-rich sandy silt to a depth of 4.6 m (15 ft.). Beneath this material, sandy silt and silty sand are present.

The test section trench was excavated by three methods that were used for construction evaluation. These methods were: (1) using a large trenching machine (ROCSAW) to cut the trench borders and blasting the interior (Figure 5); (2) using the ROCSAW to cut one trench border and blasting the remainder; and (3) blasting only. Method (1) produced a clean trench with vertical walls (Figure 6), but methods (2) and (3) produced wider trenches with irregular walls (Figure 7). The dashed line in Figure 3 indicates the limits of trench excavation that resulted from method (2) (Sta. 0 + 75M) and method (3) (Sta. 0 + 84M - Sta. 1 + 18M). Figure 8 shows the installation of the utilidor.

Figure 5 Rocsaw.

GROUND TEMPERATURES

Ground temperatures in the backfill adjacent to the utilidor during the summer after construction are shown in Figure 9. It can be seen that the closer the thermistor station is to the overexcavated area, the warmer the ground temperature observed. This is due to the warming effect on nearby ground, by water ponding in the overexcavated area. Water table measurements in the area by standpipe probing were found to be about the same elevation as the water bodies around the test site. The source of water is believed to be the melting of the active layer. Drainage is allowed through the active layer and the gravel area fill. As the water was pumped out of the utilidor, its volume was approximately related to the increase in air temperature and corresponding precipitation. However, after the winter of 1981, all thermistors indicated freezeback of the trench backfill throughout the test section, as expected.

Figures 10 to 14 show satisfactory comparisons between the predicted and observed temperatures in 1982. The initial temperature condition used in the model simulation was based on the ground temperatures on 13 May, 1981, as predicted by the model for undisturbed ground rather than those measured values shown in Figure 9. In spite of this and the ponding effect by groundwater immediately after construction, the trench backfill freezes back through the first winter and exhibits ground

temperatures close to those predicted by the model, indicating domination by the conduction over the convection mode in the ground heat transfer process. The reason for colder ground temperatures than predicted for March 1982 is partly attributed to: (1) winter activity inside the utilidor for piping installations, as indicated by large fluctuations of the utilidor temperatures over the winter of 1981 - 1982 (Figure 15) and (2) the opening of the utiliduct trenches, which were excavated and left open over the same period (Figure 3). As the utilidor operating temperatures stabilized later, the correlation between the predicted and measured temperatures improves, as indicated by Figure 16 for 11 January, 1983.

DISPLACEMENT

The movements of the utilidor were measured with an extensometer at three locations. The measurements were made at the centerline and midheight points by connecting the extensometer to permanent hooks installed for this purpose. The data (Figure 17) seem to indicate that the utilidor is contracting and expanding with time. The maximum horizontal length occurs in March and April, when the permafrost temperature is at its minimum; and the minimum horizontal length occurs in September and October, when the permafrost temperature is at its maximum. It appears that the utilidor may be experiencing the effects of volumetric changes in the surrounding permafrost due to seasonal temperature changes. The vertical displacement in conjunction with the horizontal seems to support the interpretation that the utilidor expands sideways during spring and contracts during fall. It is emphasized that further data are required to confirm this cyclic action. However, the data indicate a cross-sectional displacement of 0.5 cm for the utilidor structure, which is well within the design limit of 2.5 cm. No meaningful data were obtained by the pressure cells and piezometers.

Figure 15 Utilidor and ambient temperatures.

CONCLUSIONS

The performance of the test section to date has confirmed the adequacy of the design parameters used in both thermal and structural designs, as indicated by the ground temperatures and utilidor displacement data obtained. The construction experience obtained at the test site indicates that the ROCSAW technique proved to be the most effective excavation procedure, as it provides minimum disturbance and thus enhances rapid freeze-back of the trench backfill. Water ponding effects near the over-excavated area indicated that the groundwater movement should be kept to a minimum. As a result, trench plugs consisting of a 5:1 sand:bentonite mixture have been placed at 30 m intervals along the trench length in all utilidor installations in order to inhibit the migration of runoff water.

Figure 17 Extensometer readings.

Figure 16 Predicted vs observed temperatures.

Continuous monitoring of the test section is being maintained. It is felt that data obtained will be valuable in the preparation of maintenance guidelines for the utilidor system.
