This paper considers the one-dimensional freezing of a saturated non-colloidal soil and gives quasi-static approximations for the temperature and pore water pressure profiles. Energy and mass conservation equations that link the parameters introduced by the approximate profiles are formulated. This leads to a pair of coupled nonlinear ordinary differential equations that are solved by using a standard numerical procedure. It is thus possible to follow the development of the frozen region, ice lens and frozen fringe and to determine when and where the next lens forms. This approach is motivated by the slow nature of the freezing process and avoids the much more difficult numerical problem of solving a pair of nonlinear coupled partial differential equations. In addition, the sensitivity to and relative importance of the various physical parameters may be readily investigated.

Numerical results are presented using some typical values for the physical parameters and show

the cumulative heave, time lapse between ice lenses, and the thickness of the lenses, as functions of time.

MILLER'S THEORY OF SECONDARY HEAVE

When a column of *saturated* soil is frozen from one end and the column is observed to heave, there are three distinct regions of soil (see Figure 1):

- 1 a solid frozen region of soil that may contain distinct ice lenses;
 - 2 a partially frozen region of soil (usually known as the frozen fringe) containing soil, ice and water; and
 - 3 an unfrozen region of wet soil.
- During freezing, water moves through the unfrozen soil to enter the frozen fringe to feed the growth of the ice lens at the bottom of region 1. The water is sucked toward the lens because in region 2 the ice content increases rapidly with decreasing temperature, and so the water content correspondingly decreases and causes a large suction adjacent to the lens. The model of this process developed by Miller is termed a rigid-ice model, because the ice present in the frozen fringe is assumed to be rigidly connected to the ice of the growing lens. This pore ice moves through the soil pores by a process of microscopic regelation as heave takes place.

To describe the frost heave mechanism within the frozen fringe, a parameter ψ is introduced by the equation

$$u_i - u_w = \sigma_{iw} \psi, \quad (1)$$

where u_i is the ice pressure, u_w the water pressure and σ_{iw} is the ice/water interfacial tension. ψ can be interpreted as a mean curvature of the ice water interface. Using the Clapeyron equation, which relates the equilibrium values of u_i and u_w and the temperature T , the parameter ψ may be written as

$$\psi = Au_w + BT, \quad (2)$$

where A and B are constants. The volumetric ice

content θ_i is assumed to depend only on ψ (Koopmans and Miller (1966)) and the form of the function $\theta_i(\psi)$ used here is the one used by O'Neill and Miller (1982), which was based on data of Horiguchi and Miller (1980).

Another important component of the model is the criterion for the formation of a new lens. The stresses are assumed to be isotropic, and within the frozen fringe the neutral stress σ_n is calculated by the formula

$$\sigma_n = \chi u_w + (1-\chi)u_i, \quad (3)$$

where $\chi(\theta_i)$ is a stress partition factor. In general, σ_n has a maximum in the frozen fringe, and it is when this maximum value reaches the overburden pressure, P , that a new lens is initiated.

APPROXIMATE PROFILES

We consider a semi-infinite mass of soil that initially is at a temperature of T_1 . At time $t = 0$ the surface $z = 0$ is cooled to a temperature of $T_c < 0$. The freezing front moves down through the soil, ice lenses form and the soil heaves. If z is measured downward and the cumulative heave is $H(t)$, the surface is given by $z = -H(t)$. We denote the position of the bottom of the lowest lens by $z = z_s$, the position of the freezing front by $z = z_f$ and the level of the water table by $z = z_w$. The different levels and associated temperatures are shown in Figure 1.

Because of the magnitude of the latent heat of water, the temperature profiles in the solid frozen region is close to linear and may be written as follows:

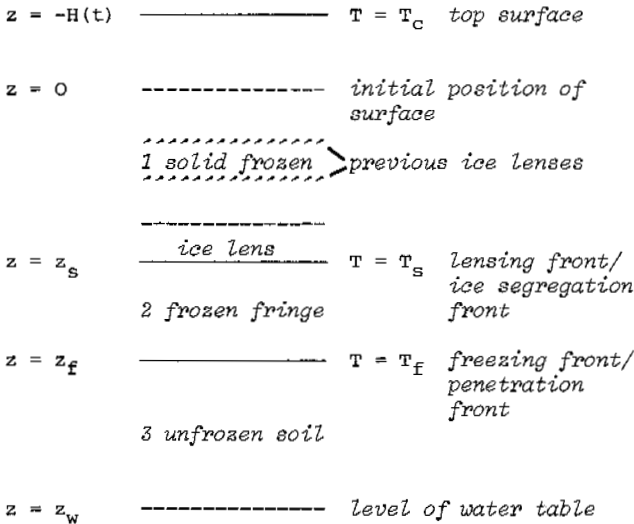

FIGURE 1 Section through freezing soil

$$T = \frac{z_s - z}{z_s + H} T_c + \frac{z + H}{z_s + H} T_s, \quad -H \leq z \leq z_s. \quad (4)$$

The temperature profile in the frozen fringe is also assumed to be linear and has the form:

$$T = \frac{z_f - z}{z_f - z_s} T_s + \frac{z - z_s}{z_f - z_s} T_f, \quad z_s \leq z \leq z_f. \quad (5)$$

In the region below the freezing front, a simple linear profile cannot be used because z tends to infinity. One possibility is to base the approximation on the classical solution:

$$T = T_f + (T_1 - T_f) \operatorname{erf} \left(\frac{z}{2\sqrt{\alpha t}} \right), \quad z \geq 0, \quad (6)$$

where α is the thermal diffusivity. This is the solution for a freezing front held stationary at $z = 0$, and for convenience we replace z by $z - z_f$, thus introducing a simple shift on the temperature profiles to give

$$T = T_f + (T_1 - T_f) \operatorname{erf} \left(\frac{z - z_f}{2\sqrt{\alpha t}} \right), \quad z \geq z_f. \quad (7)$$

The effect of this choice is to determine the temperature gradient ahead of the freezing front.

The other profiles needed are for the water pressure in both the frozen fringe and the unfrozen region. The water pressure is zero at the water table level z_w and decreases linearly up to the level of the freezing front. In the frozen fringe the ice content increases rapidly with decreasing temperature, and so the unfrozen water content decreases rapidly. This results in a rapid decrease in the water pressure u_w from the small negative value u_f at level z_f to a much larger negative value u_s just below the lens at level z_s . If we assume the water pressure gradient is continuous at z_f and a quadratic profile in the frozen fringe, we obtain:

$$u_w = \begin{cases} \left\{ (z_w - z) - \frac{(z_f - z)^2}{z_f - z_s} \right\} \frac{u_f}{z_w - z_f} + \left(\frac{z_f - z}{z_f - z_s} \right)^2 (u_s - u_f), & z_s < z < z_f, \\ \frac{z_w - z}{z_w - z_f} u_f, & z_f < z < z_w. \end{cases} \quad (8)$$

A quadratic profile was chosen as it serves to illustrate the method. Clearly, other choices of profile are possible.

Two other functions are required for the model: $\theta_i(\psi)$ and $\chi(\theta_i)$. From O'Neill and Miller's (1982) paper an approximation to their curve for θ_i is:

$$\theta_i = \begin{cases} 0.01385 - 6.144 \times 10^{-8} \psi + 3.143 \times 10^{-14} \psi^2, & 0.26 \times 10^6 < \psi < 3.6 \times 10^6, \\ 0.4 - \frac{0.28 \times 10^6}{\psi - 2.2 \times 10^6}, & \psi > 3.6 \times 10^6 \end{cases} \quad (9)$$

and the form used for the stress partition factor χ is $(1 - \theta_i / \theta_0)^{1.5}$.

CONSERVATION EQUATIONS

The equations for this model are derived by using the equations of conservation of heat energy and conservation of mass at the lensing front and at the freezing front. In addition, Darcy's law and an equation involving the load (or overburden) completes the set of equations.

If v_s is the liquid volume flux at the top of the frozen fringe, the energy balance equation at $z = z_s$ is:

$$K_f \left. \frac{\partial T}{\partial z} \right|_{z_s^+} - K_s \left. \frac{\partial T}{\partial z} \right|_{z_s^-} = \rho_w L v_s, \quad (10)$$

where K_f and K_s are the thermal conductivities of the frozen fringe and solid frozen regions, respectively, ρ_w is the density of water and L the latent heat of fusion of water.

At the freezing front $z = z_f$, the energy balance equation is

$$K_u \left. \frac{\partial T}{\partial z} \right|_{z_f^+} - K_f \left. \frac{\partial T}{\partial z} \right|_{z_f^-} = -\rho_i L \theta_{if} \frac{dz_f}{dt}, \quad (11)$$

where K_u is the thermal conductivity of the unfrozen soil, ρ_i is the density of ice and θ_{if} is the volumetric ice content at $z = z_f$.

Using the temperature profiles (4), (5) and (7), the equations (10) and (11) become:

$$K_f \frac{T_f - T_s}{z_f - z_s} - K_s \frac{T_s - T_c}{z_s + H} = \rho_w L v_s \quad (12)$$

and

$$K_u \frac{T_i - T_f}{\sqrt{\pi \alpha t}} - K_f \frac{T_f - T_s}{z_f - z_s} = -\rho_i L \theta_{if} \frac{dz_f}{dt}. \quad (13)$$

The conservation mass equation at $z = z_s$ is:

$$\rho_i (1 - \theta_{is}) \frac{dH}{dt} = -\rho_w v_s, \quad (14)$$

where θ_{is} is the volumetric ice content at the top of the frozen fringe. If we assume a Darcy law and that at the freezing front there is a jump in the value of the hydraulic conductivity due to the jump in ice content, the mass balance at this level may be written as:

$$\rho_i \theta_{if} \frac{dH}{dt} = -\frac{[k_f]}{g} \frac{u_f}{z_w - z_f}, \quad (15)$$

where $[k_f]$ is the jump in the value of k_f , the hydraulic conductivity at $z = z_f$.

We assume that the Darcy law holds at the top of the frozen fringe so that:

$$v_s = -\frac{k_s}{\rho_w g} \left\{ \left(\frac{1}{z_w - z_f} + \frac{2}{z_f - z_s} \right) u_f - \frac{2u_s}{z_f - z_s} - \rho_w g \right\}, \quad (16)$$

where k_s is the hydraulic conductivity at $z = z_s$.

The final equation comes from the assumption that the ice pressure is continuous and equal to the overburden pressure P at $z = z_s$, so that equations (1) and (2) give:

$$P - u_s = \sigma_{iw} (A u_s + B T_s). \quad (17)$$

It is implicit in the above equations that some of the pore water freezes as it moves through the frozen fringe. This is because, as the frozen fringe grows in time, the temperature and water pressure profiles change causing the ice content to increase.

Equations (12) to (17) are six equations in the six unknowns z_f , H , T_s , v_s , u_s and u_f . Elimination of T_f , v_s , u_s and u_f between these equations will give two ordinary differential equations of the form:

$$\frac{dz_f}{dt} = F(z_s, z_f, H, t), \quad (18)$$

and

$$\frac{dH}{dt} = G(z_s, z_f, H, t). \quad (19)$$

Before evaluating the functions F and G , it is advantageous to non-dimensionalize the variables so that a further simplification can be made.

NON-DIMENSIONAL EQUATIONS

The equations are non-dimensionalized using a length scale l_0 , time t_0 , thermal conductivity K_0 , temperature T_0 and pressure P . If we denote the non-dimensional quantities using a bar, the governing equations (12) to (17) may be written in the form:

$$\frac{d\bar{z}_f}{d\bar{t}} = \left(\frac{K_0 T_0 t_0}{\rho_i L l_0^2} \right) \frac{1}{\theta_{if}} \left\{ \frac{-\bar{K}_f}{\bar{z}_f - \bar{z}_s} \bar{T}_s + \frac{\bar{K}_f}{\bar{z}_f - \bar{z}_s} \bar{T}_f - \frac{\bar{K}_u (\bar{T}_i - \bar{T}_f)}{\sqrt{\pi \alpha t_0 \bar{t} / l_0^2}} \right\}, \quad (20)$$

$$\frac{d\bar{H}}{d\bar{t}} = \left(\frac{K_0 T_0 t_0}{\rho_i L l_0^2} \right) \frac{1}{1 - \theta_{is}} \left\{ \left(\frac{\bar{K}_f}{\bar{z}_f - \bar{z}_s} + \frac{\bar{K}_s}{\bar{z}_s + \bar{H}} \right) \bar{T}_s - \frac{\bar{K}_s}{\bar{z}_f - \bar{z}_s} \bar{T}_f - \frac{\bar{K}_s}{\bar{z}_s + \bar{H}} \bar{T}_c \right\}, \quad (21)$$

$$\bar{u}_s = \frac{1 - B \sigma_{iw} T_0 \bar{T}_s / P}{1 + \sigma_{iw} A}, \quad (22)$$

$$\frac{d\bar{H}}{d\bar{t}} = \left(\frac{k_s P t_0}{\rho_i g l_0^2} \right) \frac{1}{1 - \theta_{is}} \left\{ \left(\frac{1}{\bar{z}_w - \bar{z}_f} + \frac{2}{\bar{z}_f - \bar{z}_s} \right) \bar{u}_f - \frac{2\bar{u}_s}{\bar{z}_f - \bar{z}_s} - \frac{\rho_w g l_0}{P} \right\}, \quad (23)$$

$$\frac{d\bar{H}}{d\bar{t}} = \left(- \frac{[k_f]Pt_0}{\rho_1 g \bar{\lambda}_0^2} \right) \frac{1}{\theta_{if}} \frac{\bar{u}_f}{\bar{z}_w - \bar{z}_f} \quad (24)$$

The typical values for the parameters we choose are those of O'Neill and Miller (1982):

$$K_0 = 3Wm^{-1}C^{-1},$$

$$\rho_1 L = 3.072 \times 10^5 kJm^{-3},$$

$$\rho_1 g = 8.99kNm^{-3},$$

$$\rho_w g = 9.8kNm^{-3},$$

$$\alpha = 1.07 \times 10^{-6} m^2 s^{-1},$$

$$A = -2.51mN^{-1},$$

$$B = -3.4 \times 10^7 m^{-1}C^{-1},$$

$$k_s = 8 \times 10^{-12} ms^{-1},$$

$$[k_f] = 10^{-4} ms^{-1},$$

$$P = 150kPa,$$

In addition, if we choose a length scale of 1mm, i.e. $\lambda_0 = 10^{-3}m$, a time scale $t_0 = 10^2s$ and a temperature scale $T_0 = 1^\circ C$, the first of the non-dimensional coefficients is of order unity (see below). The actual values of the coefficients are:

$$\frac{K_0 T_0 t_0}{\rho_1 L \lambda_0^2} = 0.9766,$$

$$(1 + \sigma_{iw} A)^{-1} = 1.0906,$$

$$B \sigma_{iw} T (1 + \sigma_{iw} A)^{-1} / P = -8.1824,$$

$$\frac{k_s P t_0}{\rho_1 g \lambda_0^2} = 0.01336,$$

$$- \frac{[k_f] P t_0}{\rho_1 g \lambda_0^2} = -1.67 \times 10^5,$$

$$\frac{(\pi \alpha t_0)^{1/2}}{\lambda_0} = 18.33,$$

$$\frac{\rho_w g \lambda_0}{P} = 6.533 \times 10^{-5}.$$

An examination of the magnitude of the terms in equations (23) and (24) shows that if the heave rate is of order $10^{-8}ms^{-1}$, as may be expected (Jones and Lomas 1983), $\bar{u}_f / (\bar{z}_w - \bar{z}_f)$ will be of order 10^{-8} . The result is that the first and third terms in equation (23) will have a negligible effect on the heave rate $d\bar{H}/d\bar{t}$, and equation (23) becomes

$$\frac{d\bar{H}}{d\bar{t}} = \left(\frac{k_s P t_0}{\rho_1 g \lambda_0^2} \right) \frac{1}{1 - \theta_{is}} \left(- \frac{2\bar{u}_s}{\bar{z}_f - \bar{z}_s} \right) \quad (25)$$

Equation (24) is no longer required as it serves only to calculate \bar{u}_f which is negligibly small.

The system of equations (20), (21), (22) and (25) has the form

$$\frac{d\bar{z}_f}{d\bar{t}} = A_1 \bar{T}_s + B_1, \quad (26)$$

$$\frac{d\bar{H}}{d\bar{t}} = A_2 \bar{T}_s + B_2, \quad (27)$$

$$\bar{u}_s = A_3 \bar{T}_s + B_3, \quad (28)$$

$$\frac{d\bar{H}}{d\bar{t}} = E \bar{u}_s, \quad (29)$$

Elimination of T_s and u_s from equations (26) to (28) gives the formulae for the right-hand sides of the non-dimensional form of equations (18) and (19) as

$$G = E(A_3 B_2 - A_2 B_3) / (E A_3 - A_2), \quad (30)$$

$$F = A_1 (G - E B_3) / E A_3 + B_1. \quad (31)$$

METHOD OF SOLUTION

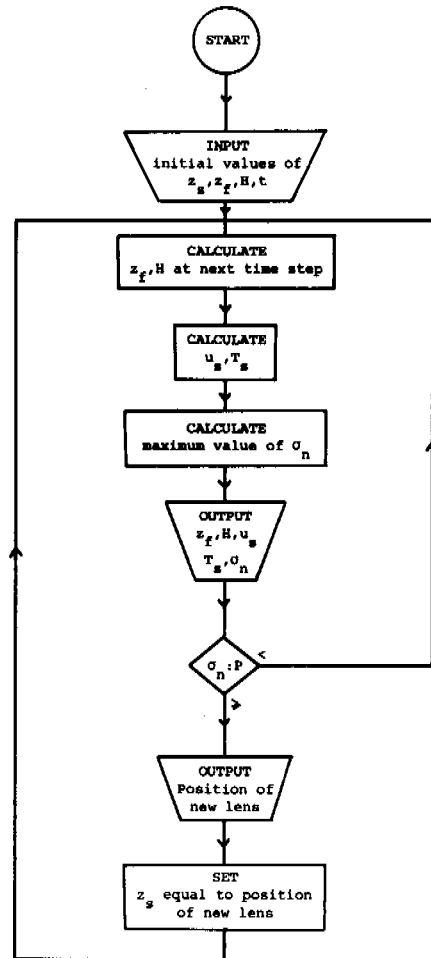

FIGURE 2 Flow diagram

The problem has been reduced to the solution of the two coupled nonlinear ordinary differential equations (18) and (19), where the parameter z_s is a stepwise constant in time. A flow diagram for the computations is shown in Figure 2. The differential equations are solved by using a standard fourth-order Runge-Kutta formula, and a simple search using divided differences is used to find the maximum of the neutral stress σ_n in the frozen fringe. During the formation of a lens, z_s remains fixed; the lens grows at this level until the maximum value of σ_n below the lens reaches the overburden P and a new lens is initiated. At this time, z_s is set equal to the position of the maximum of σ_n for the new lens to form.

In addition to the data quoted above, the values $K_s = 4\text{Wm}^{-1}\text{C}^{-1}$, $K_f = 4\text{Wm}^{-1}\text{C}^{-1}$, $K_u = 3\text{Wm}^{-1}\text{C}^{-1}$, $T_c = -1^\circ\text{C}$, $T_f = -0.08^\circ\text{C}$, $T_1 = 1^\circ\text{C}$, $\theta_{is} = 0.39$ and $\theta_{if} = 0.1$ have been used. Technically, the ice content θ_{is} and the temperature T_f are functions of ψ and thus depends on the temperature and water pressure. However, as the effect of this variation on the coefficients in the equations is relatively slight, for the present work they have been taken to be constant.

RESULTS

Numerical computations using the values of the parameters given above have been performed to evaluate the general performance of this method. It is found that the position of the freezing front z_f is directly proportional to the square root of time, which is the same as for the classical freezing problem in a semi-infinite region. The thicknesses of the ice lenses as a function of time are shown in Figure 3 and are proportional to the square root of time. The time elapsed between successive ice lenses is shown in Figure 4 which has a somewhat higher rate of increase. The cumulative heave is shown in Figure 5. All these

FIGURE 3 Lens thickness versus time

FIGURE 4 Time elapsed between successive lenses versus time

FIGURE 5 Cumulative heave versus time

results are of the same order as those given by O'Neill and Miller (1982). It should be noted that their computations are for a finite column of soil, whereas the present results are for a semi-infinite

region. The important difference is that in a finite column the freezing front effectively ceases to penetrate much sooner because of the influence of the lower boundary, and this may account for the differences between the results. The frequency of formation of lenses is also similar.

DISCUSSION

The main advantages of this quasi-static approach are as follows:

- Ease of computation. To solve the full set of partial differential equations for the heat and mass flow in the frozen fringe is difficult. This is because the frozen fringe is a relatively narrow region across which various quantities change very rapidly, so that there are large gradients present. To describe adequately the equations requires a very small mesh size and a correspondingly small time step. Except in the early stages of the computations, when a small time step is required to accommodate the frequent ice lenses, the equations in this paper may be solved using a time step appropriate for the movement of the freezing front. In addition the program is short and uses relatively little store.

- Better understanding of the model. By formulating the equations in this way, it is hoped that it will lead to a greater understanding of the model and a critical evaluation of the assumptions on which it is based.

- Evaluation of parameters. One of the difficulties with theories of frost heave is that the values of some of the parameters are uncertain since they are difficult to measure. With the present theory, we can readily investigate the effects of different values of the parameters and determine the sensitivity and relative importance of the parameters to the heave.

Having shown that this quasi-static approach does predict the formation of ice lenses and heave of the right order, some obvious refinements can be made. One is to allow θ_{is} to vary with ψ and at the same time k_s to vary with θ_{is} . The temperature T_f may also vary with ψ . The choice of temperature profile ahead of the front may be improved in one of two ways: either adapt a more complicated error function solution such as that used for diffusion problems in semi-conductors (Tuck 1974) or compute the profile directly by using a Crank-Nicolson procedure at the same time as solving equations (18) and (19). In addition, other profiles for the water pressure in the frozen fringe may be examined. Meanwhile, it remains only to reiterate O'Neill and Miller's plea for a series of experiments to be established to evaluate the theory and computations.

HYDRAULIC CONDUCTIVITY FUNCTIONS OF FROZEN MATERIALS

K. Horiguchi¹ and R. D. Miller²

¹Institute of Low Temperature Science, Hokkaido University, Sapporo, Japan
²Department of Agronomy, Cornell University, Ithaca, New York 14853 USA

A constant-volume permeameter/dilatometer apparatus was used to obtain data for unfrozen water content and hydraulic conductivity for eight materials, including four natural silts, as a function of temperature in the range 0° to -0.35°C with pore water pressure held near zero gauge. After seeding with ice, samples were first chilled and then rewarmed by small steps. Hysteresis effects were extremely large in the first freeze-thaw cycle for all materials but were small in the one natural silt subjected to a second cycle, suggesting possible malfunctions of the seeding procedure in the first round. Typically, hydraulic conductivities fell from values of the order of 10⁻⁸ m.s⁻¹ before freezing to values in the range 10⁻¹² - 10⁻¹³ at temperatures near -0.3°C. After thawing, hydraulic conductivities were higher than before freezing of the thoroughly remolded materials by factors ranging from 1.1 for a natural silt to 60 for a stock sample of Illite.

INTRODUCTION

It is generally accepted that some liquid water persists in frozen soils as a mobile phase at temperatures below 0°C. Many believe that this water has a crucial role in the dynamics of processes induced by freezing and are anxious to have appropriate data for use in mathematical models.

Efforts to measure the apparent hydraulic conductivity of frozen soils by direct methods encounter various problems that compromise credibility of the results, including those to be reported here. The objective in all cases is to measure a coefficient of proportionality (e.g., hydraulic conductivity) presumed to exist between transport and driving force at steady states in which liquid water enters one side of a frozen sample and exits from the other.

Two approaches have been used. In one, solutes are added to the liquid water bathing the two faces, reducing its freezing point to the temperature of the frozen soil (Burt and Williams 1974). Driving forces for transport are imposed by maintaining differences between liquid pressures at the respective faces or differences between their temperatures (Perfect and Williams 1980).

In a second approach, solutes are not used, but ice in frozen soil is prevented from seeding the freezing of adjoining bodies of supercooled water by interposing rigid filters with very fine pores to serve as "phase barriers" that exclude ice but transmit liquid water (Sahin 1973, Miller et al. 1975).

A constant-volume permeameter/dilatometer with phase barriers was used to obtain both unfrozen water content and hydraulic conductivity data for eight materials as functions of temperature when pore water pressure was nominally atmospheric pressure. Results obtained with one of the eight materials were reported previously (Horiguchi and Miller 1980); results obtained with all eight are reported here.

APPARATUS AND PROCEDURE

The constant-volume permeameter/dilatometer and associated apparatus used in these experiments have already been described along with results of tests intended to detect the degree to which flow might pass around the frozen soil or along grain boundaries in the pore ice (Horiguchi and Miller 1980). Results of those tests showed that such flows would normally be negligible. It was also demonstrated that fluxes increased in direct proportion to the imposed hydraulic gradient, in the manner of Darcy's law, using gradients as large as 1500 m/m at low temperatures where conductivity was extremely low.

In use, the permeameter/dilatometer is placed in the dilatometer mode in preparation for each decrement of bath temperature during stepwise chilling of the apparatus immersed in a well-stirred bath, or prior to each increment of rearming. After equilibration at each step, the system is switched to the permeameter mode. What is reported here as (apparent) hydraulic conductivity is the volume of water emerging from unit area of sample per unit time divided by a hydraulic gradient calculated from the difference in water pressures at the two faces and the thickness of the sample, corrected for head losses across the phase barriers.

In preparation for freezing, the entire apparatus, including sample and seeding tube, was thoroughly flushed with distilled water flowing from an actively boiling reservoir. After a sample had been chilled to a temperature slightly below 0°C, freezing was seeded by way of a port in the side of the sample chamber. The water-filled port led into a length of small-bore water-filled tubing which was induced to freeze by brief exposure to a jet of decompressing CO₂. Ample time (1 - 3 days) was allowed for freezing of all water in the tube and port before the next downstep of bath temperature.

Placement of a sample in its partially

assembled chamber was the most subjective step in the procedure. A thick slurry, thoroughly deaired by boiling at reduced pressure, was spooned into the open water-filled chamber (depth, 3 mm) until it was judged to be exactly filled, whereupon assembly was completed. At the end of an experiment, the sample was recovered, dried, and weighed so that the volume of particles could be calculated. Values reported as porosity, E , represent the ratio: [(Volume of chamber - Volume of particles)/Volume of chamber]. It is obvious that failure to fill the chamber completely, or subsequent consolidation of the sample, would result in ice-filled space that would be reported as if it were a part of the porosity. Such ice would modify pathways for liquid flow. This matter will be discussed further in the light of results obtained.

MATERIALS

Three of the materials used were provided through the courtesy of R. Berg, US Army Cold Regions Research and Engineering Laboratory, Hanover, N.H. These are designated CHENA, NWA, and MANCHESTER. The first two are natural silts from the vicinity of Fairbanks, Alaska, the third is a natural silt from New Hampshire. A fourth natural silt, designated CALGARY, was provided through the courtesy of J. F. Nixon, Hardy Associates, Ltd., and was collected near Calgary, Alberta. V. Snyder, of Cornell University, kindly provided us with a material designated 4-8 μm FRACTION which he had separated from the Manchester sample by repeated decantation. Laboratory stock samples of ILLITE (Grundite) and KAOLINITE (Peerless #2) and a commercial ZEOLITE (Linde 10X, 0.5-5 μm) completed the array of materials studied.

FIGURE 1 Grain analyses of three of the natural silts.

Mechanical analyses of three of the natural silts are shown in Figure 1. Specific surfaces of all but the zeolite were measured at the Institute of Low Temperature Science, Sapporo University, using the BET method and nitrogen gas. Freezing

experiments were carried out at Cornell University.

RESULTS

Data from measurements of apparent hydraulic conductivities and specific surfaces are given in Figure 2. Typical data for volumetric unfrozen water content have been plotted in Figure 3.

In Figures 2 and 3, open symbols signify points measured in chilling sequences; solid symbols are for warming sequences. In general, Millipore GSWP (0.10 μm) filters were used as phase barriers. For the 4-8 μm fraction and other examples noted, GSWP (0.22 μm) filters were used. Neither required significant head-loss corrections with the materials used. For one sample of the NWA material, dialysis membrane was used, but its impedance was too high for it to be used in the ice-free range; head loss across the membranes was roughly half of the total even when the soil was frozen and its conductivity was extremely low.

A striking feature of all results for the initial chilling is a very pronounced knee, presumably corresponding to the threshold of ice intrusion. If a similar knee existed during the second freeze-thaw cycle with the Chena material, its location shifted drastically, virtually eliminating the hysteresis that was so pronounced in the first freeze-thaw cycle.

Table 1 gives constants obtained for least-squares fits of exponential equations which approximate data obtained during warming sequences.

The effect of freeze-thaw cycles on the hydraulic conductivity of ice-free soil was very

FIGURE 2 Hydraulic conductivities of eight materials as functions of bath temperature when water pressure was near zero gauge. Specific surfaces of each are given. Data measured during chilling are plotted as open symbols. Data measured during warming are plotted as solid symbols.

large for the two clay minerals and was notable, but smaller, in all other materials. Specifically, some (before, after) values, in $\text{m}\cdot\text{s}^{-1}$, were: Chena (4.1, 7.5) $\times 10^{-9}$; NWA (1.5, 2.4) $\times 10^{-8}$ and (1.0, 1.9) $\times 10^{-8}$; Manchester (2.2, 2.5) $\times 10^{-8}$; Calgary, $E = 0.45$, (3.1, 4.2) $\times 10^{-9}$; Kaolinite (2.9, 21.7) $\times 10^{-9}$ and (2.6, 60.2) $\times 10^{-9}$; Illite (1.9, 120.) $\times 10^{-9}$; Zeolite (1.3, 2.4) $\times 10^{-8}$.

DISCUSSION

Before the results given in Figures 2 and 3 are accepted at face value it is necessary to examine possible sources of error. Two potential sources of error are obvious. One of these would be a failure of the method of seeding the freezing to work properly. The other would be the appearance of segregated ice within the sample chamber.

The method of seeding was first used in

experiments in which freezing characteristics of air-free specimens of soil were compared with drying characteristics of those same specimens after the ice had been melted by warming the samples to room temperature (Koopmans and Miller 1966). In those experiments there was no reason to suppose that the method did not work as intended on every occasion, and this justified use of the same method in the apparatus used here. Unfortunately, examination of the data obtained leaves some doubt that the method worked properly; it may have malfunctioned consistently. Evidence of such malfunction is entirely circumstantial. It has two components, one within the data for the Calgary material, one within the data for the Chena material.

In the two experiments with the Calgary material, one sample was introduced into the chamber at a higher water content (higher porosity) than the other. If the method of seeding brought ice into contact with ice-free soil at a temperature only slightly below 0°C, as

FIGURE 3 Examples of unfrozen water contents deduced from dilatometric measurements.

FIGURE 4 Hydraulic conductivities plotted as functions of volumetric water contents.

intended in each case, one would have expected that ice intrusion into the pore system, marked by a knee in the hydraulic conductivity versus temperature curve, would have occurred sooner (at a higher temperature) in the sample with the higher porosity and higher hydraulic conductivity. The reverse seemed to be true. This indication depends, however, upon the validity of a single point on one or the other of the two curves. One is reluctant to give much weight to a single point which has been plotted as if there were no possibility of slight changes in the calibration of the temperature measuring system between the two trials and as if there were no chance of small unrecorded perturbations of bath temperature during the long periods allowed for equilibration of samples before the conductivities were actually measured. If such a perturbation crossed the threshold for ice penetration when the low porosity sample was very close to the threshold, the result could be spurious because of hysteresis as the sample returned to the desired temperature. Hence this inference of possible seeding malfunction is, by itself, of little importance.

There is, however, a peculiarity in the data for the Chena material. This was subjected to two freeze-thaw cycles, but to save time, the sample was not warmed quite to 0°C between cycles, making reseeding unnecessary; the seeding channel presumably remained frozen even if ice disappeared from soil pores. Pore ice had presumably disappeared, to judge from the restoration of hydraulic conductivity, so the second chilling cycle was begun. This time, the pronounced knee that characterized the first freezing was absent. If a less pronounced knee was present, it appears to have been overstepped by the first decrement of temperature.

Is it reasonable to suggest that the knee might be less pronounced in a second freeze-thaw cycle than in the first? The answer must be yes, because if coarse pores are the first to be

penetrated by ice, they should tend to enlarge, with a corresponding reduction in the dimensions of smaller pores not yet penetrated by ice. This is what one would expect because the ice pressure is higher than the pressure of water in ice-free pores. If such broadening of the pore size distribution were induced by the first freezing of thoroughly remolded soil, then the hydraulic conductivity of the material after a freeze-thaw cycle ought to be higher than it was before freezing. This was actually observed for all eight of the materials. The induced increase in hydraulic conductivity of the Chena material was not excessive, a factor less than 2, and this is a rather small factor if the same effect were to have virtually eliminated the knee observed in the first cycle. Perhaps the other source of potential error, the appearance of segregated ice, is responsible for camouflaging the presence of the knee in the second cycle.

When a hydraulic gradient is imposed on a soil, it induces a gradient of effective stress and consolidation of soil near the outflow face with the possible appearance of a water-filled void between the upstream face of the sample and the adjoining filter. If the temperature were low enough and ice were present, the void would be ice-filled. It is known that what an observer would perceive to be a stationary ice body can be moving by pressure-induced regelation, making it possible for an observer to record an apparent hydraulic conductivity (Miller et al. 1975). The apparent conductivity would be a complicated function of several properties; the actual hydraulic conductivity of the lens-free soil would be but one of these properties. If, in the course of hydraulic conductivity measurements during the first cycle, such an ice lens were induced between filter and soil at the upstream face by the rather large hydraulic gradients used when conductivity was low, this lens would not melt until temperature reached 0°C unless the sample rebounded strongly during the rewarming steps. It is possible that a residual ice lens induced in this way persisted after the first warming sequence was completed with the Chena material. If so, its presence could have camouflaged the presence of a knee in the second cycle.

If this speculation seems unwarranted, it should be remembered that in an earlier paper (Horiguchi and Miller 1980) this same idea was proposed in the discussion of results obtained with the 4-8 μm fraction. In those studies, it was arranged to reverse the hydraulic gradient from time to time. Each time this was done it was observed that, for a few minutes, thermocouples placed near the inflow and outflow faces of the sample indicated that a temperature differential had been induced but this soon disappeared. It was suggested that this would be consistent with reversal of the location of an induced ice lens. These isolated bits of information do not form a unified and compelling rationale for dismissing the reported hydraulic conductivity values as something other than what they are supposed to be. Neither is it possible to accept those data without reservations.

A completely new and different apparatus, a controlled-stress permeater/dilatometer, has been

designed, fabricated, and put into operation at Cornell. It is intended to overcome some of the ambiguities in interpretation of data from the constant-volume permeameter/dilatometer. The new apparatus seems to have its own problems, however, and at this time it would be premature to discuss results being obtained.

CONCLUSIONS

The art of making direct measurements of hydraulic conductivity functions for frozen soils is developing slowly. While measurements of data purporting to be the desired functions can be made, the procedures developed to date require extremely precise and stable control of temperature and long equilibration periods. Even then, it is not certain that the data can be taken at face value until every source of potential error has been recognized and evaluated. The constant-volume permeameter/dilatometer is an attractively simple device, but there are unresolved ambiguities in the interpretation of results. These are probably not serious, but only further work, probably with other forms of permeameters, will resolve the questions that can be raised.

ACKNOWLEDGMENT

We are indebted to R. Berg, USA CRREL, Hanover, N.H., for some of the materials studied and mechanical analyses of the Chena and NWA samples. We are indebted to V. Snyder, of Cornell University, for mechanical analysis data for the Manchester soil and for sharing with us a portion of the 4-8 μm fraction he had isolated from that soil. This work was supported, in part, by National Science Foundation Grant ENG 77-17004 and in part by a subcontract with Battelle-Columbus Laboratories.

The time- and position-dependent locations of the 0°C isotherm were calculated using two modelling strategies: a domain method and a boundary integral method. Simulations were made for the runway embankment at Deadhorse Airport near Prudhoe Bay, Alaska. The same thermal properties, initial conditions, and boundary conditions were used in both models. Sinusoidal surface temperature variations, dependent upon surface type and exposure, were used in the simulations rather than measured surface temperatures. The positions of the 0°C isotherm determined by the boundary integral method near the time of maximum thaw penetration were essentially the same as those determined by the finite element method, and results from both models agreed closely, within a few centimeters over a total freezing depth of about 2.5 m, with the measured positions. The largest differences between measured and computed positions occurred early in the freezing and thawing seasons. The primary advantage of using the boundary integral method for problems specifically of the type considered herein is that it requires only a few nodal points, so computer simulations can be completed rapidly on a micro computer. If the two-dimensional thermal regime is necessary, the finite element method is most suitable.

During the 1977 and 1978 thawing seasons, the runway at Deadhorse Airport near Prudhoe Bay, Alaska, was improved and paved with an asphaltic concrete pavement. With cooperation from the State of Alaska Department of Transportation and Public Facilities and the Federal Aviation Administration (FAA), USACRREL installed temperature sensors beneath and adjacent to the runway. Subsurface temperatures at some locations are measured manually in liquid-filled access tubes and others are monitored automatically by a data collection platform (Berg and Barber 1982) that transmits information to USACRREL via the ERTS satellite system (McKim et al. 1975). The equipment has been in operation since August 1978.

Two modelling strategies were used to calculate seasonal thaw penetration: (a) a finite element domain method (Guymon and Hromadka 1982) and (b) a boundary integral equation method (Hromadka and Guymon 1982). The time-dependent location of the phase-change isotherm was calculated using both models. In addition, temperature variations at selected positions within the runway embankment were computed using the finite element method. Comparison of calculated temperatures and predicted 0°C isotherm locations with measured data indicate that both numerical modeling approaches are accurate tools in predicting soil thermal response in freezing/thawing environments.

DESCRIPTION OF MODELS

The domain method approximates the well known two-dimensional heat transport equation, which for a freezing or thawing soil is:

$$\frac{\partial(K_x \frac{\partial T}{\partial x})}{\partial x} + \frac{\partial(K_y \frac{\partial T}{\partial y})}{\partial y} = C_m \frac{\partial T}{\partial t} - L \frac{\rho_i}{\rho_w} \frac{\partial \theta_i}{\partial t} + C_w (v_x \frac{\partial T}{\partial x} + v_y \frac{\partial T}{\partial y}) \quad (1)$$

where x, y = cartesian coordinates

t = time

T = temperature

K_x, K_y = the thermal conductivity of the soil-water-ice mixture

C_m = volumetric heat capacity of the soil-water-ice mixture

L = the volumetric latent heat of fusion of bulk water

ρ_i = ice density

ρ_w = water density

C_w = the volumetric heat capacity of bulk water

v_x, v_y = velocity flux components

θ_i = the volumetric ice content of the soil.

The density parameters are relatively precise for modeling purposes. Although the latent heat parameter is a function of temperature and salinity (Anderson et al. 1973), all of the water is assumed to freeze at 0°C in these simulations. C_w may be regarded as a well defined constant, but the appropriate thermal conductivity and heat capacity of the soil-water-ice mixture are not exactly known and must be estimated. DeVries' (1966) weighting method for estimating these parameters is often employed; i.e.

$$\beta = \sum_n \beta_n P_n \quad (2)$$

where β is the required parameter (K_j or C_m), P_n is the volumetric content of a specific constituent, and n indicates the n th constituent. The velocity flux parameters must be assumed or calculated from a coupled moisture transport model. Since this paper is concerned with heat conduction only, it will be assumed that moisture flux is negligible; consequently, the convective component of Equation 1 is assumed to be zero.

To solve Equation 1, initial and boundary conditions are needed. Initial conditions are of the form:

$$T(t=0) = T(x,y)$$

$$\theta_i(t=0) = \theta_i(x,y) \quad (3)$$

which are usually specified at discrete points in the solution domain. While boundary conditions may be of any form (e.g. a surface energy balance simulation), we will use two types:

$$\frac{\partial T}{\partial n} = 0, \quad t > 0 \quad (4)$$

where n is a unit normal coordinate to the solution domain boundary, and

$$T(s) = N T_a(s,t), \quad t > 0 \quad (5)$$

where N is the Corps of Engineers n factor (Berg 1974), s is a tangent coordinate to the solution domain boundary, and T_a is the air temperature, which may be a function of time.

Domain Approach

Commonly used domain approaches include the finite element and finite difference methods. Hromadka et al. (1981) show that an infinity of mass lumped domain numerical analogs may be incorporated into a single matrix expression. The finite element, subdomain, and integrated finite difference schemes are represented as special cases. Depending on the subdomain of integration and the density of the state variable approximation, various domain algorithms may be obtained. These are unified into a single matrix representation called "nodal domain

integration," which yields a system matrix similar to the finite element scheme:

$$K T + C(\eta) \dot{T} = F \quad (6)$$

where K is a square-banded symmetrical conduction matrix that is a function of thermal conductivity and global discretization, $C(\eta)$ is a square-banded symmetrical capacitance matrix that is a function of capacitance parameters and a mass lumping factor (η), \dot{T} and T are vectors of unknown temperatures at discrete points and their temporal derivatives, respectively, and F is a load vector that is a function of the boundary temperatures. Hromadka et al. (1981) give complete details on the derivation of the matrices in Equation 6. Guymon and Hromadka (1982) use this technique to develop a two-dimensional model of coupled heat and moisture transport in freezing or thawing soils. In the analysis presented here, the n factor was set to a value such that a standard Galerkin finite element scheme was used in all domain computations.

Rather than solve Equation 1 in the form shown, the latent heat term is removed and is approximated as an isothermal process (Guymon and Hromadka 1982). Latent heat effects are simulated by a simple control volume approach. A discrete volume of soil is not allowed to reach subfreezing temperatures until the latent heat of fusion of all water in the volume is exhausted. Because this approximation makes it difficult to determine the position of the freezing or thawing isotherm, a pseudo apparent heat capacity approach is used by weighting the diagonal terms of the capacitance matrix. Only the heat transport component of the model was used in the study.

To solve the domain problem, the solution region is discretized into triangular finite elements, as shown in Figure 1. Temperatures are represented by linear shape functions within each triangular finite element.

Boundary Approach

For problems where phase-change effects dominate the solution, the temporal term in Equation 1 may be assumed to be negligible. If one assumes an isotropic, homogeneous medium, Equation 1 reduces to the Laplace equation:

$$\nabla^2 T = 0 \quad (7)$$

FIGURE 1 Deadhorse runway cross section showing elements and nodes used in the domain solution.

FIGURE 2 Boundaries and nodal locations for a general boundary integral solution.

where again it is assumed that moisture transport is negligible. Equation 7 is assumed to apply in both the frozen and the unfrozen regions, as shown in Figure 2.

Hromadka and Guymon (1982) have shown that boundary integral methods may be applied to geothermal problems involving soil water phase change. They applied the complex variable Cauchy integral theorem to problems where the position of the freezing or thawing isotherm is determined directly. The boundary integral approach estimates heat flux normal to a two-dimensional freezing or thawing surface. The advantage of this method is that it requires much less computer storage and execution time for certain problems than classical domain methods.

The heat flux is given by:

$$Q_x + i Q_y = -K \frac{\partial T}{\partial x} - i K \frac{\partial T}{\partial y} \quad (8)$$

where Q_x and Q_y are heat flux and $i = \sqrt{-1}$. For any arbitrary closed-contour interior of the solution domain,

$$\int Q_n ds = \int Q_s ds = 0 \quad (9)$$

where n and s are normal and tangential components of the contour. Equation 9 defines T as harmonic and is related to the harmonic conjugate q by the Cauchy-Riemann equations. The complex temperature is defined by

$$\xi(z) = T(x,y) + i q(x,y) \quad (10)$$

where $z = x + iy$. Using Cauchy's theorem, the complex temperature on the boundary may be solved by the contour integral:

$$\xi(z_j) = \frac{P}{S_i} \int \frac{\xi(z) dz}{z - z_j} \quad (11)$$

where z_j is the n th node point on Γ . P_v indicates the Cauchy principle value, and S is the interior line segment angle at node j . Equation 11 is readily solved by assuming $\xi(z)$ is described by straight line segments between each node and by assuming $\xi(z)$ can be represented as a linear polynomial (Hromadka and Guymon 1982). Interior moving freeze/thaw boundaries are located by an isothermal change approximation:

$$L \frac{ds}{dt} = \sum_j (Q_n)_j \quad (12)$$

where $(Q_n)_j$ is a normal heat flux component at a specific location along the phase change front during a time-step Δt . Time-steps of one day or longer may frequently be used because of the time-consuming phase change process in naturally freezing or thawing soils. The solution of Equation 11 requires known temperature or known heat flux conditions on the solution domain boundary, Γ .

The full system of equations is written in the form:

$$K(T,q) = 0 \quad (13)$$

where K is a fully populated matrix of known coefficients and (T,q) is the vector of the complex temperature ξ_j .

FIELD DATA

Two types of data obtained at Deadhorse Airport were used in this study. The first included properties and dimensions of the soil and pavement layers. The second type included initial and boundary temperatures and the measured subsurface temperatures, which were compared with calculated subsurface temperatures.

Properties and dimensions of the soils and pavement were obtained from boring logs (Division of Aviation 1976) made prior to improving the runway and from test data developed during reconstruction of the airport (Ingersoll et al. 1979). Physical and thermal properties of the materials that were used in the thermal models are shown in Table 1. Parameters shown in Table 1 for density and water content were determined from laboratory samples. Thermal parameters were assumed from USACRREL data.

Upper boundary conditions differed depending upon the horizontal position, but they were developed from measured air temperatures in all situations. Air temperatures were adjusted by n factors (Berg et al. 1978) to obtain the surface freezing and thawing indexes and surface temperatures used in the model simulations. A sinusoidal variation of air temperature coupled with the n -factor approach was used to approximate more closely the type of analysis an engineer usually performs. Consequently, the tests of the two models presented here are conservative.

Approximately 120 thermistors are automatically monitored by a battery-powered Data Collection Platform (DCP) and data are transmitted back to USACRREL via the ERTS satellite. Each thermistor is monitored approximately once every five days, and the temperatures are stored in a computer-accessed file at CRREL. In addition, other subsurface temperature observations were obtained manually three or four times per summer. Temperature observations were plotted in a variety of graphs, i.e. thaw depth (0°C isotherm) vs time, temperatures at specified depths vs time and cross-sections of the runway at various times showing the thermal regime (isotherms).

TABLE 1 Material properties below AC pavement.

MODELING PROCEDURE

Both numerical modeling strategies required discretization of the domain in order to approximate inhomogeneity. In the domain method (Figure 1), 126 nodes and 210 elements were utilized. Included in the element definitions were six parameter groupings (Table 1) that incorporated the various dissimilarities of parameters and initial conditions. The boundary integral solution utilized a rescaled domain so that vertical thermal conductivity was constant above and below the 0°C isotherm (that is, frozen vs. thawed). In the rescaled domain, volumetric latent heat is adjusted to preserve the proper rescaled volumetric properties. The problem chosen is amenable to rescaling. Many heterogeneous domains are sufficiently complicated so that rescaling to arrive at a Laplacian problem is difficult or impossible. The boundary integral solution was based on 28 nodal points with eight nodal points evenly spaced along the phase-change isotherm (Hromadka and Guymon 1982).

Both models used identical specified temperature boundary conditions along the top boundary. The initial temperature distributions were inferred from measured subsurface temperatures. Zero flux conditions were assumed at the bottom and at both sides in both models.

MODEL RESULTS

Results of the domain solution are shown in Figures 3 and 4. Figure 3 shows the computed temperatures (dashed line) at a depth of 4.6 m below the pavement surface and 12.2 m from the runway centerline. Measured temperatures are shown as an envelope (solid lines) for this location. Figure 4 shows the computed thaw depths (dashed line) 12.2 m from the centerline. The measured thaw depths (solid lines) are also shown. The envelope of measured thaw depths results from several temperature assemblies at different locations beneath the pavement. Results shown for the particular embankment regime are typical of results throughout the entire embankment.

Thawing depths predicted by the two modeling approaches are given in Table 2 for modeling day number 155. These depths represent the approximate maximum thawing depths. Table 2 includes two sets of predicted thawing depths from the boundary integral approach, based on step sizes of 6 hours and 3 hours. As can be seen, both modeling approaches agree with each other quite closely. Moreover, both approaches agree well with measured thaw

FIGURE 3 Comparison of measured temperatures (solid lines) with those computed in the domain solution (dashed line). Temperatures are approximately 4.6 m (15 ft) below the pavement surface.

FIGURE 4 Measured (solid lines) and calculated (dashed line represents domain method and dotted line represents boundary integral method) seasonal thaw penetration. Depths beneath the pavement surface. Calculations from the domain solution.

depths. This agreement was achieved in spite of the fact that average sinusoidal air temperature was used as a surface boundary condition in conjunction with the n -factor approach. Soil surface temperatures computed using this approach have a root mean square temperature error of at least 8°C.

In this case, the boundary integral method required significantly less computational effort than the domain method; however, this is not a general

TABLE 2 Thawing penetration depths predicted by numerical models and measured at the airfield (model day 155).

Location (x-coordinate), m	Domain solution, m	Boundary integral solution, m		Measured depths, m
		$\Delta t = 6$ hrs	$\Delta t = 3$ hrs

* Δt equals 12.48 hrs; parameter update frequency equals 124.8 hrs.

rule since the boundary integral method has a compact matrix that will lead to less efficient computational effort in some cases. It is concluded that both models can accurately predict the thermal regime of embankments, provided thermal boundary condition and domain solution initial condition information is available.

Based on analysis of data obtained from the observation of a railroad embankment in situ, the author presents mathematical formulas for calculating the lower and upper height of railroad embankments. The lower height of the embankment, is the least height that does not affect the natural permafrost table in the subgrade; it can be determined by two empirical formulas: the first expresses the maximum thawed depth in relation to the natural permafrost table, and the second expresses the elevated height of the natural permafrost table in relation to the height of the clay soil embankment. The upper critical height of the embankment is the maximum filling height for the freezing connection of the body of embankment to the natural permafrost table in the first cold season; it can be determined by an empirical formula that expresses the upper height of the embankment in relation to the time of disappearance of frozen ground with temperature of -0.5°C .

"More filling and less outting" has been the main principle used in route selection in permafrost areas, which benefits the stability of foundation for railroad, i.e. less ground surface disturbance and damage might be caused.

The natural permafrost table might be shifted by the disturbance of the thermal equilibrium of the original stratum caused by building embankments. This shift is closely related to different conditions for receiving heat which are relevant to such factors as the height of the embankment, the direction of slope and the construction season. If embankment is too low, the thawing ability of the local climate could lower the natural permafrost table, thus leading to embankment instability, while if the embankment is built in the warm season, the heat carried in by fill material is likely to deplete the remnant freezing ability of the local climate, resulting in a situation where the embankment frost core could not even be formed or could not be formed within a given period. Therefore, in view of thermal stability, there are two critical embankment heights, upper and lower.

The Lower Critical Height of Embankment

The determination of lower critical height, that is the least height that keeps natural permafrost table beneath foundation unchanged, is the key to stabilizing embankment. It depends upon the physical and thermophysical properties of the embankment and the natural stratum of foundation, and the thawing ability of the local climate; it is measured in terms of the thawing rate of the embankment. If the thawing rate of the embankment is higher than that of natural stratum of the foundation, it is worth considering raising the height of embankment or laying a heat insulating layer to prevent the natural permafrost table of foundation from descending.

Effects on Thawing Rate of Fill Material and Cross-section of Embankment

The type of embankment cross-section is advantageous to drain away water content of embankment body itself. As long as the natural permafrost table of foundation rises slightly, water content of soil body beneath foundation will generally be less than that of natural stratum and its annual variation is not significant. According to the data tested, embankment filled up with clayey soil has an annual fluctuation around 3% (Figure 1) and a comparatively stable thermal physical property. Nevertheless, the thawing rate and thawed depth of such embankment are higher than those of natural stratum because of vegetation over it, higher density after ramming, and higher heat conduction property and lower consumption of latent heat of fusion in comparison with those of natural stratum of clayey soil. The estimation made on existing embankments shows that the

FIGURE 1 The variation curve of average water content in seasonally thawing layer of embankment (0 + 295).

FIGURE 2 A comparison of embankment temperature vs. natural ground temperature.

thawed depth is increased by 20% due to change of thermal physical property.

The additional heating effect on embankment body by horizontal heat flow of embankment slope exposed to the sun makes the slope continually transfer heat towards the center of embankment, thus increasing the thawed depth. For instance, the analysis of the observation data on two low embankments in Mt. Fenghuo region, Qinghai-Xizang Plateau, showed that the annual average temperature of soil body of central plane of embankment—the plane running along the embankment at various depths within 0.5 to 3.5 m—in 1978 was higher than that of natural stratum by about 0.4 to 1.0°C (Figure 2). Corresponding to that of natural stratum, the ground temperature curves of embankment in the coldest and hottest months both shifted toward positive with a thawed depth 29% deeper than the natural permafrost table. Getting rid of the influence caused by physical difference, we found from a rough calculation that the horizontal heat flow would cause the thawing depth of

central cross-section of embankment to increase by over 10% (see Figure 2).

The heat effect (mainly the horizontal heat flow of the slope exposed to the sun) on embankment by filling material and type of cross-section again can be reflected by thawing rate. For instance, the thawing rate of embankment center in Mt. Fenghuo region is, in general, $\bar{V}_{emp} = 1.4$ to 1.7 cm/day while that of natural stratum is merely $\bar{V}_{nat} = 0.8$ to 1.2 cm/day. The former is 1.4 to 1.7 times that of the latter.

For above reasons, it is necessary to determine the minimum filling height of embankment to avoid the thermal degradation of natural permafrost table.

DETERMINATION OF LOWER CRITICAL HEIGHT

Determining H_{min} by Means of Statistics

For a low embankment in center area of permafrost regions of the Qinghai-Xizang Plateau filled with clayey soil, the observed data of embankment height H versus the risen height of natural foundation permafrost table δ are shown in Table 1. The experience equation determined by least square method for calculating the data listed in Table 1 is:

$$\delta = 1.10H - 0.61 \tag{1}$$

provided $H \leq 2.0$ m, where H = height of embankment. The statistical range of natural permafrost table is $h_0 = 1.3$ to 1.9 m, the relative coefficients being: $\gamma = 0.997$, $\alpha = 0.001$.

By equation 1, when $\delta = 0$, $H = 0.55$ m. Because of the heating effect of horizontal heat flow at railroad shoulder exposed to the sun, the thawed depth there is deeper than that of foundation for railroad center by 15%. To prevent the ground ice or frozen soil of rich ice beneath the shoulder exposed to the sun from thawing and affecting the stability of founda-

TABLE 1 The Relation Between Filled Height of Low Embankment and Rise or Drop of Natural Permafrost Table

Center height of embankment H (m)	0.00	0.15	0.60	1.13	1.25	1.65	1.75	2.04

Note*: 1. This value would be obtained by taking the mean value of testing embankment in Mt. Fenghuo region 0 + 142, highway embankments; 600 + 000, 628 + 600, 740 + 200, 779 + 600.

2. Test Emb. is the testing foundation for railroad in Mt. Fenghuo region, Highway is the Qinghai-Xizang Highway

tion for railroad, the height of embankment should be controlled by the thawing depth of the mentioned shoulder, i.e.

$$H_{min} \geq 1.15 \times 0.55 = 0.65 \text{ m.}$$

This minimum value is adaptable to foundations for railroad filled with clayey soil along continuous permafrost region with natural permafrost table of 1.3 to 1.9 m.

Determining H_{min} by Conversion

Because the natural permafrost table at the place where embankment is built is the result of weather factors affecting the stratum over a long period, which fully reflects the heat exchange equilibrium relation of weather-ground system, the course of thawing of embankment within the same climate region is bound to be closely related to the thawing process of natural stratum there. The lower critical height of embankment which is adequate for local climate and stratum conditions can be evaluated through converting and simplifying boundary conditions.

Generally, the thawing depth of stratum, h , can be determined by Stephen's equation, i.e.

$$h = \sqrt{\frac{2\lambda \sum t \tau}{q}} \quad (2)$$

Since heat-absorbing area of low embankment increases only slightly due to its geometrical shape, it is assumed that the heat condition is one-dimensional and the relation between low embankment center and thawing depth of local natural stratum can be expressed by

$$\frac{h_H}{h_0} = \sqrt{\frac{\lambda_H Q_0}{\lambda_0 Q_H}} \sqrt{\frac{\sum t \tau_H}{\sum t \tau_0}} = \alpha \cdot \beta \quad (3)$$

or
$$h_H = \alpha \cdot \beta \cdot h_0 \quad (4)$$

where h_H is the central thawing depth in meter of embankment on account of one-dimensional heat conduction; h_0 is the natural permafrost table; α is revision coefficient (Huang 1979):

$$\alpha = \sqrt{\frac{\lambda_H Q_0}{\lambda_0 Q_H}}$$

where λ_H , λ_0 , Q_0 , and Q_H are the thermal conductivities and the latent heat of volume phase shift of embankment filling material and natural stratum respectively; α is the revision coefficient of surface condition ($\alpha = 1.00$ as the surface condition of the representative natural table selected coincides with that of embankment, $\alpha = 1.06$ as the natural ground surface is covered with turf and that of embankment is filled with clayey soil, and $\alpha = 1.12$ as embankment surface is paved with gravel sand).

Taking account of the horizontal heat flow which actually exists in low embankment slope exposed to the sun, it is necessary to have an additional coefficient of heat flow m_t added to eq 4, then we have

$$h_H = h_H \cdot m_t \quad (5)$$

$$h_H = m_t \cdot \alpha \cdot \beta \cdot h_0$$

The value of m_t is generally determined empirically through field data rather than by calculation, which is bound to involve the boundary conditions difficult to be obtained in the design stage. The higher the embankment, the larger the lateral surface absorbing heat, so the larger the ratio between the thawing depth of the shoulder exposed to the sun versus the central thawing depth. For example, the ratio $K = 1.25$ as $H = 2.5$ m, while $K = 1.40$ as $H > 6$ m. For embankments lower than 1.0 m, $K = 1.13 - 1.16$, the average value being 1.15, which adequate. The coefficients of equation 4 are listed in Table 2.

Natural permafrost table is kept unaltered provided the maximum seasonally thawing depth of embankment is equal to or less than the sum of the height of embankment and the original natural permafrost table (see Figure 3), i.e.

$$h_H \leq H + h_0 \quad (6)$$

Taking critical condition:

$$h_H = H_{min} + h_0$$

TABLE 2 Coefficients for Calculating Embankment Thawing Depth

Additional coefficient of heat flow, m_t		1.15
Physical revision coefficient		$\frac{\lambda_H Q_0}{\lambda_0 Q_H}$
Revision coefficient of surface condition	Embankment surface coincides with natural ground surface	1.00
	Natural ground surface covered with turf, embankment filled with clayey sand	1.06
	Natural ground surface covered with turf, embankment filled with gravel sand	1.12

FIGURE 3 Relation between height of embankment and thawing depth. h_T = maximum seasonal thawing depth; H = height of embankment; h_0 = natural permafrost table.

Since

$$h_H = m_t \cdot \alpha \cdot \beta \cdot h_0,$$

then

$$H_{\min} + H_0 = m_t \cdot \alpha \cdot \beta \cdot h_0$$

$$H_{\min} = (m_t \cdot \alpha \cdot \beta - 1) h_0 \quad (7)$$

The change of physical property of original natural permafrost table caused by shrinkage of foundation soil layer while filling embankment has been cancelled, and the lower critical height of embankment filled in Mt. Fenghuo region $H_{\min} = 0.63$ m. Incidentally, the effects caused by factors as air temperature fluctuation etc. should be taken into account.

THE UPPER CRITICAL HEIGHT OF EMBANKMENT

The maximum filling height of embankment is determined by the local freezing capacity and is closely related to construction technology as well as construction season, etc. For embankment built in cold season, mechanical stability is mainly considered, for fill height is not dominated by the requirements of thermal calculations; while for embankments built in the warm season, the rate of dissipating heat carried into the embankment by fill material must be considered.

The necessary condition for raising the natural permafrost table is that the freezing capacity of climate at the site of project must be higher than the thawing capacity. The remaining freezing capacity after having been consumed in frozen joining of seasonally thawing layer is called remnant (or latent, potential) freezing capacity. The upper critical height tends to be greater with a higher local remnant freezing capacity. Under ordinary conditions, freezing and thawing capacity can be cumulative temperature of ground surface if thawing and freezing depths are considered as functions of it. The annual average temperature t_0 is expressed by the following equation:

$$t_0 = \frac{\sum + t\tau + \sum - t\tau}{\tau_w}, \quad (^\circ\text{C}) \quad (8)$$

where $\sum + t\tau$ and $\sum - t\tau$ is the positive and negative cumulative temperature of ground surface respectively, i.e. the sum of average daily positive and negative temperature in a whole year ($^\circ\text{C}\cdot\text{day}$) respectively; τ_w is the cycle yearly (365 days); therefore, $t_0 > 0^\circ\text{C}$ when $|\sum + t\tau| > |\sum - t\tau|$. At this moment, ground temperature of zero temperature amplitude deep (perennial ground temperature) $t_{cp} > 0^\circ\text{C}$ and no permafrost layer is formed. In heat-dissipating or stable-typed permafrost regions, i.e. where the average ground surface temperature annually is less or equal to ground temperature of zero temperature amplitude deep, $t_0 = 0^\circ\text{C}$ and $t_{cp} \geq 0^\circ\text{C}$ when $|\sum + t\tau| = |\sum - t\tau|$, no permafrost layer is formed or it exists in the form of zero temperature gradient. In this situation no remnant freezing capacity can be utilized. It is only when $|\sum + t\tau| < |\sum - t\tau|$ that the remnant freezing capacity can be considered for use, and when $|\sum + t\tau| \ll |\sum - t\tau|$, $t_0 \ll 0^\circ\text{C}$, $t_{cp} \ll 0^\circ\text{C}$, i.e. the greater the difference between positive and negative cumulative temperatures of ground surface, the lower the perennial ground temperature, namely, the higher the remnant freezing capacity.

If annual average ground temperature $t_0 < 0^\circ\text{C}$ is taken as the essential prerequisite for the existence and development of permafrost and since the perennial average ground surface temperature at various ground surfaces in the Qinghai-Xizang Plateau is higher than the annual average atmospheric temperature by 2 to 4 $^\circ\text{C}$ or more, only when the latter is lower than -2 to -4 $^\circ\text{C}$, the problem of the embankment's frozen core has to be considered comprehensively concerning water content of soil, orientation and topography. The annual average atmospheric temperature of the continuous permafrost region of Qinghai-Xizang Plateau is, in general, -4 to -7 $^\circ\text{C}$. The difference between positive and negative cumulative temperature is fairly great, being 1600-2400 $^\circ\text{C}\cdot\text{day}$, and the latter is 3-8 times the former. This provides comparatively sufficient remnant freezing capacity, which is able to make newly filled soil layer of certain height frozen and jointed with permafrost.

According to the analysis on the observation data obtained from investigating Qinghai-Xizang Highway and the test embankment, the statistical relationship between the height of embankment filled with clayey soil and the variation of natural permafrost table of the foundation could be expressed by the following equation:

$$\sigma = 0.997H - 0.54 \quad (\text{m}) \quad (9)$$

when the height of embankment $H = 8$ m and the burying depth of natural permafrost table $h_0 = 1.30$ to 1.90 m, eq 9 is suitable.

The critical height of natural table of foundation calculated by the equation that stretches

into the embankment body is

$$H > 1.85 - 2.50 \text{ m.}$$

The problem of equilibrium between embankment height and freezing capacity occurs after freezing core stretching into embankment body and it is relevant to construction season.

Effects of Filling Height on Freezing of Embankment

For high embankment built in warm season it requires certain time and condition for heat brought into embankment body with filling material to dissipate. In the course of freezing of embankment built in cold season, which carries on from top to bottom and refreezing from permafrost table upward, the conditions for heat dissipating around foundation is the worst, which frequently results in the forming of frost sandwich of rather high temperature and even thawed sandwich surrounded by permafrost. Statistical material based on tested data shows that the freezing and refreezing rates of embankment are faster (see Table 3) in comparison with those of natural stratum, while the time taken for heat dissipation on the side exposed to the sun near the foundation could be as high as more than 30 months when height of embankment is over 8 m. The relation is roughly:

$$\tau_{\text{month}} = 5.89H - 12.1 \text{ month} \quad (10)$$

Provided

$$8.0 \text{ m} \geq H \geq 3.0 \text{ m}$$

where τ_{month} is the time taken for high temperature frozen soil area (i.e. where ground tem-

perature is higher than -0.5°C) to disappear, in month; H is the central height of embankment filled, in meter.

If the unfavorable effect on freezing by heat brought into embankment body with filling material, the geometrical shape of embankment, as well as the favorable effect on heat dissipation and freezing during contraction of seasonally thawing layer of foundation are not considered, the upper critical height of frozen joining H_{max} of embankment in the first cold season can be converted by the following equation:

$$H_{\text{max}} = \left(\frac{\alpha' \cdot \beta'}{1 - \mu} - 1 \right) h_0' \quad (\text{m}) \quad (11)$$

where α' is the revision coefficient of filling material (Cf Equation 3), i.e.

$$\alpha' = \frac{\lambda_H Q_0}{\lambda_0 Q_H}$$

thermal conductivity adopted is the value under frozen state; β' is the conversion coefficient of frozen depth,

$$\beta' = \frac{\sum -t\tau}{\sum -t_0\tau_0} ;$$

$\sum -t\tau$ is the whole cold season's cumulative temperature ($^{\circ}\text{C}\cdot\text{day}$) of natural ground surface in the region where embankment is built in; $\sum -t_0\tau_0$ is the cumulative temperature of the above natural ground surface ($^{\circ}\text{C}\cdot\text{day}$) at the moment corresponding to that when frozen joining of seasonally thawing layer is achieved; μ is the coefficient of freezing, namely the ratio of refreezing depth embankment versus the integral frozen depth, which is related to permafrost ground temperature and construction season and is taken as 0.25-0.35 according to the data tested; h_0' is

TABLE 3 A Comparison between Ground Temperature and Freezing and Refreezing Characteristics of Embankments of Different Height

Natural stratum	0		3.0	1.1	Oct 3 to Nov 11 next year	39	0.32	39	0.82

Note: Isotherm 0°C serves as standard for frozen joining.

the maximum freezing depth of natural stratum in meter, freezing from top to bottom, being about 80% of the depth of seasonally thawing layer.

By the equation the calculated H_{max} for the embankment filled with clayey soil in Mt. Fenghuo region is $H_{max} \leq 7.5$ m, which has been tested and verified by the observation data on testing project.

Effect of Construction Season on Freezing of Embankment

It is proper to build embankment in cold seasons. If construction is carried out in the middle or later stage of warm season, heat exchange of embankment and foundation will be in the worst situation because of the heat stored in the ground as well as the heat brought into it by the filling material. This will unfavorably influence the restoration of the ground temperature and even thaw the ground permafrost (Huang 1980). It is, therefore, imperative to consider the effect on constructing height and stability of foundation caused by thawing compression of foundation permafrost while building embankment in the middle or later stage of warm season. Special attention must be paid to such high embankments beneath whose natural table of foundation there exists ground ice, whose sunward slope lies just on the horizontal slope of the ground surface inclining downward.

Because the heat stored in the ground and that carried into the embankment by fill material are little, the freezing duration is short, and the negative cumulative temperature consumed during joining the upper and lower 0°C isotherms is less, there is more remnant freezing capacity in an embankment built in the early stage of the warm season, which is able to further cool the embankment and its foundation already frozen or favorable for raising the height of embankment.

Comparing the data tested, we find that the upper critical height of embankment built in the early stage of warm season is over 1 m higher than that of embankment built in the middle or later stage of the season.

CONCLUSIONS

To prevent the foundation of embankment from thawing subsidence after building it, we have to make the height of embankment higher than the lower critical height in permafrost areas. It is relevant to fill materials and local climate, etc. In center area of permafrost regions of Qinghai-Xizang Plateau, the lower critical height is equal to 0.65 m when the fill materials are clayey soil.

If we want to make the embankment body and natural permafrost table of foundation joint in the first cold season, the height of embankment has to be lower than the upper critical height. It is closely related to the fill materials, local freezing capacity and construction season, etc. The upper critical height for the embankment filled with clayey soil in Mt. Fenghuo region is 7.5 m.

A GEOPHYSICAL METHOD FOR PERMAFROST SURVEY IN CHINA

Huang Yizhi, Gu Zhongwei, Zeng Zhonggong, He Yixian, and Liu Jinren

Lanzhou Institute of Glaciology and Cryopedology, Academia Sinica,
People's Republic of China

Direct-current electric prospecting has been used for permafrost investigations since the end of the 1950's, and remains a major prospecting technique. It has proved to be a useful method for locating the distribution of permafrost and taliks, mapping ground ice, and determining permafrost thickness. Recently, computers have been used to process data from electrical soundings. Experiments in seismic prospecting show that the first arrival refraction can be used to measure the depth of the permafrost table, and shallow reflection can be used to measure the thickness of noncompacted sediments. D.C.-induced polarization, dipole array potential-drop ratio, and radon emanation techniques have been tested and applied to permafrost surveying. The conductivity, acoustical properties, and dielectric constants of frozen soils have also been studied in the laboratory. Future tasks include (1) further research on the characteristics of ground electrical sections of permafrost, to increase the accuracy of quantitative interpretation of V.E.S. curves and to perfect computer data processing, (2) further research on electrical and acoustic properties, and (3) further study of the dynamic characteristics of seismic waves in permafrost.

In China, at the end of the 1950's, D.C. electric prospecting was used for engineering geological surveys on permafrost by engineering departments. At the beginning of the 1960's, the Lanzhou Institute of Glaciology and Cryopedology, Academia Sinica, began their research on geophysical methods for surveying permafrost; D.C. electric sounding was the major prospecting method (Huang Yizhi et al. 1981, 1983). Meanwhile, some colleges and departments of the railroad, highway, and forestry administrations, such as The First Railroad Design Institute, Ministry of Railroad, conducted experiments on geophysical methods for engineering geological prospecting in permafrost areas. In recent years, seismic (Zeng Zhonggong et al. 1982), D.C.-induced polarization (Huang Yizhi et al. 1983), dipole array potential-drop ratio method (Zhou Fucheng 1982), and radon emissions (Yao Baoxing et al. 1982) have been tested and applied to permafrost surveys. The computer has been used for processing of data from electrical soundings (He Yixian 1980). At present, various geophysical methods can be used for locating permafrost, taliks, and thick ground ice layers and determining the position of the top and bottom of permafrost and the thickness of frozen sediments. Preliminary laboratory studies also provided information on the conductivity, acoustical properties, and dielectric constant of frozen soils.

ELECTRIC CONDUCTIVITY, DIELECTRIC CONSTANT, AND ACOUSTICAL PROPERTIES OF FROZEN SOILS

The resistivity of frozen soil is much higher than that of thawed soil because

conductive channels are reduced by ice formation. However, even below 0°C unfrozen water can still play a role as a conductive medium. The increase of resistivity in frozen soil is very steep at temperatures in the 0 to -2°C range. A minimum value of resistivity occurs at a water content that corresponds to a materials plastic limit (Gu Zhongwei et al. 1982).

The dielectric constant of frozen soil is considerably lower than that of unfrozen soil, because most of the water that has a high dielectric constant ($\epsilon=80$) is changed into ice ($\epsilon=3.2$). The decrease of ϵ in frozen soil actually depends on the unfrozen water content. The frequency dependence of the dielectric constant for frozen soils is not as strong as that of unfrozen soil, except in the low frequency state. A maximum value of dielectric constant in frozen soil occurs near the thawed materials' plastic limit, which corresponds to the moisture content at which minimum D.C. resistivity would be obtained. Thus, the plastic limit can be a significant turning point for the electrical properties of some frozen soil (Gu Zhongwei and Liu Jinren 1983).

The elastic wave velocity varies with the moisture content. It increases steeply with increasing moisture content in samples when moisture content is less than the plastic limit for fine-grained soils and less than 70% saturation for coarse-grained soils, and then increases slowly with increasing moisture content. When the moisture content goes up to a certain value, between 11% and 20% for the sandy soil, and between the liquid limit and 100% for the fine-grained soil, the wave velocity will remain at a stationary value.

The wave velocity will decrease very slowly with the moisture content increasing and then gradually approaches the wave velocity of pure ice (Liu Jinren and Zeng Zhonggong 1983).

D.C. RESISTIVITY METHOD

D.C. Vertical Electrical Sounding (V.E.S.)

In 1963, V.E.S. was used for permafrost investigation to measure the thickness of permafrost and compare the results with bore hole temperature information at Tumengela, Xizang. This was also done in the Muli, Reshui, Qilian Shan region, and along the Qinghai-Xizang Highway with satisfactory results.

The application of V.E.S. to permafrost surveying covers the following categories (Huang Yizhi et al. 1981).

Locating the distribution of permafrost and taliks. This is done by interpreting the V.E.S. curve types and ρ_s (apparent resistivity) profile maps with the hole data as shown in Figure 1. The V.E.S. curves and the ρ_s profiles in permafrost regions are quite different from those in talik areas.

Investigating the vertical distribution of permafrost. There is a typical V.E.S. curve that sometimes has distortion in the high resistivity part of curve when the permafrost has a so-called double structure in the vertical direction. There is a V.E.S. curve at station 10 on Qumar

River along the Qinghai-Xizang Highway. It has been interpreted with the aid of the computer to have seven layers, i.e. $\rho_1=69.9\Omega\text{m}$, $h_1=0.8\text{m}$; $\rho_2=152.8\Omega\text{m}$, $h_2=0.46\text{m}$; $\rho_3=1343\Omega\text{m}$, $h_3=7.39\text{m}$; $\rho_4=71.2\Omega\text{m}$, $h_4=2.36\text{m}$; $\rho_5=10\Omega\text{m}$, $h_5=0.28\text{m}$; $\rho_6=3558\Omega\text{m}$, $h_6=36.85\text{m}$; $\rho_7=2.5\Omega\text{m}$. The curve suggests that the fourth and fifth layer form a 2.6 m thick talik.

Investigating taliks below river and lakes. If a complete talik is under a river or lake in permafrost, the V.E.S. curve shows low resistivities, without a high resistivity segment, and an obvious difference from those on permafrost.

Mapping ground ice. Ground ice with its higher resistivity and common position near the upper part of the permafrost section will cause the apparent resistivity at shallow depths to rise steeply. It was found that if the angle between the rising section at the start of the V.E.S. curve and the abscissa is larger than 40° , the curve shows existence of ground ice. A statistical analysis of many V.E.S. curves measured at Fenghuo Shan in Qinghai-Xizang Plateau showed that thickness and buried depth of ground ice can be estimated from an experimental relation developed between the value of electrode spacing at which turning point on the curves occurs and the buried depth of ground ice (He Yixian 1982).

Determining permafrost thickness. Several methods have been used for determining permafrost thickness, namely the so-

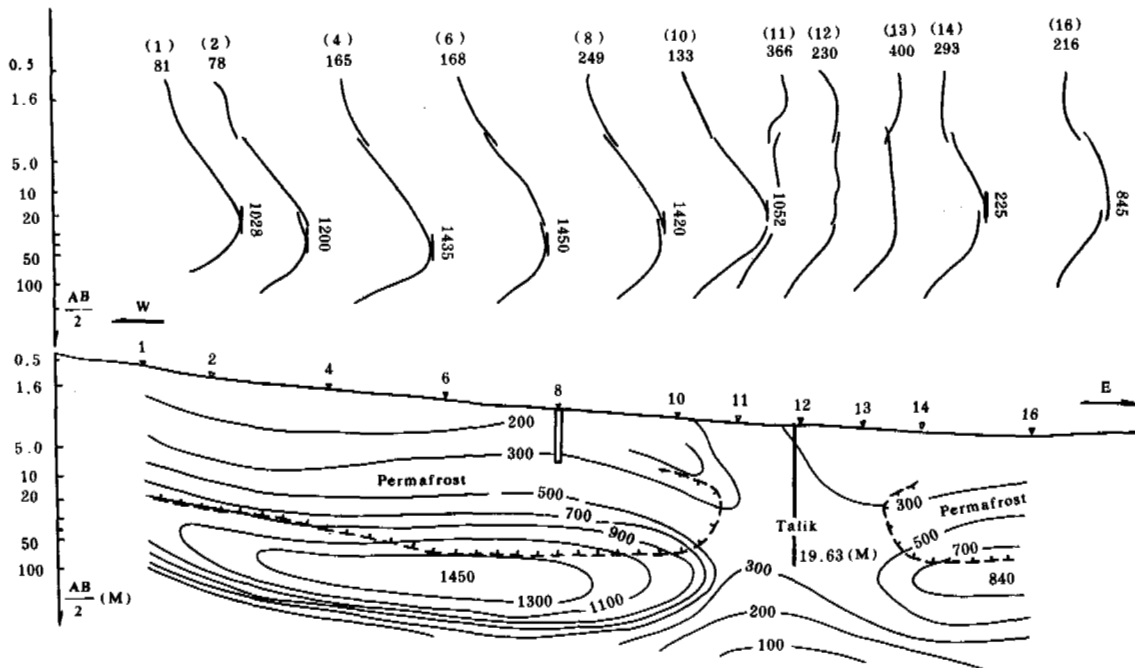

FIGURE 1 V.E.S. profile curve types and ρ_s profile near the 104-II Maintenance Squads of Qinghai-Xizang Highway.

called turning point method, the comparing of master curves, the inverse slope methods, and data processing with the computer. Of these techniques the computer processing method is most efficient due to its automatic approximating method of layer parameters. Many V.E.S. curves measured are matched by the filling program of damping least squares on a DJS-130 computer, made in China, and satisfactory results had been obtained. For example, near a hole at Tumengela at the Xizang Plateau, the lower boundary depth of permafrost determined from ground temperature measurement in the hole is 70.3 m, while the depth calculated by computer is 70.7 m.

D.C. Electric Profiling

In 1963, D.C. electrical profiling, usually a double symmetrical four electrode configuration, was used for locating the permafrost and taliks at Tumengela in Xizang. On permafrost, the difference ($\Delta\rho_s$) between the apparent resistivities from both large and small electrode spacings is larger. On taliks, values of $\Delta\rho_s$ are smaller. If $\Delta\rho_s$ is positive and large, permafrost can be considered to exist, and if $\Delta\rho_s$ is negative and small, a talik exists (Huang Yizhi et al. 1981).

Dipole Array Potential-drop Ratio Method

This method has been successfully used for locating islands of permafrost at a mining area in Heilongjiang Province

FIGURE 2 The change of AMONB array into ABMON array.

FIGURE 3 A monkcap-shape anomaly due to horizontal wood slab (from model experiment in laboratory).

(Zhou Fucheng 1982). The main points of dipole potential-drop ratio method include: 1) the change of AMONB array of the potential-drop ratio into ABMON array, and then 2) the measuring of potential-drop ratio R between electrodes ON and MO (Figure 2).

This method is excellent for mapping

FIGURE 4 A profile of dipole array potential-drop ratio method on island permafrost

by utilizing the inhomogeneity of electrical field. For example, clear monkcap-shape anomaly is obtained on a horizontal wooden plate with high resistivity from a model experiment permafrost performed in the laboratory (Figure 3). A good result has been obtained in lining the distribution of island permafrost (Figure 4). The permafrost boundary shown by the dipole potential-drop ratio method is clearer than that found by electrical profiling. However, the influence of rock inhomogeneity on the dipole potential-drop ratio at the surface is severe, making interpretation of results difficult. Therefore, it is necessary to combine it with electrical sounding.

SEISMIC PROSPECTING

In 1978-79, a seismic prospecting experiment was performed for investigating permafrost at Fenghuo Shan, Qinghai-Xizang Plateau (Zeng et al. 1982, and Zhou and Chen 1980). The experimental results show that the first arrival refraction can be used for measuring the depth of the natural and artificial permafrost table and that shallow reflections can be used for measuring the thickness of sediments. However, attention must be paid to the influence of a seasonal thawed layer on a shallow reflection. On the one hand, the temporary thaw-freeze interface could be mistaken for the top of permafrost because the former is an excellent refractor, through which the wave velocity would change abruptly. On the other hand, due to the large difference of wave impedance at the freeze-thaw interface, most of the energy from the seismic wave is reflected back to the surface, causing the refracted energy from the deeper bedrock surface to be very weak. Thus, the refraction from bedrock surfaces can hardly be recorded by using a hammer as the energy source. It is suggested that this work be done during the period when the earth surface is still frozen, in order to reduce the influence of the thawed material and the shallow reflector.

INDUCED POLARIZATION METHOD

In the summer of 1980, the field experiment of D.C.-induced polarization sounding was undertaken along the Qinghai-Xizang Highway (Huang Yizhi et al. 1983). The experimental results show that IP sounding curves on permafrost are extremely variable. The polarizability of seasonal thaw layers is slightly higher than that of permafrost, and the polarizability curve has little variability in the upper permafrost (which may be related to

ground ice) and increases strongly in the lower permafrost section. There is a negative polarizability as the half electrode separation approaches the lower boundary depth of permafrost, and the polarizability of frozen bedrock is generally lower than that of frozen sediments in which the polarizability of coarse-grained soil is generally higher than that of fine-grained soil. The polarizability of coarse-grained soil is more than 2%; finer-grained soil is usually less than 1%. Ground ice has a more steady polarizability of 1.0%-1.2% in general, while pure intrusive ice or the ice-cores of pingos are only 0.2%-0.6%. The difference of D.C. polarizability between permafrost and ground ice is small.

RADON EMISSION SURVEY

On the assumption that permafrost can restrict the migration of radon gas, an experiment to locate local permafrost bodies was undertaken in 1975 (Yao Baoxing et al. 1982). The experimental result shows that values are low in the permafrost area. However, low values were also found on thawed swampy lowland and river taliks due to the absorption of radon gas by water. Concentration at the surface also varies with the lithological characteristics and depth of the bedrock, and the composition and permeability of overlying sediments. Thus, there are two problems to be solved: it is necessary to develop equipment to measure the radon gas concentration of air and water in the field at the same time; and secondly, to study the influence of permafrost properties including variation in ice content on gas.

FUTURE RESEARCH

Permafrost is distributed widely in the alpine regions of China. In order to fully utilize geophysical skills in the study of permafrost, the following future tasks are required.

First, it is necessary to increase the accuracy of quantitative interpretation of V.E.S. curves, and to perfect the computer data processing technique.

Second, research on electrical and acoustic properties should be expanded to offer a broader basis for the interpretation of geophysical data and for the coordination with studies on the phase composition, and physical-chemical process in permafrost.

Finally, the dynamic characteristics of seismic waves in permafrost should be studied, in order to make data interpretation more efficient and accurate.

SOIL WEDGES ON SPITSBERGEN

Alfred Jahn

Geographical Institute
University of Wrocław, Poland

In the Van Mijenfjord, in the western part of Spitsbergen, the author found non-sorted polygons built of fine shale debris. Although these polygons were clearly a result of frost cracking, no traces of ice wedges were found down to the permafrost table (depth of 1.2 m). The soil structures found were active-layer soil wedges, similar to the soil wedges known from Siberia. The Spitsbergen findings indicate that such soil wedges can develop in an oceanic periglacial climate and the hypothesis that soil wedges occur only in continental periglacial zones may be incorrect.

Soil wedges (or soil veins) are known chiefly from Siberia. They have been described by Danilova (1956), Katasonov (1973), and Romanovskiy (1973), and are regarded as forms due to frost cracking, especially frost cracking of the active layer (seasonally thawing layer above permafrost). They are commonly termed "ground" or "soil veins", but have also been called "primordial (or primary) soil veins" and "soil-filled veins" in the European literature. One of the first researchers to give an excellent description of ice and soil wedges from Alaska was Leffingwell (1919).

Soil wedges are often confined to the active layer, but perennial ice wedges occur in the permafrost only. [The only exception to this rule is the Antarctic "sand wedge" as defined by Péwé (1959)]. In the Anglo-American literature, based on examples from Alaska or northern Canada, soil that fills the empty space created by a thawing ice wedge becomes an ice-wedge cast in fossil forms but may become part of an active-layer soil wedge if frost-cracking is still active. However, in many cases in the Soviet literature, based on examples from Siberia, the soil or ground wedge (or vein) is synonymous with ice-wedge cast. To avoid confusion, Washburn (1979) distinguished between contemporary and fossil forms of active-layer soil wedges and permafrost soil wedges. The term ice-wedge cast is restricted to replacement of ice wedges and as such is distinct from both contemporary and fossil permafrost soil wedges.

It is not accidental that Siberian researchers have devoted so much attention to soil (ground) wedges or veins. The Siberian summers are warm and the seasonal thaw is deep, whereas in polar climates, soil wedges are rarely identified unless they overlie ice wedges. However, Katasonov (1973) is of the opinion that active-layer soil wedges may exist that have no genetic relationship to ice wedges.

The features observed in the summer of 1978 in the Van Mijenfjord area, Spitsbergen, are of interest and importance (Figures 1 and 2). On a low coastal terrace, soil wedges are found together with the typical polygonal arrangement of frost cracks. The area is underlain by a fine-grained debris of dark Eocene shales originating from frost weathering on the slope and subsequent transport onto the coastal terrace. These flat alluvial fans

consist of several generations, from the oldest (A) to the youngest (F), the youngest being on the presently active fan surface (Figure 3). The whole area is a typical "polar desert", almost devoid of vegetation, with single grass tufts in depressed places (Figure 4). The effects of wind action are visible in the form of a stone pavement. The most striking surface features are the regular polygons, with pentagonal and hexagonal forms prevailing (Figure 5). The younger the fan surface, the larger the polygons (Figure 6). The diameter of the youngest forms is 4-6 m, but that of the oldest hardly reaches 1 m. Another regular feature is that the younger forms are flat and the furrows dividing them are shallow, whereas the older forms are convex, resembling small shield-like hills (Figure 7).

Detailed measurements revealed that the mean furrow depth of the youngest polygons is 6 cm, and of the oldest is 18 cm (Figure 3).

The polygons develop as large cells and divide into smaller ones (Figures 8 and 9). Simultaneously, these smaller polygons become convex. The structure of these forms can be traced on the edges that separate the particular fan generations. In places, several cross-sections were made to the permafrost table (Figures 10 and 11), which ranged in depth from 100 to 120 cm, at the beginning of August. It was found that the furrows of the polygons corresponded to the soil wedges, which were situated exactly below the furrows, thus proving their genetic relationship.

The wedge structures are shown in Figure 10, a drawing made in the field, and in the photographs (Figures 11 and 12). It is easy to recognize these structures, since the shale debris consists of flat and elongate particles. The arrangement of the particles gives an exact indication of the direction taken by the forces that formed the soil structures (Figure 12).

Near the soil wedges, the debris is on edge and parallel to the wedge walls, while in the interior of the polygons the clasts lie horizontally against the wedges. No upturned structures due to frost thrusting were noticed anywhere. The soil wedges of this area represent the passive element whose formation is affected only by ice melting and not by frost heaving or thrusting. This observation is important to understanding the development mechanism

of these forms.

It is not easy to determine whether the wedge material comes from the polygonal net surface or from the wedge walls, since in both cases it is of the same type, i.e. relatively homogeneous shale debris. There is no difference in color between the wedge and the inner part of the polygon. However, two facts suggest that the greater part of the material within the wedges originates from the polygonal net surface:

(1) There is a marked border between the soil wedge and the inner part of the polygon. The clasts are arranged differently, being on edge rather than horizontal (Figure 11).

(2) The granulometry of the material differs in the two parts of the polygon (Figure 13). That from the polygon interior contains, on average, 40% particles 2-5 mm in diameter, while 60% of the soil-wedge particles are of this size. The cross-sections show clearly that the wedge material is finer than the enclosing material and the material of the polygon surface. This analysis leads to the conclusion that soil-wedge formation here is characterized by a process in which the finer particles are concentrated in the wedges, while the coarser remain on the surface, mainly in the furrows.

It is easy to imagine how this process developed. Soil wedges are started by repeated frost cracking in the winter season. The cracks fill with water during spring and summer thawing, and later freezing gives rise to small ice veins that reach below the active layer and lead to the growth of perennial ice wedges. In summer, however, when the active-layer ice veins have melted, the small cracks trap debris slipping from the polygon surface into the furrow. Only debris with a diameter not exceeding the width of the crack gets into it. The grain-size analyses taken indicate that these cracks were at least 2 mm wide and did not exceed 5 mm; thus they are similar to the generally known Arctic frost cracks. At any rate, I invariably encountered frost cracks of these sizes in early spring on Spitsbergen (Jahn 1975).

Debris up to 5 mm in diameter slips into the cracks and tabular clasts settle edgewise. It would be difficult to imagine this process taking place in a dry environment, so the most reasonable explanation is that the debris is carried into the cracks by meltwater and rainwater.

The soil wedges discussed here have a complex structure. Some are of the "cone-in-cone" type (Figures 10 and 11) and show signs of slight side thrust, such as gentle folds. It is significant that all these features were produced only in the wedges and furrows, whereas the polygons themselves have a simple structure without distortion.

The overall development of the polygons and the soil wedges proceeds as follows. In the first stage large-diameter polygons develop and, as already described, frost cracks result in soil wedges in the surface layer. The regularity of the pattern and the depth of the soil wedges leave no doubt as to their frost origin. Desiccation cracking, which also occurs on the surface of the fans, is entirely different (Figures 10 and 11). The material filling these cracks does not show the regularity that was observed in the soil wedges. The division of the large polygons into smaller pentagons and hexagons is a secondary process (Figures 8 and 9).

A problem that has repeatedly attracted attention is the nature of the effect of ice- and soil-wedge growth on the structure of the enclosing deposits. It is well known that ice wedges act as a thrusting force, even on the frozen soil mass, and cause a characteristic folding or upthrusting of the layers. By contrast, active-layer soil wedges thaw in the summer and lose their dynamic pushing force. In soil wedges, small deformations may occur at wedge walls, but the deformations are considerably smaller than those associated with ice wedges, which tend to produce raised borders running parallel to the furrows (cracks). These raised borders lift the surface of the polygon higher at the edges than in the middle, leading to the concave shape of low-center polygons. The raised borders result from the polygonal block expanding and pressing against the ice and soil wedges as the ground warms. Based on observations made in Alaska and northern Canada, a diagram of the annual dynamic changes of such polygons has been presented (Jahn 1975). This has been confirmed by Mackay (1980), who shows that during the summer, the active layer has a movement away from the center of the polygon toward the furrow (wedge). This movement caused by the thermal expansion of the still-frozen part of the active layer as it warms toward 0°C can distort structures and contribute to the development of low-center polygons.

However, in the Van Mijenfjord high-center polygons, no distortions of the border edges can be found. Any uplift of the ground and surface bulging is related to the center of the polygon. As mentioned above, older polygons are more convex than younger ones, being high-center polygons. Neither the diagram presented earlier (Jahn 1975) or Mackay's (1980) results explain why developing and expanding active-layer soil wedges, which in the Van Mijenfjord area are up to 0.5 m wide in places, do not produce direct distortions in the adjoining soil. The explanation may lie in the type of material and, more importantly, in the lack of vegetation cover. The surfaces of polygon furrows of Siberia, Alaska, and the Canadian Arctic are covered with turf or peat. This vegetation cover seems to retain the effects of horizontal movement in the active layer.

Another cause of the lack of soil wedge impact on the polygon layer is the following: raised borders are known to occur in large polygonal cells up to 20 m in diameter. Even adjoining cells are of different surface shape: small ones are convex and large ones are concave (Jahn 1972). It is very likely that there is a definite limit to the polygon size that determines convexity or concavity. Most of the examples taken from the Van Mijenfjord on Spitsbergen represent the convex nets.

Based on the observations made in the Van Mijenfjord area in the summer of 1978, the following conclusions are drawn:

(1) In addition to ice wedges, which commonly occur under Arctic climatic conditions, there also exist active-layer soil wedges, with widths approaching 0.5 m. They are similar to structures known from cold continental regions, such as Siberia.

(2) These structures are linked to polygonal cells 1-6 m in diameter in fine debris devoid of vegetation.

(3) Active-layer soil wedges need not be dynamic and do not necessarily cause or contribute to thrust distortions in the bordering soil.

(4) The size of frost cracks determines the size of the material deposited in the crack. Water is instrumental in moving debris into the cracks.

(5) Soil wedge structures exist and are developing today in the Van Mijenfjord area. Thus, they are elements of the present Spitsbergen climate. Structures of this type are known from areas of the periglacial Pleistocene zone of Europe and have generally been interpreted as evidence of a climate closer to that of Siberia than to that of Spitsbergen. The Van Mijenfjord area wedges point to a possibly different climatic interpretation of Pleistocene wedge structures.

The author wishes to express his appreciation to Dr. A.L. Washburn for his critical reviews and thoughtful comments on the manuscript.

FROST HEAVE MITIGATION AND PERMAFROST PROTECTION FOR A BURIED CHILLED-GAS PIPELINE

H. O. Jahns and C. E. Heuer
Exxon Production Research Company, Houston, Texas 77001 USA

The problems of frost heave and thaw settlement are analyzed for a gas pipeline buried across discontinuous permafrost terrain. First, possible operating temperatures are evaluated, and chilling the gas below the freezing point is concluded to be the best way to minimize geotechnical problems. Next, a reasonable lower limit for the gas temperature is determined. This temperature is then used to calculate freeze bulb sizes for insulated and uninsulated pipe in initially thawed, frost-susceptible soil. The results for insulated pipe demonstrate that the additional heat input caused by the construction surface disturbance can prevent formation of a permanent freeze bulb and, therefore, preclude significant heave. However, if the soil is initially frozen and thaw-unstable, and the gas temperature is near the freezing point, or the pipeline is insulated, then the surface disturbance can also cause thaw settlement. This can be prevented by using a row of heat pipes along both sides of the pipeline. The heat pipes can keep initially frozen ground frozen, and freeze initially thawed ground without causing heave.

INTRODUCTION

In contrast to most crude oil, natural gas can be transported through pipelines at cold temperatures, and power requirements decrease with operating temperature. It is common practice, therefore, that gas pipelines across permafrost terrain are designed to operate at temperatures below 0°C. This allows the pipeline to be buried in thaw-unstable permafrost. Examples are the Tunus-Yakutsk Pipeline in Eastern Siberia and the Alyeska fuel gas line on the North Slope of Alaska. Both of these are in areas of continuous permafrost where the mean annual ground surface temperature is well below the freezing point. Due to the relatively small flow rates in these pipelines, the gas temperature approaches the ambient soil temperature after flowing through only a few kilometers of buried pipe.

The relatively simple concept of an "ambient" temperature gas pipeline in permafrost does not apply to major trunk lines in Alaska and Canada. The reason is twofold: (1) gas transmission lines to southern markets have to cross the zone of discontinuous permafrost where soil conditions below the active layer alternate between frozen and unfrozen at irregular intervals, and (2) the flow rate in a trunk line is usually so large that heat transfer through the pipe wall is no longer sufficient to maintain the gas temperature close to that of the surrounding soil. Significant temperature differences develop due to the Joule-Thomson effect and due to seasonal and climatic variations in ambient soil temperature.

Since both the gas and the soil temperature are changing along the line, and since both frozen and unfrozen ground must be traversed, at least one of the following conditions will of necessity occur: (1) a "warm" pipeline ($> 0^{\circ}\text{C}$) located in initially frozen ground, or (2) a "cold" pipeline ($< 0^{\circ}\text{C}$) located in initially thawed ground. Condition 1 is of concern where the permafrost below the pipe is ice-rich, subject to settlement during thawing, while condition 2 is of concern where the soil below the pipe is frost-susceptible, subject to heave during freezing.

Both of these conditions could be avoided by

elevating the pipeline above ground. However, despite the potential geotechnical problems, a buried pipeline is preferred because it provides much better security. It also avoids exposure to very cold air temperatures. A winter shutdown could cause condensation of heavier hydrocarbons and could also cause the pipe steel to behave in a relatively brittle manner. Insulation alone cannot prevent these problems.

WARM VERSUS COLD PIPELINE

The gas temperature can be controlled at compressor stations which are located typically 100-200 km (60-120 mi) apart. Thus, the designer can choose between the warm and the cold operating mode for each segment of the pipeline between two compressor stations. The appropriate choice will depend on the extent to which either condition 1 or 2 (discussed above) would occur in the particular pipeline segment, and on the complexity and cost of mitigative measures that would have to be used to prevent excessive pipe deformation due to settlement or heave.

In addition to the cold and warm operating modes, "hybrid" modes have also been proposed with the rationale that, by straddling the freezing point, both thawing and freezing around the pipeline could be minimized. For instance, the gas might be cooled below the freezing point during the summer and warmed above the freezing point during the winter. However, as previously discussed, unavoidable temperature changes in the flowing gas, as well as local climate variations along the pipeline route, make it impossible to achieve a perfectly "balanced" design everywhere along a given pipeline segment. Furthermore, seasonal oscillations of gas temperature around the freezing point may have a very undesirable effect resulting from the repeated formation and disappearance of small temporary thaw bulbs under the pipe in initially frozen ground: where the thaw bulb is water-saturated, the pipe could experience frost jacking due to hydrostatic pressure, even if the soil below the pipe is not frost-susceptible. Thus, the hybrid operating mode does not appear attractive.

There is a similar argument against the warm pipeline mode. A warm pipeline in ice-rich permafrost will have to be insulated to limit thaw settlement. However, where the frozen soil is near 0°C, insulation cannot fully prevent the formation of a small thaw bulb below the pipe during the summer. In order to prevent long-term growth of this thaw bulb, it must be allowed to freeze back, at least partially, during the winter. Thus, the pipe may be subject to seasonal frost jacking.

Another consideration relates to the construction surface disturbance: removal or disturbance of the natural organic layer in permafrost terrain usually causes an increase in the mean annual ground surface temperature. This shift in the thermal balance reinforces the effect of a warm pipeline, but it counteracts the effect of a cold pipeline. Thus, the net thermal disturbance will be smaller for a cold pipeline than for a warm pipeline operating at the same temperature differential relative to the freezing point.

Convective heat transfer by flowing groundwater has a similarly asymmetric effect. The thaw bulb around a warm pipeline in permafrost can be a starting point for thermal erosion unless running water is carefully diverted away from the pipeline. On the other hand, groundwater flow in initially thawed soil will retard or even prevent the formation of a freeze bulb around a cold pipeline.

From these qualitative considerations, it can be concluded that the cold pipeline mode will, in general, be the preferred alternative in discontinuous permafrost terrain; and that the optimum point for the transition from cold to warm pipeline operation will likely be near the southern limit of the occurrence of permafrost along the pipeline route.

Quantitative aspects of the thermal design of a cold pipeline in both permafrost and thawed ground are discussed in the following sections. The first subject addressed is the range of gas temperatures that will be encountered as the gas flows through a hypothetical pipeline segment between two compressor stations. This, then, will provide the boundary condition for an analysis of the soil thermal regime, and the assessment of special "mitigative" pipeline designs, for both thawed and frozen ground.

In considering special pipeline designs, it should be kept in mind that these will be needed only in certain types of soil and for certain combinations of ground and pipe temperatures. In fact, considerable efforts have been directed in recent years at minimizing the need for mitigative measures in connection with a cold gas pipeline (Myrick et al. 1982). Quantitative methods are being developed to predict pipe deformation due to frost heave and thaw settlement. Over most of a given pipeline route, the predicted deformation should be within allowable limits. Nevertheless, there is a need for special design options that can be used in those areas where the performance of a more conventional pipeline design would be either unacceptable or too difficult to predict.

GAS TEMPERATURE VARIATIONS

Gas temperature variations along the pipeline were calculated using a computer program which models the steady-state thermodynamic and gas dynamic phenomena associated with compressible flow of hydrocarbon mixtures. The program has been compared against field data and has been used to solve many different types of pipeline problems. Using a steady-state program is

acceptable because transients within the pipeline are much faster than transients within the soil. The pipeline diameter was 122 cm (48 in.), and the gas properties were based on gas produced from the Prudhoe Bay reservoir.

Heat transfer between the pipeline and the soil was calculated using "effective" heat transfer coefficients and "effective" soil temperatures as input to the pipeline program. Summer and winter values of these parameters were determined with a two-dimensional soil thermal simulator described later. For a range of constant pipe temperatures, the heat flux into the pipe was calculated throughout the year at periodic steady-state. Weather conditions typical of Fairbanks were used for the surface heat balance. The maximum and minimum values of the calculated heat flux were then plotted as functions of pipe temperature, and straight lines were obtained. The effective heat transfer coefficients were equal to the slopes of these lines, and the effective soil temperatures were equal to the abscissa intercepts. All the calculations were done for silt. Depending on the amount of insulation used, the time of year, and whether the silt was initially frozen or thawed, the effective heat transfer coefficient varied from 0.9 to 13.0 W/m²°C (0.5 to 7.5 Btu/hr-ft²°F), and the effective soil temperature varied from -6.7 to 8.3°C (20 to 47°F).

Figure 1 shows some results in the form of idealized gas temperature profiles between two compressor stations 160 km (100 mi) apart. This particular plot was calculated using winter heat transfer coefficients and soil temperatures for initially frozen silt and a flow rate of 56.6 Mm³/day (2 Gft³/day) at standard conditions. Initially frozen silt was used to obtain conservatively cool gas temperatures. An operational upper limit of -1.1°C (30°F) on gas temperature was assumed.

FIGURE 1 Gas temperature profiles.

The solid lines indicate the near-linear temperature drop along the pipeline segment that results from a combination of soil heat transfer and Joule-Thomson effect. On level terrain, the gas temperature would drop from -1.1°C at the compressor station discharge to about -8°C (17.6°F) at the end of the 160 km section, with the small indicated temperature range (-8.3 to -7.6°C) depending upon the fractional length of pipe that is insulated.

Superimposed on this idealized temperature profile will be the effects of adiabatic cooling and warming due to elevation changes on hilly terrain. This effect amounts to about a 0.7°C temperature drop per 100 m elevation increase (0.004°F/ft). The dashed lines in the figure indicate the resulting lower bound gas temperatures for a total relief of no more than 300 m (1,000

ft), which is typical for the bulk of an alignment across interior Alaska. The lower-bound temperatures only occur at the elevation peaks.

During the summer, there will be significant environmental heating of the gas in those portions of the line that are not insulated. This counteracts the Joule-Thomson effect, but gas temperature still decreases with distance. Therefore, the mean annual gas temperature at a particular point will be slightly higher than indicated by the curves in Figure 1, with the amount of the increase depending again on the length of pipe insulated.

It is concluded that at a flow rate of 56.6 Mm³/day, it should be possible to maintain the mean annual gas temperature above -9.4°C (15°F) along essentially the entire pipeline length in discontinuous permafrost. Exceptions would be a few high passes and ridge crossings. Lower gas temperatures would also result at increased flow rates. But sustained increased flow rates, rather than short-term peaks, are required to significantly affect the mean annual gas temperature. It is this mean annual gas temperature which determines the long-term growth of a freeze bulb below the pipe and the resulting heave rate in frost-susceptible soils.

Improved temperature control can be accomplished by the use of intermediate gas heater stations. For instance, if the gas were heated back up to -1.1°C at the midpoint in this hypothetical segment, the minimum winter temperature with 300 m relief would be raised from about -10.5°C (13°F) to about -6.7°C (20°F). Based on the thermal simulation results reported later in this paper, it does not appear likely that intermediate heating would be necessary at the nominal 56.6 Mm³/day flow rate. However, heater stations might be considered as a remedial measure in case frost heave problems are encountered unexpectedly, or as a means to allow higher gas throughput with a given set of compressor stations.

In the following sections, it will be assumed that the mean annual gas temperature for design purposes is in the range of -1.1 to -9.4°C, in the absence of intermediate heater stations.

THERMAL SIMULATIONS

Gas pipeline freeze bulb size and heat flux were calculated using a finite-element computer program which models transient, two-dimensional heat conduction with change of phase (Wheeler 1978). Different versions of the program have been used since 1969 on a variety of projects in Alaska and Canada, and the results have been compared against analytical solutions, laboratory data, field tests, and other programs. The program can handle a variety of boundary conditions, including a surface heat balance (Miller 1979).

The pipeline was assumed to be buried in a rectangular ditch below a horizontal ground surface. The pipe diameter was 122 cm (48 in.), and when present, the insulation thickness was 15.2 cm (6 in.). The trench was 2.1 m (7 ft) wide and 2.4 m (8 ft) deep, and pipe centerline was at a depth of 1.5 m (5 ft). The bottom boundary of the finite element grid was 15.2 m (50 ft) below the ground surface, the lefthand boundary passed through pipe centerline, and the righthand boundary was 12.2 m (40 ft) away from pipe centerline.

The native soil was assumed to be either silt or silty sand, and the trench backfill was assumed to be gravel. Thermal properties were calculated using standard correlations (Kersten 1949) and are given in Table 1.

TABLE 1 Soil thermal properties.

Soil	Silt	Silty Sand	Gravel
Dry Density (Mg/m ³)			
Frozen	0.80	1.60	2.08
Thawed	1.60	2.00	2.08
Saturation (% pore volume)			
Frozen	100	100	100
Thawed ¹	100	100	100
Specific Surface Area (m ² /g)	50	10	2.5
Conductivity (W/m-°C)			
Frozen	1.78	3.03	4.15
Thawed	1.52	2.82	3.24
Heat Capacity (MJ/m ³ -°C)			
Frozen	1.88	1.85	1.83
Thawed	2.76	2.41	2.34
Heat of Fusion (MJ/m ³)	215	124	69.3
HFUS ² (MJ/m ³)	200	120	68.2
ALP ² (K)	4.05	3.08	2.43
GAM ² (L)	0.263	0.238	0.249
Thaw Strain (% frozen length)	50	20	0
Heave Strain (% frozen length)	50	20	0

1. If soil initially thawed, thawed saturation reduced to 80%.
2. Unfrozen moisture parameters (Wheeler 1978).
3. Insulation conductivity = 0.0346 W/m-°C.

Unfrozen moisture was based on data reported by McGaw and Tice (1976). Although soil displacement due to freezing or thawing could not be directly accounted for, the thermal properties were adjusted to be consistent with the assumed strains of 50% for silt and 20% for silty sand. These strains were rather arbitrarily selected and were used for both heave and settlement. They were always based on the frozen length and are considered to be relatively high values.

The initial soil temperature distribution was uniform at either 0.06°C (32.1°F) for initially thawed soil or -0.06°C (31.9°F) for initially frozen soil. These temperatures are equal to the "effective" mean annual ground surface temperatures before construction, and they represent worst-case conditions for heave and settlement, respectively. The pipe was a constant temperature boundary, and the side and bottom boundaries of the finite element grid were no-heat-flux boundaries. For most of the simulations, the temperature of the top boundary was assumed to be constant and equal to the "effective" mean annual ground surface temperature after construction. This simplification greatly facilitated the parameter study described below. It was considered adequate to explore long-term pipeline performance and to draw preliminary conclusions. A few simulations used the surface heat balance boundary condition with Fairbanks weather. The results of these simulations were in general agreement with those obtained with the corresponding "effective" constant surface temperature and were used to determine seasonal variations. Additional surface heat balance simulations would be needed to develop the proposed design concepts in more detail.

FREEZE BULB PREDICTIONS

Two typical 30-year freeze bulbs for insulated pipe are shown in Figure 2. The pipeline is buried in silt, and at a temperature of -9.4°C. The larger freeze bulb is for a surface temperature of 0.06°C and has a maximum depth of 3.0 m (9.7 ft) below the bottom of the ditch. The smaller freeze bulb is for a surface temperature of 1.1°C (34°F) and has a maximum depth of 0.6 m (1.9 ft). The lower surface temperature represents an undisturbed surface, while the higher temperature represents a disturbed surface. The figure demonstrates that, by ignoring the surface disturbance, one tends to overestimate the rate of freeze bulb

FIGURE 2 Insulated pipe freeze bulbs.

FIGURE 3 Pipeline freeze depth and heave.

growth. Figure 3 illustrates this point further.

The plot shows predicted 30-year freeze depth below ditch bottom and the corresponding amount of heave as a function of the mean annual ground surface temperature for an insulated pipe. Heave was calculated by simply multiplying the freeze depth by the assumed heave strain. In the absence of a surface disturbance, the predicted heave is about 1.5 m (5 ft) for silt and a pipe temperature of -9.4°C . But this value decreases rapidly with increasing soil surface temperature, and goes to zero near 1.4°C (34.6°F). This shows the tremendous sensitivity of frost heave predictions for insulated pipe to slight changes in surface temperature.

These relationships will change with local design conditions. Gas temperatures will usually be higher than -9.4°C , reducing the heave potential. Most thawed soils will initially be warmer than 0.06°C . This, too, will reduce the tendency to form a freeze bulb. Soil type is important, too. For instance, in silty sand it appears that a surface temperature increase of only 0.8°C (1.4°F) would be sufficient to eliminate the freeze bulb (see Figure 3).

In contrast, large freeze bulbs will be formed around uninsulated pipe, even in relatively warm soil. For instance, with a pipe temperature of -9.4°C , silt, and surface temperatures of 0.06 and 1.1°C , the predicted 30-year freeze depths below ditch bottom are 9.0 and 8.3 m (29.6 and 27.1 ft), respectively, and are beyond the lower boundary of Figure 2.

The predicted amounts of frost heave are strongly dependent on the assumption regarding the heave strain of the soil. However, it is important to note that predictions for the zero-heave condition are independent of this assumption. The different abscissa intercepts in Figure 3 for silt and silty sand reflect mainly the difference in their thermal conductivity, and

not the difference in their heave strain: a no-heave design eliminates the need for accurate prediction of the heave strain in different soil types.

FROST HEAVE MITIGATION

The curves in Figure 3 are an expression of the fact that the heat source represented by the disturbed ground surface can offset the heat sink represented by a well-insulated cold pipeline. The important question then is whether one can count on a mean ground surface temperature increase of $1\text{--}2^{\circ}\text{C}$ ($2\text{--}4^{\circ}\text{F}$) above the freezing point in those situations where the ground is initially thawed. General experience in Alaska, and the results of specific field studies, indicate that this is likely to be the case. For instance, a study by CRREL conducted at a wooded site (Test Section C) near Fairbanks indicated a temperature increase of about 3.0°C (5.4°F) due to complete stripping of the vegetation (Linell 1973). According to Figure 3, an increase this large would prevent a permanent freeze bulb beneath an insulated pipeline for gas temperatures lower than -18°C (0°F). Other measurements by Esch (1982) demonstrate that stripping the organic layer and installing a thin gravel pad can significantly increase heat input to the soil during the summer. Additional field studies, like the above, are needed to quantitatively confirm the effect of the surface disturbance for a wide range of conditions.

Figure 4 is a schematic representation of the envisioned no-heave design with insulated pipe buried in initially thawed silt. To enhance the surface disturbance, the work pad would be extended over the ditch, and the organic layer would be removed a certain distance, perhaps 6 m (20 ft), beyond the ditch and be replaced by gravel to prevent surface erosion. Simulations with the surface heat balance instead of a constant temperature boundary showed that some seasonal freezing below the pipe may occur. However, due to the increased surface temperature, no long-term freeze bulb growth was predicted. For these simulations, the surface heat balance input data were calibrated by matching the 7.0 m (23 ft) thaw depth measured at the CRREL test site over a period of 26 years.

FIGURE 4 No-heave design.

The small amount of seasonal freezing below the pipe could be confined to the ditch backfill by providing perhaps 0.6-0.9 m (2-3 ft) of overexcavation. This design may not eliminate all frost heave everywhere along the line, but the number of exceptions should be limited.

It should be kept in mind that this approach is critically dependent on the quality of the below-ground pipe insulation. Local damage to this insulation could result in the formation of a freeze bulb and local heaving. Reliable methods will be required for field

inspection during construction and for repair of damaged insulation.

PERMAFROST THAW PREDICTIONS

The issue of permafrost protection requirements in warm permafrost will now be addressed. Two situations need to be considered: uninsulated pipe in continuous frozen ground, and insulated pipe at transitions between frozen and thawed ground. In both cases, a layer of boardstock insulation could be placed above the pipe to help limit thaw. A 15.2 cm (6 in.) insulation layer was assumed in the calculations.

Figure 5 illustrates the situation for uninsulated pipe. The upper curve indicates the predicted position of the thaw front in degrading permafrost after 30 years with a pipe temperature of -9.4°C . Initial soil temperature was assumed to be -0.06°C , and the mean annual ground surface temperature was assumed to be 2.8°C (37°F) as a result of the construction disturbance. This surface temperature is warmer than that used for the freeze bulb calculations, but it is still slightly less than that indicated by the Linell data for a stripped surface. Taking credit for revegetation by using a lower temperature was considered unconservative. The assumed soil type is silt. A potential dormant period between pipeline construction and startup was not modeled.

FIGURE 5 Permafrost degradation with uninsulated pipe.

As the figure shows, significant thawing occurs, down to about 4 m (12 ft) below the ground surface at a distance of 6 m (20 ft) from pipe centerline. However, the cold pipeline is effective in maintaining a substantial frozen region around the pipe, assuring its long-term stability.

The size of the frozen region is reduced as the pipe temperature is increased. At a pipe temperature of -1.1°C the remnant freeze bulb would extend less than 2 m (6 ft) from pipe center, which might not be large enough in view of the fact that the actual freeze bulb configuration may be smaller than the calculated one due to groundwater flow and soil settlement. Therefore, the pipeline operating temperature may need to be maintained below about -2°C (28°F).

Figure 6 shows the corresponding situation for insulated pipe. The pipe is now essentially eliminated as a heat sink in the ground and has very little effect on permafrost degradation. For a pipe temperature of -1.1°C , the 30-year melt front is almost 7 m (23 ft)

below the surface. This is close to the thaw depth measured at CRREL Test Section C. With the assumed 50% thaw strain, the predicted thaw subsidence would be on the order of 3.5 m (11 ft). Furthermore, in this case, there is not much benefit to be derived from cold gas temperatures, as shown by comparison between the curves for -1.1 and -9.4°C pipe temperatures. This means that insulating the pipeline to prevent heave could lead to settlement where permafrost is present.

FIGURE 6 Permafrost degradation with insulated pipe.

PERMAFROST PROTECTION

The problem of permafrost degradation was anticipated in the design of the Alyeska pipeline. It was solved there by the use of thermal piles. These are piles equipped with heat pipes which remove large amounts of heat from the ground during the winter to counteract the gradual warming of the soil due to the surface disturbance (Heuer 1979). A similar approach could be used for the gas pipeline.

Figure 7 shows a schematic representation of the proposed mitigative mode for permafrost protection. A row of free-standing heat pipes is placed on either side of the pipeline and embedded to a depth of perhaps 6 m or more. Permafrost degradation will occur under the work pad as it does now under the Alyeska work pad, but near the pipeline the ground would remain frozen, including the ditch backfill below the boardstock in-

FIGURE 7 Heat pipes for permafrost protection.

sulation. In marginal permafrost, the heat pipes could also be counted on to freeze thawed ground in the vicinity of the pipe to prevent the possibility of frost heave from a freeze bulb around the pipe. Experience with Alyeska and other applications of thermal piles indicates that the heat pipes themselves are generally not subject to heaving, even in thawed ground.

The rationale for the effectiveness of heat pipes in counteracting frost heave is based mainly on geometrical considerations. The long, vertical freeze bulbs around the heat pipes are inherently less conducive to vertical heave than the freeze bulb below a horizontal gas pipeline. Also, before the individual freeze bulbs coalesce, they would reduce the supply of water for ice lens formation directly beneath the pipeline. Thus, heat pipes may also be considered as a means for frost heave mitigation in areas where they are not needed for permafrost protection. For instance, heat pipes might be used as a remedial measure to arrest unexpected frost heave during pipeline operation.

The appropriate spacing of heat pipes along the pipeline may be about one pair every 3 m (10 ft). This spacing would allow the individual heat pipe freeze bulbs to coalesce after one or two winters. Thus, about 300 pairs of heat pipes may be required per kilometer of pipeline. This is about three times the number for Alyeska's thermal pile design, which was four heat pipes per pipeline support every 18 m (60 ft). However, the length of gas pipeline requiring this special protection is expected to be small, so that the total number of heat pipes should be much less than Alyeska's 120,000.

CONCLUSIONS

The optimum operating temperature of a large, buried gas pipeline crossing discontinuous permafrost terrain containing both thaw-unstable frozen soil and frost-susceptible thawed soil is slightly below the freezing point, just cold enough to prevent permafrost degradation in the vicinity of the uninsulated pipe. Calculations for a 122 cm (48 in.) diameter pipeline with 56.6 Mm³/day (2 Gft³/day) throughput and 160 km (100 mi) spacing between compressor stations indicate that it should be possible to maintain a mean annual gas temperature between -1.1°C (30°F) and -9.4°C (15°F). For this temperature range, the increased heat input resulting from the construction surface disturbance can be the same order of magnitude as the cooling effect of the pipeline. Where the soil is initially frozen, the surface disturbance can cause thaw settlement problems. However, where the soil is initially thawed, the surface disturbance can be beneficial. It can help prevent heave of the pipeline.

If the pipeline is well insulated in initially thawed soil, then only a slight increase in mean annual ground surface temperature is needed to prevent formation of a permanent freeze bulb. Without a permanent freeze bulb, no significant heave can occur. To take advantage of this effect, the pipeline design must enhance and guarantee the surface disturbance for the life of the pipeline: the organic layer should be removed from a strip perhaps 6 m (20 ft) wide on either side of pipe centerline and be replaced with gravel to prevent erosion and revegetation. One advantage of this approach is that a detailed understanding of frost heave and the mechanical interaction between a pipeline and heaving soil does not have to be developed. The design can be based on thermal considerations alone.

Thaw settlement can occur in initially frozen soil if

the gas temperature is relatively warm, or if the pipeline is insulated to prevent heave. The latter is likely at transitions between frozen and thawed soil, and it may not be practical to accurately map all these transitions. Heat pipes could be used in the general areas where transitions are expected. The heat pipes would be arranged in two rows, one on either side of the pipeline. They can keep initially frozen ground frozen, and freeze initially thawed ground without causing heave. Therefore, the design is not sensitive to the initial thermal condition of the soil.

The above results indicate that an enhanced surface disturbance, thick insulation, and heat pipes are promising design concepts for a chilled-gas pipeline. However, additional study is needed to develop these concepts in more detail. The three major areas are: (1) field tests to compare the soil thermal regime for several pairs of adjacent disturbed and undisturbed surfaces, (2) field and laboratory tests to develop a reliable pipeline insulation system, and (3) field tests and computer simulations to study the performance of an array of heat pipes. Work in these and other areas is currently underway (Myrick et al. 1982).

AN ANALYSIS OF PLANT SUCCESSION ON FROST SCARS 1961-1980

Albert W. Johnson¹ and Bonita J. Neiland²

²School of Agriculture and Land Resource Management, University of Alaska
Fairbanks, Fairbanks, Alaska 99701 USA

Plant succession on frost scars was studied at Ogotoruk Creek, Alaska. In 1961, 326 frost scars were marked for long-term study. The initial physical and biological measurements were repeated several times. In 1965, four transects were established and later revisited to learn if new frost disturbance is occurring. Frost scars at Ogotoruk Creek are convex, primarily oval areas of fine-grained soil with a modal size of about 1 m in diameter. They occur on surfaces of from 1-3° and cover up to 50% of the ground surface. Many frost scars show surface activity due to frost action, but repeated mapping of them indicates that they neither expand nor contract laterally. Repeated measurements along fixed lines suggest that new frost scars are not being formed at present. Plants invade bare areas at Ogotoruk Creek by seeds or vegetative reproduction. Plants growing on frost scars are subject to frost heaving, uplift and disruption from needle ice formation, and wind erosion and desiccation. A direct relationship exists between plant cover on frost scars and soil moisture surrounding the scar. During the 20 years of the study both positive and negative changes in plant cover were recorded. A consistent pattern of plant succession was not detected.

INTRODUCTION

On the wet, relatively flat bottomlands of the Ogotoruk Creek Valley, northwest Alaska (68°06'N, 165°46'W), two major kinds of tundra vegetation occur. On the wettest soils, sedge meadow vegetation consisting primarily of two species, *Carex aquatilis* var. *stans* (Drejer) Boott and *Eriophorum angustifolium* Honck, occurs. On better drained soils a sedge tussock meadow consisting mostly of *Eriophorum vaginatum* L. is extensive. The two types are often mixed where microtopographic differences produce a mosaic of moisture conditions. The two kinds of vegetation occupy approximately 55% of the Ogotoruk Creek watershed (Johnson et al. 1966), an area of about 100 km². The two vegetation types at Ogotoruk Creek are described more completely in Johnson et al. (1966).

A third kind of vegetation occurs between the upland vegetation of the slopes and the vegetation types of the valley floor. *Carex bigelowii* Torr & Schwein. is the most characteristic plant of several diverse communities which all together comprise about 4.6% of the area, or 458 h. In Johnson et al. (1966) they are referred to as "ecotone communities."

Scattered on the surface in these vegetation types are predominantly oval areas of frost disturbed soil commonly called frost scars or frost boils, or in the formal classification of Washburn (1956), nonsorted circles. They are common in the Ogotoruk Creek Valley, especially in sedge tussock tundra, where up to 50% of the surface may be covered by this patterned ground feature. Frost scars typically measure 1-3 m in diameter; their centers are usually convex, but they may be flat or depressed. Permafrost is deepest under the center of the scar and shallowest at its margins. They are sometimes covered by plants; but in the

majority of cases they are sparsely covered or are nearly bare.

At Ogotoruk Creek, frost features are important landscape features and probably play an important role in the dynamics of the plant communities. Nonsorted circles of this type are known from other areas of the Arctic (see especially Hopkins and Sigafos 1951). Because of the absence of long-term observations, relatively little is known of their genesis, growth, activity, relationship to environmental variables, or other details of their history or future. The colonization of frost scars by plants has been observed, but not followed long enough to determine if plant succession in the traditional sense occurs. Inasmuch as the usual longitudinal method utilized in successional studies does not work well in conditions of soil instability, it was decided to engage in a long-term study of frost scars and their vegetation in order to investigate the following questions:

1. Are frost scars forming under the present climate?
2. Do frost scars exhibit cycles of activity, i.e., initiation, growth, equilibrium, and senescence?
3. Does plant succession on frost scars follow regular and predictable courses?

Preliminary studies were conducted by Johnson (1960) who listed the kinds of patterned ground features present in the Ogotoruk Creek Valley and described the relationships between vegetation and frost features, emphasizing the three vegetation types in which frost action is most important.

In 1961, Neiland permanently marked 326 frost scars located in 24 one acre plots that had been previously established for the study of the vegetation of the Ogotoruk Creek Valley (Neiland et al.

1962, Johnson et al. 1966). She documented the physical details of each scar, mapped its dimensions on a 2 m grid, and described the kinds, amounts, and locations of plants on each scar. Each scar was photographed from a fixed point for future reference.

In 1962, 1963, and 1965, Johnson rephotographed 240, 242, and 299, respectively, of the scars established by Neiland. In 1965, 60 of the scars in 4 plots were remapped in order to determine if physical changes in the scars were detectable. In 1972, 15 of the plots were redescribed, mapped, and photographed, and in 1980 this was repeated for 13 of the plots.

In 1965, in an effort to identify any new areas of disturbance that may have occurred, four lines measuring 640, 305, 457, and 213 m, respectively, were established. Along each line, the areas of disturbance intersecting the line were measured and recorded. Two of the four lines were relocated in 1972 and the measurements repeated.

This paper will concentrate on the differences observed in 189 of 326 frost scars between 1961 and 1980. The detailed descriptions of frost scars made in 1961 will not be given here. Rather, changes, if any, in the physical dimensions of the scars and in the kinds and amount of plant cover associated with them will be emphasized.

OCCURRENCE AND SIZE OF FROST SCARS

Are New Frost Scars Forming Today?

The conditions under which frost scars originate are a matter of speculation, but it is assumed by some authors (e.g., Hopkins and Sigafos 1951) that they do so under the conditions of the existing climate. This belief is difficult to evaluate, because few, if any, studies have demonstrated it. If frost scars are forming today at Ogotoruk Creek, one should expect to find new scars appearing in a 20 year period. This is not the case. In the study plots at Ogotoruk Creek, no new frost scars have been detected from 1961 to 1980. Once formed, frost scars tend to be self-perpetuating because of differences between the temperature-moisture relations of the scar and its better insulated surroundings. It is possible, as has been proposed for sorted circles by Ballantyne and Matthews (1982), that following a period of initial activity under somewhat colder, wetter periods than those of today, nonsorted circles became more or less stable.

In an effort to establish an additional baseline against which the occurrence of new frost scars might be measured, four long lines were established in 1965. The areas of bare soil were mapped along each line in order to determine (1) if any new bare areas occurred and (2) if existing bare areas changed in extent. In 1972, two of the lines were again measured (Table 1). Five new bare areas were recorded along transect 3 in 1972, and 78 of the areas of existing bare soil remained essentially unchanged. The transects were not measured in 1980, but they should be examined again to determine if the 1972 observations are measuring errors, represent newly formed bare areas, or are areas on which renewed activity is taking place.

It is also stated in some of the literature on frost scars that they grow or become reduced in

area over a period of years. Hopkins and Sigafos (1951), for example, suggest that a frost scar can be enlarged under favorable years by marginal needle ice formation, and they speak of the "net growth of many scars."

Are Frost Scars Expanding or Contracting Today?

In order to test the idea that frost scars grow (or contract) in one or more directions, maps of frost scar area were compared among 1961, 1965, 1972, and 1980. An example of these comparisons is given for one scar as it was mapped in 1961, 1965, 1972, and 1980 (Figure 1). A potentially significant error occurs in making these determinations. The precise margin of a frost scar is a matter of interpretation--along any edge it may grade into undisturbed tundra without a clear distinction between it and its surroundings.

What is apparent from this example is that over the periods measured, relatively little change in the shape or areal extent of this frost scar has taken place. Of course, the time periods involved are short and the number of frost scars measured is rather small, but all of the data available support a conclusion that the conditions that occurred at Ogotoruk Creek between 1961 and 1980 did not favor the growth or contraction of frost scars.

The belief that new frost scars are arising or growing is encouraged by the appearance of new frost activity within the margins of the scar. At times the combined action of frost heaving due to the presence of subsurface segregated ice and of surface needle ice gives the appearance of intense activity on the scar surface. Neither form of cryogenic activity implies expansion of the areal extent of the scar. Scars that have been inactive for some time may show a burst of renewed surface activity. For example, at several locations along the Trans-Alaska Oil Pipeline haul road, renewed frost scar surface activity occurred where construction activities blocked drainages and apparently increased the amount of soil moisture in the scar surroundings.

PLANT SUCCESSION ON FROST SCARS

Plants invade the bare soils of frost scars by direct seeding and by vegetative growth from their surroundings. A direct relation exists between the degree to which plant invasion is successful and cover established and the average wetness of the site. Scars occurring in sedge meadow vegetation, the wettest of the three being considered here, show the greatest cover of vegetation (Figure 2); those in ecotonal plant communities, the least.

The results of the plant succession study are summarized in Table 2 and in Figure 3. Two major conclusions are apparent. First, the proportion of frost scars showing changes in plant cover between 1961 and 1980 is highest in the sedge meadow vegetation type and lowest in the ecotone communities. This, together with the data summarized in Figure 2, suggests that the availability of moisture may be a controlling factor in frost scar plant succession. Frost scars occurring in the wettest habitats show the greatest degree of change in plant cover--both positively and

negatively. The presence of moisture during the growing season favors plant growth but in the cold periods favors the formation of more soil ice which in turn disrupts plants.

Second, the proportion of frost scars in any vegetation type that show changes in plant cover increases with time. In 20 years the direction of change in plant cover has not been consistent on any single scar.

The discussion that follows describes only the gross changes that occur on frost scar surfaces. Detailed and quantitative descriptions are not given here.

The scars of the sedge meadow show the greatest fluctuations in plant cover of any of the three types (Figures 1 and 4). Plant cover on a few of these scars has changed by nearly 100% over the 20 year period. The large changes that occur in this type are nearly always the result of the establishment or the loss of one or two major species, particularly *Eriophorum angustifolium* or *Carex aquatilis*. The former is particularly susceptible to being uprooted (or detached from its rhizomes) by the effects of needle ice. At least temporary stability with complete plant cover can occur on scars of this type if they can maintain their cover long enough to produce an organic layer over the base mineral soil.

On scars occurring in *Eriophorum* tussock vegetation, changes in plant cover generally involve different species than is the case in sedge meadow vegetation. Some of the most noticeable changes on scars of this type involve tussock forming species, especially *Eriophorum vaginatum* and *Deschampsia cespitosa*. The latter, especially, seeds into the bare surface of the scar and forms small tussocks. These tend to persist and enlarge over several years, but they eventually decompose and are replaced by other tussocks in different locations on the scar. *Eriophorum vaginatum* shows the same kind of behavior, but it is not as abundant as an invader as *Deschampsia cespitosa* (Figure 5). In addition, once established it persists longer and grows to a much larger size. Because the pattern of change on these scars is more like a loss and replacement cycle than an invasion and subsequent elimination, changes in total cover tend to be small. Plant cover in general is lower on these scars than on those in the sedge meadow.

Plant cover on scars of the ecotone is very low, and changes are not obvious. Occasionally plants become established, usually by seeds, on these base gravelly surfaces, but they do not persist for more than a few years. Invasion of plants from the surroundings of the scar is very slow, if it occurs at all. The surface of these scars tends to be dry, and the substrate coarse and, during the growing season, very hard. Although little evidence of needle ice formation is seen in any of the scars of this type, they show substantial heaving from subsurface ice during the freezeup period. Of the three types of scars, these ecotonal ones as a group show the least changes over the 20 year period.

SUMMARY

This review of a very large number of observations on frost scars at Ogotoruk Creek emphasizes

changes that have taken place in the physical and biological characteristics of 188 frost scars between 1961 and 1980. In general, the evidence suggests that the physical dimensions of the scars have changed little in the 20 year period. Although surface activity is high on many frost scars, the lateral dimensions of the scars do not change, at least within our capability of consistent measurement. Neither is there conclusive evidence that new frost scars are forming at present.

Plant succession occurs on frost scars, but not in a directional or progressive sense. Rather it appears that on most frost scars, plant cover waxes and wanes as year-to-year climatic changes occur. Our data and observations suggest that plant cover is likely to be highest on frost scars occurring in the wettest habitats and least on those of the driest habitats. Although high levels of soil moisture encourage plant growth, they also create the most favorable conditions for the formation of soil ice, so it is also true that these frost scars show the greatest and most rapid changes in plant cover. Likewise, frost scars in the driest habitats change least over time. The idea of cycles of frost scar genesis, activity, invasion, and stabilization by plants and ultimate disappearance is not supported by this study. Indeed, the most striking feature of frost scars is their persistence.

The activities on frost scar surfaces involve an interplay of physical and biological phenomena. Only rarely do the biological forces achieve a transient dominance over what are fundamentally the powerful physical effects of the freezing and thawing of soil water.

RECOVERY AND ACTIVE LAYER CHANGES FOLLOWING A TUNDRA FIRE IN NORTHWESTERN ALASKA

L. Johnson¹ and L. Viereck²

¹U.S. Army Cold Regions Research and Engineering Laboratory,
Fairbanks, Alaska 99701 USA

²Institute of Northern Forestry, U.S. Forest Service,
Fairbanks, Alaska 99701 USA

An upland tundra fire, started by lightning, burned 48 km² near the Kokolik River (69°30'N, 151°59'W) in northwestern Alaska during late July and early August 1977. Permanent plots were established to monitor recovery of severely, moderately, and lightly burned areas as well as unburned tundra. During the following 5 years the original permanent plots and other portions of the burn were observed annually. Vegetative recovery was most rapid and active layer effects were least on the moist sedge-shrub tundra. Recovery was slower on a high-centered polygonal area and on severely burned tussock tundra. By August 1979 the sedge-shrub vegetation had largely recovered while both the polygonal ground and the tussock tundra were still readily recognizable as burned areas. Accelerated hydraulic and thermal erosion had occurred on some slopes, resulting in exposures of massive bodies of ground ice. Active layer thicknesses averaged 27 cm in the unburned areas and 35 cm within severely burned areas in August 1977 and reached a maximum at all but one site in August 1979. Depth of thaw decreased between 1979 and 1982 in the sedge-shrub tundra and in the lightly burned shrub tundra and remained at the same increased level through 1982 at all other sites.

INTRODUCTION

There has been increasing recognition of the importance and influence of tundra fires in the last decade (Viereck and Schandelmeier 1980). For example, numerous fires burned more than 200,000 ha of tundra in northwestern Alaska during the dry, hot summer of 1977 (Racine 1979, 1981).

This paper reports on a 1977 tundra fire, started by lightning, that burned 48 km² (4800 ha) of upland tundra located southwest of the Kokolik River in northwestern Alaska (69°30'N, 151°59'W). The fire was exceptionally large for a tundra fire north of the Brooks Range. Wein (1976) found that most arctic tundra fires are less than 1 km². Of five Arctic Slope tundra fires reported by Barney and Comiskey (1973) only one (1620 ha) exceeded 30 ha. The fire burned from approximately 26 July to 7 August 1977. Early observations of the fire and remote sensing analyses were reported previously (Hall et al. 1978, 1980).

SITE DESCRIPTION

The Kokolik River fire site lies on the boundary between the Arctic Coastal Plain and the northern hills of the Brooks Range. Maximum topographic relief in the area is approximately 100 m. Most of the rolling to flat upland areas are covered with sedge tussock tundra (Viereck and Dyrness 1980) dominated by Eriophorum vaginatum tussocks with scattered shrubs of Ledum decumbens, Betula nana, and Salix planifolia subsp. pulchra. Shallow drainage depressions and drained thaw lake beds are covered with a wet sedge and sedge-shrub tundra, Carex aquatilis, Eriophorum angustifolium, and Salix

planifolia subsp. pulchra being the important species. In one very localized area of exposed ridges there are small patches of mat and cushion tundra that were largely unburned by the 1977 fire. Along the streams that border the burned area are herbaceous snow-bed communities and shrub patches dominated by Salix planifolia subsp. pulchra and Salix lanata subsp. richardsonii. Much of the actual burned area was sedge tussock (Eriophorum vaginatum) tundra with smaller areas of wet sedge-shrub tundra.

The burn lies within the zone of continuous permafrost in northern Alaska. Active layer depths north of the Brooks Range average 30-50 cm with permafrost extending up to 625 m. Permafrost temperatures below the active layer range as low as -11°C, and the upper 1-10 m of soil may include large volumes of ice (Brown and Grave 1979, Osterkamp and Payne 1981).

This fire site is particularly interesting because of its extreme northern location. Most other tundra fire studies have been conducted at locations further south or in warmer climatic areas (Mackay 1977; Racine 1979, 1981; Wein and Bliss 1973; Weber 1975).

Therefore the Kokolik site offers an interesting comparison for both vegetation and permafrost changes following fire.

METHODS

The burn was visited by one or both of the authors yearly during late July to late August from 1977 to 1982. Due to the remoteness of the site, access was by float plane or helicopter, and not all study areas could be revisited each year. (See

Table 2 for areas visited.) In the summer of the fire, 1977, only the southeastern portion of the burn was observed. At that time three 1-m^2 quadrants were established in each of the following types of areas: severely burned tussock tundra, moderately burned tussock tundra, lightly burned shrub tundra adjacent to a stream at the fire's edge, and unburned tussock tundra. The estimates of fire severity were based upon visual observations of the percentage of biomass removed by the fire. All sites are within tussock area 1. Similar plots were established in August 1978 on high-centered polygonal ground, wet sedge-shrub tundra, and another burned and control (unburned) tussock tundra (tussock area 2) in the northeastern portion of the burn.

Our investigations were concentrated in the tussock tundra areas because it is the most wide-spread vegetation within the burned area. Controls were established only in this type. The unidentified vegetation type that was part of the polygonal complex seems to have a high density of shrubs. The polygonal and the wet sedge-shrub tundra were sampled because they represented the extremes (severe and light) of fire severity.

The following data were collected at each site unit: (1) depths of thaw, 5 depths/plot on burned plots and 5 depths within tussocks plus 5 depths between tussocks on unburned (control) plots; (2) total vascular plant cover, (3) total moss and liverwort cover; and (4) soil temperatures at 5, 10, 20, and 50 cm or until permafrost was reached. In addition, in 1978 the density of living and dead shrubs and tussocks on burned tussock tundra, the areal extent of frost boils in unburned vs. burned tussock tundra, and an estimate of relative biomass volume of cottongrass tussocks in unburned vs. burned areas were recorded.

RESULTS

Although vegetation regrowth on all parts of the burned area was rapid, the extent of change from the original vegetation after 5 years varied greatly depending upon the severity of the fire and the original vegetation. Data from tussock area 1 indicate the severity of the fire in this area. In August 1977 it was visually estimated that 80-90% of the tussock biomass had been consumed in the fire (Hall et al. 1978). In August 1978 tussock volumes were estimated in 5 m^2 of unburned (control) and 5 m^2 of burned tundra within tussock area 1. Burned areas averaged 30% of the tussock biomass of the control. This includes both residual (unburned) and new growth within burned areas.

Within tussock area 2 in August 1978 only 16% of the cottongrass tussocks (Figure 1) and none of the shrubs were regrowing on severely burned plots, while 78% of tussocks and 18% of shrubs were regrowing in moderately burned plots (Table 1). In contrast, all shrubs survived on the lightly burned wet sedge-shrub tundra site, and by August 1978 only some singed mosses and a few burned shrub leaves indicated that the area had even been burned.

Another indication of the fire severity is the increased areal extent of frost boils on burned vs. unburned areas of tussock area 1. Exposed areas of mineral soil averaged 52% greater in severely burned

FIGURE 1 Cottongrass tussocks one year after the burn (August 1978). Only 16% of the tussocks regrew in the severe burn in tussock area 1 after at least 70% of the tussock biomass was consumed by the fire.

TABLE 1 Status of Shrubs and Cottongrass Tussocks One Year After the Burn (August 1978). Based on Three 4-m^2 Plots.

Vegetation type	Severity of burn	
	Severe	Moderate
Tussocks/ m^2		
Live	0.8 (16%)	6.4 (78%)
Dead	3.9 (84%)	1.8 (22%)
Shrubs/ m^2		
Live	0	0.9 (18%)
Dead	4.6 (100%)	4.2 (82%)

FIGURE 2 An area of massive ground ice near tussock area 1 exposed by hydraulic erosion and thawing 5 years after the burn (July 1982).

FIGURE 3 Post-fire active layer thicknesses from August 1977 to July 1982. Control, moderate, and severe burn intensities are in tussock area 1 with predominantly sedge tussock tundra. Points shown are means ($n = 30$ for control and 15 for others) with standard errors greater than 1.5 denoted by I.

areas than in unburned tussock areas, based upon measurements of comparable 30 m^2 sections. This increase was due, at least in part, to combustion of the thin layer of litter and living plants covering the edge of frost boils. However, the fire may also have intensified frost action (Hall et al. 1978), which could increase the areal extent of frost boils.

At least two areas of the burn had massive ice exposed as a result of hydraulic and thermal erosion on slopes. One of these was observed in August 1978 near the eastern shore of the northernmost lake. This area seemed to be stabilized by August 1981, but another exposure of massive ground ice was observed in July 1982 near tussock area 1 (Figure 2).

Active layer thickness increased at all burned sites for at least 2 years after the fire (Fig. 3). Maximum thicknesses at burn sites were recorded in August 1979 except for the maximum overall measurement of 61.0 cm (August 1981 polygon). In contrast, active layer thicknesses in the control plots remained constant with less than 3 cm of annual variation for four of the years and a 6-cm annual variation for 1981. There were unburned (control) plots for comparison only in the tussock tundra areas at tussock areas 1 and 2. The active layer in severely burned plots in tussock area 1 increased by an average of 13.6 cm between August 1977 and August 1979 and was 20 cm thicker than the comparable control plots. These differences persisted through August 1982.

Although no quantitative data are available, melting and subsidence of individual ice wedges did occur following the fire. This was especially noticeable in the polygon study units where surface relief increased for at least the initial 2-3 years of the study. Surface relief also seemed to increase within the severely burned plots in tussock area 1.

Soil temperatures in the active layer were also affected by the fire and its intensity. Although soil temperatures could be measured only once each summer, the measurements should reflect the degree of summer warming of the profile since we visited the sites near the end of the short summer season.

FIGURE 4 Soil temperature profiles in unburned tussock tundra, moderately and severely burned tussock tundra, severely burned polygonal area, and lightly burned sedge-shrub tundra. Temperatures were recorded at the Kokolik fire site on 20-21 August 1980 ($n=3$) (TA1 = tussock area 1).

Figure 4 shows the results of the soil temperature measurements taken on 20-21 August 1980. These soil temperature profiles are similar to those obtained in other years. The unburned tussock tundra soil-temperature profile for 20 August 1980 is representative of this vegetation type in this area. At 5 cm the temperature was only 1.6°C and temperatures decreased with depth, reaching 0°C at the active layer-permafrost boundary at only 27 cm. For the tussock type and the polygonal area, the severe burn has resulted in soil temperatures that average 2° to 3°C warmer throughout the thawed zone compared with unburned tussock tundra. This warming effect occurs to depths of at least 50 cm.

The moderately burned tussock tundra has soil temperatures intermediate between those of the control and the severely burned sites. The wet sedge-shrub tundra, which was only lightly burned and recovered rapidly, had higher temperatures at 5 and 10 cm (similar to those of the severely burned

TABLE 2 Percent Plant Cover on Burned and Control (Unburned) Areas, Kokolik River, Alaska.

-- = no data collected that year.

sites), but at depth they were lower (similar to the moderately burned site).

Vegetation recovery (Table 2) was rapid for the first 2-3 years, but by August 1979 recovery rates had dramatically decreased or stopped on most study areas. For example, severely burned plots on tussock area 1 had 30% total vascular plant and 20% total moss and lichen cover in August 1979, and only 33% cover for each category in late July 1982. Vegetation cover largely paralleled changes in active layer thickness. Interesting exceptions were the sedge-shrub area, which had rapid recovery of mosses between August 1978 and August 1980, and the polygon area, which, although totally revegetated by mosses and the liverwort *Marchantia polymorpha* by August 1979, also had some recovery of vascular plant cover by 1982.

DISCUSSION

The Kokolik fire offers several interesting comparisons with other tundra fire studies. Although there was limited exposure of massive ice, most of the impact upon the permafrost seems to have been chronic, rather than catastrophic. Active layer thicknesses continued to increase for only 2 years, but remained deeper on more severely burned portions of the fire at least 3 more years. It is uncertain how long these increased thicknesses will persist. The reported increases in the active layer thicknesses are a minimum indication of changes in permafrost. The observed subsidence due to ice melting was not measured, although Mackay (1977) ob-

served subsidence of 50 cm following a fire near Inuvik. All or an unknown portion of the organic layer at Kokolik was consumed, particularly in the severely burned areas. Racine (1981) estimated that at least 5-15 cm of organics were consumed by fires on the Seward Peninsula.

More southerly fires reported thawing that continued to increase for longer periods. At Inuvik (Mackay 1977) and near Fairbanks (Viereck 1982) thaw depths were still slowly increasing 8 years and 9 years, respectively, after fire. These results are consistent with the hypothesized cooler climatic conditions at the Kokolik site, although the paucity of climatic data makes correlations impossible.

Vegetation recovery was quite distinct, at least on severely burned portions of the Kokolik fire. For example, shrub recovery in severely burned areas (tussock areas 1 and 2, polygon) was still very limited 5 years after the fire (less than 10% by August 1982), although controls in tussock tundra averaged 30-40% shrub cover. The dramatic and rapid recovery of the liverwort, *Marchantia polymorpha*, on the severely burned polygonal area is also noteworthy. Since no liverwort was observed in unburned tundra, it either regenerated from buried spores or else spores are readily and widely dispersed in tundra. In contrast, Racine (1981) reports a very low total cover (1% or less) of *Marchantia* in burned areas.

Racine (1981) also reported low recovery rates for shrubs, but this was only one year after the burn. In contrast, tundra fires in four more southerly or warmer areas averaged 55% of their original shrub biomass only 2-3 years after the burn (Wein and Bliss 1973).

CONCLUSIONS

The Kokolik River fire shows the following:

1. Massive thermal and hydraulic erosion can continue at specific sites for at least 5 years after a tundra fire.
2. Increased depths of thaw can persist for at least 5 years on severely burned portions of tundra, although no new increases were seen after 2 years.
3. Vegetation recovery, although initially quite rapid (2-3 years), dramatically slows or halts on many parts of the burn between years 3 and 5. In addition, the species composition of burned areas may remain quite different (especially shrubs and lichens) for at least 5 years after a tundra fire.
4. Severe tundra fires can in fact kill many shrubs and cottongrass tussocks, presumably by elevating soil temperatures during combustion of the organic mat.

PERFORMANCE OF AN INSULATED ROADWAY
ON PERMAFROST, INUVIK, N.W.T.

G.H. Johnston

Division of Building Research, National Research Council Canada,
Ottawa, Ontario, Canada K1A 0R6

In 1972 four insulated and two uninsulated test sections were installed and instrumented on the Mackenzie Highway (a gravel-surfaced, all-season road) near Inuvik, N.W.T., to evaluate the use of extruded polystyrene board insulation to control permafrost degradation. Two test sections were insulated with a 90-mm layer of insulation, another with a 50-mm layer, and a fourth with 115 mm. Preliminary analysis had indicated that an optimum insulation thickness of about 90 mm would be required. Ground temperature and settlement observations over a 6-year period showed that permafrost aggraded under all insulated test sections, whereas under the uninsulated (control) sections it receded by as much as 60 cm. Approximately 60 cm of settlement was experienced by the control sections, about 30 cm by the 50-mm insulated section, and little or none by the sections having 90 and 115 mm of insulation. The 90 mm of insulation was shown to provide adequate protection against thawing; 50 mm of insulation was not sufficient.

INTRODUCTION

A layer of insulation placed in an embankment constructed on permafrost can prevent or control thaw penetration and settlement and reduce the quantity of fill required. In 1972 a field study was undertaken by the Canadian Government Interdepartmental Committee on Highway Insulation to evaluate the performance of an insulated, gravel-surfaced roadway constructed on permafrost. Cooperating with the Division of Building Research, National Research Council Canada, were the Departments of Indian and Northern Affairs, Public Works, and Transport Canada, and Dow Chemical of Canada Ltd. Several insulated and uninsulated test sections were constructed on the Mackenzie Highway about 22 km east of Inuvik in April and September 1972. Extruded polystyrene foam boards were placed in the road embankment and ground temperatures and settlements were measured. Design and construction of the test sections and the results of observations made during the period 1972-1978 are summarized.

SITE CONDITIONS

Climate

The mean annual air temperature at Inuvik for the 24-year period 1958-1981 is -9.7°C . For the same period the mean air freezing and thawing indices are 4,690 and 1,210 degree-days Celsius (DDC). Air temperature observations were made at the test site from July 1974 to July 1978. Some mean annual air temperatures and the freezing and thawing indices for Inuvik and the test site are given in Table 1. It is somewhat colder at the test site than at Inuvik, due mainly to more severe winters, as indicated by the freezing indices; thawing indices for both sites are similar. The number of days having mean temperatures below and

above freezing were almost identical at both sites for the periods noted.

Terrain

The test site is relatively flat, but the entire area is covered with large hummocks. Depth of thaw in undisturbed areas varies from 15 to 120 cm. Permafrost extends to depths exceeding 100 m in the Inuvik area, which lies within the continuous permafrost zone. Site investigations showed that the soil profile consists of a layer of organic material 15-60 cm thick underlain by grey, silty clay to a depth of 3-4.5 m. Beneath the silty clay is a dense grey, sandy silty till extending to at least 18 m. The organic layer contains typical random inclusions and thin lenses of ice; the layer of silty clay is ice-rich, containing as much as 50% ice by volume, mainly in the form of lenses from hairline to 2.5 mm thick. The underlying till matrix is generally well bonded with ice, but does contain occasional lenses up to 10 mm thick.

DESIGN OF TEST SECTIONS

Because of the complex nature of the layered embankment/subgrade system and the variable surface thermal conditions, numerical methods for ground thermal analysis were used to predict the optimum thickness of insulation to be used and the changes that would occur in the ground thermal regime (Goodrich 1974a,b). The basic profile consisted of 60 cm of gravel, a layer of insulation, and 45 cm of gravel over an ice-rich silt clay subgrade. Several computer runs were made using assumed values for ground temperature distribution, physical and thermal properties of the subgrade and fill materials, and seasonal fluctuations in air and ground surface temperatures. The ground surface temperature was assumed to be either the same as the

INSTRUMENTATION

air temperature or several degrees warmer and to vary sinusoidally during the year. Various thicknesses of extruded polystyrene foam insulation were considered, as well as construction under winter (subgrade completely frozen and fill placed on a snow cover) and summer (active layer thawed) conditions. The road surface was assumed to be free of snow during the winter. Observations at Inuvik indicated that the mean annual ground temperature at a depth of 15-30 m was about -3.3°C .

The results of these computations indicated that an optimum thickness of about 90 mm of extruded polystyrene insulation would be required to prevent thawing of the subgrade below the original ground surface at the center of the roadway. Edge effects from the side slopes were not included in the calculations, nor were changes in geometry that might occur as a result of settlement caused by thawing of the subgrade. The analysis also indicated that major changes in the ground thermal regime would occur during the first 5 or 6 years following construction, and that equilibrium conditions would not be reached until some time later. It showed that if insulation were placed during the summer or fall, the thawed layer underlying it would not refreeze for several months, so that the full advantage of insulation would be lost during the first summer. At least 2.5-3 m of gravel fill would be required to prevent thawing below the original ground surface under an uninsulated gravel embankment. This has been verified at the Inuvik airstrip (Johnston 1982).

CONSTRUCTION OF TEST SECTIONS

Test sections containing different thicknesses of insulation were installed under both winter and summer conditions. Two 38-m insulated test sections separated by a 38-m uninsulated (control) section were constructed at each of two test sites. The "winter" site was constructed in April 1972 and the adjacent "summer" site in September 1972. The width of the layer of insulation at all test sections was 11 m. No special measures were taken to insulate or protect the slopes.

The right-of-way had been cleared by hand of trees and brush early in 1970. Construction of the Mackenzie Highway south from Inuvik (Huculak et al. 1978) began in late summer 1971 and by late November a 0.6-1-m thick "pioneer" fill had been placed across the test area. To construct the test sections about 0.6 m of this fill was removed by bulldozer and ripper. The insulation boards (each 600 by 2,400 mm) were then placed by hand and secured by 150-mm-long steel spikes driven into a 15-cm thick bedding layer of relatively dry silty sand. All joints between boards were staggered horizontally and vertically (where more than one layer of boards was used). About 0.6 m of relatively dry sandy gravel was backfilled over the insulation by bulldozer and carefully rolled on the boards to prevent displacing them. A grader was used to shape the embankment to the desired section. A plan showing the layout of the test sections is given in Figure 1 and construction operations at the sites are shown in Figure 2.

Thermocouples were installed to measure temperatures in the fill above and below the insulation to depths of about 6 m below the roadway and 15 m below the ground surface in undisturbed areas at both sites. The location of all cables is shown in Figure 1 and a typical arrangement of sensors at one location is shown in Figure 3. Temperatures were read manually two to four times each month until June 1974, when a specially designed automatic data acquisition system was installed to record temperatures at 360 points every 1-2 h on magnetic tape. Observations were terminated in August 1978 when the equipment was damaged by vandals. Four brass plates were installed in each of the six test sections to monitor settlements (Figure 1). Once or twice each year surveys were made to determine the plate elevations and changes in the shape of the embankment. A special deep bench mark was installed to ensure that a reliable datum was available for elevation survey control.

OBSERVATIONS AND DISCUSSION

The annual thaw pattern and settlement under the center of the road at four of the test sections are shown in Figure 4. In September 1973, 1977, and 1982, trenches were excavated across the road at each of the insulated sections. Three cross-sections showing conditions in 1972 (as built) and in September 1982 are plotted in Figure 5. Differences in the positions of the insulation layers indicate actual movements that have occurred in the 10-year period; differences in the shape of the roadway do not reflect the total settlement since fill was added to maintain a suitable road surface.

Changes in the ground thermal regime under the center of the 90-mm insulated section at the winter site are illustrated in Figure 6. Isotherms show the variation in ground temperature under and adjacent to the winter site insulated and uninsulated test sections (Figure 7). They represent fall and late winter conditions, when ground temperatures are nearing their warmest and coldest values.

Considerable settlement occurred in the control sections (Figure 4). At the winter site total settlement was about 55 cm; approximately 36 cm of this occurred during the first thaw season, due partly (9 cm) to melting of the compacted snow layer under the pioneer fill. The remaining settlement is the result of compression of the thawed fill and subgrade materials caused by the weight of the embankment and, to a lesser extent, traffic loading. Total settlement measured at the summer site control section was much less, averaging about 30 cm. A great deal of settlement (not measured) had occurred during the summer prior to construction of the test sections in the fall of 1972. Thus, observed settlement is due mainly to compression of subgrade soils as thawing of the permafrost occurred.

About 30 cm of settlement occurred at the center of the 50-mm insulated section; again, most of it took place in the first thaw season. Settlement of the 90- and 115-mm insulated sections was negligible. About half of the 15 cm of total settlement experienced by the 90-mm section at the winter site occurred in the first two thaw seasons. Little or no settlement of the two insulated sections occurred at the summer site.

At all test sections settlement of the embankment near the shoulders was from 3-15 cm greater than that at the center of the road. Surveys since 1978 indicate that settlement of the control sections and of the 50-mm insulated section is still continuing, but at a greatly reduced, almost negligible rate. No further significant settlement of the other insulated sections has been observed.

As predicted, freezeback of the subgrade under the summer site insulated sections did not occur until 3 to 4 months after the active layer at the control section and undisturbed areas had refrozen (Figure 4). Between 1972 and 1978 the permafrost table beneath the uninsulated control sections was lowered from 30 to 60 cm. Beneath the insulated sections, however, it rose almost to the bottom of the embankment (i.e., to the original ground surface) under the 50-mm insulation, and where the insulation was thicker it was raised and contained within the embankment.

The foregoing applies to the center of the road and much of the embankment width (Figure 5). As expected, thaw penetration was significantly greater under the slopes. This resulted in considerable sloughing and cracking of the slopes, and owing to the irregular and sharply dipping thaw plane the insulation settled differentially, cracked, broke, and moved outward. The major movements occurred during the first 3-4 years when substantial cracking occurred inside the shoulders. Since then the shoulders and slopes have essentially stabilized in most areas, although some minor cracking and sloughing still occurs.

The marked influence of the insulated and uninsulated embankments on the ground thermal regime is illustrated in Figures 6 and 7. In general, the initial effect was a lowering of ground temperatures to a depth of about 5 m and an increase in temperature amplitude. At all test sections a return to natural conditions is clearly taking place and for most practical purposes equilibrium appears to have been reached by the end of the 6-year study period.

Snow cover plays an important role with respect to the ground thermal regime. During the winter, snow is ploughed from the road surface and deposited on the shoulders and slopes, substantially retarding removal of heat from the underlying ground (Figure 7).

CONCLUSIONS

Observations over a 6-10 year period at several insulated and uninsulated test embankments constructed on ice-rich permafrost on the Mackenzie Highway near Inuvik, N.W.T., confirm that insulation can be used to great advantage to prevent or control thawing of frozen subgrade soils and reduce the quantity of fill required. The predicted 90-mm optimum thickness of extruded polystyrene insulation has given satisfactory protection against thawing at this site; 50 mm of insulation is not adequate. Although no special measures were incorporated to prevent anticipated problems with cracking and sloughing of the shoulders and slopes, it is clear that they are needed, especially if the roadway is to carry any volume of heavy vehicles. On the other hand, it appears that relatively stable conditions will prevail within 5-6 years of construction. During that period only limited maintenance was required, although admittedly traffic volumes and loads were very light.

Construction procedures will have to be modified somewhat if synthetic insulation is used extensively. For satisfactory long-term performance a suitable levelling course must be placed on the ground surface and the backfill carefully placed on top of the insulation to prevent damage and displacement. It is apparent that the most opportune time for construction of an insulated embankment is the early spring, when the snow cover has just disappeared and the ground is still completely frozen. Unless suitable dry materials have been stockpiled in advance or are available in easily excavated borrow pits, however, procurement of good fill may be a problem at that time of the year.

ACKNOWLEDGMENTS

Many people, too numerous to mention individually, participated in the project at various times, and the author is grateful to them all for their cooperation and assistance. He is indebted particularly to J.C. Plunkett for his unflagging assistance and enthusiasm through all stages of the project. This paper is a contribution from the Division of Building Research, National Research Council Canada, and is published with the approval of the Director of the Division.

THE FROST SUSCEPTIBILITY OF GRANULAR MATERIALS

R.H. Jones¹ and K.J. Lomas²

¹University of Nottingham, Nottingham, U.K.

²Loughborough University of Technology, Loughborough, U.K.

The frost susceptibility and suction characteristics of fifteen granular materials ranging from silty soils to crushed rock sub-base aggregates were determined by the British Transport and Road Research Laboratory (TRRL) test and an osmotic suction technique, respectively. The test specimens were prepared at a number of standardized gradings and compacted to their maximum density at optimum moisture content. The heaves after 250 hours ranged from 2 to 50 mm so that both frost susceptible and non-frost susceptible materials were included. The results for all but one of the materials lay on a single curve relating frost heave to $\theta_{2.5}$, the total volumetric water content at a suction of pF 2.5 (31 kPa). Using the segregation potential approach it appears that there is a characteristic suction that controls the average permeability of the frozen fringe. For most of the materials considered, this suction approximates to pF 2.5. Materials with $\theta_{2.5}$ less than 9% were non-frost susceptible, but tests are required on many more materials to establish whether this relationship has general validity.

INTRODUCTION

The British Transport and Road Research Laboratory (TRRL) frost susceptibility test has been revised recently; self-refrigerated units (SRU's) have superseded cold rooms, specimen preparation has been improved, and the test has been shortened (TRRL 1981). The results of a study carried out under contract to TRRL in which testing in the SRU and the cold room was compared have been reported elsewhere (Lomas and Jones 1981). During that investigation the frost susceptibility of four naturally occurring sandy gravels and two crushed rock sub-base aggregates were determined. Earlier or associated investigations provided data about six more crushed rock sub-bases, a silty soil and mixtures of sand and limestone filler, which had gradings equivalent to those of silty soils. These materials varied from non-frost susceptible to very frost susceptible in the TRRL test.

Previous work had shown that the frost susceptibility of porous limestones could be related to the rock suction characteristics (RSCs) determined by an osmotic technique (Hurt 1976, Jones and Hurt 1978). In the present paper the frost susceptibility is related to the aggregate suction characteristics (ASC). (The ASC reflects the distribution of pores both within and between the particles, unlike the RSC, which characterizes only the within particle pores).

MATERIALS

The authors were concerned jointly with series 100 (the first six aggregates listed below) and series B tests. Hurt (1976) and Thompson (1981) undertook series (H) and (T), respectively. Brief descriptions of the materials are given below and in Table 1.

Ashton Keynes (102): A sand and gravel consisting of weathered fragments of Jurassic Limestone.

Spencers Farm (103): A flint hoggin (gravel-sand-fines mixture).

Stanley Ferry (106): A flood plain sand and gritstone gravel.

Woodhall Spa (114): A sandy hoggin containing flint and chalk particles.

Croft (105): A crushed granite with some honey-combed particles.

Dene (119) (B) (T): A crushed carboniferous limestone.

Whin 2 (B) (T): A crushed fine grained dolerite containing some vesicles up to 5 mm across and phenocrysts.

OOL2 (B): A fine grained calcitic mudstone with shell fragments.

OOL1 (H): Oolitic and shelly limestone.

DOL (H): Buff dolomitic limestone.

MIC (H): Yellow microcellulitic calcite/dolomite.

CAL (H): Grey or yellow dolomitic limestone.

Sand limestone filler mixtures (SF): Standard Leighton Buzzard sand (600 to 300- μ m fraction) was mixed with various proportions of limestone filler to provide reference materials corresponding in grading to silty sands.

Attenborough silt: A non-plastic silt obtained from the washings at a local gravel pit.

Gradings

The materials of series 100 were washed on a 63- μ m sieve and separated into component fractions using the 20-, 10-, 5-mm, 600- μ m, and, for Woodhall Spa only, the 300- μ m sieves. The individual fractions were recombined in an attempt to give the initial gradings F1 and F2 for Woodhall Spa and M for the remainder. (Figure 1). These gradings are typical of sub-bases in Britain. Some difficulty was experienced in achieving the target gradings as the washed materials tended to

be short of fines. For the purposes of most comparisons this was not a serious drawback.

Series B and H materials were prepared in a similar fashion except that generally they were not washed. In series H, the proportions were adjusted to achieve the M and F1 gradings after compaction.

Sand and limestone filler were mixed to give the gradings SF4/80 and SF4/60 (Figure 1).

Specimen Preparation for Frost Heave Tests

The materials were compacted into a mould in three layers to their maximum dry density at the optimum moisture content by using a vibrating hammer. In the final stage the end plugs were vibrated home to ensure that the required density was achieved. In series H, the final compaction was achieved by static loading of the end plugs after initial compaction with a vibrating hammer, except for the softest aggregate, MIC, which was compacted on a vibrating table.

After compaction and extrusion, specimens were weighed and placed in an apparatus (see below) for 24 hours to allow them to imbibe water prior to the onset of freezing.

THE TRRL FROST SUSCEPTIBILITY TEST

In the TRRL test, nine cylindrical specimens 102 mm in diameter and 152 mm high are placed in an apparatus (Lomas and Jones, 1981) so that the air temperature above them can be maintained at $-17 \pm 1^\circ\text{C}$. The specimens rest on porous ceramic discs within copper carriers. The discs are in contact with water, which is maintained at a constant level and at $+4 \pm 0.5^\circ\text{C}$. The sides of the specimens are wrapped with waxed paper, and the intervening space is filled with loose, dry sand (5 to 2.36 mm fraction). Push rods bearing on caps placed on top of the specimens enable the heave to be measured. Heave and water intake is

FIGURE 1 Grading Curves

recorded every 24 hours. Thermocouples are used to monitor the boundary and internal temperatures of the specimens.

Tests are normally done in sets of either three or nine. Until very recently, freezing continued for 250 hours and materials were judged frost susceptible, in England and Wales, if they heaved more than 13 mm. The freezing period has now been reduced to 96 hours (TRRL 1981) with a limit of 10 mm set by the Department of Transport.

Although the SRU is now the specified testing facility, properly conducted tests in which an insulated trolley containing the specimens was pushed into a cold room, gave similar results at least within the working range (Lomas and Jones 1981). Series H tests were done entirely in the cold room, but both facilities were used for the remaining series and the heave recorded was the average of all the relevant data.

To facilitate comparison with earlier data, only the 250 hour heaves are considered in this paper. (See Table 1).

The TRRL test is one of a number of direct freezing tests used in various parts of the world. There is some evidence that other tests, e.g., the CRREL test, would rank materials in the same order (Jones 1980).

FIGURE 2 Osmotic Cell (Section and Elevation)

DETERMINATION OF SUCTION CHARACTERISTICS

The technique of applying suction by osmosis to the pore water in granular materials, (Jones and Hurt 1978) was further developed with a number of detailed improvements particularly in relation to specimen preparation.

The osmotic cell, figure 2, consisted of a central specimen chamber 110 mm diameter in which a slice of compacted aggregate 15 to 20 mm thick was flanked on either side by a semi-permeable dialysis membrane. The cells were immersed in a tank of polyethylene glycol (carbowax 6000) solution that was maintained at a constant temperature. Water then flowed from the specimen across the membrane, which was impermeable to the long chain carbowax molecules. Equilibrium was established (in five to seven days) between the suction in the pore water and the osmotic suction of the carbowax solution. A calibration curve was determined for each batch of carbowax by using an osmometer. Thereafter the suction could be found simply by measuring the density of the solution with an hydrometer. The effective range of the technique is pF 1.5 to about 4.4 (4 to 2500 kPa). A capillary rise method was used for lower suctions.

FIGURE 3 Suction Characteristics

Specimens of the harder aggregates were formed by compacting the material into a plastic pipe 102 mm diameter, 100 mm high that was sealed at its base with a disc to form a water-tight container. The entire assembly was frozen in the cold room at -17°C for 24 hours. While still frozen, it was sliced into discs 15 to 20 mm thick with a water cooled diamond studded saw, and the rough edges of the pipe smoothed with a file. The disc of aggregate, still contained within its plastic collar was then placed into the osmotic cell and clamped up. During the suction test, air could easily be drawn into the specimen between the collar and the flexible membrane.

FIGURE 4 250 Hour Heave vs $\theta_{2.5}$

FIGURE 5 Heave Ratio vs $\theta_{2.5}$ (After Gorle, 1980)

Specimens of sand/filler and of the softer limestones used in series H were prepared without freezing and were extruded from the collars prior to the suction test.

Typical aggregate suction curves are shown in figure 3. Each point was determined by using a separate specimen.

RELATIONSHIP BETWEEN SUCTION CHARACTERISTICS AND FROST SUSCEPTIBILITY

Comparison of figure 3 and column 7 of Table 1 showed that at about pF 2.5, (31 kPa) the volumetric moisture contents, θ ranked the materials in the same order as the frost heave. Figure 4 shows a plot of H_{250} against $\theta_{2.5}$. With one exception (DOL from the earlier series of tests in which slightly different techniques were used) the points lie fairly closely on a smooth curve. For $\theta_{2.5}$ less than 20, the heave increases with H_{250} but thereafter there is a decrease.

A similar dependence between heave behaviour and $\theta_{2.5}$ was observed in results published by Gorle (1980). A plot of heave ratio (heave/depth of frost penetration) against $\theta_{2.5}$ is shown in figure 5.

Significance of $\theta_{2.5}$

In both the secondary heaving theory (Miller 1978) and the segregation potential theory (Konrad and Morgenstern 1980, 1981), the crucial zone is the frozen fringe between the ice lens and the freezing front (Figure 6); the segregation potential theory is simpler and can be readily applied to the interpretation of the results presented earlier; in this theory, frost heave is viewed as a problem of impeded flow to the lens due to the low permeability associated with the high suctions present in the frozen fringe. Salient equations are presented in Table 2.

Estimates of the variation of permeability with suction were made by Thompson (1981) for two of

$\bar{k}_{ff} = \frac{8.04 \times 10^{-5} v}{\text{grad T}} \left(\frac{h_s}{h_s - h_o}\right)$ (6)	SP = segregation potential ($\text{mm}^2 \text{ s}^{-1} \text{ }^{\circ}\text{C}^{-1}$)

the materials by using series parallel pore iteration theory (Kunze et al 1968) (Figure 7). Other data relevant to the onset of the terminal lens in these materials is given in Table 1. The velocity of flow was calculated from the heave/time curves by using equation (2). The segregation potentials are lower than $100 \times 10^{-5} \text{ mm}^2 \text{ s}^{-1} \text{ }^{\circ}\text{C}^{-1}$ observed for Devon silt at $h_o = 100 \text{ cm}$ by Konrad and Morgenstern (1981).

Calculations using Figure 7 and equations (5) and (6) indicated that h_o was of the order of 100 cm or less and h_s was of the order 1000. Similar values for h_o were noted for a compacted glacial till by Garand and LaGanyi (1982). Assigning an average value of 1.05 to $h_s/(h_s - h_o)$ enabled \bar{k}_{ff} to be found from equation (6). The corresponding pF values, of 2.6 for Dene and 2.8 for Whin, were read directly from Figure 7.

These values are in reasonable agreement with pF 2.5, which was shown earlier to be the suction at which the suction characteristics ranked the frost susceptibility. However, this agreement needs to be confirmed by further comparisons with directly measured permeability values at the appropriate suctions.

Nevertheless, it would seem reasonable to associate the average permeability \bar{k}_{ff} with a characteristic suction h_c . This is the suction at the point where the suction gradient is equal to its average value (Figure 6). The characteristic suction h_c will not normally be the average suction. A graph of H_{250} against θ_c , the volumetric water content corresponding to h_c would be expected to show a monotonic increase. Thus pF 2.5 appears to approximate to the characteristic suction of all the materials with an OMC less than 10%.

For finer materials, for example the Attenborough silt or clay soils, the characteristic suction is likely to be higher so that the θ_c would be lower than $\theta_{2.5}$. Similarly, the high internal porosity of the MIC particles could lead to $\theta_{2.5}$ being an overestimate of θ_c . This behaviour is reflected by the higher OMC values in the materials which plot on the decreasing limb of Figure 4.

USE OF $\theta_{2.5}$ AS A FROST SUSCEPTIBILITY INDEX

The five materials with $\theta_{2.5}$ less than 9% were all non-frost susceptible according to the TRRL test. If further testing on a considerable number of other granular materials were to show similar behaviour, then this criteria could be used as a method of assessing frost susceptibility. However, the time taken and the operator effort involved in assessing a single material is similar for the suction method and for a four-day direct freezing test. The latter is therefore likely to remain as the preferred method of assessing frost susceptibility.

Nevertheless, the apparatus required by the suction method is simpler than that needed for direct freezing tests and it is easily duplicated. Thus the suction method could be a useful adjunct

FIGURE 7 Estimated Permeability Characteristics (After Thompson, 1981)

especially when only small samples were available, or when large numbers of materials needed to be assessed simultaneously, e.g., at site investigation or tender (bidding) stages.

CONCLUSIONS

1. For a range of granular materials, frost heave and $\theta_{2.5}$ (the volumetric water content at a suction of pF 2.5, 31 kPa) were related by a single curve.
2. The average permeability in the frozen fringe is associated with the average suction gradient. The suction corresponding to the average gradient, can be considered as the 'characteristic suction' for the fringe.
3. The characteristic suction approximates to pF 2.5 for a wide variety of granular materials with an optimum moisture content less than 10%.
4. Materials for which $\theta_{2.5}$ was less than 9% were non-frost susceptible according to the TRRL test.
5. Further testing is required on a considerable number of materials to establish whether a limit based on suction characteristics is of general applicability.

ACKNOWLEDGEMENTS

We wish to thank TRRL for a contract and the British Quarrying and Slag Federation for grants that provided the main funding for this work, and Drs. K.G. Hurt and J.D. Thompson for their contributions to the overall research program.

Deformation behaviour and strength of frozen sand-ice materials containing 0.1 to 0.6 weight fraction of sand were studied by testing the samples at -11°C in compression at a strain-rate of $7.7 \times 10^{-5} \text{ s}^{-1}$, under hydrostatic pressures varying between 0.1 and 85 MPa. The peak strength increased with increasing hydrostatic pressure, reached a maximum for confining pressures around 25 MPa, and decreased for further increase in pressure. The results are compared with those obtained earlier in pure polycrystalline ice and frozen saturated sand.

INTRODUCTION

The effects of hydrostatic pressure on the deformation behaviour, and strength, of frozen saturated sand of uniform grain size containing about 20% moisture by weight of sand, were reported earlier (Parameswaran and Jones, 1981). As a sequel to that work, the authors continued to study the behaviour of frozen sand-ice mixtures of various sand to ice ratios, under triaxial conditions. The present paper reports results on these new materials.

The objective of this project is to obtain an overall picture of the deformation behaviour of sand-ice materials with increasing percentages of sand dispersed in ice, starting from pure ice at one end of the spectrum (Jones, 1978) to saturated sand at the other end (Parameswaran, 1980). Such a study will enable us to understand the physical processes involved in the deformation of frozen earth materials under triaxial conditions, and will also be helpful in evolving design criteria for foundations in ice rich permafrost soils. Also, the sliding of glaciers on their beds is controlled by the deformation of such ice-rich materials (debris-laden ice) at the bottom of the glaciers, and subjected to hydrostatic pressures due to the overburden.

Very little work has been reported on the study of mechanical behaviour of sand-ice materials under high confining pressures. Besides Chamberlain et al. (1972), Alkire and Andersland (1973) and Sayles (1974), the only others are the work of Simonson et al. (1974), and our own work reported earlier (Parameswaran and Jones, 1981).

EXPERIMENTAL PROCEDURE

(a) Specimen Preparation

The sand used for preparing the test specimens was from Ottawa, Illinois, corresponding to specification ASTM C-109, and having a uniform grain size between 0.2 and 0.6 mm. Cylindrical

sand-ice test specimens with different compositions were prepared in split acrylic molds (51 mm i.d., 180 mm deep) having provision for evacuation from the top and suction of water from the bottom. Figure 1 shows a mold and a sample made in it.

In the present experiments the compositions of the samples used were 10 to 20% sand by weight dispersed in ice, and sand-ice containing 37 to 50% ice. Test specimens were prepared in a cold room kept at -6°C . A specimen of the required composition was made as follows: The volume fractions of sand and ice for a specimen of desired composition were calculated, snow and sand in the proper weight fractions were mixed to obtain the volume fraction calculated above, the acrylic mold was filled with the snow sand mixture (without compacting, but with light tapping), the mold was evacuated to some extent, and distilled water, precooled to just above 0°C , was drawn into the mold through a port at the bottom, with the vacuum pump running, until the mold was full. The water froze immediately, with the snow particles and the cold sand particles acting as nucleating agents. In this procedure it was impossible to eliminate the air bubbles completely, but the test specimens obtained had a fairly uniform distribution of sand throughout their volume. This was confirmed by cutting a sample perpendicular to its axis into several discs, and determining the moisture content of each by drying.

After allowing the sample in the mold to sit in the cold room overnight to attain temperature equilibrium, the specimen was removed from the mold, 25 mm length was cut off from either end, and the ends faced in the lathe in the cold room. Stainless steel end caps were mounted at either ends of the specimen using precooled distilled water. The finished test specimens had a nominal gauge length of about 108 mm between the end caps, so that the length to diameter ratio was greater than 2. Prior to testing, the diameter and length of each sample were accurately measured.

(b) Test Procedure

The frozen cylindrical sand-ice specimens were tested in a high pressure triaxial cell capable of withstanding hydrostatic pressures up to 200 MPa (2 k bar). Figure 2 shows a schematic diagram of the pressure vessel. The pressure vessel was kept inside a cold box maintained at -11°C , on the base of a universal testing machine (Instron Model 1116, having a capacity of 250 kN). All tests were carried out at a constant rate of crosshead motion of 0.5 mm/min, which amounts to a nominal strain rate of about $7.7 \times 10^{-5} \text{ s}^{-1}$ on sample. The hydrostatic pressure was varied for each test. The pressurizing medium was Dow Corning silicone fluid 200. Uniaxial compressive force was applied by a piston (P) sealed by two O-rings. The hydrostatic pressure inside the cell, as a sample was deformed, was constantly monitored by a Bourdon type of pressure gauge connected at the port H of the pressure vessel. Thus the exact hydrostatic pressure inside the cell at the peak load could be known for each test. The load on the specimen at any instant was obtained by subtracting the load due to friction and the hydrostatic pressure from the total load indicated by the load cell of the testing machine. The "nominal strain" shown on the various figures was calculated from the speed of crosshead motion and elapsed time divided by the original sample length. The temperature inside the pressure vessel was monitored by a thermocouple connected to the port T. During a test, the variation in temperature was usually less than 0.1°C . After a test, the sample was taken out of the pressure vessel, drained of silicone fluid, photographed and dried in an oven to determine the moisture content.

RESULTS AND DISCUSSIONS

Figure 3 shows typical deformed sand-ice samples. Figure 4 shows some representative stress-strain curves from samples of various compositions. The deformation behaviour of these samples and their stress-strain curves were more similar to pure polycrystalline ice samples tested under high pressure (Jones, 1978), than the saturated sand samples reported earlier (Parameswaran and Jones, 1981). Unlike the latter, which showed an initial yield point, post yield work hardening behaviour and a peak stress, the present sand-ice samples showed a peak stress coinciding with the yield point at the end of the pseudo elastic region. After this peak the stress dropped rather rapidly at first, and later on more slowly, but continuously. Table I shows the data of peak stress, hydrostatic pressure, strain at peak, etc. for the various samples. The samples tested could be divided into 4 groups with the following sand concentrations: (a) $11.7 \pm 1.0\%$, (b) $16 \pm 2\%$, (c) $48 \pm 2\%$, and (d) $63 \pm 3\%$. The results of these are shown in Figure 5, where the peak stress is plotted against hydrostatic pressure for various samples.

All the curves in Figure 5 show that the peak stress increases with increasing confining

pressure and reaches a maximum at a pressure of about 25 MPa, (12 MPa in case of 50:50 sand ice) and then decreases for further increase in hydrostatic pressure. The behaviour is similar to that observed earlier in frozen saturated sands (Parameswaran and Jones, 1981). Chamberlain and others (1972), Alkire and Andersland (1973), and Sayles (1974) have also reported the increase in strength with increasing hydrostatic pressure as observed by us and shown by the early part of Figure 5. This behaviour could be due to the closure of voids and microcracks in the samples. The decrease in strength with further increase in hydrostatic pressure, after the maximum, is thought to be due to increasing amounts of unfrozen water in the samples due to pressure melting around the sand grains.

Simonson et al. (1974) have reported testing ice and frozen soils at -10°C under confining pressures of up to 200 MPa. Their results, at first sight, seem to be the opposite of earlier observations quoted above. They reported that the peak strength in ice decreased monotonically with increasing pressure, whereas in frozen saturated soils (Ottawa sand and kaolinite), the peak strength at first decreased with increasing hydrostatic pressure, reached a minimum at a confining pressure of 120 MPa, and then increased again for further increase in confining pressure. This latter increase in strength was attributed to the frictional effect arising from interparticle contact. A review of their test data (given in Appendix A of their paper), however, shows that all their tests were done at atmospheric pressure (1 bar of 0.1 MPa), or at pressures exceeding 50 MPa (0.5 k bar), except for one sample of polycrystalline ice tested at 40 MPa, and two samples of saturated Ottawa sand tested at 46 and 48 MPa, respectively. From our tests we saw that the strength reaches a peak value at a confining pressure of about 25 MPa for ice and sand-ice materials, and hence Simonson et al. (1974) could have missed this in their tests.

In Figure 6 the present results on sand-ice materials are compared with our earlier results on frozen saturated sand and on ice (Parameswaran and Jones 1981, and Jones 1978, respectively). Curves (a), (b) and (c) are the same as those of Figure 5. Curve (d) is the expected behaviour of ice at a strain rate of $7.7 \times 10^{-5} \text{ s}^{-1}$ (as used in the present tests), calculated from the results of Jones (1978), using the formula for the dependence of strain rate $\dot{\epsilon}$ on the strength σ :

$$\dot{\epsilon} \propto \sigma^n$$

where the exponent n was found to have a value of 5.4 at atmospheric pressure (0.1 MPa) and 3.9 in high pressure tests. Curve (e) in Figure 6 shows the variation of peak strength with hydrostatic pressure, for frozen saturated sand containing 20% moisture by weight of sand (this corresponds to a sand/ice ratio of 83/17 by weight, or a volume fraction of 63/37).

These results seem to indicate that the macroscopic strength and deformation behaviour of ice is not considerably affected by the addition of sandy material up to 20% by weight. The strength of the sand-ice material was only slightly higher than that of pure ice. (Similar results on frozen sand-ice materials were reported earlier by Goughnour and Andersland (1968) from uniaxial compression and creep tests, and by Alkire and Andersland (1968) from uniaxial compression and creep tests, and by Alkire and Andersland (1973) from triaxial tests.) This would seem to support the criterion of the application of the flow law for ice for the design of piles in ice-rich soils (Morgenstern et al. 1980). In the sand-ice material containing 48-63% sand, the effect of interparticle soil grain friction also comes into play and causes an enhancement of strength. These samples showed a higher strength than the samples with 11-16% sand, but considerably lower than the frozen saturated sand (containing about 83% sand). For all these materials the strength after the peak drops with increasing hydrostatic pressure, presumably due to increasing amounts of unfrozen water caused by pressure melting at the ice-soil interface. (In polycrystalline ice the pressure melting presumably starts at the grain boundaries).

Further tests on sand-ice materials containing sand fractions between 0.2 and 0.8 are underway and these will be reported elsewhere.

CONCLUSION

Sand-ice materials containing about 10 to 60% sand dispersed uniformly in ice were tested in compression in a high pressure triaxial cell under hydrostatic pressures varying from 0.1 to 85 MPa, at a temperature of -11°C and a compressive strain-rate of $7.7 \times 10^{-5} \text{ s}^{-1}$. The macroscopic deformation behaviour and strength of those samples which contained 11-16% sand were very close to the behaviour of polycrystalline ice tested under similar conditions. For samples containing 48-63% sand, the strength was higher than the previous samples, but much lower than the frozen saturated sand (containing about 17% moisture by weight) tested under similar conditions.

For all these materials the peak strength increased hydrostatic pressure, reached a maximum at a particular confining pressure (about 30 MPa for polycrystalline ice, about 40 MPa for frozen saturated sand, and about 25 MPa for the present sand-ice materials), and then decreased with further increase in confining pressure. The decrease of strength with increasing pressure after the maximum is presumably due to the increase in unfrozen water content caused by pressure melting round the sand particles.

ACKNOWLEDGEMENTS

The authors would like to thank Colin Hubbs (DRB/NRC) and Hemming Chew (NHRI/DOE) for their help in sample preparation and testing.

PERMAFROST-RELATED TYPES OF LARGE-SCALE DISSECTION, DEGRADATION, AND DEFORMATION OF MARTIAN LANDSCAPE

Heinz - Peter Jöns

Geologisches Institut, Technische Universität Clausthal, Leibnizstrasse 10, 3392 Clausthal-Zellerfeld, Federal Republic of Germany

Aureoles, mega-aureoles and chaotic terrains are among Mars' most significant permafrost-related surface structures. In areas of high relief the melting of a proposed layer of underlying permafrost led to downslope sliding of overlying rigid material. The results were aureoles with a maximum diameter up to about 1,600 km which surround the largest volcanoes (Olympus Mons, Elysium Mons). Large-scale downslope sliding on the flanks of very large updomings led to the development of mega-aureoles with a diameter up to about 6,000 km.

In areas of low relief the melting of underlying permafrost led to the origin of much smaller arcuately bordered depressions with maximum diameters up to about 300 km, the chaotic terrains. Most depressions of this type are related to the Chryse Planitia by large outflow channels. All these features seem to have no counterparts on Earth.

INTRODUCTION

Chaotic terrains and aureoles are members of a larger family of permafrost-related features of the Martian surface. Chaotic terrains were initially recognized and described from Mariner 6 frames (Sharp et al. 1971) and later observed in detail from Mariner 9 (Sharp 1973). Their existence has been confirmed by Mariner 9 and Viking pictures. The origin of chaotic terrains has commonly been attributed to undermining or sapping mechanisms or ground ice deterioration (Sharp et al. 1971, Sharp 1973) and was recently attributed to melting of underlying ice deposits and/or permafrost (Soderblom and Wener 1978, Jöns 1982a). Carr (1977) mentions chaotic terrains "as additional supporting evidence for extensive ground ice in the cratered uplands". The role of the chaotic terrains during the development of the Mars surface relief has been explained by Jöns (1982a).

The aureole material which surrounds Olympus Mons was first described from Mariner 9 pictures (Carr 1973). The aureole extending from the volcano contains a series of overlying lobated thin units with arcuate boundaries. Olympus Mons itself is bordered by a scarp which stands 2-8 km high (Wu et al. 1981). Among the numerous theories which have been proposed to explain the origin of the aureole are postulates that the aureole has been caused by the weight of Olympus Mons on bedded deposits (Harris 1977) and subglacial volcanic deposits (Hodges and Moore 1980). Morris (1982) has reinterpreted the aureole materials to be the products of at least six pyroclastic eruptions prior to the construction of Olympus Mons. Lopes et al. (1980, 1982) proposed a mass movement origin for the aureole. They interpreted the scarp as the

scar left by the removal of material. Lopes and Guest (1981) have considered "that the emplacement of these rockslides was probably aided by melting of permafrost".

Jöns (1982b, 1983a,b) has pointed out that very large aureole-like features are existing in the surroundings of the Tharsis-Noctis Labyrinthus-Valles Marineris (TaNoVa) updomings and in the surroundings of the Elysium dome. According to the very large diameter of those structures he has called them mega-aureoles.

In this paper it is proposed that both groups of features, the different types of chaotic terrains as well as the aureoles and the mega-aureoles are the result of (?partial) melting of underlying permafrost, with reference to Anderson (1982) who has pointed out that "Calculations based on the Viking Mission Data results indicate that permafrost thicknesses range from about 3.5 kilometers at the equator to approximately 8 kilometers in the polar regions".

AREAS WITH A HIGH RELIEF

If one assumes a melting of underlying permafrost, a reduction in shear strength in the area of the future sliding would produce a high fluid pressure and a low shear stress. Under such conditions slides could occur under their own weight on slopes of 1% (Hubbert and Rubey 1959, Lopes et al. 1982). Therefore it seems to be possible that downslope sliding of overlying rigid - mainly volcanic - material could form aureoles of different scales on Mars in areas with a sufficient degree of relief.

Aureoles

Aureoles have been described from the sur-

FIGURE 1 Fully developed aureole around Olympus Mons (OM).

roundings of some large volcanoes (Olympus Mons, Elysium Mons). The best example of a fully developed aureole is situated around Olympus Mons (Figure 1). It consists of many overlapping lobate units which indicate a multiple phase origin. Because the aureole around Olympus Mons has been discussed in detail elsewhere, it will not be discussed further here.

The author is of the opinion that it is quite possible that the numerous concentric features which surround Elysium Mons represent a special type of an aureole the development of which came to a halt in a very early stage. Lobate units do not exist but Christiansen and Greeley (1982) suspect mega-lahars in this region (Figure 2).

FIGURE 2 Aureole around Elysium Mons.

Mega-Aureoles

Mega-aureoles which surround the TaNoVa updomings and the Elysium dome have been identified by Jöns (1983a,b). In the case of the TaNoVa updomings large parts of the surrounding landscape became unstable - perhaps due to melting of underlying permafrost - and formed a special series of narrow landscapes during downslope sliding of overlying rigid material (for detail see Jöns 1982b). All those features run concentrically with respect to Syria Planum - the highest part of the TaNoVa updomings - and have been interpreted as shove structures (Jöns 1982b, 1983a,b).

East and Southeast of the Elysium dome remnants of a former mega-aureole are suspected (Jöns 1983b). The relief of this area is characterized by wrinkle ridges and numerous erosional outliers which run concentrically with respect to the center of the Elysium dome. On the Northwest flank of this dome mega-lahars have been suspected by Christiansen and Greeley (1982), (Figure 3).

AREAS WITH LITTLE RELIEF

Chaotic terrains are characterized by polygonal fracture systems, angular mesas and rounded hummocks arranged disorderly in irregular hollows, circular depressions, or at the base of scarps (Lucchitta, 1982). Further characteristics are arcuate steep escarpments which stand up to about 3,000 m high and deeply incised straight running outflow channels which connect many chaotic terrains with the Chryse Planitia. Most chaotic terrains are found in the Margaritifer Sinus and in the Oxia Palus quadrangle. Sharp (1973) ascribed the origin of the chaotic terrains to possible collapse through the degradation of ground ice. Lucchitta (1982) is of the opinion that some chaotic terrains are associated with fluvial depositional centers and suggests that chaotic terrains may have developed preferentially on sedimentary deposits. In a preliminary classification of the chaotic terrains Jöns (1982a) has distinguished three types: the nonprogressive and the progressive chaotic terrains and the linearly delineated collapse structures. Careful investigations have shown that at least five types can be distinguished.

Nonprogressive Chaotic Terrains

These structures are encircled by arcuate escarpments which stand up to about 3,000 m high. Probably due to degradation of ground ice (Sharp 1973) the overlying rigid material sank and cracked. This led to the origin of numerous linear shallow grabens which transect the remnants of that material within the chaotic terrains. Most of these depressions are related to the Chryse Planitia by large and deeply incised straight outflow channels (e. g. Ares-, Tiu-, Simud Vallis), (Figure 4).

FIGURE 4 Nonprogressive chaotic terrain (CH) with large outflow channel (O).

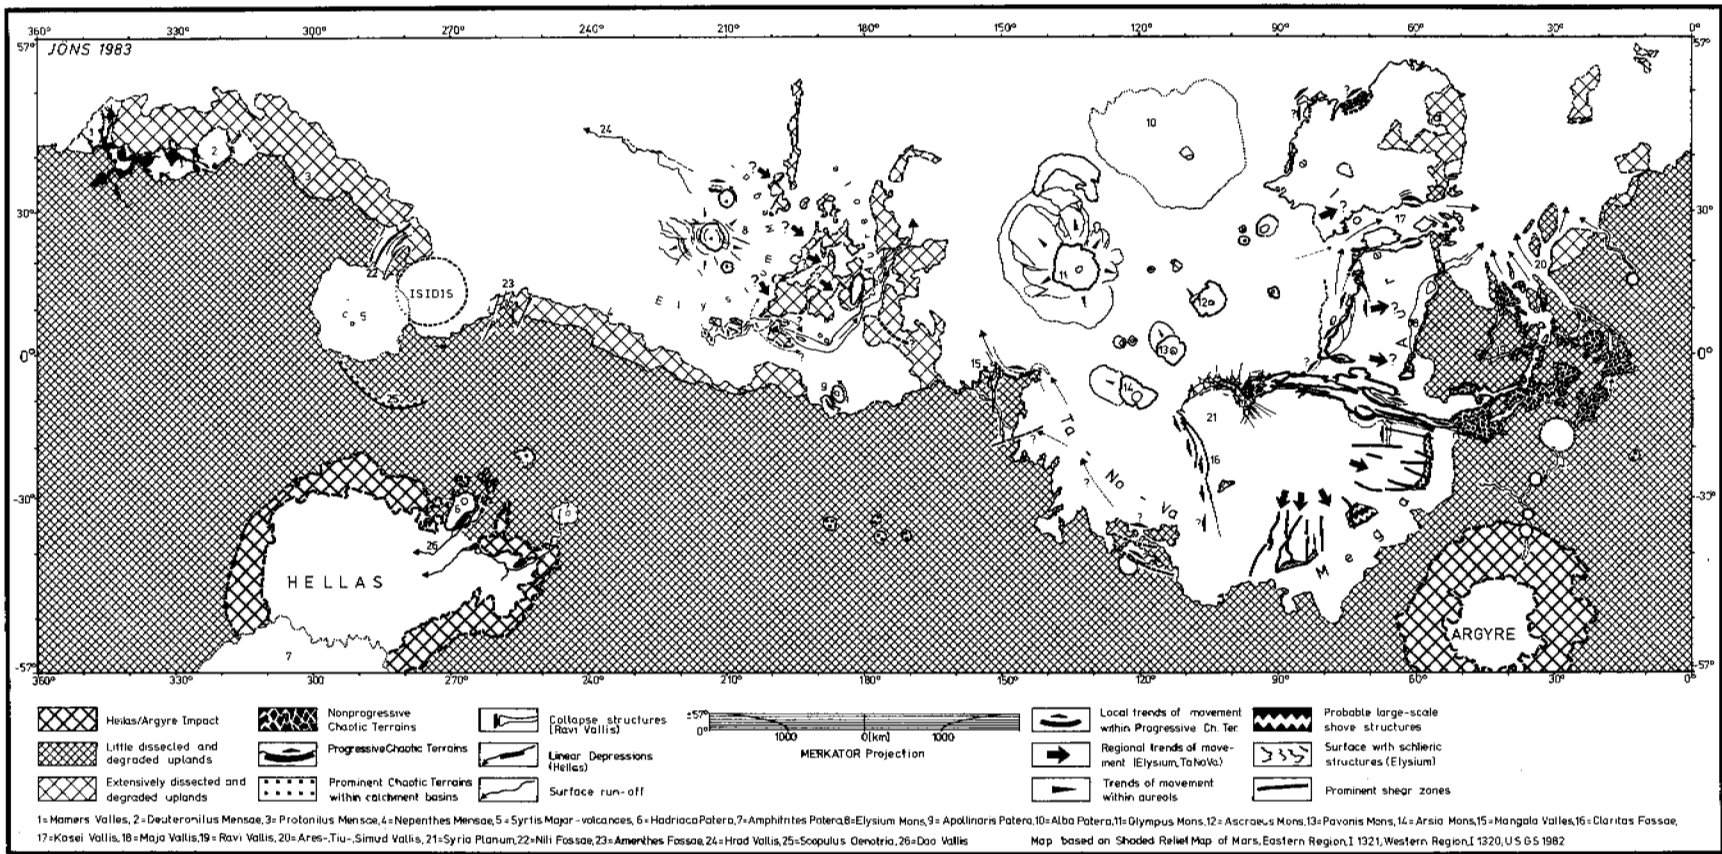

FIGURE 3
Permafrost-Related Types of Large-Scale Dissection, Degradation, and Deformation of Martian Landscape.

Progressive Chaotic Terrains

Chaotic terrains of this type dissect the landscape by cutting off sickle-shaped parts of the adjacent upland. Hence the remnants of the overlying material are characterized by series of arcuate shallow grabens. As no true outflow channels have been formed, the degradation of ground ice probably started with wide fronts along the flanks of preexisting channels (e. g. Echus Chasma) and/or shallow depressions. The best example of a progressive chaotic terrain is situated near Hecates Tholus/North Lowlands (Figure 5).

FIGURE 5 Progressive chaotic terrains (CH) near Hecates Tholus (HT).

Chaotic Terrains Within Catchment Basins

Recently, chaotic terrains in apparent shallow depressions (ancient crater scars?) have been described (Lucchitta 1983a). These depressions probably became filled with sediments from local runoff which seem to thin out near their border. Hence many chaotic terrains of this type are characterized by a complex drainage pattern in their surroundings and by the absence of encircling escarpments. They have been identified on the Southern Uplands as well as in the lowest areas in Candor Chasma/Valles Marineris (Figure 6).

Linear Depressions

Linear depressions seem to exist only in the vicinity of Hadriaca Patera/Southern Uplands. They are characterized by linear escarpments which run more or less parallel to each other forming box-shaped depressions. In contrast to the chaotic depressions described above the average trend of these structures seems to correspond with the main trends of the planets tectonics. The depressions of this type are related to the Hellas Planitia by shallow outflow channels (Figure 7).

FIGURE 6 Chaotic terrain within catchment basin (Southern Uplands).

FIGURE 7 Linear depressions near Hadriaca Patera (HP).

Collapse Structures

Collapse structures seem to have been created by release of water from probably confined aquifers (Carr 1979). They consist of broad shallow outflow channels which emerge full born along linear escarpments. The best example of this type is Ravi Vallis. It contains a chaotic terrain of medium size, Aromatum Chaos, which is situated in front of the linear escarpment from which Ravi Vallis emerges (Figure 8).

FIGURE 8 Collapse structure with Aromatum Chaos(a) and outflow channel (b), Ravi Vallis.

CONCLUSIONS

As most of the features described in this paper are situated within a broad transition zone between the Southern Uplands and the Northern Lowlands, the possibility can not be ruled out that at least parts of the Northern Lowlands came into existence by ground ice deterioration and/or melting of permafrost.

Consequently it seems to be possible that large-scale permafrost-related dissection, degradation, and deformation of landscape were among Mars' most important relief generating processes.

FIELD EVIDENCE OF GROUNDWATER RECHARGE IN INTERIOR ALASKA

Douglas L. Kane and Jean Stein

Institute of Water Resources, University of Alaska,
Fairbanks, Alaska 99701 USA

Increased utilization of groundwater resources in discontinuous permafrost regions requires that we develop a better understanding of the system and its processes. This paper discusses the mechanics of one of the processes, groundwater recharge. Two distinctly different soil conditions exist; generally permafrost inhibits drainage and these areas are poorly drained, whereas nonpermafrost areas are better drained for the same soil type. Field studies near Fairbanks, Alaska, show that the infiltration and hydraulic conductivity properties for frozen and unfrozen soils vary substantially. Freezing of a soil reduces the infiltration rate because of the existence of ice in soil pores. Further, frozen soils with high ice contents have lower infiltration properties than frozen soils with low ice contents. Frozen but relatively dry soils behave in a manner similar to unfrozen soils. Therefore, substantial infiltration can occur in seasonally frozen soils from snowmelt. Our field studies have shown that most of the groundwater recharge occurs during the snowmelt period in nonpermafrost areas. This is partly because of the soil condition and partly because of the large quantity of water available. Recharge during the summer is limited by the pattern of summer precipitation coupled with the ongoing process of evapotranspiration.

INTRODUCTION

Various uncertainties exist in some regions as to the long-term availability of groundwater resources. This problem is compounded in permafrost areas by the lack of data on groundwater availability as related to permafrost distribution. Excessive groundwater withdrawals may exceed natural recharge rates, and thus increase both pumping and development costs due to the water level declines. The potential for groundwater recharge is primarily controlled by the geologic conditions near the ground surface. In cold regions, the hydraulic properties of near-surface soils can vary substantially, depending upon the moisture regime and whether the soil is frozen or unfrozen.

This paper presents a discussion of the potential for groundwater recharge in areas of permafrost and extensive seasonal frost.

GROUNDWATER SYSTEM

In permafrost regions, a delineation should be made between areas of continuous and discontinuous permafrost. This division is very critical when examining groundwater flow in cold regions. In continuous permafrost areas, there is essentially no hydraulic connection between groundwater in the active layer and subpermafrost groundwater. Soil temperatures are colder in continuous permafrost areas, so the permafrost is thicker. Hydraulic properties are also temperature-dependent, and this dependence is more critical at temperatures below 0°C. In discontinuous permafrost areas, a hydraulic

connection exists between subpermafrost groundwater and the surface through unfrozen zones in the permafrost. These zones are generally found on south slopes and beneath most lakes and large rivers.

Groundwater zones in permafrost regions are classified as either suprapermafrost groundwater or subpermafrost groundwater. Suprapermafrost groundwater is the saturated zone above the permafrost, and subpermafrost groundwater is the saturated zone below the permafrost. In areas of discontinuous permafrost, there is a transition from the subpermafrost groundwater to the groundwater in the permafrost-free areas. It should be noted that permafrost acts as a relatively impermeable confining layer, so subpermafrost groundwater can behave as water in a confined aquifer.

Because of the shallow nature and limited volume of water, suprapermafrost groundwater cannot be used directly for domestic water. However, drainage of water through this layer to streams and lakes can result in a potential water supply. Many engineering problems are associated with drainage into and out of the active layer.

Development of subpermafrost groundwater has been quite successful in many regions of discontinuous permafrost. In areas of heavy groundwater usage, substantial declines in groundwater levels have been observed, but not explained.

For understanding or estimating groundwater recharge, the mechanics of water infiltration and movement into the unsaturated zone is of the greatest importance. It is through this layer that all groundwater recharge must flow. This layer can be less than 1 m thick in the active layer above permafrost or more than 100 m thick

in permafrost-free areas near ridgetops. The unsaturated zone may consist of primarily organic soils in the active layer. The hydrologic role of these organic soils should not be underrated because they act as an important buffer, both hydraulically and thermally, between the atmosphere and mineral soil (Slaughter and Kane 1979). Soil moisture levels can vary, but generally high moisture levels exist in the active layer above permafrost. Better-drained soils with lower water contents are found in permafrost-free areas (Kane et al. 1978a). The permafrost is responsible for impeding drainage and for the development of high moisture levels. In turn, the high moisture levels dictate the type and density of vegetation and subsequent evapotranspiration rates.

The climatic variables of interest in groundwater recharge are the intensity, duration, and timing of the precipitation event. Low-intensity events allow infiltration to occur without producing runoff. High-intensity events may exceed infiltration rates and produce runoff. Duration of the event is important because longer events have greater potential for groundwater recharge. Timing of a hydrologic event is important because the source of water can be either snowmelt or rainfall, or a combination of both. In Alaska, except at high altitudes and along the coast, areas of continuous and discontinuous permafrost are classified as arid climates, based on annual precipitation. Both rainfall and snowmelt intensities are rather low. But the duration can be quite long, especially for snowmelt events. Whereas the occurrence of rainfall events are much less predictable, it is certain that a snowmelt event will occur every spring and that a potential for groundwater recharge exists because the snowpack can represent 40-80% of annual precipitation.

FIELD EVIDENCE OF GROUNDWATER RECHARGE

Reported here are selected results from numerous studies performed by the authors that help provide knowledge of the process of groundwater recharge in cold regions. Some comparative data on hydraulic properties of frozen soils that were reported by other authors are included in the latter part of this section.

Field data were collected near Fairbanks, Alaska, in an area of discontinuous permafrost. Permafrost is found on north-facing slopes and in valley bottoms; south-facing slopes are generally permafrost-free. The predominant soil type in this forested area is wind-deposited silt loam overlain with organic material. The thicknesses of the organic soils vary (generally 0-50 cm, thicker in permafrost areas) as do the mineral soils (0-60 m, greatest thickness in valley bottoms). Permafrost thicknesses can exceed 60 m. We collected field data with two primary goals (1) to assess the potential for groundwater recharge from rainfall and snowmelt events, and (2) to evaluate the potential for groundwater recharge in permafrost and nonpermafrost areas.

Recharge from Rainfall

Numerous studies (Kane, Seifert, and Taylor 1978, Kane et al. 1978b) have been carried out in which tensiometers installed at various depths were used to monitor soil moisture conditions. With a characteristic curve (pore pressure--moisture content relationship), one can estimate the moisture content from tensiometer readings, as well as determine the hydraulic gradient. From this, the direction of flow is determined. Tensiometer readings indicated that for nonpermafrost sites, the soils were very dry for much of the summer. Even during rainfall periods, very little reduction in the soil tensions occurred. The general trend was for the soils to become drier over the summer season. In unsaturated soils, lower moisture content yields lower hydraulic conductivity. For significant groundwater recharge to occur, strong downward vertical gradients are required. These did not occur. We concluded that most of the soil water was lost to evapotranspiration. Braley (1980) examined evapotranspiration losses from barley and rapeseed near Delta, Alaska. He concluded that summer precipitation was equivalent to measured evapotranspiration.

Precipitation events have already been described as being of low intensity and of variable duration, resulting in low quantities of annual precipitation. From the tensiometer data (Luthin and Guymon 1974, Kane et al. 1978a), we concluded that little, if any, recharge occurs during the summer months. The only exception would be periods of sustained precipitation (> 3 cm), which are rare. We then looked at snowmelt as a source of groundwater recharge.

Snowmelt Lysimeters

The first attempt to quantify snowmelt infiltration into seasonal frozen soils was to construct several lysimeters that only allowed vertical movement of meltwater. These one-dimensional lysimeters are described by Kane et al. (1978a). Numerous lysimeters were built so that evaporation losses, moisture retention of organic soil, and moisture retention of mineral soil could be determined.

Some lysimeters collected and measured just snow. The next series of lysimeters collected snowfall, but the snowmelt had to flow through a 10-cm layer of organic material. The last series of lysimeters collected snowfall, and the snowmelt water flowed through the organic layer, plus a 20-cm layer of mineral soil. The system, associated processes, and type of results are shown in Figure 1. Water leaving the bottom of the lysimeters at base of snowpack, organic layer, and mineral layer was collected and measured. The data shown in the figure are for 1976, and the maximum water content prior to ablation of the snowpack was 10 cm. We measured between 17 April and 27 April that 2.1 cm of water was retained in the organic layer, 2.7 cm was retained in mineral soil, and 3.5 cm of water passed through the lysimeters. From this

INFLUENCE OF MOISTURE CONTENT ON INFILTRATION

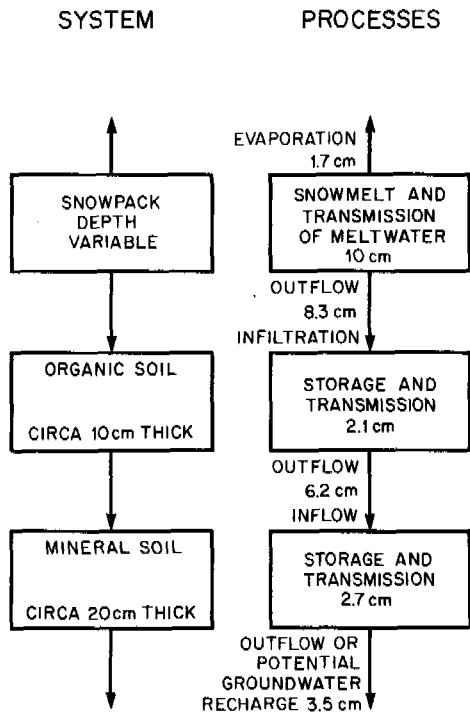

FIGURE 1 One-dimensional field model showing the path of snowmelt.

data we concluded that a maximum of 1.7 cm was lost to evaporation. The combined soil depth of 30 cm in the last series of lysimeters represents the root zone where evapotranspiration would occur. Infiltration water reaching greater depth was considered to be potential groundwater recharge. In this case, 3.5 cm of water (35%) represented potential groundwater recharge. Similar data were collected for 1977.

Because drainage of the soils was allowed from the bottom of the lysimeters, these conditions were only representative of well-drained soils found on nonpermafrost sites. Also, no water was allowed to leave the lysimeter except by evapotranspiration or drainage through the bottom of the lysimeters.

It was concluded (1) that significant groundwater recharge can occur annually from snowmelt in well-drained, although seasonally frozen soils; but (2) that it is necessary to examine the influence that higher moisture contents have on the infiltration rates of seasonally frozen soils to assess the potential for groundwater recharge on sites with other than well-drained soils.

We used two types of infiltrometers: auger hole and double ring. The auger-hole method used a hole 11.1 cm in diameter and 20 cm in depth that was drilled into the seasonally frozen soil. Infiltration rates were obtained and compared for a variety of moisture contents in both frozen and unfrozen conditions (Kane 1980). The major advantage of this method is that one can obtain samples for determination of moisture content and presence of ice lenses from the collected soil core. The main disadvantage of this method is that true vertical infiltration is not obtained, because lateral flow is not prevented. So the measured infiltration rates are greater than actual values. From these data, relative values for a wide range of soil conditions showed that high infiltration rates existed for dry, frozen soils and that infiltration declined as the moisture content of the frozen soil increased.

Double-ring infiltrometers were used to overcome the lateral-flow problem. To minimize the disturbance of the seasonally frozen soil during installation, we decided to install the infiltrometers prior to the development of seasonal frost. To minimize the effect of the infiltrometer on the thermal regime, the surface organic layer was replaced around and inside the infiltrometer until the testing began at the onset of ablation. The diameters of the rings were 18 cm and 36 cm. The ring was installed 9 cm into the mineral soil, and a constant head of 6 cm was maintained. Moisture contents must be measured outside the infiltrometer; soil cores were collected near each infiltrometer to define the moisture profile.

Data from these double-ring tests are shown in Figure 2. These tests were carried out over a longer period of time to observe the infiltration rate variation as the frozen soil thawed. In most cases, the initial infiltration rate was high, but rapidly declined to equilibrium conditions (equivalent to saturated hydraulic conductivity). On the experimental plots, however, we observed occasional increases in the infiltration rate for short periods of time. Then the infiltration rate decreased rapidly to approximately the previous equilibrium value. We attribute this to thawing of an ice-rich layer of soil and vertical variation in total moisture content (ice and water).

We found, from these infiltration tests that very high infiltration rates could be obtained in seasonally frozen soils of low moisture content. In fact, the saturated hydraulic conductivity at equilibrium conditions was reduced only by a factor of 2 when compared to unfrozen Fairbanks silt loam (at 14.8°C). Most of this reduction can be explained by changes in the fluid viscosity that are brought about by lower temperatures (Kloch 1972). For an ice-rich soil, however, a reduction of 2 orders of magnitude occurred at equilibrium conditions.

Both Burt and Williams (1976) and Horiguchi and Miller (1980) have shown that the hydraulic

conductivity of frozen soils is further reduced as the temperature is lowered below 0°C because the ice content increases. The magnitude of this reduction is quite significant, because the reduction in the hydraulic conductivity is several orders of magnitude for a small decrease in temperature (< 0.5°C). As the temperature is lowered, the unfrozen-water-to-ice ratio is reduced. This means that there is more ice in the pores and the thickness of the unfrozen water films is reduced. Research on the unfrozen-water-to-ice ratios versus temperature has shown the relationship to be hysteretic. Therefore, one would expect the temperature and hydraulic conductivity relationship also to be hysteretic, as was shown by Horiguchi and Miller (1980).

Daily snowmelt rates measured in this area have varied from zero to a maximum near 2.5 cm. These data are interesting, because when one compares these data with the data in 2b and 2c of Figure 2 for equilibrium rates, it is obvious that somewhere in between the two equilibrium infiltration rates the snowmelt rate exceeds the infiltration rate, and runoff should be produced. If the drier frozen soil is representative of the nonpermafrost areas, groundwater recharge can occur; and if permafrost sites are poorly drained with high moisture contents, the potential for groundwater recharge is reduced, and the potential for runoff is enhanced.

Daily infiltration as calculated from equilibrium rates (Figure 2) is 17.2 cm/day for dry frozen soil and 0.35 cm/day for poorly drained frozen soil. This assumes that infiltration can occur for 24 hours. It is difficult to assess this because of the presence of surface organic material and the capability of this soil to retain some soil water. However, during periods of high snowmelt, saturated conditions should develop in the surface organic layer for soils with low infiltration rates. This should produce near-surface runoff as water moves downslope along the organic-mineral soil interface. A number of runoff plots were designed for studying the influence of moisture content on runoff from seasonally frozen terrain.

INFLUENCE OF MOISTURE CONTENT ON RUNOFF

Prepared runoff plots were 6.1 m wide and 12.2 m long. The plots were situated on a south-facing, permafrost-free forested slope with 15% slope, with approximately 10 cm of organic material over the Fairbanks silt loam, and seasonally frozen depths ranging from 150 to 200 cm. A collection system was constructed at the base of each plot to collect all near-surface runoff moving downslope through the surface organic layer. There were two runoff plots during the winter of 1979/80, three runoff plots during the winter of 1980/81, and four runoff plots during the winter of 1981/82. To alter the soil moisture levels, some plots were irrigated by water sprinklers in the fall 3-4 weeks before the onset of seasonal frost. Large areas outside the plots were irrigated for collecting soil moisture cores throughout the winter and during ablation.

2a. Unfrozen Fairbanks silt loam.

2b. Frozen Fairbanks silt loam (dry case).

2c. Frozen Fairbanks silt loam (ice-rich case).

FIGURE 2 Infiltration rates for various soil conditions for both frozen and unfrozen conditions.

The infiltration tests described earlier were also performed in this same area.

Data from the runoff plots revealed that for very dry, seasonally frozen soils, no runoff existed. This is the same conclusion that we reached from the infiltration test. From the irrigated runoff plots, measurable runoff always occurred during snowmelt. The ratio of the volume of runoff to total water content of the snowpack varied from 17% to 68%. No clear relationship exists between infiltration rate and runoff volume because of the variation in climate and snowpack from year to year. We found in 1982 that runoff from a control plot (not irrigated) occurred for the first time. This was attributed to rainfall just prior to freeze-up (3.7 cm). It should be noted that 1982 was the first year since 1973 that we observed surface runoff in the natural depressions around this site.

The maximum allowable daily melts that can occur without runoff for various infiltration rates (at 0°C) are shown in Figure 3. In addition, superimposed on this figure are laboratory and field measurements under frozen conditions with the exception of unfrozen Fairbanks silt loam. With the added data of actual measurements, one can see how the infiltration rate relates to soil type and soil condition.

FIGURE 3 Maximum allowable daily melts occurring without runoff for various infiltration rates (at 0°C).

If runoff is generated, snowmelt rate exceeds infiltration rate, and this water is lost as potential groundwater recharge. Our field plots had daily snowmelts from 0 to 25 mm. Figure 3 shows that runoff should be generated if the mineral soil has a high ice content (high moisture level). However, no runoff would be predicted in a well-drained soil. This graph assumes that uniform melt occurs during a 24-hour period, and uniform infiltrations occurs throughout this period. The melt actually occurs over a shorter period of time, but the organic layer can provide temporary storage to minimize the effect of nonuniform melt.

CONCLUSIONS

It appears that the most consistent and predictable period of groundwater recharge in cold regions is during spring snowmelt. Field data demonstrate that most summer precipitation is used for evapotranspiration. The only exceptions occur during long periods of summer precipitation, but these hydrologic events do not occur every year. After 6 months of accumulation, ablation of the snowpack represents a significant annual hydrologic event. For seasonally frozen soils that are well drained and therefore have a low moisture content at the time of ablation, all meltwater that does not evaporate can enter the soil system. Since evapotranspiration is low at this time of year, the potential for groundwater recharge is quite good. As the ice content in the soil pores increases and ice lenses develop, the potential for near-surface runoff increases and the potential for groundwater recharge decreases. Areas underlain by permafrost are generally poorly drained and represent areas of runoff generation rather than groundwater recharge. Some meltwater may enter the active layer, but further downward at the permafrost table, movement is hindered by the presence of ice with much lower transmission properties. So in discontinuous permafrost zones, we conclude that the majority of groundwater recharge occurs in permafrost-free areas during snowmelt, and no significant recharge occurs in permafrost areas of either continuous or discontinuous zones.

CONTINUOUS GEOPHYSICAL INVESTIGATION FOR MAPPING PERMAFROST
DISTRIBUTION, MACKENZIE VALLEY, N.W.T., CANADA

² Canterra Energy Limited, Calgary, Alberta, T2P 2K7 Canada

A continuous inductive conductivity survey using a 10 m station interval was carried out over a distance of 868 km along the Interprovincial Pipe Line route in the Mackenzie River Valley, N.W.T. The work reported herein was done as part of a contract for Interprovincial Pipe Line (NW) Ltd. The study provides a case history for delineating frozen ground along a route that traverses a zone of scattered discontinuous permafrost and a zone of widespread discontinuous permafrost. Terrain conductivity meters were used to measure apparent conductivities along the entire proposed pipeline route. Air photo interpretation was used to map the terrain type distribution along the pipeline route. This information was correlated with vegetation, topographic, and geophysical data to delineate the boundaries of frozen ground. This interpretation was checked by boreholes drilled at an average spacing of 1 borehole every 4 km. The interpreted results provide information useful for the design of the pipeline and substantially reduced the number of boreholes that would normally be required. Statistical analyses were obtained between the occurrence of frozen ground and different terrain types. The results of the analyses indicate that soil texture is a major controlling factor in the occurrence of frozen ground.

INTRODUCTION

Information on the presence and distribution of frozen ground is necessary for the proper planning and construction of engineering projects in permafrost regions. The use of electromagnetic induction methods has become routine for shallow subsurface investigations in permafrost environments (Arcone et al. 1978, Rennie et al. 1978). This investigation reports on a geophysical survey performed along the Interprovincial Pipe Line route from Norman Wells in the Mackenzie River Valley to Zama in Northern Alberta (Figure 1). The survey was carried out during the winter-spring seasons of 1981 and 1982. The geophysical work consisted of electrical conductivity mapping using an electromagnetic induction technique. The purpose of the geophysical work was to delineate the presence of permafrost along the pipeline right-of-way. Since the pipeline route crosses many frozen/unfrozen boundaries, locating and documenting these transitions greatly affects costs and design considerations dealing with frost heave in unfrozen ground and thaw settlement in frozen ground. For the purposes of this study frozen ground is defined as the presence of at least 3 m of frozen ground anywhere in the subsurface down to a depth limit of 10 m. This criterion was chosen on the basis of design considerations for the pipeline.

TECHNICAL APPROACH FOR MAPPING PERMAFROST

The technical approach used in the survey relies on the differences in electrical conduct-

ivity (or resistivity) of frozen and unfrozen soils.

Figure 2, after Hoekstra and McNeill (1973), indicates the changes in resistivities of several

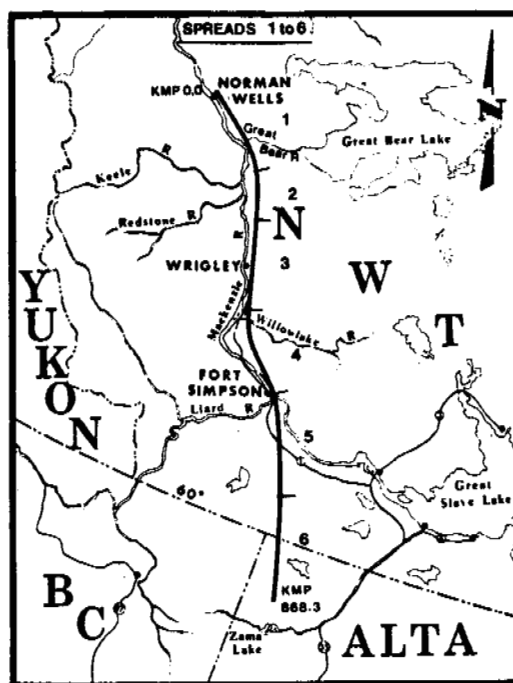

FIGURE 1 Location of geophysical survey route, kilometer post 0 to 868.3.

FIGURE 2 The resistivity of several soils and one rock type as a function of temperature (Hoekstra and McNeill, 1973).

soil types and one rock type as a function of temperature. Resistivity is shown to increase when the ground freezes. Clay-rich soils demonstrate a gradual change in comparison with coarse-grained soils, which undergo an abrupt change. This difference results from the gradual change of pore water to ice in fine-grained soils as temperature drops below 0°C. In general, however, frozen and unfrozen soils can usually be distinguished by electrical resistivity or conductivity measurements, particularly when the soil type is known.

Inductive measurements of conductivity require no electrical contact with the ground and can be made much more rapidly than galvanic measurements. Inductive techniques use an electromagnetic transmitter, which induces localized eddy currents in the ground beneath the system. A receiver senses the strength of the eddy currents, which is proportional to the conductivity of the ground. Apparent conductivity is measured in units of siemens/meter (or 1/ohm-meters) or more conveniently in millisiemens/m (mS/m).

The apparent conductivity values measured at the borehole sites were interpreted by computer forward modelling to obtain the true conductivities of the different soil types where the layer thicknesses were known. This analysis assumed horizontal layering. Then this information was correlated with the vegetation, terrain type and other data to enable the delineation of frozen/unfrozen transitions along the pipeline route. These transitions were assumed to be vertical boundaries since there were generally sharp changes in the apparent conductivity profiles across these boundaries.

SURVEY PROCEDURE

Apparent conductivity readings were taken along the entire survey route from kilometer post (kmp) 0 to kmp 868.3. Measurements were obtained at 10 m

station intervals; stations were flagged every 100 m.

The geophysical instruments used in the survey were the Geonics EM 31 and EM 34-3 terrain conductivity meters. The EM 31 was used in two modes of operation. The first mode was in an "up" position, that is, with the coils in a horizontal position. The second mode of operation was in a "side" position, that is, with the coils in a vertical position. The two readings provided information to depths of about 7 m and 3 m respectively (McNeill 1980). The EM 34-3 was used with a 10 m cable and vertical coil orientation to provide information to an approximate depth of 10 m (McNeill 1980). Since two instruments are used at each station, an independent check on the quality of the data is always available.

The use of different coil orientations and spacings with the EM 31 and EM 34-3 allows considerable variation in depth of investigation. The instruments are calibrated to measure apparent conductivity. For a homogeneous half-space this apparent conductivity equals the true conductivity of the subsurface material. For an electrically layered earth, the measured apparent conductivity represents the sum total of responses of subsurface conductivities down to depths somewhat greater than the coil separation.

FIELD PROFILES

A representative set of field profiles is presented to illustrate a variety of conditions encountered during the geophysical survey. These conditions include variations in soil type, frozen/unfrozen boundaries, bedrock influence, cultural disturbances, and effects of north- and south-facing slopes on river banks.

Figure 3 shows the geophysical response observed during a transition from a clay veneer over till soil to a till. The higher apparent

FIGURE 3 Effect of soil type transition on apparent conductivity profiles.

FIGURE 4 Frozen/unfrozen ground transitions in organic terrain.

FIGURE 5 Influence of conductive, near surface bedrock on apparent conductivity measurements.

conductivities in the first part of the profile are due to the presence of the conductive clay veneer. Nearby borehole information indicated that there was no frozen ground along this profile.

A frozen/unfrozen transition in an area of discontinuous peat is shown in Figure 4. This type of response is very common in areas with appreciable amounts of peat landforms, where the boundary between frozen peat bogs and unfrozen adjacent terrain can be very sharp. The unfrozen ground in this profile was confirmed by a borehole drilled approximately 1 km away from the vicinity of this profile.

The effect of near-surface bedrock on the apparent conductivity values can be quite dramatic. If the bedrock is resistive, such as a sandstone, then the apparent conductivity values are quite low (< 3 mS/m). If, however, the bedrock is a shale, then the apparent conductivity values are quite high (Figure 5) even when the rock is frozen. In the absence of any borehole control the high peaks on the apparent conductivity curves would probably be interpreted as unfrozen, but the borehole logs clearly indicate frozen ground and a highly variable depth to bedrock.

Cultural influences such as cutlines and winter roads that intersect the proposed pipeline right-of-way are usually reflected on the geophysical profiles (Figure 6). In most cases an increase in depth of thaw to the frozen ground occurs beneath the disturbed zone.

Studies have shown (Heginbottom et al. 1978, for example) that north-facing slopes of river banks are generally wetter and hence are more likely to be frozen than south-facing slopes. Factors other than slope orientation that can

FIGURE 6 Indication of permafrost degradation on apparent conductivity profiles.

FIGURE 7 Apparent conductivity profiles indicating a frozen north-facing slope and an unfrozen south-facing slope.

influence the presence of frozen ground include lithology, slope aspect, and slope angle. An example of a river valley with a frozen north-facing slope and an unfrozen south-facing slope is illustrated in Figure 7. An elevation profile for the Ochre River indicates that the north and south slopes are very steep. The south slope, which faces north, is probably not exposed to sunlight most of the year and thus remains frozen.

STATISTICAL ANALYSES OF FIELD DATA

The distribution of frozen ground interpreted from the geophysical profiles was digitized and compared with the terrain typing. A statistical breakdown of percentage of frozen ground in each terrain type is important in determining design criteria for the pipeline. Thaw settlement and frost heave considerations will vary depending on terrain type and on the percentage of frozen ground in a particular terrain type.

The data are divided into six spreads with the following kmp boundaries, starting from Norman Wells (Figure 1):

kmp 0 to kmp 149.5	Spread 1
kmp 149.0 to kmp 269.3	Spread 2
kmp 269.3 to kmp 380.4	Spread 3
kmp 380.4 to kmp 528.8	Spread 4
kmp 528.8 to kmp 695.8	Spread 5
kmp 695.8 to kmp 868.3	Spread 6

Tables 1-6 summarize all the statistical information for spreads 1 to 6, respectively. They list the percentage of each terrain type in the spread and the percentage of frozen ground within that terrain type. The percentage contribution of frozen ground in a particular terrain type to the total frozen ground for the entire spread is indicated as percent of total km frozen.

The terrain types are grouped according to divisions established for the Norman Wells Pipeline Project borehole data bank. These groupings are divided on the basis of genetic origin and provide useful information for the design of the pipeline. The terrain-type codes for this data bank are given in Table 7.

A total of 83.7% of the ground is frozen in spread 1, 66.3% in spread 2, 69.2% in spread 3, 31.6% in spread 4, 16.0% in spread 5, and 34.7% in

spread 6. The percentage of frozen ground generally increases in a northerly direction.

Sands, clays, and till are the predominant soil types in the northern sections in spreads 1, 2 and 3, while tills are dominant in spread 4. A significant portion of spreads 5 and 6 is over boggy terrain as seen by the high percentages of organic terrain types in Tables 5 and 6.

In spread 3 (Table 3) the two largest terrain groups are LP (clays) and MG (tills). Terrain type LP has a higher percentage of frozen ground (81.4%) than tills (55.2%) in this spread.

In spreads 5 and 6 approximately 50% of the total frozen ground occurs in organic terrain types. A large part of the frozen ground in this southern section is thus associated with organic landforms.

DISCUSSION

The entire geophysical survey profile lies within the discontinuous permafrost zone (Brown 1967). The profile section north of Fort Simpson lies in the widespread permafrost region, while the section south of Fort Simpson lies in the southern fringe of the permafrost region. Both the geophysical data and statistical information indicate that the amount of frozen ground generally decreases from north to south. The actual values of percentage frozen ground in spreads 1 to 6 were calculated to be approximately 83.7%, 66.3%, 69.2%, 31.6%, 16.1%, and 34.7%, respectively. The exception is spread 6, but this appears to be a topographic effect, since the elevation averages 300-400 m higher than the elevation in spread 5. In addition, the amount of frozen ground in spread 5 is quite low because of the presence of very wet terrain at a relatively lower altitude.

A major controlling factor for the occurrence of frozen ground is the soil distribution along the pipeline route. Sands and clays are predominant

soil types in the northern sections in spreads 1, 2, and 3 while tills and organic terrain are dominant in spreads 4, 5, and 6. Previous studies in the literature (Heginbottom et al. 1978) have shown that finer textured soils have poorer drainage and therefore are more likely to allow ice accumulations. Areas with thick peat cover generally contain frozen ground because of the insulating property of the peat.

The most difficult problem to resolve when mapping the presence of frozen/unfrozen ground with electromagnetic methods is whether a change in apparent conductivity values is due to a change in the frozen/unfrozen state of the ground or due to a change in the soil composition.

Thus it is important to incorporate all available information in the interpretation of geophysical data for delineating frozen/unfrozen ground. This information includes terrain typing, vegetation, borehole logs, and topographic data. The use of this information with the geophysical data has demonstrated that it is possible to delineate the occurrence of permafrost along the pipeline route and supply valuable information for the design considerations of the pipeline. It has also significantly reduced the number of boreholes that would normally be required for such a detailed investigation.

ACKNOWLEDGEMENTS

The authors would like to express their appreciation to Interprovincial Pipe Line (NW) Ltd. for permission to publish this material. The work reported herein was performed as part of a contract for Interprovincial Pipe Line (NW) Ltd.

THE REDISTRIBUTION OF SOLUTES IN FREEZING SOIL: EXCLUSION OF SOLUTES

B.D. Kay and P.H. Groenevelt

Department of Land Resource Science, University of Guelph
Guelph, Ontario, Canada, N1G 2W1

The redistribution of "non-reactive" solutes during ground freezing has been studied. The combination of field studies, laboratory experiments and theoretical analyses lead to the conclusion that exclusion of a solute by an advancing freezing front may not be a particularly significant mechanism for solute redistribution. However substantial redistribution due to convective transport during the process of ice lens formation does occur.

INTRODUCTION

The redistribution of solutes in a porous medium which is freezing is significant for the engineer attempting to control frost heaving in a marine environment or attempting to use solutes to control frost heaving in non-marine environments. In addition the redistribution of solutes under conditions of seasonal freezing is important to the pedologist studying soil development and the agronomist wishing to optimize the use of agricultural chemicals. This paper summarizes the processes which may influence the redistribution of solutes when ground freezing occurs. Field data on the redistribution of solutes due to seasonal freezing are presented. Finally the dynamics of solute exclusion by a rapidly advancing freezing front is treated theoretically and related to a laboratory study involving coarse sands.

THE REDISTRIBUTION OF SOLUTES BY GROUND FREEZING

Processes which influence the redistribution of solutes in frozen and unfrozen soils are similar. Differences in the relative significance of the different processes in frozen and unfrozen soils relate to the role that the ice phase exerts on the processes. Therefore the extent of reaction with soil colloids, precipitation, physical or chemical transformation, and to a degree biological immobilization or transformation, depends on the degree of exclusion of solutes from the ice phase and the amount of ice present. Likewise diffusion, dispersion and convective transport are influenced by concentration in the liquid phase. In addition, the presence of ice at subzero temperatures may substantially alter the potential of unfrozen water which will influence the convective transport of solutes.

Isolated studies have been carried out to illustrate the influence of the ice phase on the reaction of solutes with colloid surfaces, on chemical transformations, and on biological transformations (eg Nelson and Romkens, 1972; Lahav and Anderson, 1973; Bremner and Zantua,

1975). Exclusion of solutes to thin unfrozen films next to colloid surfaces was considered by these authors to provide the medium whereby such transformations occurred in frozen soils. These data apply to the behaviour of solutes within the frozen zone. However these studies provide little insight into the redistribution which solutes may experience in the vicinity of the freezing front as a freezing front is progressing into soil. The advancing freezing front would be expected to exclude solutes with a resultant accumulation of solutes in unfrozen films of water just behind the freezing front and in the unfrozen soil ahead of the freezing front. In the absence of unfrozen water and complete exclusion of solutes by ice, one might speculate that an advancing freezing front would effectively remove or "leach" all of the solutes from the frozen zone (note review by Hallet, 1973). However studies to confirm such speculation have not been published.

The behaviour of water and the behaviour of solutes in freezing soils are linked through processes such as the influence of solutes on the freezing point of the water and the convective transport of solutes within the frozen zone. The influence of solutes on the freezing point depression of water in porous media appears to be quantitatively similar to that in normal solutions (Banin and Anderson, 1974).

The flow of water within the frozen zone due to temperature-induced gradients in liquid pressure will result in solute redistribution (Cary and Mayland, 1972; Campbell et al., 1970; Cary et al., 1979). Solutes transported within the frozen zone would be expected to accumulate in the vicinity of ice accumulation. This in turn will modify the freezing point of the water in this zone, the amount of unfrozen water and consequently the hydraulic conductivity of this zone.

FIELD STUDIES ON SOLUTE REDISTRIBUTION

The field site was located at the Elora Research Station (43°39' N and 80°35' W), which is about 23 km northwest of Guelph, Ontario, Canada. Instrumentation was installed on the site for the

purpose of measuring soil temperature profiles, soil moisture profiles, depth to the water table, and displacement of the ground surface. Further details regarding site characterization and instrumentation employed are provided by Sheppard et al. (1981).

The solute selected for investigation was the nitrate ion. Soil cores were obtained from positions that were randomly selected on the site each week during the winter of 1975-1976. At least three completely intact cores were obtained weekly. The cores were sectioned at 1 cm or 2 cm intervals depending on the depth and/or presence of ice lenses. The gravimetric water content was determined by oven drying. The samples were then rewet with excess water (a 1:2 soil:water mixture), shaken, and the nitrate concentration in the supernatant fluid determined. Nitrate analyses were expressed on an oven-dry soil weight basis.

Nitrate profiles for five representative weeks are shown in Figure 1. Two features of these data are salient: the nitrate level appears to fall slightly with the onset of freezing in the zone near the surface (0-10 cm), and the nitrate level appears to increase progressively with time at greater depth (15-35 cm).

Figure 1: The redistribution of NO_3^- under field conditions due to ground freezing.

Changes in water content due to redistribution in the profile are shown in Figure 2. These data were obtained for the same samples referred to in Figure 1. These data show a progressive increase in water content near the

surface (0-10 cm) and at greater depth (15-25 cm). The increase in water content can be attributed to discrete ice lenses formed by the upward movement of water. Near the surface the ice lenses were microscopic in thickness; at depth the ice lenses were often 1-2 mm in thickness. Laboratory studies (Loch and Kay 1978) suggest that the zone of maximum ice accumulation should occur just above the 0°C isotherm when minimum overburden is involved.

A comparison of Figures 1 and 2 illustrates contrasting behaviour in the 0-10 cm zone and the 15-25 cm zone. In the near surface zone the fall in nitrate level coincides with an increase in water content, whereas at greater depth both nitrate and water contents progressively increase.

In the near-surface zone, part of the decrease in nitrate levels may be due to the exclusion of solutes during repeated advances of the freezing front as a consequence of a number of freeze-thaw events between 75-11-27 and 75-12-23. Denitrification and leaching may also have occurred during this period.

At the 15-25 cm depth the increase in nitrate level coincides with the increase in water content. The increase in nitrate level between 75-11-27 and 75-12-23 must reflect the cumulative effect of solute exclusion by an advancing freezing front, and the accumulation of solutes resulting from the convective transport of solution into this zone as a consequence of ice lens formation. However, between 75-12-23 and 76-1-28 the rate of advance of the 0°C isotherm diminished substantially, with visible ice lenses accumulating in the 15-25 cm zone. The depth of maximum water content appeared to move from 20 cm to 25 cm between 75-12-81 and 76-2-11. These data are remarkably similar to data obtained by Dirksen and Miller (1966) during laboratory studies. The maximum in the nitrate profile appears to remain at 20 cm. This observation would suggest that the advancing freezing front is not totally effective in excluding solutes.

The results of the field study demonstrated that significant redistribution of solutes occurred as a consequence of ground freezing. Convective transport of solutes arising from water being drawn into the freezing zone appeared to be a significant mechanism in the redistribution process. The contribution of exclusion of solutes by an advancing freezing front could not be confirmed in either the near-surface zone (where rapid and repeated freezing occurred) or at greater depth (where the rate of advance of the freezing front was slower).

LABORATORY STUDIES

Laboratory studies were initiated in order to clarify the role of solute exclusion by an advancing freezing front on the redistribution of solutes.

A coarse sand (45% w/w 250-500 μm , 33% 500-1000 μm) was used as the soil material. This material is not frost susceptible and would be

Figure 2 The redistribution of water under field conditions due to ground freezing.

expected to have minimal unfrozen water contents at subzero temperatures. Therefore any redistribution of solutes during the freezing of this medium would be expected to be due to exclusion at the advancing freezing front.

The solute selected for study was Cl^- . The sand was packed into Plexiglass columns (length 8.0 cm, I.D. 3.73 cm) that were segmented in 1 cm sections. Columns were vacuum saturated with a KCl solution (369 ppm Cl^-).

Unidirectional freezing was achieved using the equipment described by Loch and Kay (1978). Columns were equilibrated at $+0.5^\circ\text{C}$, a 4°C step change in temperature was introduced at the lower boundary, and the columns were then frozen for different lengths of time. At the termination of a freezing experiment the Plexiglass column was segmented and the contents of each segment extracted and chemical analysis of the pore solution carried out.

An example of the redistribution of solute observed at the conclusion of a freezing event is illustrated in Figure 3. This type of distribution is generated by a 0°C isotherm, which advanced upward through the column at rates illustrated in Figure 4. Two features are significant from these figures. First, there is no evidence of effective exclusion of the solute from the frozen zone. The ratio of concentration of solute in the frozen zone to that in the

Figure 3 Redistribution of Cl^- during the unidirectional freezing of a saturated sand.

Figure 4 Rate of penetration of 0° isotherm into saturated sand.

unfrozen zone varies from .81 to 1.12. Second, the 0°C isotherm has not moved uniformly through the sample but has moved in "leaps".

It is hypothesized that exclusion of solutes does occur on a local scale. As ice is forming, the freezing front advances slowly because of the release of latent heat. However, with this advancing freezing front is associated an accumulation of solute excluded from the ice. Increasing the concentration of solute results in increasing the freezing point depression and decreasing the tendency to form ice. As the rate of ice formation diminishes, the rate of advance of the 0°C isotherm begins to rapidly increase until nucleation occurs at some point just beyond the zone of solute accumulation. The process is

then repeated. An analysis of Figure 4 suggests that at least three bands of solute accumulation may exist within the zone whose temperature is less than 0°C in this column. Sectioning the frozen zone in 1 cm increments provides concentrations averaged across microregions of solute rejection and solute accumulation. However, the net effect is that solute rejection does not occur on a macroscale, and therefore models designed to predict the redistribution of solutes should take this into account when freezing occurs at the rates used in this study.

THEORY

Theory is developed to describe the temperature profiles and the rate of freezing in a saturated medium. Predictions based on these equations are then compared to the rates of freezing observed in the laboratory studies. Theory describing the rates of solute accumulation at the freezing front is presented and then related to the conditions of the laboratory study in order to evaluate why solute exclusion does not occur on a macroscale.

The temperature profiles and the rate of advance of a freezing front in a saturated medium are calculated using a form of solution to the heat flow equations that is similar to the Neumann solution. Adjustments are made to account for the flow of fluid away from the freezing front due to the differences in volumes occupied by the liquid and ice phases when the matrix is rigid. It is assumed that all of the ice formation occurs at the freezing front. Under these conditions, the temperature profile can be described using the equation:

$$T = T_i - \frac{(T_i - T_f)}{\operatorname{erfc}\{(\lambda_f - 2F)/2\sqrt{K_u}\}} \operatorname{erfc}\{(\lambda - 2F)/2\sqrt{K_u}\} \quad (1)$$

$$\text{where } F = \frac{(\rho c)_l}{(\rho c)_m} \times 0.04 \theta_i \lambda_f,$$

where ρc is the volumetric heat capacity and subscripts l and m refer to the liquid and matrix respectively, θ_i is the volumetric ice content, T is the temperature, subscripts i and f refer to initial temperature and temperature at the freezing front, K is the thermal diffusivity in the unfrozen zone, $\lambda = x/\sqrt{t}$ where x is the distance coordinate, t is time, and $\lambda_f = \lambda$ at the freezing front ($x = x_f$).

The value of λ_f is found from the heat balance at the freezing front, i.e.:

$$\frac{k_f}{\sqrt{K_f}} \frac{(T_b - T_f)}{\operatorname{erfc}\{(\lambda_f - 2F)/2\sqrt{K_f}\}} \exp[-\lambda_f^2/4K_f] + \frac{\sqrt{\pi}}{2} H_f \rho_i \theta_i \lambda_f + \frac{k_u}{\sqrt{K_u}} \frac{(T_i - T_b)}{\operatorname{erfc}\{(\lambda_f - 2F)/2\sqrt{K_u}\}} \exp[-(\lambda_f - 2F)^2/4K_u] = 0 \quad (2)$$

where T_b is the cold side boundary temperature, k_f is the thermal conductivity of the frozen zone, K_f is the thermal diffusivity of the frozen zone, and

H_f is the latent heat of fusion. The first term of Eq. (1), represents the amount of heat flowing from the freezing front towards the cold end. The second term, represents the source of heat due to freezing. The third term, represents the amount of heat flowing from the warm end to the freezing front, this term is very small in comparison to the first two terms, at least for the present boundary conditions. This means that the convective heat flow due to the expansion of water upon freezing has a negligible effect on the position of the frost front. The value of λ_f and the temperature profiles for the case that all the water freezes can now be calculated. In this case $F = 0.023 \lambda_f$. In the experiments it was found that the temperature at the soil surface was -3.3°C. By setting $T_b = -3.3^\circ\text{C}$ and $T_f = 0$ it is found from Eq. (2) that $\lambda_f = 0.0337 \text{ cm}/\sqrt{\text{sec}}$.

The temperature profiles for the experiment illustrated in Figures 3 and 4, are given in Figure 5. Each point is also replotted as a function of λ ($\text{cm}/\sqrt{\text{sec}}$). It appears that for the frozen part, the points fall reasonably well on one line. This means that the similarity principle (scaling) holds for the frozen part. From these graphs it is found that $\lambda_f = 0.06$. An analysis of the data in Figure 4 gives a similar value for λ_f . This large value of λ_f indicates that at the frost front ($T_f = 0$) only part of the water freezes. It further appears that the $T(\lambda)$ line is not straight. This indicates that ice is continuously formed in the frozen zone (behind the frost front). Thus, there are "heat sources" in the frozen zone. This causes the temperature gradient to be the steepest near the boundary ($\lambda = 0$). The sand used in this experiment is expected to have minimal amounts of unfrozen water at subzero temperatures when the pore water does not contain solutes. Therefore

Figure 5 Actual and scaled temperature profiles observed during the unidirectional freezing of a saturated sand.

this will not provide a heat source behind the freezing front. Heat sources in the frozen zone must be associated with brine pockets or bands in which the solute is concentrated.

Ahead of an advancing frost front, i.e. in the not yet frozen part of the soil, the solute present in the liquid phase moves by diffusion and convection. Under these conditions, the concentration profile can be described as:

$$(C - C_i) = A \operatorname{erfc} [(\lambda - 2B)/2 \sqrt{D_0^1}] \quad (3)$$

where C (λ) is the solute concentration, C_i is the initial solute concentration, D_0^1 is the effective diffusion coefficient, A is the integration constant, $B = 0.04 \theta_i \lambda_f / \theta$, and θ is the liquid water content ahead of the freezing front. The value of A may be found from the mass balance of the solute.

The initial amount of solute (before freezing) per unit bulk volume is θC_i . We assume that a certain (constant) amount of solute remains after the frost front passes by. This amount is a fraction of initial amount and is equal to $(1 - k) \theta C_i$, where k is the segregation constant. If we assume that no solute is built into the ice lattice, then $(1 - k) = (\theta C)_f / \theta C_i$ where $(\theta C)_f$ is the product of the volumetric liquid content in the frozen zone and the concentration of solute in that liquid. Using a mass balance approach by equating the amount of solute removed from the frozen zone to the amount of solute added to the unfrozen zone, it is found that:

$$A = k C_i (\lambda_f / 2 \sqrt{D_0^1}) / \operatorname{ierfc} [(\lambda_f - 2B) / 2 \sqrt{D_0^1}] \quad (4)$$

The concentration at the frost front follows from Eq. (3):

$$C_f = C_i + A \operatorname{erfc} [(\lambda_f - 2B) / 2 \sqrt{D_0^1}] \quad (5)$$

Equations (3) and (4) now provide the opportunity to calculate the salt concentration profiles ahead of the freezing front. For reasonable values of the different parameters one finds from Eq. (5) the following approximate relation between C_f and C_i :

$$C_f = C_i + 80 k C_i$$

This indicates that if there is no salt inclusion in the frozen zone ($k=1$) the concentration at the frost front would rise to about 80 times the initial concentration. The resulting freezing point depression would cause the frost front to "leap" over the zone of high solute concentration. This, in turn, would cause a considerable reduction in the k -value on a macroscopic scale.

LATEGLACIAL PALEOTEMPERATURES AND PALEOPRECIPITATION AS DERIVED FROM PERMAFROST:
GLACIER RELATIONSHIPS IN THE TYROLEAN ALPS, AUSTRIA

Hanns Kerschner

Institut für Geographie, Universität Innsbruck, A-6020 Innsbruck, Austria

Numerous fossil rock glaciers in the Alps, situated 450-550 m below the presently active rock glaciers, can be correlated with the Egesen Stadial cold phase (11,000 to 10,000 BP). Fossil rock glaciers of Daun and Senders age (probably older than 13,000 BP) are situated 650 m below the active rock glaciers. From the lowering of the Egesen rock glaciers, a lowering of the mean annual air temperature in the order of -3.5°C against modern values is inferred. The lowering of the summer temperature, as inferred from the lowering of timberline, was in the order of -2.5°C during this period. For the Daun and Senders Stadials, a lowering of the MAAT in the order of -4.5°C is estimated. With the help of a permafrost-glacier-precipitation relationship, paleoprecipitation is estimated. During the Egesen Stadial, precipitation was reduced by 30% in the sheltered valleys of the Tyrolean Alps, whereas precipitation was about equal to present-day values along the northern slope. During the Daun and Senders Stadials, precipitation was reduced by 40% and 25% respectively in some valleys of the northern slope.

INTRODUCTION

In the past paleoclimatic studies in the Alps were concerned with the inference of summer temperature fluctuations from snowline and timberline fluctuations (Patzelt 1975, 1980). A first attempt to derive fluctuations of the annual temperature from rock glacier altitudes was made by the present author (Kerschner 1978). Statements on paleoprecipitation had been qualitative, relying mainly on paleobotanical information. For the last cold phase of the Alpine Lateglacial, the Egesen Stadial (Younger Dryas cold phase, 11,000 to 10,000 BP), a quantitative estimate of the precipitation could be given on the basis of equilibrium line altitudes and timberline altitudes (Kerschner 1982a). As

paleobotanical information on timberline fluctuations is limited for various reasons, the distribution of lateglacial fossil rock glaciers is used as a source of paleoclimatic information in this paper. This attempt is largely based on the permafrost-glacier-precipitation model developed by Haeblerli (1982, 1983), which relates the mean annual air temperature at the equilibrium line of glaciers with precipitation.

STRATIGRAPHY

The Alpine Lateglacial covers the period of the final recession of the large valley glacier systems

from approximately 16,000 BP until 10,000 BP. By 9,500 BP, glaciers had already readvanced within their mid-19th century limits (Patzelt 1973). This period of general downwasting of the glaciers was interrupted several times by periods of readvance ("stadials"). These stadials, which are named after type localities near Innsbruck (Tyrol), have been described in detail by Mayr and Heuberger (1968), Heuberger (1966) and Kerschner and Berkhold (1982).

During the past decade, extensive mapping by several authors showed that the stratigraphical system developed in the Tyrolean Alps is equally applicable in other areas of the Austrian and Swiss Alps (bibliographies in Müller et al. 1981, Maisch 1981). These readvance periods were usually not single phased but consisted of a series of advances and retreats, each one smaller than the preceding. The correlation with the lateglacial stratigraphy of northwestern Europe still presents some problems, mostly for the older stadials. The most likely correlation is given in Table 1.

In the course of mapping lateglacial deposits, a large number of fossil rock glaciers of lateglacial age was found. These rock glaciers developed from talus as well as from morainic debris. Their average length is in the order of 300 to 500 m, but some are more than 1,000 m long and several hundred metres wide. From the collapse structures, a former ice content in the order of 50 to 70% is estimated. A transition from rock glaciers to push moraines (Haerberli 1979a) and vice versa can be observed at numerous localities. Rock glaciers with a core of glacier ice are presently uncommon in the Alps. This is also true for lateglacial rock glaciers. In most cases the transition between the former glacier and the rock glacier can be clearly delineated in the field or from aerial photographs. The period of activity of these rock glaciers can at least be partially fixed with correlation to nearby moraines of known age.

Most fossil rock glaciers at lower altitudes were active during the Egesen Stadial (11,000 to 10,000 BP). Many of them cover large areas which were glacierized during the Daun Stadial as can be deduced from nearby moraines (Kerschner 1978, Maisch 1981). They indicate that a major warming period preceded the Egesen Stadial, which led to an extensive deglaciation. This warm phase is probably identical with the Allerød-Bølling Interstadial complex (13,000 to 11,000 BP; Welten 1982, Eicher 1979, Eicher et al. 1981). As the Younger Dryas cold phase lasted for about 1,000 years and as sufficient debris was available from intense frost shattering and moraines, it is assumed that these rock glaciers closely approached their lowermost position as controlled by topography and climate. In places with appropriate topography, they extend to altitudes between 1,900 and 2,000 m a.s.l., about 450-550 m below presently active rock glaciers. The available data show that there is no significant spatial variability of the altitude of Egesen rock glacier termini in the study area. Similar altitudes can be observed in central and southwestern Switzerland. Rapid warming after 10,000 BP, as it can be inferred from numerous paleobotanical and glaciological studies (e.g. Welten 1982, Patzelt and Bortenschlager 1982) suggests that the activity of these rock glaciers came to an

end at the Lateglacial/Postglacial boundary around 10,000 BP.

While there exists already a fair amount of data on the distribution of rock glaciers of Egesen age, information about rock glaciers of older age is still limited. This is mainly due to the fact that large valley glaciers were more frequent during older phases of the Alpine Lateglacial. These glaciers occupied large areas suitable for rock glacier formation and ended at altitudes that were obviously too low for the existence of permafrost. Rock glaciers of Daun age in the Tuxer Voralpen, 30 km south of Innsbruck, are 620-680 m below the present-day lower boundary of permafrost (Patzelt 1983). Push moraines of Daun age in the Karwendel to the north of Innsbruck can be observed 150-200 m below Egesen rock glaciers. Rock glaciers which can be correlated with the Senders Stadial seem to have been at similar altitudes as the Daun rock glaciers (Kerschner and Berkhold 1982).

PALEOCLIMATIC INTERPRETATION

Numerous measurements show that the surface velocity of rock glaciers in the Alps rates from approximately 0.1 to 1.0 m/yr. A surface velocity of 0.3 m/yr is chosen as a reasonable average by Barsch (1977a,b). From this it is deduced that the formation of a rock glacier of considerable length (i.e. several hundred metres) demands at least several centuries (Vietoris 1972). Possible former periods of fossilization and reactivation can usually not be recognized in the field. From this it follows that fossil rock glaciers only provide a general picture of climatic changes on a time scale of several centuries.

About the same level of resolution can be attained for the inference of timberline fluctuations from lateglacial pollen diagrams, which have also been used as a source of paleoclimatic information (Kerschner 1982a). Thus, paleoclimatic models with rock glacier data as input variables should be comparable with models which use timberline fluctuations as one source of information. Both models cannot make full use of the much more detailed, but unrevealed paleoclimatic information which is present in the large number of lateglacial morainic systems.

Mean Annual Air Temperature (MAAT)

The spatial pattern of the distribution of active rock glaciers--as permafrost phenomena--reflects the pattern of annual isotherms in the study area very well (Fliri 1975, Barsch 1977a, Haerberli 1979b). The same should hold true for fossil rock glaciers which had sufficient time to develop. Hence, as a first approximation, the vertical difference between active and fossil rock glaciers of identical exposure, comparable extent and comparable morphologic setting is proposed as a measure of the lowering of the MAAT (Kerschner 1978). This vertical difference is converted into the lowering of the MAAT with the help of a temperature lapse rate of $-0.65^{\circ}\text{C}/100\text{ m}$. From the lowering of the Egesen rock glaciers (-450 to 550 m) a lowering of the MAAT in the order of -3.0 to

-3.6°C can be inferred for the period 11,000 to 10,000 BP. This is more than the lowering of summer temperature, which can be calculated from the lowering of timberline (approximately -400 m throughout the study area) as about -2.5°C to -3.0°C. These results suggest an increase in seasonal contrasts of temperature between summer and winter during the Egesen Stadial. The same figures seem to apply for the late Egesen Stadial, when glaciers were already much smaller than during the maximum.

From the lowering of the Daun and Senders rock glaciers and push moraines (approximately -650 m) a lowering of the MAAT in the order of -4.0°C to -4.5°C is inferred. Due to a lack of data, no direct estimates can be given for the summer temperature during these periods.

The figures for the lowering of the MAAT during the Egesen Stadial seem to be rather reliable due to the long duration of the cold phase and the large sample size. The figures calculated for the Daun Stadial and the Senders Stadial are less well supported due to the small sample size and our still insufficient knowledge of the duration of these cold phases.

Paleoprecipitation

Active rock glaciers are abundant in the rather dry valleys of the central Alps which are sheltered from the precipitation bearing air masses from the north and south. Precipitation at 2,000 m a.s.l. is in the order of 750 to 1,200 mm/yr in these areas. The equilibrium line (EL) of glaciers there is high compared with the humid northern slope, where precipitation is in the order of 1,600 to 2,000 mm/yr (Gross 1983, Kuhn 1983). Active rock glaciers are almost absent in the humid northern areas of the Alps where the EL is close to the lower boundary of permafrost, thus leaving no space for the development of rock glaciers. The vertical distance between the termini of active rock glaciers and the equilibrium line altitude (ELA) increases markedly with decreasing precipitation. From this it follows that the MAAT at the ELA in dry areas is lower than in humid areas (Haeberli 1979b, 1982, 1983). Hence, the MAAT at the ELA can be taken as an indirect measure for the precipitation in a given area. The relationship between the MAAT at the ELA and the precipitation at 2,000 m a.s.l. in the Alps (Figure 1) can be expressed as

$$\text{Precipitation}_{2,000} = 3613 \cdot (-\text{MAAT}_E)^{-0.8679} \quad (1)$$

from the data of Haeberli (1982). A standard altitude of 2,000 m a.s.l. is chosen for practical reasons. It is also used in other models for the determination of paleoprecipitation (Kerschner 1982a).

Equation (1) serves as the basis for the quantitative estimation of paleoprecipitation during some of the lateglacial stadials. The MAAT at the ELA is calculated from the vertical difference between the altitude of the termini of fossil rock glaciers and the ELAs of nearby glaciers of similar age. Following the lines of Haeberli (1982), it is assumed that the MAAT at the termini of rock glaciers varies between -2.0°C and -4.0°C, depending on aspect and topographic setting of the respective rock glaciers.

Most of the available data come from glaciers and rock glaciers of the Egesen Stadial cold phase (11,000 to 10,000 BP). They show that at the humid northern margin of the study areas the MAAT at the ELA was not below -2.5°C, from which a precipitation in the order of 1,600 to 2,000 mm/yr can be calculated with the help of equation (1). This is about equal to the present-day precipitation in this area. In the sheltered valleys of the central Alps, the MAAT at the ELA was about -6.0°C to -7.0°C indicating a precipitation in the order of 650 to 800 mm/yr, which is about 25-33% less than present-day values.

During the late stages of the Egesen Stadial, glaciers were much smaller and their EL was at higher altitudes than during the maximum. In some areas rock glaciers developed within the area which was glacierized during the maximum advance (Müller et al. 1981, Maisch 1981, Kerschner 1982b). Estimates show that the MAAT at the ELA was of the order of -3.5°C along the northern slope but -8.0°C in the sheltered valleys, thus pointing to a reduction of precipitation by 25 and 55% respectively.

These results can be cross-checked with a stochastic glacier-climate model (Figure 1) which relates the summer temperature at the ELA and the precipitation at 2,000 m a.s.l. (Kerschner 1982a) and with a glacial-meteorological model, which relates ablation and accumulation at the EL through a system of equations defining heat and mass exchange at the glacier surface (Kuhn 1980, 1982). In these models, data on the change of the altitude of tim-

Figure 1 Relation among mean summer temperature at the equilibrium line (MST_E) and precipitation at 2,000m a.s.l. ("glacier-climate-model", Kerschner (1982a)) and relation among mean annual air temperature at the equilibrium line (MAAT_E) and precipitation at 2,000 m a.s.l. ("glacier-permafrost-model" after Haeberli (1982), slightly modified).

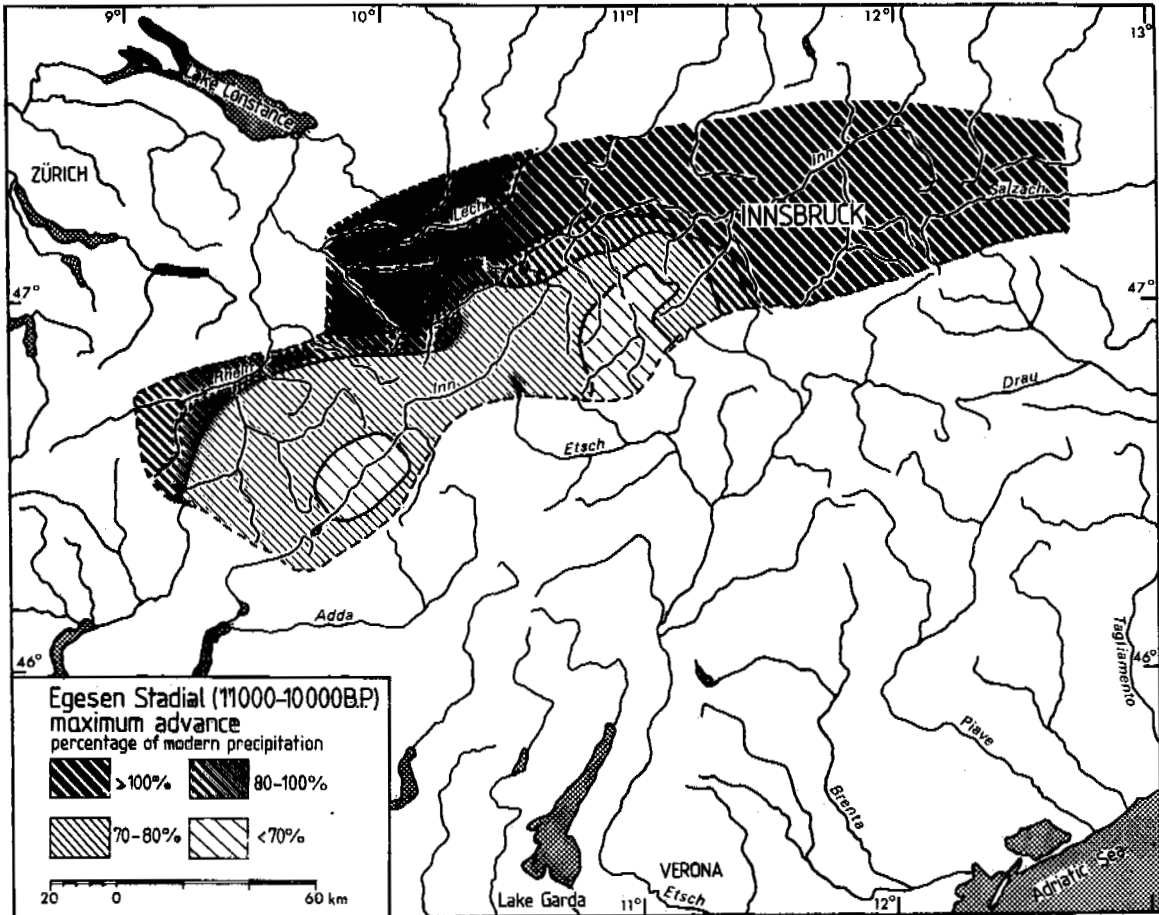

Figure 2 Distribution of precipitation in the central Alps during the Egesen maximum advance, expressed as percentage of present-day precipitation at 2,000 m a.s.l.

berline are used as an independent variable to determine the change of summer temperature at the EL. The use of summer temperature in a glacier-climate model is physically more correct than the use of the MAAT, because summer temperature is an important factor governing ablation. The use of both models is limited to periods for which estimates of the timberline altitude can be made from palynological data. This precludes their application to stadials which preceded the Allerød-Bølling Interstadial complex (13,000 to 11,000 BP). They give similar values of paleoprecipitation during the Egesen Stadial as the permafrost-glacier model discussed in this paper. Differences do not exceed 5% on the average.

A combined application of the glacier-climate model and the permafrost-glacier model allows the plotting of a map of the change of precipitation from present-day values to the precipitation during the maximum advance of the Egesen Stadial (Figure 2). The map covers an area of approximately 250 x 100 km of the central and northern Alps in western Austria and eastern Switzerland. It shows the rapid decrease of precipitation from the northern slope towards the central valleys, which was much more pronounced during the Egesen Stadial than it is today. The transition between humid and dry

areas during this period was sharp and concentrated along mountain chains with altitudes of more than 2,700 m a.s.l. to the south of the Inn valley.

Data on the Daun and Senders Stadials are still limited, so only a few remarks on the former climatic conditions can be made. These data come from valleys which were part of the humid northern area during the Egesen Stadial with 100% of the present-day precipitation. They indicate that precipitation in this area was about 25% lower during the Daun Stadial. During these Stadials, the ELA was much lower than during the Egesen Stadial (Table 1). By employing the glacial-meteorological model (Kuhn 1982) the lowering of summer temperature can be calculated. The precipitation values determined with the permafrost-glacier model are serving as input data. During the Senders Stadial, the lowering of summer temperature was in the order of -4.5°C or more. During the Daun Stadial, summer temperatures were approximately -3.5°C to -4.0°C lower than at present-day. These changes of summer temperature cannot be tested quantitatively against other information and thus must be regarded as orders of magnitude only.

The overall impression of the climate during these phases of the Alpine Lateglacial is that of a rather cold and dry mountain climate which seems to

be readily comparable with the present-day climate in the high mountain regions of central Asia. It seems that the stadials started with cool and comparably moist conditions which changed to cold-dry conditions within a time span of a few centuries or less. This pattern, which was obtained from glaciological and geomorphological information, agrees favourably with the paleobotanical record of the Alpine Lateglacial. This record shows a cold and dry climate favouring a cold steppe vegetation in the upper reaches of the valleys above timberline (Welten 1972, 1982, Markgraf 1973; extensive bibliographies in Burga 1980, Küttel 1979). Results of $^{18}\text{O}/^{16}\text{O}$ -investigations on lake marls in Switzerland agree also well with this pattern (Eicher 1979).

CONCLUSIONS

Fossil rock glaciers in the Alps seem to be a valuable source for paleoclimatic information. Fluctuations of the MAAT can be inferred from the difference in altitude between fossil and active rock glaciers, if data are derived from rock glaciers of identical exposure comparable extent and comparable morphologic setting. The permafrost-glacier model discussed in this paper seems to provide reliable values of the paleoprecipitation during certain cold phases of the Alpine Lateglacial. It seems to be a useful model for the determination of paleoprecipitation for periods, for which timberline data are absent but rock glacier data are available.

The use of rock glacier data in paleoclimatic considerations allows to extend quantitative paleoclimatic studies in the Alps to the northern Alps, where timberline altitude is not so much controlled by climate, but by relief and the limestone substratum. With some precautions, paleoclimatic estimates can be made for cold phases older than the Allerød-Bølling Interstadial complex (13,000 to 11,000 BP), when timberline had not yet reached its highest possible position. Thus, rock glacier studies allow to broaden the scope of quantitative paleoclimatic studies in the Alps both in space and in time.

ACKNOWLEDGEMENTS

I would like to express my gratitude to Dr. Wilfried Haerberli (Versuchsanstalt für Wasserbau, Hydrologie und Glaziologie, ETH Zürich), who provided valuable encouragement during all stages of the preparation of this paper and to Dr. Klaus Frantz, who assisted in the final stages of the preparation of the manuscript. I greatly appreciate many valuable suggestions for the improvement of the paper by the reviewers of a first draft of the manuscript.

SOME ABIOTIC CONSEQUENCES OF THE CANOL CRUDE OIL PIPELINE PROJECT, 35 YEARS AFTER ABANDONMENT

G. Peter Kershaw, Department of Geography, University of Alberta, Edmonton, Alberta Canada, T6G 2H4

The Northwest Territories portion of the CANOL No. 1 crude oil pipeline has been abandoned since 1945. A number of terrain disturbances were initiated by the construction and operation of this pipeline that are comparable to those associated with contemporary developments in northern environments. Abiotic alternations include the removal, compaction, or burial of the often peaty soil surface layers. In all cases there was less organic matter at the surface than in undisturbed areas. Disturbance subsurface temperatures were warmer than controls and it was the amelioration of this ecologically limiting factor that led to a rapid rate of organic matter accumulation (e.g. up to 98% of control values). Subsurface moisture was less for most disturbance types except where depressions resulted from compaction or thermal subsidence in Organic Cryosols. Biological and geomorphological processes continue to respond to the initial surface disruptions and have as yet not stabilized, although the degree of "recovery" varies with the type of disturbance and the terrain in which it occurs.

INTRODUCTION

The CANOL Pipeline Project, 35 years after abandonment, provides an example of how a major, large-scale development has altered the local environment in this mountainous, discontinuous permafrost zone. The Project affected a diversity of environments over a broad geographical area. However this study only reports on the abandoned section within tundra areas in the Northwest Territories, Canada. This area extends over 1.5° of latitude and 3° of longitude between Road Mile Post (R.M.P.) 56.6 near the Mackenzie River at 64°41'N, 127°10'W, and R.M.P. 231.3 on the Continental Divide at 63°14'N, 130°02'W. Elevations of the tundra affected by the CANOL Project range from 775 m near the Mackenzie River to 1,740 m on the Plains of Abraham.

The term "substrate", as it is used in this paper, refers to the surface and near-surface layers of the ground (Agriculture Canada 1976). It includes "soils" of both disturbed and control sites.

Within the study area the pipeline, road, and associated telephone system were constructed between 10 October 1942 and 12 March 1944 and abandoned by 31 May 1945. During the 39 years since the initial disturbances were created, no artificial rehabilitation was attempted and this area still remains closed to auto traffic.

METHODS

Field sampling was carried out between 23 June and 29 September 1979 on those sites where vegetation information had been previously collected. Two criteria were used in selecting representative disturbance and control sites for sampling. These insured that valid comparisons with control conditions could be made.

1. A variety of sites had to be located in close proximity to one another.
2. Each set of sites had to be contained

within an area of homogeneous vegetation (i.e., in terms of structure and species composition), considered representative of larger regions.

Layers were numbered and each measured to the nearest 0.5 cm. All subsurface temperatures (i.e., 10 cm depth) for a set of disturbances and their control were determined over a maximum of a few hours time on the same day. At this depth temperatures were expected to vary little from day to day (Geiger 1959).

Samples were thawed in the laboratory and the moisture content determined gravimetrically (McKeague 1976 and Kalra 1971). Moisture content was expressed on an oven dry weight basis. Organic matter was determined by weight loss-on-ignition (McKeague 1976 and Kalra 1971) and expressed as a percentage of precombustion weight. Sieving separated four soil fractions: 1) gravel, 2) very coarse to medium sand, 3) medium to very fine sand, and 4) very fine sand, silt, and clay (McKeague 1976).

Control or reference sites were selected from nearby undisturbed areas. The control soil pit was dug within the plant community in which the initial disturbance was effected.

Discussion is based upon control-corrected values (CC) which are the means of the differences between disturbances (D) and associated controls (C)

$$CC = [(D_1 - C_1) + (D_2 - C_2) \dots + (D_n - C_n)]/n$$

If the mean of the differences between the control-disturbance pairs was positive, then this indicated that disturbances, on average, had greater amounts of a particular characteristic. Negative values indicated that, on average, disturbances were lower than their controls.

In total, 132 substrate descriptions were made from 33 sampling localities with 33 control soil descriptions. The substrate sampling followed two years of investigations during the growing season and winter and selection of sites was

based on these studies. The substrates described represent 43% of the 310 stands from which plant community information was collected (Kershaw 1983).

RESULTS AND DISCUSSION

Within the study area, eight distinct types of disturbances were recognized - road, false start road, bladed trail, camp yard, bulldozer track, gravel pit, gravel pit access road and oil spill. In all cases, the road had an aggregate surface, but particle size varied with the source material because no crushing or washing facilities were used at the time of construction. The road substrates remain highly compacted as a result of vehicular use.

False start roads included graded winter roads, poor-weather alternate roads, and partly constructed road reroutings. They were infrequently, if ever, used and as a consequence were less compacted than the Canol Road.

The pipeline right-of-way was bladed to create a level surface and to remove shrubs, large stones, or hummocks (Figure 1). In many cases, low spots would be left intact while hummock tops were planed off. The resulting bladed trail was generally a shallow depression dominated by mineral exposures.

Camp yards were temporary or permanent areas used as parking, storage or building sites. Generally they were bladed level and seldom infilled but were driven over by tracked and tired vehicles. Relatively undisturbed sites were found immediately adjacent to highly altered, bladed surfaces.

Bulldozer tracks were identified by the presence of two tread furrows that resulted from compression of the organic horizons and therefore were most apparent in areas with peaty surface layers (Figure 1).

Gravel pits were excavated in glacial outwash, till, and modern alluvium as well as in blockfields (Figure 1). They often contained ponded water year round as a result of local drainage into the closed depression or excavation below the local water table (Figure 1). The gravel pit access roads were generally no more than a buildup of loosely compacted, rutted material that fell from trucks as they left the pit (Figure 1).

Oil spills were readily identified by their odor and blackened appearance, and usually lacked vegetation. In some cases, these substrates had high organic content but in others, deflation and running water had left only a mineral surface. A thick, waxy or tarry coating was also present on some sites. The parameters chosen for study do not necessarily reflect the degree of substrate disturbance associated with oil spills. The addition of oil has altered the substrate by introducing substances toxic to plants and thereby dramatically affecting rates of revegetation. Oil spills therefore will be discussed separately.

An initial evaluation of the results indicated that reaction to a particular disturbance varied among the major plant communities in the study area. Further discussion will therefore be

grouped by plant community (Figure 1).

Erect Deciduous Shrub Tundra

This type of tundra was found to generally occupy well-drained landforms of alluvium and till throughout the study area. However, the thick surface covering of lichens reduced moisture losses and therefore these soils were also moist (Figure 1). The sporadically distributed patterned ground appeared to be active. However, to a large extent this was the result of needle ice activity and deflation processes, both of which prevent or restrict plant colonization.

Ice-rich permafrost was restricted to wet lands containing isolated palsas, where organic layers were relatively thick. These features were small in area and the soil here was classified an Organic Cryosol.

Dystric Brunisols were most common in this plant community and were typically found beneath *Betula glandulosa*- and *Salix planifolia*- dominated sites. *Salix alaxensis* was the dominant shrub in riparian plant communities with Humic Gleysol the most common soil. Bare ground generally accounted for less than 15% of the total area and was restricted to fine materials in areas of patterned ground.

Twenty-eight samples were taken in this plant community, including six control sites and representatives of all eight disturbance types (Figure 1). A number of relationships were apparent. The large absolute differences in moisture content between controls and disturbances probably resulted from the much higher gravel content and lower organic matter content on the disturbances (Figure 1). The lower moisture content, combined with less organic matter, resulted in disturbances having warmer subsurface temperatures. With the exception of false start roads, rooting depths were shallower on all disturbances. This could be a response to the relatively short period (34-36 years) that roots have had to penetrate the ground. Alternatively, the plant species growing on the disturbances may be more shallow rooted than those on undisturbed terrain.

It is apparent from Figure 1 that substrates of bulldozer tracks and oil spills were most similar to the controls, a result of the limited initial mechanical disturbance of these sites. The gravel pit access roads had 98% of the organic matter on their associated controls. Haag (1973) and Babb and Bliss (1974) reported that the organic surface layer was important in retarding subsurface moisture loss and heat gain. The gravel-dominated disturbances provide drier, warmer substrates. Even those disturbances that left the preexisting soil relatively intact have warmer, drier substrates (Figure 1).

Initially, all of the disturbances removed the shrub canopy. Even without excavation or the addition of gravel, increased exposure to sunlight would result in greater surface warming and greater advection of these areas with a consequent removal of moisture from the surface. When combined with improved drainage (both surface and internal), these factors resulted in dramatic substrate differences between controls and their associated disturbances in this plant community

(Figure 1).

Decumbent Shrub Tundra

This plant community was most common on landforms composed of colluvial and alluvial deposits. Species of *Dryas*, *Salix*, and *Potentilla* were the dominant plants and total cover varied from 60 to 100%. Areas with active needle ice, deflation, or seasonal frost churning processes were devoid of plants. The nine control soil samples were classified as Humic Regosols. These soils were well-to excessively-drained as a result of their high gravel content.

A total of seven disturbance types were described in this plant community and 35 substrate samples were taken. It is noteworthy that over 34-36 years, some disturbances which buried or removed the preexisting soil (i.e., roads, gravel pits) have since accumulated from 55 to 67% of the amount of organic material found in adjacent control areas. This relatively rapid rate of organic accumulation may be a result of enhanced production on disturbances or a reduced rate of decomposition. In this environment, where temperature is a biological limiting factor, the warmer substrates of disturbances must be a positive factor in plant growth. The shallower rooting

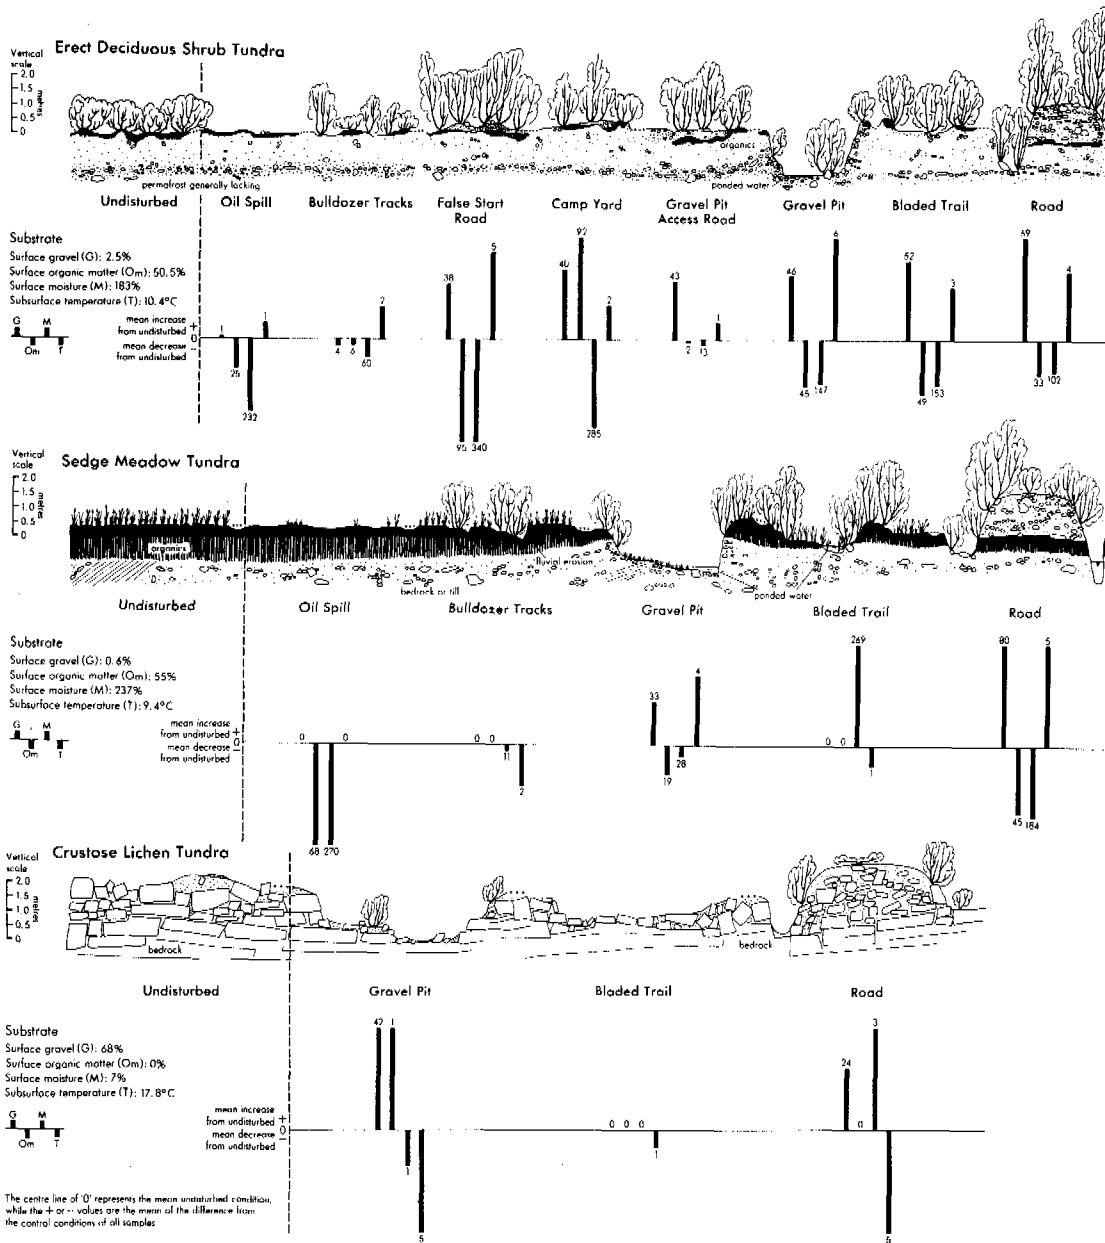

FIGURE 1. CANOL Disturbance Substrate Characteristics in Three Mackenzie Mountain Plant Communities.

depths on disturbances may indicate that plants are capable of taking advantage of these warmer substrate conditions. This also suggests that in this plant community moisture is not a significant limiting factor since the organic accumulations produced by the plants on the site have developed despite drier substrate conditions.

Sedge Meadow Tundra

Sedge dominated wetlands contained Organic Cryosols and Humic Gleysols. The Organic Cryosols had organic layers more than 50 cm thick and a late August thaw layer of 50-60 cm. Sedges in *Carex* and *Eriophorum* were the dominant plants with underlying mats of *Sphagnum* spp. and *Hylacomium splendens*. Plant cover on Organic Cryosols was 100% whereas on the Humic Gleysols it was as low as 75%.

Five control and nine disturbed sites were sampled in Sedge Meadow Tundra, including examples of five disturbance types (Figure 1). Surface layer thickness on bladed trails and bulldozer tracks was reduced by excavation and/or compaction. As a result, bulldozer track substrates were wetter and cooler than their associated controls (Figure 1). Despite the 40% gravel content, in the gravel pit, it had accumulated 81% of the organic matter found in its control (Figure 1). Rooting depth is approximately equal to that of the associated control while subsurface temperature was higher (Figure 1). These conditions have enhanced organic matter production and a rapid rate of accumulation. The roads have warmer but drier substrates and have accumulated 55% of the organic matter found in their controls (Figure 1). If decomposition is also accelerated by warmer substrate temperatures, then the rates of organic matter production must be very high indeed. Loré (1977) has shown that enhanced annual production of standing crop occurred on 50-year-old cart tracks. Thus rates of organic matter accumulations can be greater than those of controls within 50 years of disturbance.

Lichen Heath Tundra

This plant community occurs primarily on landforms composed of colluvium. No permafrost was encountered in this community. Here, the Dystric Brunisol soil supported a plant cover of 90-100%. Dominant plants included *Cassiope tetragona* and *Vaccinium uliginosum* with lichen species of *Cladonia* and *Cetraria* forming mats at ground level. In addition, *Polytrichum* spp. were common.

One set of four disturbances with their associated control were sampled in Lichen Heath Tundra. These well-drained materials with low moisture retention were warmer because of the removal of the insulating surface organic layer and the reduced moisture content. The thick lichen carpet which graded gradually into the organic layer on undisturbed sites was removed and no longer acted as a barrier to ground heat and moisture flux. The low organic matter accumulation over the 34-36 years since the initiation of the disturbance may indicate that moisture was a limiting factor in this plant community, with the higher substrate temperatures (twice as high as

those of the control) causing periods of drought and subsequent mortality of seedlings and/or adult plants.

Fruticose Lichen Tundra

This type of tundra was found on well-drained, gravelly landforms composed of alluvium or colluvium with Humic Regosols and Dystric Brunisols. Lichen species of *Cladonia* and *Cetraria* were the dominant plants and generally formed over 80% of the normally 100% plant cover.

Six disturbances were described with four control and 14 disturbed sites sampled. Where a disturbance affected both soil types in this plant community, the differences in organic and moisture content relative to the controls were greater in Humic Regosols, despite the fact that control soil conditions were similar. Rooting depth in Humic Regosols was greater on all disturbances (with the exception of gravel pits) whereas in Dystric Brunisols the depth of rooting was generally less than that of the controls. It is evident that warmer substrates result from the removal or burial of organic surface layers and the insulating lichen surface covering in addition to the deposition or exposure of coarse, well-drained materials.

Cushion Plant Tundra

This plant community was most common on colluvial deposits where soils were Regosolic with Humic Regosols under plant cover. These soils were well to excessively drained and gravelly, often with a shallow lithic contact. This, combined with their location in the rainshadow of the Mackenzie Mountains, has produced dry soils. Plant cover values ranged from 3 to 20%. Dominant plants included *Dryas octopetala*, *D. integrifolia*, *Silene acaulis*, and *Salix dodgeana*.

Five controls and 10 sites representing four types of disturbances were described from Cushion Plant Tundra. Many substrate parameters were similar on disturbed and control sites because of the naturally coarse soils. In comparison with other plant community substrates, those of Cushion Plant Tundra had little difference between controls and disturbances.

Crustose Lichen Tundra

This plant community is most common in blockfields. Some of these landforms frequently had finer material beneath a surface layer of blocks and/or in isolated islands dispersed throughout (Figure 1). All of these areas were classified as rockland since they did not meet the criteria of Regosols.

The 90-100% plant cover was dominated by long lived and slow growing lichen species in *Rhizocarpon* and *Lecanora*.

Three types of disturbances were studied in this plant community with a total of five samples and three controls described. Most disturbances had more fine-textured materials and therefore had greater moisture storage ability than did their controls (Figure 1). Disturbances were lighter in color than the black lichen covered

controls and with a higher albedo, had lower surface temperatures (Figure 1). These conditions offered a much less harsh environment for vascular plants on disturbances than on controls. The high temperatures and low moisture of control substrates would create water stress conditions for most vascular plants, and disturbances would provide a more habitable environment. The fine materials found on disturbances also provided a rooting medium for vascular plants that was absent in undisturbed areas.

Oil Spill Disturbances

The type and amount of oil residue remaining in the soil after 35 yrs. varied from one oil spill to the next (Kershaw 1983). Oil spills were deposited on the ground surface and the soil structure was little altered by the addition of oil. Surface vegetation and organics usually absorbed the oil and have undergone some consolidation over the past 35 years due to the weight of the oil. Moisture content was less than controls, as a result of the sealing of the surface by oil and the filling of mineral soil spaces to prevent water infiltration (Bliss and Wein 1972). In organic layers, oil was absorbed by the litter which acted as a sponge. This was also noted by McCown et al. (1972). Most oil spills produced a low surface albedo that persists and produced warmer subsurface temperatures (Figure 1).

SUMMARY

On road, false start road, bladed trail, gravel pit, and gravel pit access road disturbances the loss of organic matter most affected moisture, and subsurface temperatures. These characteristics control seed germination and survival success as is reflected by rooting depth and organic matter accumulations (on initially mineral dominated substrates) 34-36 years after the initial disturbance. As expected in control plant communities where organic matter is lacking or limited in the surface layers (e.g., Cushion Plant Tundra, Crustose Lichen Tundra) and on disturbances where surface layers have remained relatively intact (e.g., some bladed trails, bulldozer tracks) the overall substrate differences between controls and disturbances were relatively small.

Many surfaces were denuded of plants when they were disturbed. The current accumulations of organic matter on disturbances in several plant communities were a surprisingly high proportion of what was found on the associated controls. Accumulation of organic matter must be accelerating with time as plants reestablish (unless it is now in an equilibrium with decomposition). This implies that substrate conditions on some disturbances are not especially limiting to plant production in general.

Several disturbances in all plant communities had substrates with different particle size composition than was found in their controls. The most significant difference was the greater gravel content found on several disturbances.

The absence of fine fractions, combined with the removal of surface organics on several disturbances increased through flow, decreased internal storage, and increased the effectiveness of evaporation. All these conditions have been described for short-term disturbances (Haag and Bliss 1974). Roads, false start roads, camp yards, gravel pits, and gravel pit access roads were generally drier and warmer than controls (Figure 1). Important exceptions to this occurred in Cushion Plant and Crustose Lichen Tundra where the controls lacked significant organic layers. Despite increased or unchanged gravel content, disturbance substrates here had more fine material and were able to retain more moisture. Consequently subsurface temperatures were generally cooler than in control areas.

CONCLUSION

Undisturbed soils in the study area were generally not well developed with thin surface organic layers (except Cryosols) and weakly developed mineral layers. This was the case despite the extreme age of sections of the study area lying within the unglaciated portion of the Mackenzie Mountains. Soils were generally cold and in areas with thick accumulations of organics, permafrost was often present. Regosols, Brunisols, Gleysols, and Cryosols were described from the region.

With the exception of oil spills, there are numerous cases where disturbed substrates have responded positively after 34-36 years. Certainly, differences exist between controls and disturbances. However, it is difficult to equate or compare a substrate that is 34-36 years of age with a soil that is thousands or, in the unglaciated area, even a million years old. Even those substrates on such devastating disturbances as roads and gravel pits have accumulated organic matter and offer warmer substrates (Figure 1) to colonizing plants in an environment where temperature is a major ecologically limiting factor. However, the removal or reduction of organic matter (primarily in the L-H horizon) and the lower fine particle content on many of the disturbances has created drier conditions (Figure 1) that can limit plant recolonization (Johnson 1981 and Johnson et al. 1981).

No efforts were made to minimize the initial CANOL disturbances. The project proceeded with virtually no preplanning, was executed without restrictions on construction and operation practices and no rehabilitation program was instituted following its abandonment. However, the CANOL disturbances provide confirmation that rehabilitation would have resulted in much greater recovery than has been observed. For example, false start roads where the pre-disturbance soil was removed had highly irregular surface topography, no drainage ditches, slight compaction, and included some organic matter. These disturbances were frequently more similar to controls than were roads, which provided quite different substrates (Figure 1). It is also possible that attempts to rehabilitate some types of disturbances (e.g., bulldozer tracks) might

result in greater disruption than if left to recover naturally.

ACKNOWLEDGEMENTS

Financial support for this research was provided by the Boreal Institute for Northern Studies, the Arctic Institute of North America, and the National Wildlife Federation. Some logistical support was provided by Imperial Oil Limited and AMAX Northwest Mining Co. Figure 1 was drafted by the Reprographics Section of the Department of Geography, University of Alberta. Linda Kershaw contributed and collaborated during all phases of this research.

SITE INVESTIGATION AND FOUNDATION DESIGN ASPECTS OF CABLE CAR CONSTRUCTION
IN ALPINE PERMAFROST AT THE "CHLI MATTERHORN," WALLIS, SWISS ALPS

H. R. Keusen¹, W. Haerberli²

¹Geotest AG, Zollikofen Bern, Switzerland

²Versuchsanstalt für Wasserbau, Hydrologie und Glaziologie, ETH Zürich, Switzerland

The construction of the uppermost section of the cable car leading from Zermatt (1,600 m a.s.l.) to the "Chli Matterhorn" ("little Matterhorn", 3,884 m a.s.l), Wallis, Switzerland, posed several geotechnical problems related to the presence of alpine permafrost. One important pylon had to be designed to withstand the creep pressure from a perennially frozen historical moraine, rich in ice. The site was investigated by geoelectrical D.C. resistivity soundings, core drillings, and geodetic measurements of creep displacements. Pits excavated for the foundation of the pylon were filled with pure ice. This ice has first to be squeezed out by creep of the frozen moraine before the full creep pressure can be exerted on the pylon. In the rocks of the summit station (with a mean temperature of about -12°C), the anchorage of heavy cables had to be effected in a purely mechanical way, in tunnels which were specially excavated for this purpose. Attention was given to the thermal insulation of buildings in order to avoid any melting of ice in cracks and joints. Deformation of the rock mass is being measured periodically and has remained small.

INTRODUCTION

High mountain construction work related to tourism and to scientific and military activities has often encountered permafrost conditions in the Swiss Alps (Salomon 1929, Barsch 1969, Furrer and Fitze 1970, Haerberli et al. 1979). However, the phenomenon of high altitude permafrost in low latitude mountains has only relatively recently appeared in the scientific and technical literature. Thus the occurrence of permafrost at high altitude construction sites was often, and sometimes still is, somewhat of a surprise, causing unexpected technical and financial problems of considerable extent. In contrast, permafrost aspects were taken into account from the very beginning of construction for the cable car to the "Chli Matterhorn" (i.e., little Matterhorn) near Zermatt. This paper discusses some of these aspects, especially questions of site investigation and foundation design in perennially frozen sediments and anchorage of heavy cables in negative temperature bedrock.

Today the tourist can travel easily and quickly from Zermatt at 1,600 m a.s.l, where permafrost is sporadic, to the "Trockener Steg" at 2,939 m a.s.l, at the border of the "Oberer Theodul-

Figure 1:
View from the station of "Trockener Steg" to pylons 1, 2, and 3 and the "Chli Matterhorn." Pylon 2 is situated on a historical lateral moraine of the "Oberer Theodulgletscher" (off the right of the picture). This moraine is perennially frozen, contains a large amount of ice, and creeps downhill at a speed of a few centimeters per year. An icefall of the "Unterer Theodulgletscher" is visible in the background.

gletscher" within discontinuous permafrost, up into the belt of continuous permafrost at the spectacular summit of the "Chli Matterhorn" at 3,884 m a.s.l. Permafrost-related engineering problems were restricted to the section leading from the "Trockener Steg" to the "Chli Matterhorn" (Rieder et al. 1980).

PLYON 2: CREEP OF PERENNIALY FROZEN SEDIMENTS

Before crossing the "Unterer Theodulgletscher" with a cable approximately 3 km in length, the cable car passes over three pylons, situated between about 2,950 and 3,050 m a.s.l. (Figure 1). As is also the case for the lower station of the cable car at "Trockener Steg," two of these pylons (pylons 1 and 3) have their foundations in bedrock, and geotechnical problems specifically related to permafrost were not encountered at these positions. Pylon 2, however, had to be installed at a place where the bedrock (serpentinite) was covered by a layer of lateral moraine, still occupied by the "Oberer Theodulgletscher" during the early twentieth century. Based upon experience from a study of permafrost distribution in alpine regions with comparable climate (Haeberli 1975, p. 121), it was estimated that this moraine was in a perennially frozen state, and adequate site investigation was necessary.

Geoelectrical resistivity soundings (Röthlisberger 1967) using the Schlumberger configuration were carried out across the moraine in August 1974. The results are summarized in Figure 2. Below the thin, low resistivity, active layer (1,200-3,000 Ωm, about 2 m thick), frozen sediments with a very high resistivity were encountered (145,000-156,000 Ωm). Similar resistivity values have been reported from rock glacier permafrost by Fisch et al. (1978). No low resistivity layer was observed between these sediments and the bedrock—the latter being a massive serpentinite with a resistivity of about 18,000-25,000 Ωm. The absence of a low re-

Figure 2: Cross section through the perennially frozen moraine near pylon 2, as determined by geoelectrical resistivity soundings.

sistivity layer indicated that the sediments were frozen throughout and that permafrost conditions had also to be expected in the underlying bedrock. Dead glacier ice with resistivity values of the order of many million Ωm (Röthlisberger 1967, Röthlisberger and Vöggtli 1967, Fisch et al. 1978) was either too thin to be detected by the resistivity soundings or was not embedded in the frozen morainic sediments et all. Because of the rather unexpected existence of a local depression in the topography of the bedrock surface, the thickness of the frozen moraine at the proposed site for pylon 2 reached about 30 m. As a consequence, the construction site for pylon 2 was shifted to a place where bedrock depth was expected to be shallower. Three core drillings furnished supplementary information about the thickness and the properties of the frozen sediments (Figure 3). A double-wall core drill was used to avoid the melting of ice in the cores as much as possible. As was expected from the resistivity soundings, bedrock was encountered here between 6 m and 11 m below the surface. Core drilling C penetrated a snow and ice patch of limited thickness. All three drillings recovered frozen, silty sands and gravels

Figure 3: Three core drillings taken at the site of the foundation for pylon 2. 1-5: samples for laboratory analysis.

with some larger rocks, and ice lenses. More than 30% of the frozen moraine consisted of relatively pure ice. Five samples were analyzed in the laboratory. All of them contained very limited amounts of air—only 1–2% by volume on average. Ice lenses (samples 2 and 5, Figure 3) were almost completely free from air and gave density values of $1\text{--}1.2 \text{ Mg m}^{-3}$, corresponding to an ice content of about 85–95% by volume. Samples 1, 3, and 4 (Figure 3), taken from sections of frozen moraine without macroscopically visible ice, had densities between about 1.4 and 1.6 Mg m^{-3} and ice contents above 60% by volume. The overall ice content (around 75% by volume) in the obviously supersaturated frozen sediments was therefore higher than the porosity of comparable nonfrozen sediments by a factor of 2–3. These observations were in good agreement with the results of scientific core drillings in rock glacier permafrost (Barsch 1977, Barsch et al. 1979).

Supersaturated frozen sediments with reduced particle-to-particle contacts were known to creep following a stress-strain relationship quite similar to that of ice (e.g., Vyalov 1962, Thompson and Sayles 1972, Anderson and Morgenstern 1973, McRoberts and Morgenstern 1974, Sayles and Haynes 1974, cf. also Huder 1979). The creep velocity of the frozen sediments at the construction site of pylon 2 was therefore geodetically measured at 5 poles. These were anchored by concrete within the permafrost (below the active layer). However, rough estimates of creep displacements were already needed before the end of the observation period (1975–1978) in order to design the foundation for planned pylon 2. On the basis of Glen's flow law for pure ice (Glen 1955) and taking into account results from photogrammetric movement studies (Messerli and Zurbuchen 1968, Barsch and Hell 1975, Haerberli et al. 1979) on alpine rock glaciers (which represent natural large-scale experiments on the long-term creep behavior of frozen supersaturated sediments), $1\text{--}10 \text{ cm yr}^{-1}$ seemed to be a reasonable order of magnitude for the considered $11^{\circ}\text{--}18^{\circ}$ slope, with the given geometry and density of the frozen moraine. The direct observations finally gave $5\text{--}8 \text{ cm yr}^{-1}$ with one exception (23 cm). It is worthwhile noting that the displacement vectors deviated considerably from the line of maximum slope.

Three approaches were used to determine creep pressure against the pylon within the frozen moraine: (1) the method of "passive earth pressure" after Haefeli (in Mohr et al. 1947) which considers the combined effect of passive earth pressure and shear stresses acting at the sides of an obstruction with cylindrical cross-section; for the case under consideration, internal friction was assumed to be zero and a long-term shear strength had to be introduced (1 t/m^2 for ice and 2 t/m^2 for frozen sediments were chosen to give upper limits for the estimation of creep pressure); (2) the use of an empirical relationship for the calculation of creep pressure against cylindrical piles, after Haefeli; and (3) the use of an equation for piles of circular cross section, by Wenz (Schenk and Smoltczyk 1966)

$$Q_c \approx 2.5 \gamma(z + d)d \quad (2)$$

$$Q_c = 1.7(1 + \pi)dc_u \quad (3)$$

where Q_c is creep pressure (per m pile height); γ , specific weight of the creeping mass; z , depth below surface; d , pile diameter; and c_u , "long-term shear strength" of the creeping material. Because of the geometrical and structural complexity of the creeping mass, all pressure determinations are necessarily rather rough approximations. Safety considerations were based upon all three approaches.

A scheme of the system selected for the foundation of pylon 2 is shown in Figure 4. Anchors had to be installed within the bedrock, below the foundation, because rock resistance, even with fixation depths of 3.8 and 4.8 m, was not high enough for the required safety. Since all three

Figure 4:
Foundation design for pylon 2.

approaches used for the estimation of creep pressure gave smaller pressures for ice than for frozen sediments, the pits excavated for the foundation were refilled with ice instead of morainic material. This ice has first to be squeezed out by the creeping moraine before the full creep pressure is exerted on the pylon by the frozen sediments. During this time, not only the pylon can be observed but also the nearby glacier. If the present glacier advance in the Alps continues (Kasser 1981), the ice of the "Oberer Theodul-gletscher" could build up irresistible pressures against pylon 2 within a time period of a few decades.

SUMMIT: ANCHORING HEAVY CABLES IN NEGATIVE TEMPERATURE BEDROCK

The summit station (Fig. 5) was anticipated to be within the alpine belt of continuous permafrost and to have a mean rock temperature of around -10°C (cf. Haerberli 1976, p. 211). During the excavation of a tunnel from the steep north side to

Figure 5: Concrete transportation to the construction site of the summit station at 3,820 m a.s.l. Concrete was prepared at "Trockener Steg" to avoid frost problems. Mont Blanc (French Alps), the highest peak of the Alps, is visible in the background. (Photograph taken by Air Zermatt.)

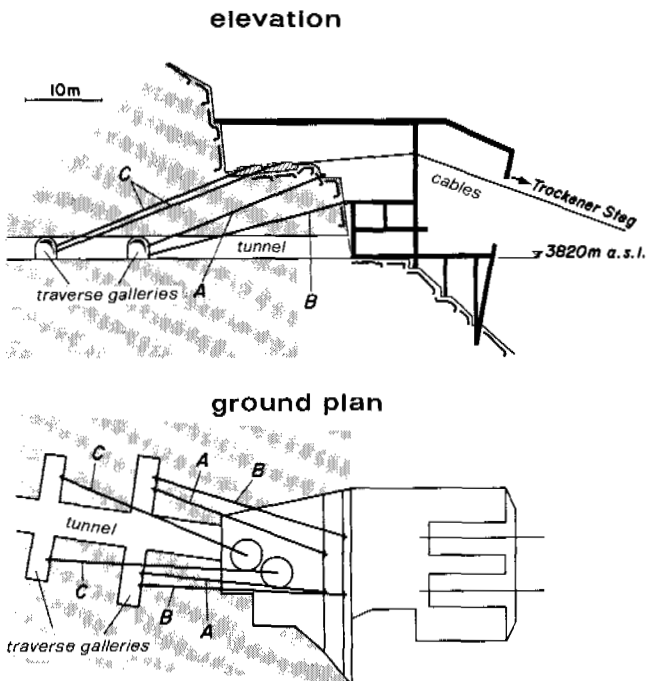

Figure 6: Scheme of the anchor arrangement in the summit rocks of the "Chli Matterhorn." A, B, C: anchor groups.

the glaciers on the south side of the mountain, rock temperatures were measured by infrared thermometry of tunnel walls in the section which was barely disturbed thermally by the excavation. However, in the section where heating was inevitable because water was employed during drilling, rock temperature was determined by thermistor readings in shallow boreholes near the tunnel front. The observed -10° to -12°C temperature values represent thermal conditions within the nearby west side of the mountain. Ice-filled cracks were noted at both ends of the tunnel.

The existence of this tunnel made it easy to avoid frost problems normally associated with injections of concrete in anchors for the steel construction and cables of the cable car were, in fact, fixed on blocks installed in small transverse galleries which were specially excavated for this purpose (Figure 6). Each group of anchors was designed with a safety factor of $F = 1.5$, to cover the case that one anchor in the group should fail. This arrangement permits periodic control and even, if necessary, replacement of anchors without major interruptions to the cable car operation. Anchor force at each group is observed with permanently installed strain gauges. Relaxation caused a decrease in anchor force of about 1.5% of the initiated tension during the first year. Attention was given to thermal insulation of the summit station to avoid any melting of ice in cracks and thus any related destabilization of the negative temperature bedrock around the anchors.

Rock deformation is measured with an extensometer arranged parallel to the anchors and by convergence measurements between the anchor blocks and the opposite tunnel walls. The extensometer did not give measurable deformations while putting the anchors under stress, whereas the convergence measurements showed displacements of the anchor blocks toward the rock wall of up to 0.5 mm, followed by long-term reverse movements of about 1.6 mm, probably as a consequence of rock relaxation.

Cable car operation started at the end of 1979.

ACKNOWLEDGEMENTS

The authors are grateful to the Burgergemeinde Zermatt for giving permission to publish this study, to many colleagues for scientific and technical advice, and to P. Alean for helping to prepare this manuscript.

SELECTION OF PRINCIPLES FOR THE USE OF PERMAFROST MATERIALS
AS A FOUNDATION FOR BUILDINGS AND STRUCTURES

L. N. Khrustalyov

Research Institute of Foundations and Underground Structures
Vorkuta, USSR

In designing buildings and structures in the North two principles are applied in using permafrost materials as a foundation (the permafrost materials are used either in a frozen state or in a thawed state). The choice of one of these construction principles represents a sophisticated technical and economical problem. It is made on the basis of optimization of the reliability of the foundation in terms of cost. Calculations of the reliability of the foundation and of the costs involved were made by computer using an algorithm developed by the author and construction of a design nomogram that interrelates foundation reliability, costs involved, and the controlling parameters of the foundation. Then the nomogram was used to select one of the principles for using permafrost materials, the foundation depth and the depth of preliminary thawing or freezing of the foundation materials.

STATE OF THE PROBLEM

Either of the following two construction principles of permafrost ground utilization as soil bases is currently in use for designing soil bases and foundations for building and structures to be built in northern areas.

Construction Principle 1 — The permafrost ground of soil bases is utilized in the frozen state, which is preserved over the construction period and throughout the entire service life of a building or structure.

Construction Principle 2 — The permafrost ground of soil bases is utilized in the thawed state (its thawing is permitted to the design depth prior to the structure use, in the course of the structure use, with the upper permafrost boundary stabilized).

In selecting the construction principle of permafrost ground utilization, the following rules should be observed:

1) For sites where the seasonal thawing layer is in contact with the permafrost strata over the entire area of a structure under design, it is recommended to utilize soil bases in the frozen state (construction principle 1). This rule does not cover those cases when special technological or structural features of the building or structure make the arrangement of a cooling system either impossible or economically disadvantageous.

2) For sites where the seasonal freezing-thawing layer is not in contact with the permafrost strata at all or is in contact with it not over the entire area of a structure under design, soil bases may be utilized both in the frozen state (construction principle 1) and in the thawed state (construction principle 2). Principle selection will be made on the condition that the minimum construction costs are provided.

3) For sites with deep permafrost ground occurrence it is more advantageous to use construction principle 2.

Such a small body of information affords ample opportunities for adoption of peremptory decisions that cannot be put up with in the engineering practice.

Let us now consider this problem in terms of the reliability theory.

DETERMINATION OF THE SOIL BASE RELIABILITY

The reliability of a soil base is understood as its capacity to take up external loads and effects (thermal and mechanical) while maintaining serviceability of the erected building or structure. The reliability of a soil base is thought to be ensured if the ultimate conditions for the bearing capacity and the deformation (settling) of soils are met (design in terms of ultimate stressed state of soils). Nevertheless, the answer to what extent it is ensured and what guarantee there is for the conservation of reliability over a specified period of time profiting by the deterministic approach adopted now in the engineering practice cannot be given yet. But the probabilistically statistical approach provides a means for getting it. This approach consists in coherent understanding of the fact that thermal and mechanical interaction of a building with its base is a time-developing stochastic process that is dependent on a set of natural climatic and technogenic factors that are accidental by their nature. According to the general concepts of the reliability theory a stochastic process is developed within the system quality space (Bolotin, Gol'denblat, & Smirnov, 1972). A set of the system states to be allowable in terms of quality forms a region of allowable states (Ω_0) within the quality space (V). If a stochastic process intersects the boundaries of this region, then the system quality will be lost and a failure will occur. The probability of quality conservation over a specified period of time is system reliability.

The quality space of the system "base" is formed

by its elements which are as follows: the bearing capacity of base and the quantity of simultaneous deformation (settling) of the base and building or structure. The boundaries of the allowable states region are the load imposed by the building or structure on its base and the allowable limiting quantity of simultaneous deformation (settling) of the base and building or structure. Proceeding from the methodology of the ultimate states we shall think that the base quality is conserved if the bearing capacity of base exceeds the load imposed by the building on its base and the simultaneous deformation (settling) of the base and building is less than the allowable limit. The probability of this event throughout the in-service life of a building will be termed base reliability and the entire flow of values of this time-allowable probability will be termed base reliability function.

The determination of the reliability function comprises three stages. The first stage consists in schematization of the system and the external effects it is exposed to, as well as in selection of the quality space and the allowable states region. The second stage involves determination of the stochastic behaviour of the system being exposed to accidental effects. The problem comes therefore to solving the following stochastic equation (1):

$$v = L \cdot u \quad (1)$$

where v = the component of the quality space V ;
 u = the component of the entry parameters space U ; and
 L = the system operator.

The third stage incorporates determination of the reliability function $P(t)$ as equation (1's) complement of a probability of the process accidental fall-out from the allowable states region.

The entry parameters space U is understood as a set of natural climatic and technogenic factors, which determine conditions of thermal and mechanical interaction between the building or structure and its base.

The system operator L represents the algorithm for sequential solving of the following problems:

- Temperature calculation for soil surface under building as well as beyond its area.
- Temperature and freezing-thawing depth calculation for soil layer under building.
- Calculation of ground base on the first ultimate stressed state of soils (bearing capacity).
- Calculation of ground base on the second ultimate stressed state of soils (settling).

In virtue of extreme complexity of the operator L we recommend to compute reliability functions by the method of statistical tests (the Monte Carlo method). This method is based on running a mass experiment on a computer, which allows one to apply multiple solving (testing) of a determinate problem on a computer instead of solving a statistical problem (Ermakov, 1971). The required number of tests is evaluated by the formula:

$$N = \frac{4P(1-P)}{\Delta^2} \quad (2)$$

where P = the expected probability; and
 Δ = the given accuracy of calculation.

After completion of tests the statistical estimate of the reliability function is computed:

$$P(t) = P(\Delta t \cdot i) = 1 - \frac{n_i}{N} \quad (3)$$

where n_i = the number of failures within the time interval ranging from 0 to $\Delta t \cdot i$;
 Δt = the time spacing;
 i = the ordinal number of time interval (a total of m time intervals is all that can be expected from the condition $m\Delta t = t_{\text{use}}$; and
 t_{use} = the in-service period.

A block-diagram of the program for solving the problem of base reliability estimation by the Monte Carlo method is shown in Fig. 1. It consists of 19 operators.

With the known operator L and the specified boundaries of the allowable states region Ω_0 the form of the reliability function $P(t)$ will be completely determined by the input parameters, i.e. by elements of the population U . A part of them, namely constructive elements, included in the group of technogenic factors, has a particularly strong effect on the function value and unlike the rest of these elements they may be arbitrarily specified by a designer, i.e. they are the governing elements.

If the structure was predetermined, the basic governing parameters will be as follows: the thickness of the thawed layer left under the building or structure H ; the depth of the foundation, h , and the type of the foundation; the number of ventilation openings (ducts) in the basement of the building or structure (ventilation modulus of ventilated basement μ).

A combination of these governing parameters completely determines the construction principle of permafrost ground utilization as soil bases of buildings or structures. For example, if $h > H$ and this inequality is met during the entire service life of a building or structure, we use the first construction principle of permafrost ground utilization as soil bases; if $h < H$, we use the second construction principle and if, in addition, $\mu \neq 0$ the principle of stabilization is used for the building or structure construction.

The task is to select and to apply such a combination of the governing parameters which will ensure the optimal reliability of the system.

OPTIMIZATION OF THE SOIL BASE RELIABILITY

There are no systems with the absolute reliability in Nature. All systems have reliability less than one. As it was mentioned above, the reliability is understood as a minimum of the reliability function, i.e. it is its value at the end of the in-service period. As a consequence, the failures are bound to occur causing collapses of some built-up structures and appearance of a detriment. The higher the reliability, the less the detriment. On the other hand, the high reliability requires high costs to develop a structure. It is evident that the system must be designed in such a way as to ensure its optimum

reliability.

The problem of determining optimum reliability has been formulated more than once (Khotsialov, 1929; Rzhnitsyn, 1961), but in doing so the time factor has been disregarded.

A more correct formulation of this problem (Bolotin, 1971) is that for every point of the quality space V , for every time moment t , there is a definite value of the payoff function $C(v,t)$ equal to the detriment over a unit time provided the system is to be found in the point of the quality space V involved. If the system is within the region of the allowable states Ω_0 , the value of the payoff function $C(v,t)$ is taken as zero. Mathematical expectation of the total detriment (the value of risk) is determined by the formula:

$$C_1 = \int_0^{t_{use}} dt \int_V C(v,t) P(v,t) dV \quad (4)$$

where $P(v,t)dV$ = the probability of finding in the time moment t of the component v existing in volume dV of the quality space V .

The soil base, foundation, and frame of the building are generally considered to be nonrecoverable systems. In systems of that kind any type of failure results in the collapse of the structure. Therefore, in the case considered, the value of the payoff function will only depend on whether the system is within the region of the allowable states or not.

Analytically it is represented by:

$$C(v,t) = \begin{cases} 0 & \text{with } v \in \Omega_0 \\ C(t) & \text{with } v \notin \Omega_0 \end{cases} \quad (5)$$

The payoff function $C(t)$ is in turn introduced for the reasons which are as follows.

If a building fails before its in-service period expires, the detriment will be equal to the depreciated cost of the failed building, which is determined as a difference between the renewal cost and the depreciation cost. Besides, the building's failure will cause an indirect detriment: either underproduction of products or reduction in transport service operations, or reduction in housing facilities. The indirect detriment is generally expressed as a fraction of the building's renewal cost. In order that the time-differentiated costs could be compared, they should be reduced to a common time. The start-up of the building use is generally taken as a reference date for comparison. Based on the statement above, the payoff function may be described as follows:

$$C(t) = \frac{C_0(1+k_{econ.} - 0.01k_{renewal} \cdot t)}{(1+E)^t} \quad (6)$$

where C_0 = the acquisition cost of a building or structure;

E = the standard reduction coefficient for the time-differentiated costs;

t = the period of reduction;

$k_{renewal}$ = the charge rate for complete renewal,

it is taken according to the capitality class of a building or structure; and

$k_{econ.}$ = the coefficient of economical responsibility, it is taken as ratio between the indirect detriment and the acquisition cost of a building or structure.

Subject to expression (6), for determination of the value of risk, expression (4) may be redescribed as:

$$C_1 = C_0 \int_0^{t_{use}} \frac{(0.01k_{renewal} \cdot t - k_{econ.} - 1) P^1(t)}{(1+E)^t} dt \quad \dots (7)$$

where $P^1(t)$ = the first-order derivative of the reliability function.

There are discerned systems characterized by economical detriment and systems characterized by moral detriment. In the case of systems with economical detriment the minimum of the reduced costs serves as the optimization criterion:

$$C_0 + C_1 = \min. \quad (8)$$

In the case of systems with moral detriment it is the minimum of the reduced costs with the given reliability:

$$\left| C_0 + C_1 \right|_{P \geq P_1} = \min. \quad (9)$$

where P_1 = the reliability with which safety of a building or structure use is provided.

The problem of finding an optimum solution involves the selection of the best combination of the governing parameters at which the conditions of expression (8) or expression (9) will be met. As it was stated above, the combination of the governing parameters determines completely the construction principle of permafrost ground utilization as soil bases of buildings or structures.

For design purposes it is necessary to calculate the reliability P as well as the reduced cost C as functions of the soil base parameters H , h , and μ . Determination of these relations is connected with a large volume of calculations which can be performed on the computer only. The algorithm for these computations is shown in Fig. 2. It comprises 9 operators.

The acquisition cost of a building or structure is computed as the sum of the superstructure cost, $C_{superstructure}$, costs of foundations and the cost of soil base preparation. The value of risk C_1 is computed by formula (10) which interprets formula (7) in terms of finite differences:

$$C_1 = C_0 \sum_{i=1}^m (1+k_{econ.} - 0.01k_{renewal} \cdot i\Delta t) \frac{P[(i-1)\Delta t] - P(i\Delta t)}{(1+E)^{i\Delta t}} \quad (10)$$

The reduced cost C is determined as a percentage of the superstructure cost:

$$C = \frac{C_0 + C_1 - C_{\text{superstructure}}}{C_{\text{superstructure}}} \cdot 100\% \quad (11)$$

Calculation results serve as a basis for drawing the nomogram which illustrates the relationship between 5 parameters (P , C , h , H , μ) as well as for selection of the construction principle.

EXAMPLE OF THE CONSTRUCTION PRINCIPLE SELECTION

An example of the design nomogram drawn for a 5-storeyed large-panel building on a pile foundation is shown in Fig. 3. The foundation depth, h , is plotted on the ordinate of the nomogram, on the abscissa—the thickness of the thawed layer H to be left in the base of the building by the beginning of its use. The line $h=H$ is the boundary between the first and the second construction principles of permafrost ground utilization as soil bases. On the left side of the nomogram field the reliability levels fitting the minimum value of the reliability function cut off a region where preparation of a base defined by the given reliability is impossible. On the nomogram there are also drawn the isolines of the reduced costs of the building's substructure works expressed as a percentage of the superstructure cost. The isolines of the reduced costs outline the region of the optimum reliability.

Let us illustrate how the construction principle of permafrost ground utilization as a soil base and the values of the governing parameters are selected through the use of the nomogram. If the building is classed with the systems featuring a purely economical detriment, then it is evident that on the nomogram the design point is to be found in the region of the minimum reduced cost. In our example it will be the point with the parameters $h=8$ m and $H=10$ m. This point is positioned in the region associated with the second construction principle; to be more precise, in the region associated with the method of stabilization $\mu = 5.9 \cdot 10^{-4}$. It fits the reduced cost of the substructure works amounting to 12% of the superstructure cost and the minimum value of the reliability function 0.78.

In the case referred to, reliability has an indirect effect on the selection of the governing parameters via the reduced cost; to be more precise, via the detriment function. It is not assigned beforehand, but it is obtained from expression (8) as a consequence.

The picture will be quite different if the building is classed with the systems featuring the moral detriment. In such a case the reliability is the governing factor in the selection of the construction principle. Let us assume that the value of the reliability function should not be less than 0.99 to ensure safety. In our specific example we shall have two isolines $P = 0.99$. The first one is to be found in the region associated with the first construction principle and the other—in the region associated with the second construction principle. Any point on these two isolines will assure the specified reliability

and, hence, may be taken as a design one. However, the reduced cost is dependent in many respects on what specific region of the nomogram this point is positioned in. It goes without saying that the optimum solution will be that at which the specified reliability will fit the minimum of the reduced cost. Moving along the isolines $P = 0.99$, we shall find this solution. It will fit the point with the coordinates $h=12$ m; $H=4$ m. This point is positioned in the region associated with the first construction principle and fits the reduced cost of the substructure works amounting to 40% of the superstructure cost.

Thus, in the first case the building should be constructed on the method of stabilization. The depth of pile sinking into the thawed ground should be put equal to 8 m and the minimum thickness of the thawed layer equal to 10 m. This means that in those areas where the permafrost ground occurs at higher depths, it is necessary to prethaw it down to a depth of 10 m. In the second case the building should be constructed on the first construction principle. The depth of pile sinking into the frozen ground should be put equal to 12 m and the maximum thickness of the thawed layer equal to 4 m. This means that in those areas where the permafrost ground occurs deeper than 4 m, it is necessary to prefreeze the thawed ground layer.

In the design practice, application of the procedure set forth in this paper enables one to perform a scientifically grounded selection of the construction principle of permafrost ground utilization as soil bases which secures a building or structure against the untimely failure due to an unfavourable combination of factors and offers therewith the least reduced construction costs.

HIGH MOUNTAIN PERMAFROST IN SCANDINAVIA

Lorenz King

Geographisches Institut der Universität Heidelberg, Im Neuenheimer Feld 348,
D-6900 Heidelberg, West Germany

In the vicinity of the highest elevations of northern Europe, the Kebnekaise Massif in northern Sweden (peak of Kebnekaise is 2,100 m a.s.l.) and the Jotunheimen area in southern Norway (Galdhøpiggen and Glittertind reach about 2,470 m a.s.l.), extensive permafrost occurrences could be proved. Two test areas, the Tarfala Valley (67°55'N, 18°35'E) and the Leirvassbu/Juvasshytta area (61°40'N, 8°20'E), have been investigated in detail by means of ground temperature measurements, hammer seismic soundings, dc-geoelectric soundings and studies of snow depth and snow temperature (BTS values). In both areas a permafrost thickness of more than 100 m could be proved above 1,500 and 2,200 m, respectively. A continuous alpine permafrost zone seems to exist here. Additional information concerning the Sognefjell and Rondane/Dovre area and the Lyngen Alps is given, and a model of alpine permafrost zonation for the central parts of the Scandinavian high mountains is derived from these findings. Cross sections through the high mountains of Scandinavia show that large areas underlain by widespread and patchy discontinuous permafrost must exist and help explain the rich periglacial morphology well known from Scandinavia.

INTRODUCTION

Knowledge of permafrost distribution in Scandinavia is still limited and rather restricted to two very special features: palsas and ice-moraines. Since the study of Fries and Bergström (1910), the number of studies on palsa formation and distribution in Scandinavia has increased rapidly (cf. references in Åhman 1977), and further studies are still being conducted (e.g. Seppälä 1982). Some papers even state that permafrost in Scandinavia is restricted mainly to these specific features (cf. Vorren 1967, Wramner 1973). The study of ice-cored moraines requires sophisticated methods, and Østrem (1964, 1965) after thorough studies, was able to present an inventory of ice-cored moraines covering large parts of Scandinavia. Barsch (1971) discusses the assumption that in general ice-cored moraines are rock glaciers (cf. also Østrem 1971). In so far, Østrem's inventory of ice-cored moraines represents a collection with information about high mountain permafrost in Scandinavia, although this was not recognized by many researchers. Besides these papers, there are only a few punctual findings of permafrost (see Rapp and Annersten 1969, Ekman 1957). This paucity of detailed work on alpine permafrost is characteristic of many high mountain areas in the world and has been regretted by scientists such as Haeberli (1978) and Harris and Brown (1978). In Scandinavia, until very recently, this lack is especially due to the absence of engineering work. In 1977, Åhman could still state with full justification that in Scandinavia "permafrost in the ground outside palsas exists in different parts, (but) little is known of its distribution."

Our studies began in 1976, when we could prove that in general, permafrost exists also in ridges

located in the vicinity of ice-cored moraines (King 1976). This discovery, together with climatic studies, led us to the assumption that large areas of the Scandinavian high mountains must be underlain by permafrost. Systematic studies on permafrost in Scandinavia were started in 1977, and we are now able to present some highlights of permafrost distribution. The most important results have been summarized recently (King 1982 and King unpublished manuscript).

INVESTIGATED AREAS

In order to give a valid picture for many areas of the Scandinavian high mountain belt, four widely separated regions were selected: Jotunheimen and Dovre/Rondane in the southern part, and the Lyngen Alps and Kebnekaise/Abisko north of the Arctic Circle (Figure 1). The important environmental features of these areas are given by Sømme (1960), Østrem et al. (1973), Østrem and Ziegler (1969) and King (unpublished manuscript). The purpose of the project was to obtain a pattern of permafrost and lower limits of permafrost distribution that may be correlated with the climatic parameters along an east-west gradient and a north-south gradient. The intention was to obtain a picture of the permafrost distribution that should be valid for most areas of the Scandinavian high mountain belt.

STUDY METHODS AND METHODOLOGICAL RESULTS

In all four test regions, investigations were carried out in summer and in winter. The methodological results obtained during our studies

FIGURE 1 Location of investigated areas Jotunheimen, Dovre/Rondane, Kebnekaise/Abisko, and Lyngen.

are presented in detail in King (Manus.) and can be summarized as follows: For the detection of permafrost, four methods prove to be most efficient: (1) hammer seismic field work that reveals qualitatively the existence of permafrost in debris (p-wave velocities are 2,200 - 3,800 m/s) and gives the thickness of the active layer; (2) dc-geoelectrical soundings; (3) ground temperature measurements over several years, the latter two methods give an indication to the total permafrost thickness; and (4) measurement of the basal temperatures of the snow cover (BTS) at the end of the winter, permitting very efficient mapping of permafrost on a larger scale, provided that there is a mean minimum snow thickness of about 80 cm. The electrical resistivity in unfrozen debris usually amounts to values between 100 and 10,000 Ohm-m, and that in frozen debris to values between 10,000 and 900,000 Ohm-m. Mainly in frozen rocks the resistivity values increase significantly with lower temperatures, and at a temperature of about -6°C the resistivity of schistose plutonic rock may be 5 times higher than at a temperature of -1°C (cf. Bogolyubov et al. 1978, Séguin 1978). Geoelectrical and seismic soundings in permafrost near the freezing point may give equivocal results, since the resistivity and p-wave velocity values of frozen and unfrozen ground are over-

lapping (cf. Dzhurik et al. 1978). Accurate ground temperature measurements and diggings will then have to prove permafrost. However, dc-geoelectrical sounding provides a very effective tool for detecting larger ice cores or ice lenses, as these show electrical resistivities of several tens of MOhm-m. The method as developed by Haerberli (1973, 1978) of measuring the basal temperature of a snow cover in the Alps yields good results also in northern Europe. The limiting temperature values for distinguishing between areas with unfrozen ground from those with questionable and reliable permafrost occurrences are -2° and -3°C at a snow depth of 150 cm. The limiting values are dependent on the snow depth, the minimum snow cover being 80 cm. BTS values furthermore may give a good indication of the mean annual ground temperature at the depth of the Zero Annual Amplitude (King unpublished manuscript). Figure 2 gives an idea of the number of soundings in our main test area, Tarfala, just east of the Kebnekaise peak, Sweden's highest point. BTS sites are not shown, but 172 BTS values have been recorded at the end of the winter of 1979/1980, and many more snow depths were measured, too.

REGIONAL RESULTS

In the Kebnekaise/Abisko area (cf. Figure 1), where mainly the Tarfala Valley has been intensively studied, a permafrost thickness of more than 100 m is probable at altitudes of more than 1,500 m a.s.l. (mean annual ground temperature is about -4°C ; thickness of active layer is about 130 cm). Widespread discontinuous permafrost is encountered between 1,500 and 1,200 m a.s.l. (mean annual ground temperature is in the range of -4° to -2°C ; thickness of the active layer attains 200-400 cm). Active permafrost is mostly missing on the valley floor due to a thick snow cover in winter and probably hydrological heat transport (cf. Figures 2 and 3), but inactive permafrost seems to occur here. Sporadic permafrost exists in palsas down to the lowest places along the shores of Lake Torneträsk (342 m a.s.l.).

In the Lyngen Alps the valleys Veidalen and Gjerdeldvalen have been investigated. The lower limit of discontinuous permafrost was found at about 960 m a.s.l. in block tongues exposed to NW. The lower limit of widespread permafrost is reached on Falsnesfjellet (1,200 m a.s.l.). Theoretically, areas with continuous permafrost should exist only at the highest elevations of the Lyngen Peninsula (peak of Jiekkevarre is 1,833m a.s.l.).

In Jotunheimen, where the Juvasshytta area has been studied in detail, a permafrost thickness of 100-200 m occurs at 2,200 m a.s.l. (estimated mean ground temperature is about -6°C ; thickness of active layer is about 110 cm). Permafrost is still very widespread between 1,900 and 1,600 m a.s.l. (mean ground temperature is about -3°C ; active layer is about 150 cm). In the Leirvassbu area 15 km SW of Juvasshytta, scattered permafrost may be found between 1,600 and 1,400 m a.s.l. As at the test sites in the Lyngen Alps, it seems that the limit of permafrost distribution is lower in the Sognefjell area and the area of permafrost

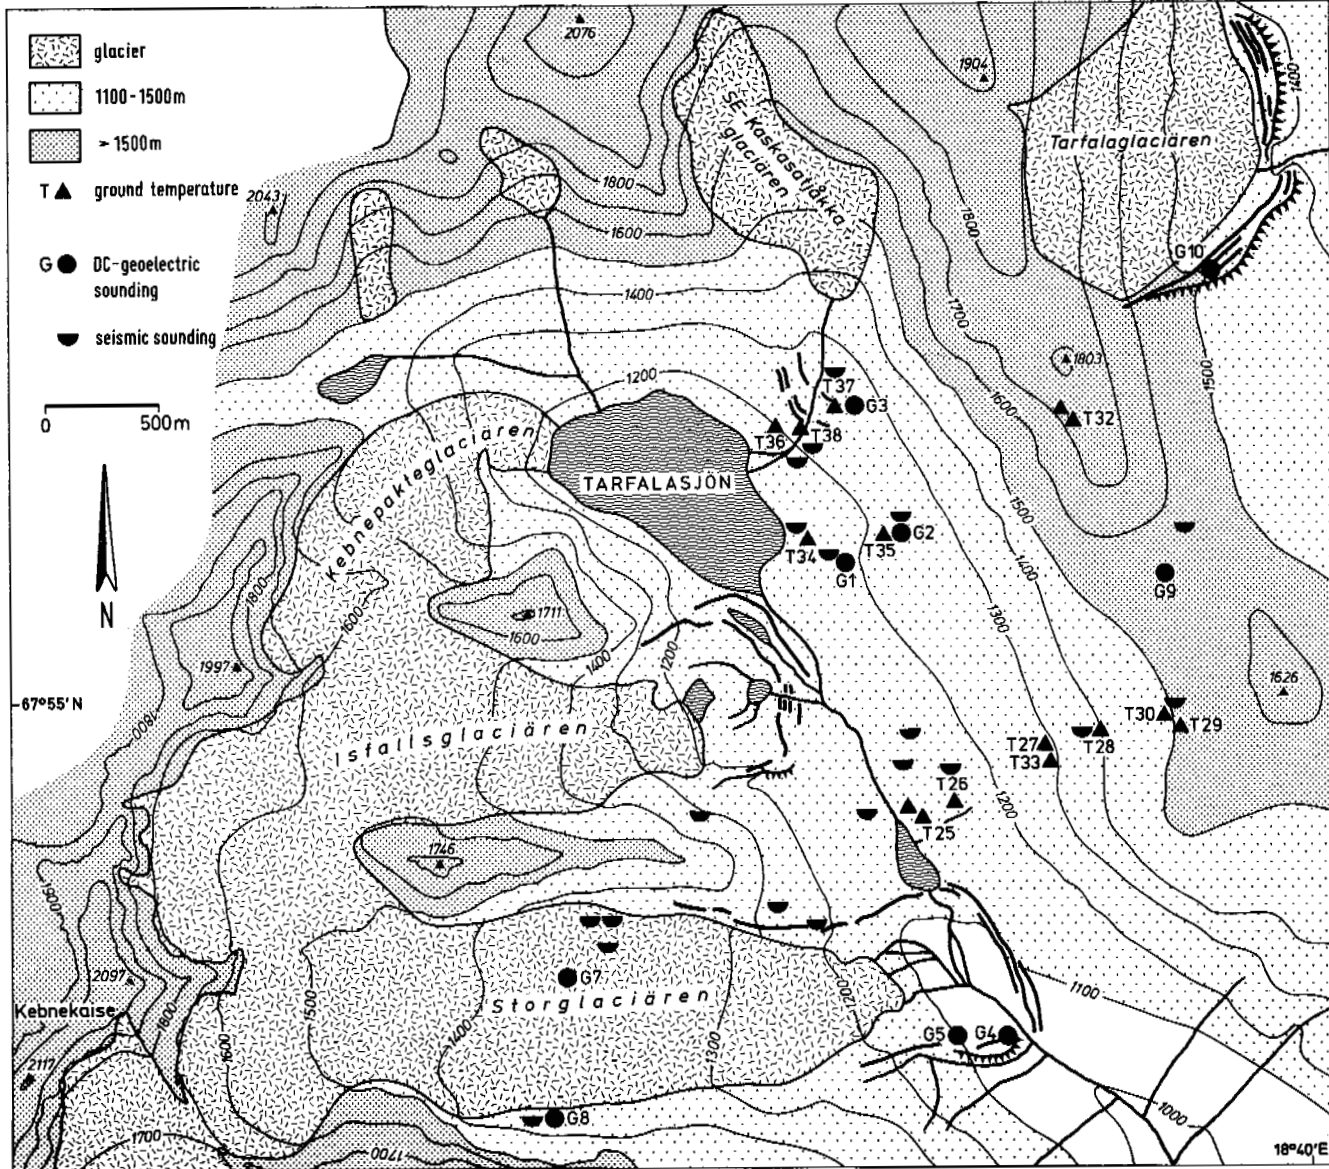

FIGURE 2 Map of the test area Tarfala (Kebnekaise region) with location of ground temperature, geoelectric, and seismic sites. In addition, 172 BTS values and many more snow depths have been measured in the Tarfala Valley.

occurrences is increased due to the existence of perennial snow fields.

In Rondane/Dovre, sporadic permafrost is often encountered in palsa fields down to 940 m a.s.l. (Meløya, Einunndalen), and relict permafrost seems to exist here in windswept terraces. The lower limits of discontinuous permafrost in slopes exposed to the NW could be found in the Rondane area at 1,330 m a.s.l. Measurements at the top of Simlepiggen suggest that the lower limit of continuous permafrost is not much higher than 1,720 m. The highest peaks of the Rondane area should reach into the continuous permafrost zone but have not been investigated to date.

CONCLUSIONS AND ZONATION

Permafrost distribution in alpine areas is primarily controlled by relief (altitude, angle, and slope) and secondarily by the duration and thickness of the snow cover (cf. Gorbunov 1978). Other factors such as vegetation, thermal conductivity of the ground, and hydrology may be of importance for local permafrost occurrences but are of minor interest for the regional distribution. The lower limit of discontinuous permafrost in the alpine areas investigated may be defined as the lower limit in slopes exposed to the north. There, angles of not more than 45° still allow geoelectrical, seismic or temperature soundings in an economical way. Steeper slopes could not be investigated

FIGURE 3 Ground temperatures of selected sites (cf. Figure 2). The temperature envelopes mark minimum and maximum temperatures registered between August 1977 and September 1980.

safely, especially in winter time (avalanches!). The same principle applied to the lower limit of continuous permafrost and corresponding soundings in slopes exposed to the south. The limit between widespread and patchy permafrost separates areas where more or less than 50% of the ground, respectively, is frozen (Karte 1979). It corresponds to the altitude of those valley floors where snow free ridges contain permafrost but where the ground in flat areas is only partly frozen, depending on the thickness of the snow cover.

The lower limits of continuous, discontinuous widespread, and patchy discontinuous permafrost in the four investigation regions correspond closely to the mean annual air temperature (MAAT) of -5° , $-3,5^{\circ}$, and $-2,5^{\circ}$ C for most of the investigated places (slopes up to 45°). If the lower limit of continuous permafrost (walls exposed to the south) is fixed at the altitude of the -6° C isotherm of the MAAT and the lower limit of discontinuous permafrost (walls exposed to the N) at the altitude of the $-1,5^{\circ}$ C isotherm, sites that cannot be investigated economically by our methods should be included in our model, too (Figure 4).

We realize that the -6° C isotherm is a rather high value compared with $-8,5^{\circ}$ C in the zonation of high latitude permafrost (Brown and Pêwê 1973). Haerberli (1978) mentions field observations that suggest that the lower boundary of continuous permafrost may be somewhat lower in the Swiss Alps (-7° C) and states a limit of perhaps -6° oder -7° C in his most recent report (Haerberli 1982). We would like to leave this question open for further research and think that this might not only be a matter of permafrost findings but also a matter of definition of the term "continuous".

The lower limits of permafrost occurrences seem to be lower due to the maritime influence of unfrozen fjords in the western part of our investigation regions, and similar differences might also be found toward more continental areas of Finnish Lapland. Research in these areas is certainly needed and also intended.

The fact that the altitude of the lower limit of permafrost coincides with the altitude of a certain MAAT allows us to propose an extrapolation for the noninvestigated areas. A permafrost map of Lapland

MAAT

FIGURE 4 Zonation of alpine permafrost. The corresponding altitudes for the investigated areas are given in Table 1

and southern Scandinavia is in preparation (King, unpublished manuscript). Four cross sections through the Scandinavian high mountain range are shown in Figure 5. Forest limits (taken from topographical maps) and glaciation limits (cf. Østrem et al. 1973, Østrem and Ziegler 1969) are also marked. It is noteworthy that contrary to the permafrost limits, the forest limit and the glaciation limit are rising with increasing continentality. The uppermost cross section shows that large potential forest areas rise above the altitude of the $-1,5^{\circ}$ C isotherm in Finnish Lapland. These are the areas where the most impressive palsas in Scandinavia exist favored by climate, vegetation, and relief. They belong to the discontinuous permafrost zone (cf. King 1979). In the other cross sections the forest limit hardly reaches up to the altitude of the $-1,5^{\circ}$ C isotherm, and minute palsa forms belonging to the sporadic zone are reported from there (Sollið and Sørbel 1974).

Further permafrost research is urgently needed especially in the areas outside the main mountain range. Models with freezing and thawing indices are developed by the author (cf. Harris 1982). We trust that already now the model for permafrost distribution in Scandinavia presented above will bring new aspects to other research topics. We especially think of the study of periglacial processes and forms by Scandinavian scientists in several classical studies (Rapp and Rudberg 1964, Rudberg 1977). Geomorphological surveys in the investigated areas have been done by the author. They suggest that "the spatial extent of periglacial regions not underlain by permafrost of one sort or another is limited" (French 1979). Apparently, this seems to be true for many alpine regions, too.

ACKNOWLEDGMENTS

Research was carried out with the support of the Deutsche Forschungsgemeinschaft, Bonn. Special

thanks are due to V. Schytt (Stockholm), director of the Tarfala Research Station, and to D. Barsch (Heidelberg), who both supported the studies with logistic help and discussions. The author is very grateful to many other persons who helped him to obtain the results that form the background of this paper. Although the long list of friends and colleagues cannot be published here, the author realizes that these studies could not have been done without their support and will keep them well in mind.

The importance of the Central Gas Injection Facilities at Prudhoe Bay, Alaska, prompted a detailed study of its adfreeze pile foundation when differential settlements were noticed in some piles. As a result, an extensive data gathering program was initiated to monitor pile movement, subsoil temperatures, and microclimate temperatures beneath the facility. The data gathered indicated that pile settlement was occurring and that settlement was not related only to the magnitude of applied load. Studies indicated that settlement was more related to soil temperature and the creep characteristics of soil near the pile. A theoretical analysis successfully predicted observed settlement rates on those piles showing the most settlement. The theoretical model assumed the piles were embedded in ice or ice-rich soils. Remedial measures were undertaken to control and limit the pile movement. The ground surface beneath the entire facility was insulated, many piles were converted to thermosyphons, exposed pile surfaces were painted white to increase their reflectivity, and an impervious membrane was installed over the insulation to control moisture and contaminant infiltration. These remedial measures appear to have controlled pile movement to an acceptable level and to within the accuracy of survey measurements.

INTRODUCTION

The Central Gas Injection Facilities at Prudhoe Bay, Alaska, are located on a 1.8 m thick, 13 ha gravel pad on the east side of the Prudhoe Bay field. The gravel pad was placed directly on the tundra mat which covers about 5 m of silt overlying sands and gravels. The area contains polygonal ground, and massive ice was encountered in many of the borings.

The facilities consist of approximately 40 modules having a total first level floor area of nearly 15,000 m². The modules are elevated 2.5 m above the pad and are supported on approximately 1200 steel pipe piles. The piles are 46 cm in diameter, about 6.5 m long and are slurried and frozen in the silt and ice permafrost which overlies the sand and gravel. The modules were constructed in Tacoma, Washington, and barged to Prudhoe Bay in 1975, 1976, and 1977. Field start-up of the facilities occurred in mid-1977. Photograph 1 is an aerial view of the facilities.

The Central Injection Facilities consist of the Central Compressor Plant (CCP), the Field Fuel Gas Unit (FFGU), and the gas injection system. The function of the CCP is to compress the natural gas produced from the entire field for injection into the Prudhoe Oil Pool gas cap. The function of the FFGU is to condition produced gas for use as fuel throughout the field. Nearly 254,000 KW of compression equipment inject as much as 57 million m³ STP of gas per day into the gas cap. The equipment enclosed in this facility is critical to the production of oil from the entire Prudhoe Bay field.

This paper discusses the history of a differ-

ential foundation settlement problem at the Central Injection Facilities. The foundation stabilization procedure used and its effectiveness are described.

HISTORY

In the summer of 1976, Central Injection Facilities module foundations were suspected of movement because of observed architectural, structural, piping, and equipment alignment problems. Door frames in the facilities were

PHOTOGRAPH 1 Central Gas Injection Facilities

racking causing doors to bind, intermodular connections were showing distress, instances of unsupported piping were occurring, and rotating equipment realignment requirements were excessive. A pile monitoring program was implemented at this time to track and verify suspected differential pile movement.

By the end of 1979, 20 piles had shown relative settlements greater than 3 cm. One pile had settled 8.5 cm, while other piles had negligible movement. In general, the rate of settlement was greatest during the late summer, fall, and early winter when subgrade temperatures were maximum, and nearly stopped during the spring when the ground temperature was at a minimum.

Several hypotheses were developed to explain the settlements. Subgrade temperatures may have been increased due to elevated ambient temperatures below the turbine modules and solar radiation at the south and west module perimeters. Glycol spilled in one area may have penetrated the soils and depressed the freezing point. Ponding water under and around the modules may also have resulted in an increased ground temperature. There was a lack of quality control on pile slurring during construction which may have resulted in poor workmanship, and the original pile adfreeze bond strength design criteria were optimistic.

In the spring of 1981, a program was undertaken to stabilize the foundation of the Central Injection Facilities. The subgrade below 22 modules was insulated by placing a 10 cm thick layer of polystyrene board insulation on the ground surface and anchoring it with a shallow layer of gravel. This was intended to reduce the active layer thickness. In addition, nearly 500 of the piles exhibiting high settlement rates were converted to two-phase thermosyphons to provide additional cooling to the ground surrounding the pile during winter months.

INSTRUMENTATION AND MONITORING

Vertical movement of selected piles at the Central Injection Facilities has been monitored since 1976. A comprehensive and sophisticated pile monitoring program was implemented in September 1981 to carefully track and analyze foundation movement on a larger scale. The pile monitoring program is designed to obtain first order level accuracy or better. Pile elevations are referenced to four arctic bench marks, which are referenced to a U. S. Geological Survey monument.

Accuracy is a primary concern when dealing with the small vertical movements of piles frozen in permafrost. The environmental extremes of the arctic affected survey procedures and the accuracy of the elevation data collected. Large temperature variations and ground movement caused by seasonal freezing and thawing cycles affected the reference bench marks and caused apparent cyclic movement of the piles. Extreme low temperatures, long hours of darkness, and whiteout conditions caused hardships on men and equipment during winter surveys. Bright sunlight and radiation heat waves caused distortions and difficult sight conditions in the summer months.

Special techniques were used in the pile monitoring program to maintain errors of closure on level loops to within ± 0.100 cm and individual pile elevation readings to within ± 0.015 cm. Seasonal movement between the arctic bench marks over several years has been approximately 0.02 cm. It is estimated that pile elevation differences between studies are accurate to ± 0.090 cm, neglecting the effects of thermal expansion and contraction. Thermal effects on piles between studies can be as great as 0.100 cm. Correction for this condition is possible but has generally not been attempted on this project.

The subgrade thermal regime below the Central Injection Facilities has been monitored on a monthly basis since July 1981. Twenty-eight thermistor strings with over 250 thermistor points were placed below the insulation (approximately 40 cm below existing grade) to monitor temperatures in the horizontal plane. Eighteen vertical thermistor strings with 25 thermistors each were installed throughout the site at locations such as at the ends of the facility, beneath the facility, at locations having unique shading conditions, and spaced radially from selected piles converted to thermosyphons. All but one vertical string extend 9 m below grade. One 30.5 m vertical string was installed to obtain temperature information below depths affected by seasonal temperatures. Three thermistor strings were installed within steel piles which were converted to thermosyphons in an attempt to record internal pile wall temperatures.

Early in the project localized climatic conditions were observed at various locations beneath the turbine modules. In addition, weather at the Central Injection Facilities site is notably different from that of the nearest meteorological station, the Prudhoe Bay airstrip. Instrumentation was placed below two typical turbine modules to collect and record ambient air temperature, surface soil temperature, pile wall contact temperature, and wind speed and direction. Maximum, minimum, and average values were recorded on the hour. The system has been somewhat unreliable and limited usable data have been collected to date.

REMEDIAL DESIGN DEVELOPMENT

Large differential settlements of many piles prompted the search for a design that would limit additional pile settlements to within tolerable limits. In order to formulate a design to minimize settlements, it was first necessary to investigate the settlement history and determine potential causes for pile settlement.

Generally, the piles exhibiting the greatest settlements were placed during the late winter of 1975-1976. The specification that governed pile placement for many of those piles called for warm water to be placed in the annulus between the pile and the drilled hole. Sand was then dumped into the water and vibrated to cause densification. Piles were placed in position without pile caps or covers. Freezeback of the slurry occurred naturally.

Seasonal thaw penetration at the site varied

THERMOPILE CONVERSION PROCEDURE

from 1.2 m to 2.3 m, depending upon the location, the local depth of gravel fill, and the microclimate. Pile settlement measurements revealed that the piles with excessive settlement settled most during those portions of the year when the ground temperature throughout the depth of the pile was relatively warm and portions of the gravel pad were thawed.

A structural analysis that incorporated settlement data showed that settlement was not proportional to loading. The greatest settlement was measured on a pile with a calculated axial load of less than 23 metric tons; while analysis showed that other piles were loaded to more than 135 metric tons and showed comparatively little movement.

Pile settlement rates were analyzed using techniques based on those presented by Nixon and McRoberts (1976), Weaver and Morgenstern (1981a), and Morgenstern et al (1980). Data from full-scale proprietary pile tests conducted by British Petroleum/SOHIO at Prudhoe Bay in 1971, as well as other data from Weaver and Morgenstern (1981b), and Johnston (1981), were used to estimate the creep rate relationships for the piles. Back-calculated creep relationships from pile settlement rate data during periods of rapid creep on those piles experiencing settlement indicated that adfreeze stresses were on the order of those for ice below the active layer. This indicated that support along those piles showing appreciable settlement was primarily by ice.

Glycol spills and the subsequent solution of ice within the soil probably increased the settlement rates in those areas where the glycol spills occurred. Heat conduction into the subgrade and along the pile walls may have been increased by solar heat gain in exposed areas and by exhaust heat in the vicinity of exhaust stacks. Water from the roof condensers and snowmelt may have caused increased subgrade temperatures.

The remedial measures that were used to limit future pile settlement consisted of the following four components: the ground surface beneath all modules was insulated with 10 cm of expanded polystyrene insulation extending a minimum of 5 m beyond the structure, an impervious membrane was installed above the insulation, all exposed portions of piles were painted white, and selected piles were converted to two-phase thermosyphons. The remedial measures were designed to reduce the depth of the active layer and to reduce the maximum ground temperatures throughout the depth of the piles, thereby providing additional adfreeze area and a lower creep rate within the supporting soils. The impervious membrane was installed to inhibit further glycol and water infiltration into the subgrade.

Piles were selected for conversion to thermosyphons based on the following order of importance: (1) piles with the highest settlement; (2) piles directly supporting turbines, compressors and exhaust stacks; (3) piles in the glycol spill area; and (4) additional piles as needed to provide bulk heat removal from the subgrade.

Each pile selected for conversion was de-iced, pressure tested, evacuated, and charged with refrigerant. The piles at the site contained various quantities of snow and ice. The snow apparently entered the piles during the interval of time between pile placement and pile cap attachment. A layer of ice capped the snow in the piles whenever snow levels were as high as the bottom of the preconversion active layer adjacent to the piles.

Refrigerated methanol was used to de-ice pile interiors to prevent warming of the material around the pile. Chilled methanol was sprayed into the piles, coating the walls with a thin film to ensure thorough de-icing. The methanol remained in the piles until all of the snow and ice was in solution with the methanol. The normal time period required for complete solution of the snow and ice was between 1 and 2 days.

Once the de-icing procedure was completed, the piles were pressure tested for fitting leaks to 310 kPa. The piles were then evacuated to a vacuum of 4 kPa. After evacuation the piles were charged with Refrigerant-12 (R-12). R-12 was selected because it was readily available at a reasonable cost and it would operate at a low positive pressure.

After approximately 2 months of operation, the thermosyphons were checked for operation and noncondensing gases were purged from the units. Most commercially available fluorocarbon refrigerants contain small quantities of impurities. After thermocycling has taken place, the noncondensing impurities effectively cut off the available condensation area, thus reducing the heat transfer capability of the system.

Snow and ice were not the only items inside of the piles. Sand slurry, pieces of wooden boards, a coffee cup, glycol, and a section of 40.64 cm O.D. steel pipe were some of the items discovered inside the piling. Many times in the field, ingenious techniques were devised to sidestep problems caused by debris in the piles.

Thermosyphon pressures are monitored annually prior to cold weather activation. Temperature of the liquid/vapor interface within the pile is derived from the measured pressures using published data for the refrigerant. Monitoring has shown that the average maximum pile wall temperature at a depth of 4 m decreased approximately 1°C during the first year of operation.

DATA ANALYSIS

Pile Settlement

Only a few piles were initially surveyed, and as a result complete sets of settlement data do not exist for most of the piles. Figure 1 shows a typical settlement trend exhibited by many piles. Initially, settlements occurred during late summer and fall, with little settlement, and in some instances apparent heave, occurring during the winter and spring. The pile represented in Figure

FIGURE 1 Typical pile displacement

It was converted to a thermosyphon in early 1981 with ground surface insulation being placed shortly thereafter. Negligible settlement has been observed since the thermosyphon conversion and ground insulation placement. Analyses indicate that the reduction in settlement rate was caused by the remedial measures and not by the natural reduction in secondary creep rate with time.

Recent survey measurements taken throughout 1982 show many small heave and settlement fluctuations, many of which do not tend toward overall heave or settlement of a pile. These fluctuations in surveyed elevations are of a greater magnitude than expected heave or settlement, making prediction of future performance based on these settlement measurements difficult. It appears that the fluctuations are predominantly a result of survey inaccuracy and thermal effects above the ground surface, and are not real pile movement within the ground.

Microclimate

Microclimate conditions beneath two compressor train modules were monitored with 42 thermistors placed to record: air temperature 30 cm above ground, ground surface temperature, and pile surface temperature. Several trends were observed in the microclimate data.

During warm periods, pile temperatures were generally observed to be cooler near the center of the modules. Temperatures 1°C to 3°C colder than ambient air were noted. Pile temperatures near the exhaust stacks and along the perimeter of the modules generally followed the ambient air temperature at the CCP during periods when the thermosyphons were expected to be inactive. As expected, active thermosyphons had surface temperatures warmer than the ambient air temperature.

Microclimate air temperatures beneath the modules follow the same trend as pile surface temperatures, however, the temperature extremes and fluctuations are greater. Ground surface temperatures appear to vary closely with the microclimate air temperature at a given location.

FIGURE 2 Minimum and maximum temperatures

Soil Temperatures

Vertical thermistor strings were placed at numerous locations around the facilities to gather data that would be representative of different conditions. Profiles of the minimum and maximum temperature versus depth are shown for various conditions on Figure 2. Placing a gravel pad on the surface increased the width of the temperature range at the surface but decreased the temperature range at the surface of the organic layer. The average temperature at a depth of 9 m was decreased about 1°C.

The temperature ranges recorded under the insulation and under the building were smaller, and the average temperature at a depth of 9 m was about 1°C colder than in those areas without the insulation. Near piles converted to thermosyphons, the average temperature at a depth of 9 m was approximately 1°C colder than at greater distances from the converted piles.

FIGURE 3 Effect of thermosyphon on temperature

Vertical thermistor strings were placed inside the pile and at 0.6 m and 1.8 m radial distances from converted piles at three locations. A typical relationship between temperature and time is shown at the 4 m depth in Figure 3. As expected, the thermosyphon wall became colder than the surrounding soil when the air temperature dropped below the ground temperature. Once the air temperature became warmer than the pile wall, the thermosyphon ceased to function and the pile soon warmed to the same temperature as the surrounding soil. Between November 1981 and November 1982, the net decrease in temperature of the soil surrounding the converted piles at a depth of 4 m was approximately 1°C.

Based on data from the thermistors placed immediately below the insulation, the warmest temperatures under the module were on the order of -3°C and were about 1°C colder in the summer of 1982 than the summer of 1981. No significant difference in the change in warmest temperatures could be detected between those areas immediately adjacent to thermosyphons and those areas at least 6 m from any thermosyphon indicating that the cooling effect is widespread. The data does not indicate whether the cooling is caused by climatic changes or the thermosyphons. The thermosyphons should have caused cooling, however, the climate was also getting colder. The thermistors do not show isolated hot spots such as under exhaust stacks.

PILE ANALYSIS TECHNIQUE

The settlement rates of the piles were calculated assuming that the piles exhibiting the most settlement were embedded in ice. Using the measured temperature-depth profile at various times of the year it was possible to determine the creep rate versus stress dependency of the ice around the pile at any depth and at any time of year. Since the pile displacement rate (ice creep rate) is uniform throughout the length of the pile, it was possible to determine the stress level on the pile at any depth and time, given the pile displacement rate and the temperature. Since the sum of the pile wall stresses is the total load on the pile, it is possible to calculate the pile displacement rate throughout the year under any total load.

As shown in Figure 1, the calculated pile displacement rates throughout the portions of the year when settlement rates are greatest qualitatively agree with the displacement rates measured on those piles that have undergone the most settlement (excluding the piles in the glycol spill area). During those portions of the year when ground temperatures are coldest, the predicted settlement rate is greater than the measured settlement rate. During this portion of the year, the gravel pad is frozen, providing high shear stresses on the pile near the top, within a material that is subject to low creep rates. The theoretical model used for the predictions shown on Figure 1 did not take this into account.

Accurate theoretical analyses of pile creep rates are not possible because of the uncertainty of the load on a given pile and of the actual

material surrounding each pile. The load on a given pile may not be the same as the design load due to redistribution of the load caused by differential pile movements.

CONCLUSIONS

Pile Settlement

The remedial measures undertaken to decrease or stop the settlement of piles have appeared to work well. Pile movement over the first year since they were implemented has been, on the average, less than ± 0.1 cm, in contrast to earlier years when as much as 2 cm was observed in a single year. The magnitude of pile movement recorded in the first year appears to be within the limit of survey accuracy and therefore, it is difficult to accurately predict future pile performance based on trends developed in pile movement over the one year.

Subgrade Temperatures

Within the first year after remedial measures were completed, the maximum temperature at the base of the pad had been reduced from about -1°C to about -7°C, and the gravel pad has remained frozen throughout the year. The thermosyphons reduced the ground temperature within about 0.6 m of the pile at the 4 m depth by about 2°C by June. The temperature near the pile-soil interface comes to equilibrium with the surrounding soil within a few weeks after the air temperature rises above the pile wall temperature.

THE PROCESS OF NALED (ICING) FORMATION IN THE TROUGHS OF
THE PACIFIC MOUNTAIN BELT

I. V. Klimovskiy

Permafrost Institute, Siberian Branch,
Academy of Sciences, Yakutsk, USSR

The formation and existence of belts of icings are pre-determined by the geology and evolutionary history of the regions during the Pleistocene and Holocene. These belts are related geomorphologically to the activities of former and contemporary glaciers. The action of the latter has led to the formation of moraine-and-riegel complexes, series of which have resulted in the icing belts. Icing formation occurs within the moraine-and-riegel complexes. A definite interrelationship exists between the icings and sub-icing taliks. The dimensions of the moraine-and-riegel complexes and of the icing complexes regularly decrease with altitude. There may be several separate taliks, or a single extensive one, but they are always smaller in area than the area occupied annually by icings. The number of icings corresponds to the number of talik basins, which in turn coincides with that of the erosional valleys draining the sides of the troughs. Freezing of the taliks and icing formation always begin from the upper part of the area affected by the icing and the freezing barrier migrates from higher to lower altitudes.

In many mining developments in East Siberia, within the so-called mobile Pacific belt, traces of stadial contraction of Sartan glaciation have been revealed to date. In different regions the number of stadial formations, because of their different conditions of preservation and variations in the de-glaciation process, does not remain constant.

Marginal moraines forming part of the above-mentioned stadial complexes had formed mainly along the edges of glaciers as these discontinued their advance, or originated as the advancing ice was pushing debris material, thus fixing the maximum advance of the glaciers at that particular stage. The thickness of moraines reached considerable values; their fragments, still well preserved, are arch-shaped hills 150 to 200 m high. In front of such obstacles many large moraine-dammed lakes formed. Their breakthrough took place outside the former bed of valleys and the river network was then reshaped. Such a moraine-dammed lake, well preserved to date, is exemplified by Tabanda Lake in Chibagalakhsky Ridge (Chersky Mountain Range) which represents a trough scoured during the Sartan glaciation and later flooded for a distance of more than 11 km. An example of a sharp curve in a river in front of an obstacle such as a terminal moraine is in turn presented by the valley of the Buordakh River near its confluence with the Lyunkide River (Ulakhan-Chistaisky Ridge). The rivers just mentioned had been north-flowing, but once blocked by the huge Sartan moraines, they first filled large depressions and produced lakes. The lake in the valley of the Lyunkide River drained at the eastern termination of the moraine dam, and it was this that altered the original direction of the river. At the present time, the Lyunkide River, meandering on the bed of the drained lake, discharges into the Buordakh River and abruptly turns eastward in

front of the aforementioned terminal morainal ridge.

Simultaneously with the formation of terminal moraines, stadial riegels were forming in the valleys. They were produced by the combined action on the valley floor of a glacier trough and the water flow from beneath it. Somewhat upstream from the termination of the glacier tongue, there was an area of intense glacial erosion (Markov, 1941; Avsyuk, 1948; Evteev, 1964; et al.). Right beneath the snout of the glacier, the valley floor practically does not erode, while downstream from it the floor is strongly affected by fluvial erosion. After the glacier melts away, a riegel with well-defined relief remains in such a place, forming a ledge in the bedrock floor of the valley shaped by the glacier, on which a ridge of the stadial terminal moraine is superimposed. The "choking" effect on the valley due to a moraine-riegel complex is further intensified because at the time of glacial stagnation, the trough edges above the stadial moraine continue to be affected by intense glacial erosion whereas downstream in the valley there is no such impact and here the river erodes predominantly downwards into its bed. After the river overcomes the moraine-riegel obstacle, there normally arises a canyon- or ravine-shaped valley with narrow precipitous sides.

Under severe continental climatic conditions in the mountains of East Siberia, the contraction of Sartan glaciation seems to have been accompanied only by stoppages and thereafter only by minor re-advance of glaciers. It was the duration of the still-stands of the retreating Sartan glaciers that contributed to the formation of well-defined moraine-riegel complexes, whose unconsolidated sediments, in the presence of a perennially frozen substrate within the sides of the valleys, changed into a frozen state which further enhanced the preservation of the formations in question (Sheinkman, 1978).

After the Sartan glaciers had melted away, the valley floors of that region were affected by cryogenic processes. The most active of them is the formation of icings which not infrequently was pre-determined by the dynamic evolution of Sartan glaciers. Thus, most of the major perennial icings in the troughs of the region are associated with moraine-riegel complexes. This is largely due to the alternation of extended and contracted areas, to the presence within their floors of a large thickness of glacial and alluvium-sand sediments, as well as due to the stepped profile of the valleys (Sheinkman & Nekrasov, 1976, 1978). In addition, present-day streams commonly flow on broad, even valley floors and meander strongly, which is not typical of mountain rivers; on such places at shoals there arise fairly large (but only seasonal) icings.

In general, in the middle and lower parts of the troughs within the moraine-riegel complex, an icing first develops on an area of the bedrock riegel which is intersected by a river. This is due to the fact that at such places the alluvium layer within the valley floor is of small thickness and within it there are no water-bearing taliks below its bed. An icing is produced owing to the waters coming from the upper portions of the valley.

After the formation of an icing on a portion of the canyon, the groundwater collector that exists upstream from the riegel in an erosional basin filled with morainal material, becomes dammed. As the pre-riegel basin is frozen, there is an increase in pressure in the groundwater, concentrated within ground-seepage taliks within these sediments (according to N. N. Romanovsky's classification, 1972). Ultimately, these waters dig through the frozen roof, forming an icing, the size of which is determined by the configuration and water-bearing capacity of the taliks (Klímovskiy, 1980). An icing can also form downstream from the moraine-riegel obstacle when there exist glaciofluvial sediments of considerable thickness which store groundwater.

It is interesting to note that if under the best conditions the number of stadial complexes in Sartan troughs of the region under consideration is as large as eight, systems of associated perennial icings occur only in some cases. This is explained by the limited amount of water available to form icings. A perennial icing complex, including the three types of icing mentioned, on occasion forming part of a single ice mass, forms only in areas with the best conditions for feeding groundwater. Generally, this occurs in middle parts of Sartan troughs, where the flow of icing-forming waters is sufficient to form a large perennial icing. Besides, the moraine-riegel obstacles in the middle parts of Sartan troughs have already been somewhat destroyed, and the flow of icing-forming water, escaping out of the pre-riegel collector, is able to transit the region of the canyon-shaped valley, and to contribute to feeding groundwater within the accumulation of glaciofluvial deposits associated with the riegel.

Downstream in the valley, the icing-forming groundwater flow is sufficient to form large perennial icings only toward the lower reaches of the troughs, especially as the formation of an icing here will be facilitated by a thinning of the

glacial deposits (Preobrazhenskiy, 1963). In this case, however, the oldest moraine-riegel obstacle is usually largely destroyed, and the groundwater flow from the pre-riegel collector will largely traverse this section freely. In such a situation no icing will form upstream from the riegel.

As far as the upper reaches of Sartan troughs are concerned, the dynamics of the icing process is rarely the same, as discussed above, but more often has a quite different character. This is particularly true in cases where troughs are incised into the middle or upper terraces (for example, the upper reaches of the Garbynya River).

From the engineering-geological point of view, the formation of icings in such areas involves two aspects: hydrological and geocryological. The former implies the determination of basic trends in the association of icings with individual elements of the relief, the detection of the sources that feed them, and the delineation of thawed basins and the establishment of the nature of taliks. The latter involves the study of the geomorphological activity of an icing as a distinctive cryogenic phenomenon.

In this connection, it is interesting to elucidate some questions concerning permafrost and geohydrological behavior that reflect the main properties of the icing process within the youngest moraine-riegel complexes, and to show the ratio between icing areas and unfrozen areas.

It is known that upstream from each bedrock riegel ridge along the axis of main troughs, there occurs a pre-riegel basin. Like the entire trough bed, even in the upper reaches of troughs, this basin is always filled with morainal debris with generous porosity and permeability. Upstream in the valley the thickness of these deposits declines rather sharply, and present-day alluvium has not yet formed. Hence it is also evident that the largest amounts of water below a river bed can concentrate only within a pre-riegel basin.

However, as is shown by geomorphological research, ridges of lateral moraines between two neighboring riegels occur as a rule on the sides of the trough, and are intersected by present-day erosional valleys, for which the bottom of the main trough is a local base level of erosion. In this connection, at the mouth of the valleys there are large alluvial fans composed of a thick layer of boulder-shingle deposits. These fans not infrequently merge to form bajadas and thereby can have substantial influence not only upon redistribution of loose coarse debris, but also upon the hydrogeological regime of the waters below a river bed. This, in turn, gives rise to changes in the dynamics of the icing process and in the regime of the taliks below river beds, determining their morphology (both in horizontal and vertical sections) and icing duration.

A vertical section shows that within through floors the bedrock is covered by young alluvium while moraine suglinoks* with a large number of boulders predominate toward the sides. It should be noted that moraine deposits may lie directly on bedrock.

* Editor's Note: *Suglinok* is loam or loamy soil.

The flows of streams that drain glacial terraces and moraine ridges have high energy owing to steep gradients. As a result, they wash out and remove practically all finely dispersed matrix material. Therefore, alluvial fans are formed of shingly uncemented deposits containing boulders. The zone of fine washed out material exceeds substantially the width of the channels of these streams, and extends deep into the masses of sediment. Its maximum depth is observed at the upper parts of the alluvial cones, and it can vary from 3 to 10-15 m. This value increases at the mouth of each subsequent downstream tributary along the valley of the trough. This is associated with increasing depth of the erosional incision. Such wash-out zones exhibit very good collector properties, and contribute to intensive deep penetration of surface waters which warm the sediments deposited on the sides and floors of the valleys of tributary streams and of the main trough and they thereby contribute to the formation of taliks. Taliks, initially having the form of isolated capsules, grow in size and merge together, forming a talik of complex configuration extended downstream along the river valley: expansions of the talik alterate with narrowing. A maximum cross-section of collector taliks occurs within trough floors, opposite the mouth areas of erosion valleys. Downvalley the size of the talik gradually decreases, reaching a minimum near the mouth of the next tributary, i.e. where the flow velocity drops off and the alluvium of the floodplain and terraces is saturated with a sufficient amount of fine-grained material. This decreases the permeability properties of the unconsolidated deposits.

The above-mentioned morphological features of collector-taliks regularly repeat themselves downstream along the axis of the trough, with the only difference being that the size of the talik increases in both expansions and contractions. The total number of talik basins corresponds to the number of tributary erosional valleys that drain the slopes of the trough or erode the terrace surface.

Thus, the vertical section along the longitudinal axis of trough valleys shows that the lower and upper boundaries of the talik below the river bed are not patterned after the relief and inclination of the bedrock floor, but behave in a wavelike manner: the lower talik boundary rises and the upper one descends near mouths of tributary erosional valleys, i.e. at the site of alluvial fans.

As far as the morphology of a talik below a river bed as seen in plan view is concerned, a bead-like structure is clearly marked here: expansions usually correspond to wash-out zones and are fixed on the trough bottom by sections where alluvial fans are well developed, while abrupt contractions occur where fragments of above-floodplain terraces have remained. These are mainly the low interfluves of neighboring erosional tributary valleys.

From the above analysis we can draw the following conclusions.

1. In the upper reaches of troughs, within one moraine-riegel complex and icing area, there can exist one common talik or several separate taliks

with a complex configuration as viewed horizontally and vertically. The area of these taliks is everywhere smaller than that of icing areas and they do not repeat their shape in a plan view.

2. Icing masses form owing to discharge of groundwater stored in several talik basins, coinciding with one icing area. Therefore, within one moraine-riegel complex an icing consists of several merging icings, the number of which is determined by that of the erosion valleys within the trough sides.

3. The formation of an icing, as a specific hydrocryogenic process, starts in the upper part of the icing area where the first frozen barrier forms with the beginning of cold weather because, in this case, the supply of water in the talik below a river bed is the smallest and the cross-section of the supply collectors is also small.

The icing formation extends gradually downvalley and reaches the riegel. The freezing taliks merge to form a single frozen body. Hydrodynamical stresses arising in the process contribute to the formation of icing frost mounds in areas upstream from the riegel.

4. The outwash zones extending far beyond the boundaries of present-day alluvial fans, being good collectors for groundwater below a river bed moving at depth through the sediments considerably warm the adjacent areas of moraine relief and of Holocene terraces. This can lead to the formation of single masses of "non-convergent permafrost".

The above mechanism of icing processes in the upper reaches of Sartan troughs does not, however, rule out formation of rather large perennial icings. This occurs when bedrock hills delineating troughs reach high absolute altitudes, and accumulate on their slopes a considerable amount of precipitation which decreases abruptly for mountains of more moderate altitude. This situation favours an ample supply of surface water and ground water which contribute to the formation of icings. The best conditions for icing-forming water supply exist when contemporary glaciers have been preserved in the upper reaches of Sartan troughs. Here icings are steadily fed by glacier melt water and coincide with the youngest, and therefore, best-preserved moraine-riegel formations. Icings, formed upstream from a riegel and in the area of a down-cutting canyon, practically entirely intercept the icing-forming ground water flow. As a result, no icing forms downstream from the riegel, especially because glaciofluvial sediments associated with young glacial stadial formations do not reach large thicknesses, and are unable to accumulate considerable reserves of ground water.

Because in the mountains of East Siberia the clastic material in valleys (under conditions of neo-tectonic uplifting of rock structures) is of considerable thickness, particularly within Sartan troughs, these are the processes of talik formation that determine the formation of icings. But this icing formation, as shown above, is then to a considerable extent due to the dynamics of Sartan glaciers and current denudation.

As for tectonics, however, the contribution of which to the formation of icings is unquestioned (Simakov, 1961; Tolstikhin, 1966; et al.), we will remark here that Sartan troughs occur mostly within the region of deeply circulating ground water, and

only the lower reaches of valleys can intersect the flow lines of this water discharge. These situations frequently occur in the near-margin parts of inter-mountain depressions, the floors of which, in turn, had commonly been the source for propagation of Sartan glaciers. Thus, on the one hand, part of the waters from the ground water collectors, produced by the activity of Sartan glaciers in the upper and middle parts of these troughs, can go to supply the deep-circulation waters along tectonic fractures that break the integrity of permafrost. On the other hand, in the lower reaches of troughs, such collectors may be intersected by deep water circulation, and therefore the formation of icings there will be still more intense.

Thus, icings in Sartan troughs of mountain regions of the Pacific belt represent part of a regulated drainage system, corresponding to a given stage of evolution of nature. Any changes in the regulation of this system will immediately entail an increase in the icing effect in some places, and conversely, a decrease of icing activity in others. In the end, this will cause the icings to migrate to benches of moraine-riegel complexes, and the migration will go on until the entire system is in equilibrium with the new conditions. One of the most important regulators of this process is the deglaciation that caused a stadial contraction of the Sartan glaciation (Sheinkman & Nekrasov, 1976, 1978).

As is known (Alekseev, 1973; Romanovsky, 1973), icings contribute much to the transformation of valleys. Therefore, when the icing system, as deglaciation develops, migrates along the valley, the earlier positions of icings are marked by relict sites of annual icings, yet are free from ice and well defined in the relief. As a result, the bench-like profile of valleys in areas of moraine-riegel complexes, as well as the whole appearance of troughs, becomes more sharply expressed.

After the site of annual appearance of an icing changes into a relict state, taliks within the valley floor deposits start to freeze up. For some time thereafter, ground water still moves through them but they are usually no longer capable of breaking the frozen talik roof, because most of the icing-forming flow is intercepted by newly emerged icings. In this case within unconsolidated deposits, there arise only layered deposits of injection ice.

From the aforesaid, we can conclude that along with general regularities of the formation of fluvial valleys, in glaciated regions of the Pacific belt, this process will exhibit features of its own. These features are determined by the peculiarities of interaction of tectonic, glacial, and cryogenic processes. Icing formation and icing glaciation are the most active external agents determining the present-day appearance of the valleys. The most important regulator of development of both phenomena proved to be the stadial process, developing throughout the Holocene.

The above considerations confirm once more that numerous icings and sources feeding them are closely related, not only to the area of a water collecting basin and the river flow rate, but also primarily

related to the geological and geomorphological structure of regions, and the position of various sections in relief (Shvetsov, 1968).

To date we have sufficient observational data to state that in high-altitude regions of the Verkhoyansk-Kolyma Mountain Range, as well as in the mountains of the North Trans-Baikal, the distribution of icings allows us to identify an "icing belt" (according to O. N. Tolstikhin, 1974), confined to an altitude range with an upper boundary 400-900 m lower than the altitude of drainage basin divides, and a lower boundary observed about 50-100 m below the regional base level of erosion.

The formation and existence of an "icing belt" is due not only to the properties of the geological structure of the region, but also due to its evolutionary past, especially during the Quaternary epochs, i.e. Pleistocene and Holocene, for which development of glaciation over considerable areas was typical.

The formation of "icing belts" is closely linked geomorphologically with the activity of Pleistocene glaciers, and in some regions (Ulakhan-Chistai Range, Kodar Range) of present-day glaciers as well. Consequently, geomorphological activity of glaciers implies not only glacial erosion and general planation of the relief, but also the formation of a great variety of moraine-riegel complexes. It is a series of such complexes that produces an "icing belt".

THE EFFECTS OF GRAVEL ROADS ON ALASKAN ARCTIC COASTAL PLAIN TUNDRA

Lee F. Klinger, Donald A. Walker, and Patrick J. Webber

Institute of Arctic and Alpine Research
and Department of Environmental, Population, and Organismic
Biology
University of Colorado, Boulder, Colorado 80309 USA

Gravel roads on the Alaskan Arctic Coastal Plain may induce considerable habitat alteration through snowbanks, flooding, and dust. An integrated sampling approach is taken to delineate the magnitude and extent of these impacts on the tundra communities along the West Road at Prudhoe Bay, Alaska. After 1 year of monitoring, minor vegetation changes are noted. Snowbanks within 10 m of the road are 5-10 times deeper than the natural snowpack. Unlike roads with heavy winter traffic where dust on the snow surface decreases albedo which hastens snowmelt, the West Road receives no winter traffic and snowbanks persist for many weeks after natural snowpack melt. These snowbanks block culverts which causes extensive early summer flooding which is the predominant impact of the road, inducing greater depth of thaw and greening of the vegetation. The level of dust fallout along the road is relatively low, only about one-third of that measured along other roads in the area. A matrix of predicted impacts is presented and certain mitigative measures are suggested for gravel road construction and maintenance.

INTRODUCTION

The present approach of building gravel roads in the Arctic is to build the roadbed thick enough to prevent thawing of the underlying tundra. In northern Alaska, 2-m thick roadbeds are generally used. Although this design is successful in maintaining the integrity of the roadbed, there are certain consequences which may drastically alter the adjacent physical and biological environments. The three main effects of these roads on the adjacent tundra are: a deepening of snowpack, the impedance of surface drainage with resultant flooding and dust fallout. These effects have been noted for several years by numerous authors (Benson *et al.* 1975, Everett 1980, Walker and Werbe 1980, Spatt and Miller 1981). There is still, however, a lack of understanding of the integrated system of road-tundra interactions. This paper integrates the observations from earlier studies with provisional results of a multiyear, monitoring study documenting the abiotic and biotic changes adjacent to a gravel road on wet Arctic Coastal Plain tundra at Prudhoe Bay, Alaska. This work was performed for the Department of the Army, Alaska District, Corps of Engineers, Anchorage. The monitoring program is sponsored by ARCO Alaska, Inc. and Sohio Alaska Petroleum Company and is required to fulfill permitting stipulations. The program was managed by Woodward-Clyde Consultants in 1981-1982, and by Envirosphere Company in 1982-1983.

Studies of this kind are useful in understanding the cumulative impacts of roads on tundra communities and in determining reliable mitigative measurements for road construction and maintenance. The additive effects of road-induced

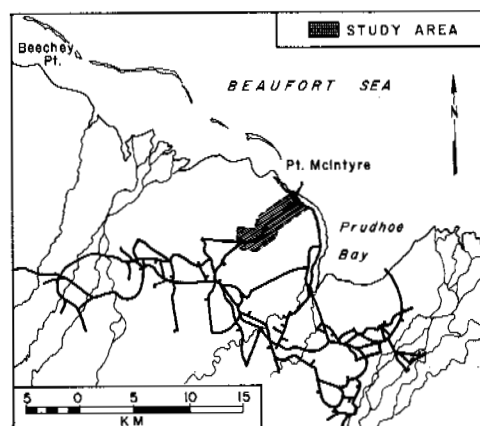

FIGURE 1. Location of the West Road study area (lat. $70^{\circ} 22'$, long. $148^{\circ} 36'$) at Prudhoe Bay, Alaska. Heavy lines denote gravel roads.

snowbanks, flooding, and dust on the vegetation result in notable losses and gains in wildlife species through habitat alteration. By examining road usage and design in the context of habitat changes, sound recommendations can be made in route selection, culvert location, and road maintenance.

The new results were gathered along the West Road (Figure 1). It was constructed in the winter of 1980-1981 and extends from the Arctic coast for 7 km southwest, traversing an area of continuous permafrost. The area is flat with numerous shallow lakes and drained lake basins. The vegetation, soils, and landforms of the region are described by Walker *et al.* (1980).

Monitoring of the West Road impacts is being

accomplished with four principal methods: mapping, road transects, dust measurement, and permanently marked study plots. The mapping approach utilizes vertical aerial photographs to delineate the extent of snowbanks and flooding (Figures 2a and 2b, respectively). A dust distribution map (Figure 2c) was constructed by plotting isolines of equal dust fallout using the results of the dust measurement. Road transects are used to monitor changes in snow, water, and thaw depths adjacent to the road. Dust quantity and quality measurements are being made on material collected in dust settlement traps located at each plot. Traffic and meteorological monitoring are being performed as well. Permanent study plots are being sampled nondestructively for vegetation cover, community composition, and numerous soil and environmental variables. Plots are distributed on both sides of the road evenly between impacted, experimental and nonimpacted control areas and among the three main tundra moisture regimes: dry, moist, and wet.

MAJOR EFFECTS OF THE ROAD

Snowbanks

Benson *et al.* (1975) have reported on snowbank formation along roads in the Prudhoe Bay region. They observed that roads oriented perpendicular to the prevailing winter winds generated deep and extensive snowbanks, whereas roads running parallel to the winds did not cause a deepening of the natural snowpack.

Changes in snow depth with distance to the road are characterized by transect measurements (Figure 3) which show a deeper, more extensive snowbank on the west (downwind) side. The winds that built the 1982 snowbanks apparently prevailed from an easterly direction with strong secondaries from the west. This accumulation pattern is somewhat different from the results of Benson *et al.* (1975), who found deeper snowbanks on the east side of the roads. During the winter of their observations, most of the storms with significant snowfall had winds from the west and southwest. There is considerable variation among years with respect to wind patterns and total snowfall, and both of these factors are important with regard to the size and position of the road snowbanks.

The snow distribution map for 1982 (Figure 2a) indicates that the majority (over 80%) of the study area is under patchy snow cover or is entirely snow free just prior to breakup. It is the snow free areas that are most utilized by early breeding bird species. Snowbank formation due to the road has clearly diminished the extent of this habitat in the early summer. Road-augmented snowbanks overlie 0.65 km^2 of the 22.21 km^2 study area which may be better expressed as 9.2 ha km^{-1} (37 acres mi^{-1}) of road.

One of the main effects of snowbanks is the blockage of culverts. This effect is reduced by heavy winter traffic when dust accumulation on the snow surface near a road decreases albedo and snowmelt is hastened. Even though snowbanks next to the elevated roads may be 5-10 times deeper than the average winter snowpack as a result of drifting and/or plowing, these are often the first

areas to melt (Benson *et al.* 1975). Conversely, roads with little or no winter traffic have insignificant dust fallout and snowbanks may persist for many weeks after natural snowpack meltout and completely block culverts. This situation can cause the deepest and most extensive flooding following spring runoff.

Certain plants are likely to respond favorably to increased snow accumulations. Prostrate willows, lichens, horsetails, and numerous forbs flourish in snowbanks of the Prudhoe Bay region (Walker 1981). It should be noted, however, that snowbanks associated with roads are quite different than most natural snowbanks in the Prudhoe Bay region. Most of the larger natural snowbanks are associated with pingos, creek bluffs, and other areas of high relief which are well drained. These natural snowbank areas are relatively well drained, and the vegetation has a mesic or xeric character. Road-associated snowbanks, in contrast, commonly occur in the very wet areas since this is the most common moisture regime on either side of the road.

A notable consequence, so far, of snowbanks is a significant suppression of graminoid cover in wet areas. Snow is naturally deeper on wet plots and additional snow is likely to delay vascular plant phenology to a measurable extent. Since graminoids make up over 95% of the vascular plant cover in wet plots, this is the growth form in which the change is manifested most.

Flooding

Flooding is the predominant impact of the West Road both in terms of areal extent and observable and measurable change. Extensive flooding can occur during snowmelt in areas where a drainage basin is traversed by an elevated gravel roadbed. Normally, culverts in the roadbed at the tundra surface can prevent deep ponding if they are designed, installed, and maintained properly. However, numerous problems render many culverts inoperable. Roadway compaction can deform culverts, causing the ends or middle to bow (Berg 1980). Ends of culverts can clog with gravel from road shoulder grading (Berg 1980). Early in the summer, snow and ice may block the passage of water through the culverts. Walker's (1981) study of the vegetation of the Prudhoe Bay region noted that thermokarst was associated with road-induced flooding. Ponding caused by the Dalton Highway (formerly called the TAPS Haul Road) has been well documented by Berg (1980). He also discussed some possible effects of ponding on permafrost and roadbed degradation.

Along the West Road, 99% of the road-related flooding occurs on the east side. This is due to the main axis of the road running obliquely to the northerly direction of surface water flow. The area of flooding shown in Figure 2b is 1.34 km^2 or 18.2 ha km^{-1} (75 acres mi^{-1}) of road. In 1982, additional culverts were properly placed along sections of the road which brought about more rapid drainage of the impoundments than in 1981.

Early season water levels are very high in areas next to the east side of the road, but drop off rapidly by mid-season to depths slightly above

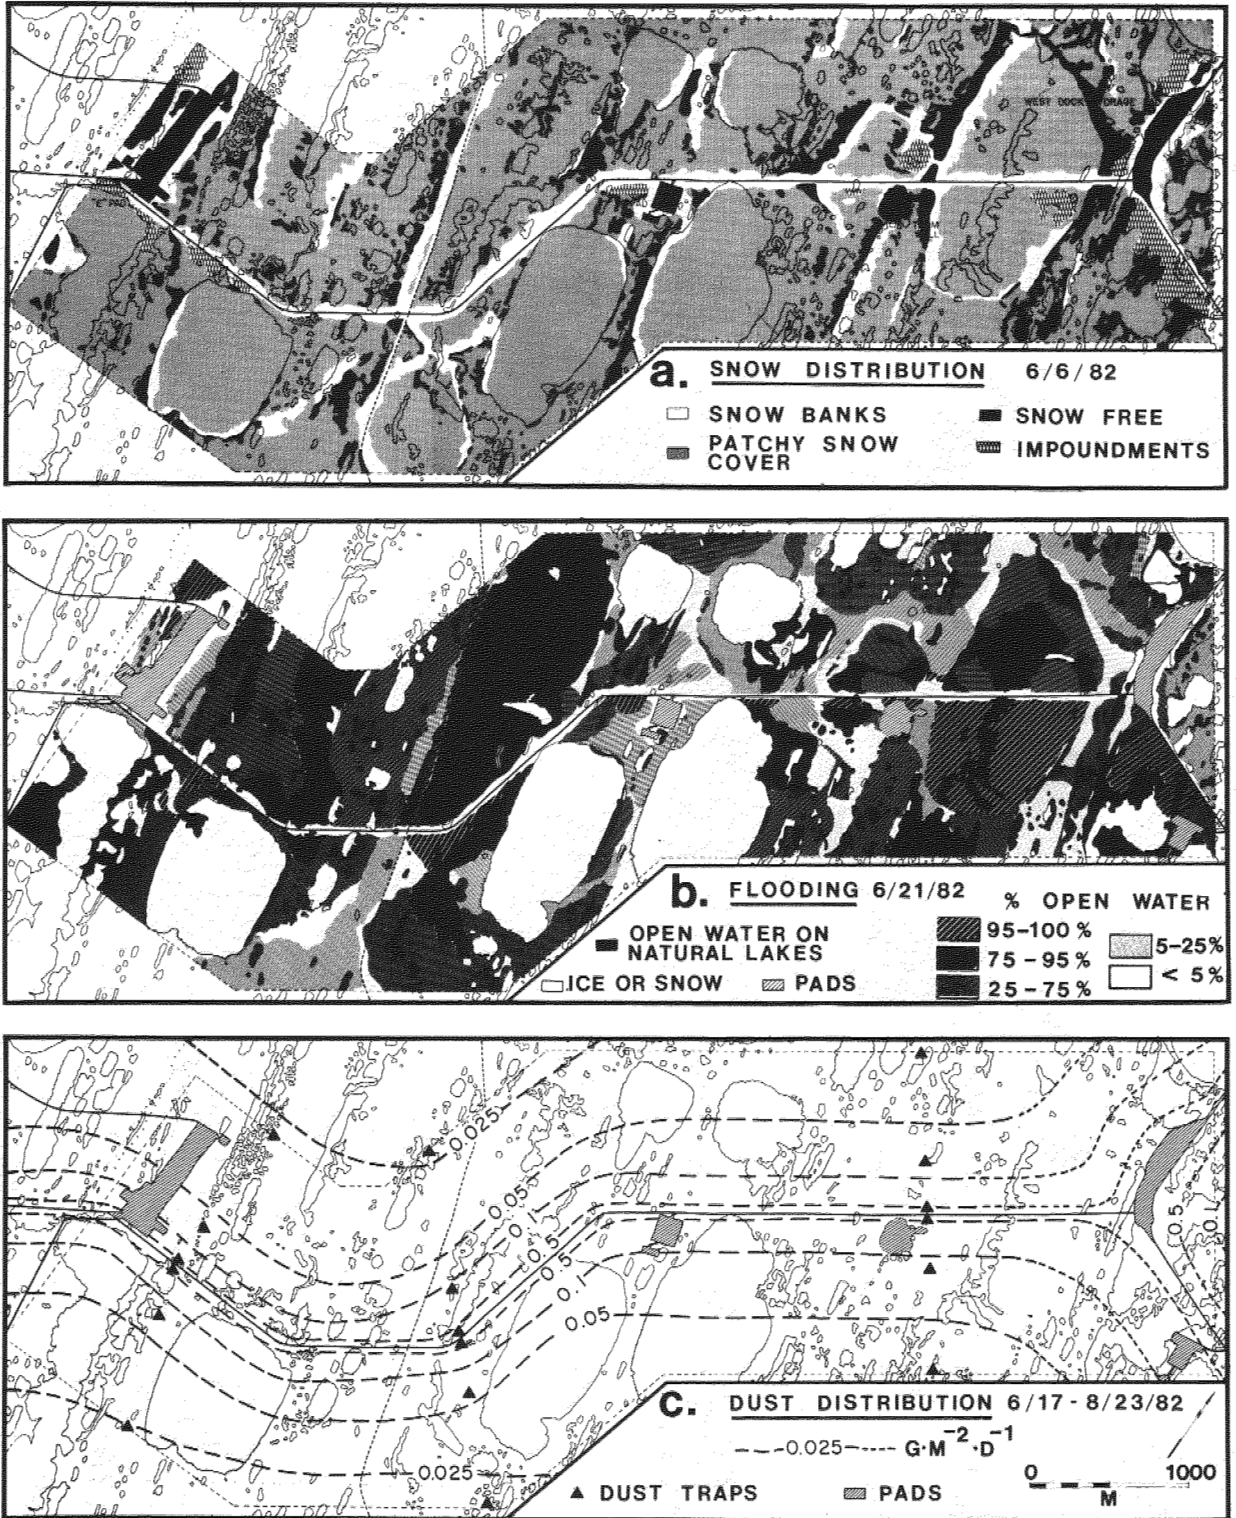

FIGURE 2 West road impact maps. (a) Snow distribution shows extensive snowbanks adjacent to roads and pads. (b) Flooding maps shows flooding concentrated on the southeastern side of the road. (c) Dust distribution map delineates isolines of dust fallout.

FIGURE 3 Snow, water, and thaw depths at Transect B in 1982. Note the deeper snowbank on the northwest (downwind) side, and the greater thaw depths on the southeast (flooded) side of the road.

those in control areas (Figure 4). Flooding also induces greater thawing of the active layer. A flooding index was calculated for each permanent plot. This index is based on the depth of flooding, the duration of flooding, and the normal (preroad) water levels. End of season active layer thickness is highly correlated ($p < 0.001$) with this index. Similar increases in depth of thaw due to flooding have been noted by other authors (e.g., Berg 1980).

The most apparent effect of flooding on plants is a deep greening of the vegetation evident later in the summer when water levels are at a minimum. This probable increase in graminoid production is likely caused by several factors including warmer temperatures associated with ponds, increased nutrient availability and changes in phenological patterns. The assumed increase in plant productivity in greening areas has not yet been demonstrated; however, changes in cover of certain plant categories can be correlated with the flooding index. In moist plots, which are not regularly subject to persistent standing water, lichens and shrubs are responding unfavorably to flooding, whereas bryophytes, which often flourish in a water-saturated environment, appear to be benefiting from an enhanced water regime.

Road Dust

Everett (1980) has studied the physical and chemical properties of road dust and its distribution patterns at Prudhoe Bay and along the Dalton Highway. He has demonstrated clearly the log-log relationship between the mass of dust fallout and distance to the road. The effects of road dust on the vegetation along the Dalton Highway have been reported by Walker and Werbe (1980), and Spatt and Miller (1981). They have shown that heavy dust loads are detrimental to many mosses and lichens and certain vascular plants, such as *Cassiope tetragona* and *Lycopodium annotinum*.

Dust fallout along the West Road in 1982 was only one-third of that measured along other roads in the Prudhoe Bay region by Everett (1980). This is the result of restricted access to the West Road throughout most of the year. Most of the dust accumulating along the road was produced during July and August when traffic was unrestricted. Dust was distributed fairly evenly on both sides of the road (Figure 2c) and followed the log-log relationship mentioned above.

Walker (1981) has described the two distinct vegetation regions at Prudhoe Bay. The first is

FIGURE 4 Seasonal progression of water and thaw depths at the wet plots along Transect B in 1982. Southeast side experimental plots show greater water and thaw depths due to flooding.

TABLE 1 West Road Vegetation Impacts Observed After 2 Years and Expected Impacts After 10 Years.

Vegetation Type	Impact Type			
	Snowbanks	Flooding	Dust ^{a/}	
Dry Prostrate Shrub Tundra	<u>Impact after 2 years:</u>	No negative effects Increase in lichens. (?)	None.	Little or no effect.
	<u>Expected impact after 10 years:</u>	Will probably be difficult to detect snow effects because of overriding impact of dust.	Areas of high-centered polygons will have thermokarst in the troughs. Tops of polygons will be eroding into the troughs.	Near the road most mosses and lichens will be smothered by dust. Low growing forbs will be doing poorly. Sedges and low shrubs will be doing relatively well.
Moist Graminoid Tundra	<u>Impact after 2 years:</u>	No negative effects Possible increase in bryophyte and forb productivity.	Decrease in lichens and <u>Dryas</u> Increase in bryophyte production.	Possible increase in forbs.
	<u>Expected impact after 10 years:</u>	Will probably be difficult to detect snow effects because of the overriding impact of dust. Willows near the road may increase in stature due to winter protection afforded by the snow bank.	Most moist areas will not be impacted. Where they are, <u>Dryas integrifolia</u> , lichens and many mosses will be eliminated. Sedges and hydrophilous mosses will increase.	Less tolerant taxa that will decrease include <u>Cassiope tetragona</u> , <u>Tomenthypnum nitens</u> , <u>Catascopium nigratum</u> . These may be eliminated near the road. More tolerant taxa include <u>Dryas</u> , <u>Drepanocladus</u> spp., <u>Campylium stellatum</u> willows and sedges.
Wet Graminoid Tundra	<u>Impact after 2 years:</u>	Decrease in standing crop algae and live vascular plants. Difficult to separate snowbank effects from flooding effects.	Decrease in graminoids in the deepest flooded areas, also decreases in algae, live vascular plants and standing crop. Greening of graminoids and possible increase in production in some flooded areas.	Increase in algae, possible increase in standing crop.
	<u>Expected impact after 10 years:</u>	Will probably be difficult to detect snow effects because of the overriding impact of flooding. Species composition of unflooded wet areas with deep snow will change very little.	Deepest flooded areas will increase in depth due to thermokarst. Graminoid production will probably decrease in these areas. In less deeply flooded areas, many forbs and mosses will decrease or be eliminated. Areas flooded only during the early season melt will not change much.	Some species of moss such as <u>Catascopium nigratum</u> will be eliminated near the road. Other dominant mosses such as <u>Drepanocladus</u> and <u>Scorpidium</u> are relatively tolerant of dust.
Wet Graminoid Tundra	<u>Impact after 2 years:</u>	Decrease in standing crop algae and live vascular plants. Difficult to separate snowbank effects from flooding effects.	Decrease in graminoids in the deepest flooded areas, also decreases in algae, live vascular plants and standing crop. Greening of graminoids and possible increase in production in some flooded areas.	Increase in algae, possible increase in standing crop.
	<u>Expected impact after 10 years:</u>	Will probably be difficult to detect snow effects because of the overriding impact of flooding. Species composition of unflooded wet areas with deep snow will change very little.	Deepest flooded areas will increase in depth due to thermokarst. Graminoid production will probably decrease in these areas. In less deeply flooded areas, many forbs and mosses will decrease or be eliminated. Areas flooded only during the early season melt will not change much.	Some species of moss such as <u>Catascopium nigratum</u> will be eliminated near the road. Other dominant mosses such as <u>Drepanocladus</u> and <u>Scorpidium</u> are relatively tolerant of dust.
Aquatic Graminoid Tundra	<u>Expected impact after 10 years:</u>	No effects.	Generally no effects, except in deeply flooded areas that fail to drain because of lack of culverts. Here all plants are likely to be eliminated and permanent lakes formed. Areas with <u>Arctophila fulva</u> will be unaffected.	No effects except immediately adjacent to the road where some aquatic mosses may be smothered by dust.

^{a/}Projected dust impacts after 10 years are based on observations from along the Prudhoe Bay Spine Road and the Dalton Highway haul road (Walker and Werbe 1980).

an area of alkaline tundra associated with loess from the Sagavanirktok River, and the second is from acidic tundra that is outside the main area of loess deposition. The study area lies entirely within the region of acidic tundra. This situation is important when considering the effects of road dust. The roadbed material is quarried from calcareous alluvial deposits. The high pH of the dust released from traffic across this roadbed ultimately can be expected to change the acidic tundra by reducing or eliminating many of the acidophilous plant taxa.

Certain species in the region of alkaline tundra are preadapted to a more calcareous environment and experience no change or even an increase in productivity next to the road. Conversely, acidophilous species, such as *Sphagnum* spp. and *Dicranum* spp., are likely to be eliminated near the road. Along older roads in northern Alaska, many cryptogams have been eliminated due to smothering and toxicity effects of road dust (Walker and Werbe 1980). By removing this important insulating layer, thermokarst potential is greatly enhanced.

The impacts of dust from the West Road on the vegetation at this time are slight. The only noteworthy effect of dust to date is an increase in the alga *Nostoc commune* which is apparently responding to a changed nutrient regime near the road. We expect that with time, other dust-related changes will be apparent.

CONCLUSIONS

The monitoring of the road impacts has shown that flooding is the major impact both in terms of magnitude and extent. The most important abiotic effect noted at this time is a significant increase in the active layer of flooded areas. Snowbanks and dust are currently relatively minor impacts along the West Road.

It is important to note that the West Road is very different in many respects from other roads at Prudhoe Bay. The restricted vehicle access is causing low levels of dust fallout. The road is located in an area of tundra that is somewhat wetter and more acidic than most of the region. Furthermore, the road runs obliquely to the drainage patterns, causing more flooding than other roads in the area which parallel the direction of drainage. Due to these high levels of flooding, considerable attention has been paid to the number and placement of culverts in the West Road.

Based on the preliminary results of the West Road study along with many years of observations around the Prudhoe Bay region, a predictive impact matrix is presented which summarizes the short-term and long-term effects of gravel roads on tundra vegetation (Table 1). Measurable changes in the vegetation, so far, have been slight. Most tundra plants are long-lived perennials with large below-ground food reserves and are likely to persist for many years after the habitat has changed. However, road effects are likely to be cumulative over many years, and vegetation changes may occur very quickly once a critical level of impact is reached.

To reduce the level of impact along gravel road, certain mitigative measures are recommended. First, culverts should be installed during the summer thaw season when drainage patterns can be more readily observed, rather than during the winter which is the current practice. Second, culverts should be kept free of snow and ice during snowmelt to prevent extensive flooding. This can be accomplished by removing snow from culvert openings and by using steam pipes to prevent ice clogging in the culvert. Third, dust suppression techniques should be used on a regular basis.

Future plans for development on the Arctic Coastal Plain call for many hundreds of kilometers of gravel roads. The potential impacts of this extensive road system on wildlife and habitat are immense. With a good understanding of road-tundra interactions derived from integrated studies on existing roads, well-devised mitigative measures can be applied to minimize future impacts.

ALPINE PLANT COMMUNITY COMPLEX ON PERMAFROST AREAS OF THE DAISETSU
MOUNTAINS, CENTRAL HOKKAIDO, JAPAN

Takeei Koizumi

Department of Geography, Tokyo Gakugei University, Koganei City, Tokyo, 184 Japan

On the summit areas of the Daisetsu Volcanic Mountains, the existence of permafrost is recognized. In this area an alpine plant community complex is distributed widely. It is composed of alpine windblown herb-heath, an alpine stony desert plant community, and two kind of *Salix* (*Salix pauciflora* and *Salix yezoalpina*), which are thought to grow in a humid habitat. To clarify the cause of this complex, the depth of the active layer in mid-July, vertical changes of soil temperature, and the depth of the water table were examined. It became clear that the depth of the water table was the only factor controlling the distribution of the two species of *Salix*, though there were no relations between the distribution of windblown vegetation and three conditions. *Salix* is limited to the humid places of the shallow water table, less than 35 cm in mid-July. They do not emerge in the dry places of the low water table. Owing to the rise of the water table caused by the permafrost, two species of *Salix* are thought to have mixed in windblown vegetation, which is ordinarily a dry type plant community. And as a result, the alpine plant community complex is formed.

INTRODUCTION

There are some investigations on the influences of permafrost on vegetation. Johnson (1966) suggests the following effects of permafrost; the impeder of the drainage of water, the cooling of the surficial soil, the making of the surficial irregularities and the provision of an impervious substrates which reject the penetration of the plant root. Ronning (1969) investigates the relationships between microtopography, permafrost and vegetation in Spitzbergen. He shows that the *Dryas* community occupy the dry ridges with the low groundwater level, though the *Deschmopsia* community grows in the wet depressions with the high groundwater level. Dingman and Koutz (1974) studies the relationships between the forest types and the distribution of permafrost, in the discontinuous permafrost areas of Alaska. Brown (1970) makes clear that the terrain formed by permafrost decides the vegetation in pala areas. In any case, the groundwater level is considered to be very important (Ito 1978, Peterson and Billings 1980, etc.).

In Japan the distribution of permafrost is recognized in only two places: one is the summit area of Mt. Fuji and the other is the summit areas of the Daisetsu Mountains (Fukuda and Kinoshita 1974). However, the influence of permafrost on the alpine vegetation has not been studied yet. This paper discusses the influences of permafrost on the alpine vegetation, especially on the composition of plant communities. The studied area is the summit area of Mt. Koizumitake (2,158 m) in the eastern part of the Daisetsu Mountains.

OUTLINE OF STUDIED AREA

The Daisetsu Mountains are located in the central part of Hokkaido, the northernmost part of Japan. It is a plateaulike large volcano composed of many volcanic cones and pyroclastic or lava flow

plateaus. The altitude of these cones and plateaus is about 2,100-2,300 m a.s.l. (Figure 1). Gentle slopes are conspicuous (Plate 1).

The forest line runs at about 1,600 m and the above belongs to the alpine zone. In the alpine

FIGURE 1 Location of studied area.

PLATE 1 View of the Daisetsu volcano.

zone *Pinus pumila* scrubs are eminent. However, in summit areas or areas along the main rounded ridges there are periglacial debris fields and windblown herb-heath and alpine stony desert plant communities. They emerge as summit phenomena. Because of strong northwest monsoons, there is less snow in winter on summit areas. So *Pinus pumila* cannot grow in such places and windblown herb-heath and alpine stony desert plant communities emerge instead. There is frost action and many kinds of patterned ground, for example, sorted stripes, solifluction lobes, or turf-banked terraces, are distributed (Koaze 1965).

Mt. Koizumitake is one of the rounded peaks of the Daisetsu volcanos (Plate 2).

COMPOSITION OF PLANT COMMUNITIES OF MT. KOIZUMITAKE

The author set the 21 quadrant for vegetation surveying from the top of the Mt. Koizumitake to the gentle col between Mt. Koizumitake and Mt. Hakuundake (Figure 2). One quadrant is 2 x 2 m width. Results of vegetation

FIGURE 2 Topography of Mt. Koizumitake and the location of surveying point.

surveying are shown in Table 1.

Generally speaking, the vegetation cover is poor and the periglacial debris fields are extensive (Plate 3). The main plants are *Diapensia lapponica* var. *obovata*, *Carex flavocuspis*, and *Loiseleuria procumbens*, etc., which make up the windblown herb-heath. However, reflecting the complexity of the habitat, the components of alpine stony desert plant community are also present. These species, for example, *Viola crassa*, *Dicentra peregrina* var. *pusilla*, etc. grow on unstable habitats as the part of the fine-size gravels of solifluction lobes.

PLATE 3 Plant communities and periglacial debris fields on Mt. Koizumitake.

In addition, two species of *Salix* (*Salix pauciflora* and *Salix yezoalpina*) mix in these plant communities. They are distributed on points 2, 4, 5, 6, and 8. Usually *Salix* is thought to grow in a rather humid habitat. In the Japanese Alps they are not distributed on the windblown areas, which are usually dried. So this distribution phenomenon means that the plants of humid habitat get mixed with the dry-type windblown plant communities.

Therefore, the alpine vegetation consists of a plant community complex here.

This plant community complex is reported already (Ito and Nishikawa 1977, Ito and Sato 1980). But the reason of the distribution of this complex in not been clarified.

INFLUENCE OF PERMAFROST ON VEGETATION

The distribution of such a plant community complex is limited on the permafrost areas of the Daisetsu Mountains. To clarify the cause of this complex, the influences of permafrost on vegetation

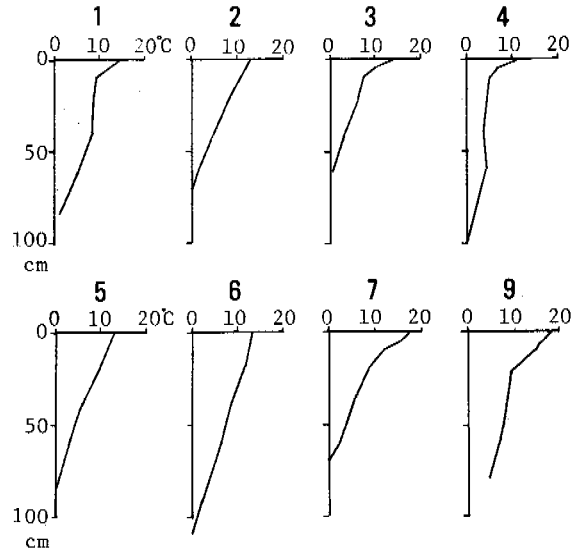

FIGURE 3 Vertical change of soil temperature in each point

were checked, specifically, the cooling of surface soil or the change of a habitat to a humid state caused by permafrost. So the distribution of permafrost, the depth of the active layer in mid-July, the vertical changes of soil temperature, and the depth of the water table were examined.

In these conditions, permafrost is recognized at all points on Mt. Koizumitake. Therefore, the existence of permafrost itself has no relation to plant distribution. Cooling of surface soil is not recognized in each point. The soil temperature of the earth's surface rises to 15-20 C or more in mid-July (Figure 3). So it is improbable that the cooling of soil limits the growth of plants. For the same reason, the the depth of the active layer has no relation to plant distribution (Table 2).

But it becomes clear that the depth of the water table has a close relation to the distribution of the two species of *Salix*. In this area the water table exists generally in shallow places (Table 2, Figure 4). The reason for such a high water table is that the permafrost prevents the penetration of groundwater.

The water table is especially shallow on the gentle mountain slope (point 4-6), but around the col it becomes rather deep. The two species of

 Numbers show the surveyed points.

Salix emerge in the habitat with a shallow water table but not in the dry places of the low water table. The borderline is at -35 cm in mid-July.

As mentioned already, the surveyed areas are located on windy places, so the mixture of the two *Salix* is an abnormal phenomenon in a sense. But the presence of permafrost enables such a distribution to exist. And the formation of a plant community complex is also the result of such a distribution. Since such a habitat does not exist other high mountains, the plant community complex in this mountain is unique to Japan.

ACKNOWLEDGEMENTS

The author expresses grateful thanks to Mr. H. Shinsho and Mr. O. Yanagimachi for the help in the field study and also to Mr. M. Tamura for the aid with illustrations.

COVER SANDS IN SOUTHERN JUTLAND (DENMARK)

Else Kolstrup

Danmarks Geologiske Undersøgelse, Thoravej 31, DK-2400 København NV, Denmark

Investigations in southern Jutland (Denmark) have revealed the presence of Older and Younger Cover Sands. By means of pollen analysis and stratigraphic comparisons with neighbouring countries, it is suggested that the Upper Pleniglacial is represented by the Older Cover Sand I and II, with a phase of fluvial activity, deflation, and frost action in between. There is a Late-Glacial succession of Younger Cover Sand I, peat of Allerød age, and Younger Cover Sand II on top of the Older Cover Sand II. Holocene peat is found on top in some areas. Within the area glaciated during the Weichselian, diamicton is locally overlain by cover sand, while west of the glaciated area a period of cold climate is reflected within the cover-sand sequence. It is suggested that the conditions for the accumulation of cover sands are: a flat or very gently sloping relief in the area of deposition, (short?) vegetation to catch and retain the sand and silt, winds, and a sandy-silty source area without protective vegetation cover.

INTRODUCTION

The geology of large parts of Denmark was mapped during the early half of this century. The maps (including descriptions) of western and southern Jutland (e.g., Hansen 1965, Milthers 1925) show large areas covered by eolian deposits, most of which constitute a thin, usually only a few decimeters thick, cover on the landscape. This cover of eolian sand very often lies on and in the vicinity of so-called "fresh-water" deposits and "layered sand", deposits which were thought to be water-lain, but descriptions and further suggestions concerning their environment(s) of deposition are scanty.

A gas pipe line system has been under construction in Denmark since 1981. The locations of the gas pipe line trenches, Frøslev-Egtved (S-N), and Egtved-Lillebælt (W-E), are indicated on the map of southern Jutland in fig. 1 together with an outline of the geology of that area. The gas pipe lines are buried in continuous trenches approximately two meters deep. These trenches made it possible to study the vertical succession of sediments and the lateral changes of layers. In the areas with a top sheet of eolian sand, the top layer as well as the underlying sediments were investigated in vertical section with regard to structure, texture, and stratigraphic succession.

SEDIMENTS

Two types of sediments were found to be prevalent in the areas with a top sheet of eolian sand (Kolstrup & Jørgensen 1982).

Type 1

Type 1 corresponds to the eolian sand sheets of the Danish geological maps. This type consists of horizontal to subhorizontal layers from mm to a few centimeters thick (fig. 2). Consecutive layers are well-sorted and normally they have approximately

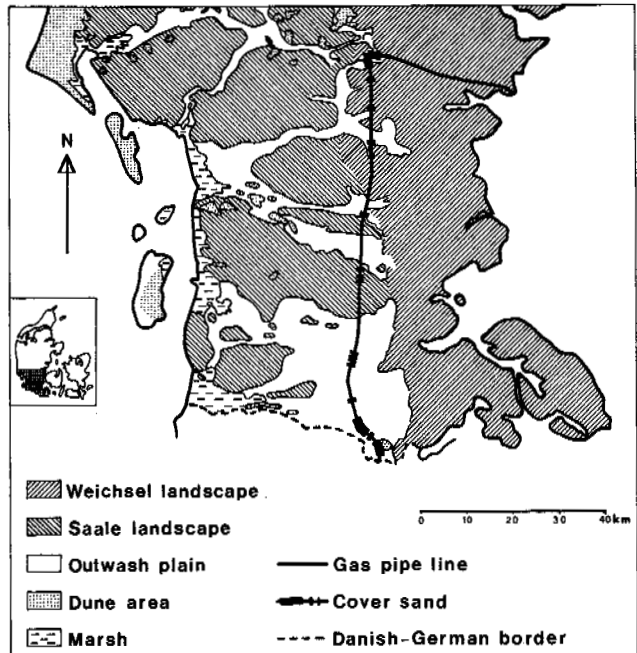

Figure 1. Map of southern Jutland with locations of cover-sand occurrences indicated along the gas pipe line trenches Frøslev-Egtved (S-N) and Egtved-Lillebælt (W-E). The geological boundaries are based on P. Smed, 1982, Landskabskort over Danmark, Blad 3, Sønderjylland, Fyn. Geografforlaget, Brenderup.

the same grain size, with a maximum usually between 150 μm and 300 μm (dashed lines to the left in fig. 3), but layers dominated by grains about 2 to 4 mm in diameter may be found locally, as well as single pebbles up to 1.5 cm in size. The composition of the sand is strongly dominated by quartz grains which are rounded to well rounded and polished. In some localities this unit is divided

Figure 2. Photograph of Older Cover Sand II (lower half of profile) with a gradual transition upwards to Younger Cover Sand. The ruler is two meters long.

Figure 3. Grain-size distribution of Younger Cover Sand (dashed lines), Older Cover Sand I (full lines), Older Cover Sand II (dotted lines), and a fine-grained layer in the Older Cover Sand (dashed-dotted line).

by a peat layer or by a somewhat finer horizon which may possess bioturbation. Although type 1 may be up to 1.5 m thick, its thickness is usually less than one meter. It makes up the top layer of the profiles where it is present, and the original layering in its upper part is therefore often disturbed by surface processes or has disappeared altogether. In some depressions type 1 is overlain by peat. The good sorting and the polished grains of this unit, together with its appearance as a morphologically inconspicuous surface layer covering flat and slightly undulating areas, makes an eolian origin probable.

Type 2

Type 2 is included in the "fresh-water" deposits and "layered sand" of the geological maps. Also, this sediment normally consists of horizontal to subhorizontal from mm to a few centimeters thick layers (fig. 2); however, there is a vertical alternation of fine and medium sand layers in this deposit. In some places the fine fraction, usually dominated by particles ranging between $63 \mu\text{m}$ and $105 \mu\text{m}$, may be dominant in vertical profile; in others, the coarse fraction prevails. The dotted-dashed line in the right-hand part of fig. 3 represents a decimeter-thick layer of the fine fraction, and it can be seen that individual layers are well sorted. Field observations reveal that the medium sand layers of type 2 are similar in texture and sorting to the sand of type 1. Bulk samples of type 2, therefore, are made up of various mixtures of the pure populations (dotted and full lines in fig. 3). The larger grains of this unit are well rounded and polished whereas the smaller grains are more angular and shiny.

In the southern part of the Frøslev-Egtved stretch, type 2 is divided into two subunits by a gravel layer with a horizontal to subhorizontal layer of wind-polished and faceted pebbles and stones on top. The upper subunit, which rests upon this pebble layer is usually undisturbed, whereas the part underlying the pebble layer is usually strongly involuted and includes somewhat coarser sand and gravel.

In the northern part of the above-mentioned stretch, and in the western part of the Egtved-Lillebælt trench, undisturbed type 2 sediment is found on top of a diamicton, predominantly till, with grain sizes ranging from clay to boulders with wind-polished and faceted stones on top. The upper (undisturbed) subunit of type 2 is usually between 0.5 and 1 meters thick, although in some areas it may be more than two meters thick. This deposit either grades upwards into type 1 sediment, or there may be an up-to-10-cm-thick layer of fine sand and loam separating the two. Due to the texture of the individual sand grains, the sorting, and the polished and faceted pebble layer, the type 2 deposit is also thought to be of eolian origin.

POLLEN ANALYSIS

The peat within type 1 contains fairly high percentages of *Betula* pollen including both larger and smaller grains. Pollen of Gramineae, Cyperaceae and herbs are also fairly well represented, as are

Figure 4. Pollen diagram representing organic layers within the Older Cover Sand II near Frøslev. The black parts in the spectra of the resolved diagram are of the same scale of percentage as that of the main-diagram to the left; the scale of the open bars is indicated below the resolved diagram.

spores of *Gymnocarpium*. Pollen from trees other than *Betula*, *Pinus*, and *Salix* are absent. This pollen composition points to a vegetation of short plants, with scattered occurrences of birch (*Betula pubescens* and *B. nana*) and willow.

Within the upper, undisturbed subunit of type 2, four approximately 1-cm-thick layers containing organic material could be followed laterally for

more than 350 meters in the southern part of the Frøslev-Egtved trench. The composition of the pollen from the organic layers is given in fig. 4. The pollen is strongly dominated by Cyperaceae and Gramineae, and a number of herb pollen types are present, notably *Gentianella* and *Saxifraga* in the lower spectra. *Betula* is almost exclusively represented by small pollen, viz., pollen deriving from *Betula nana*, and the pollen of *Salix* probably also represents short forms rather than trees. The spectra in fig. 4, therefore, indicate that short plants were growing in a moist environment.

STRATIGRAPHY

A comparison of type 1 and 2 deposits with deposits from The Netherlands, western Belgium, northern Germany, and Poland shows that type 1 and 2 are similar to the Younger and Older Cover Sands respectively (compare, e.g., van der Hammen 1951; Nowaczyk 1976).

Lithostratigraphy

Two types of stratigraphic sequences were exposed in the trenches (fig. 5). In the southern part of the Frøslev-Egtved trench, the lower part of the sequence consists of a water-lain deposit of sand and gravel, sometimes covered by a layer of wind-polished gravel. Above this is type 2, viz., Older Cover Sand deposit, which in turn is covered by another water-lain deposit of sand and gravel. This part of the sequence is usually strongly involuted or undulating, and, locally, frost-wedge casts extend downward from within the involuted layer. In the northern part of the Frøslev-Egtved

trench, and in the western part of the Egtved-Lillebælt trench (i.e., within the area glaciated during the Weichselian), the lower part of the sequence usually consists of a diamicton, mostly till.

On the surface of both the involuted sequence and the diamicton, a layer of wind-polished and faceted pebbles and stones is found, which is overlain by an undisturbed deposit of type 2, viz., Older Cover Sand. The upper part of both sequences consists of type 1 deposit, i.e., Younger Cover Sand, except for sites where peat has accumulated later.

The stratigraphic sequence in southern Jutland is identical to the Dutch, western Belgian, and northern German sequences (e.g., Dücker & Maarleveld 1957, van der Hammen 1971, Zagwijn & Paepe 1968) and it can therefore be suggested that the sequence of changes in the environmental conditions are similar. Chronostratigraphic correlations have been made between the cover-sand sequences in western Belgium, The Netherlands, and northern Germany (Dücker & Maarleveld 1957, Zagwijn & Paepe 1968).

In the northern part of the investigated area in Denmark, only that part of the column overlying the diamicton is comparable to others, i.e., undisturbed Older Cover Sand overlain by Younger Cover Sand.

Chronostratigraphy

Investigations of peat found upon the Younger Cover Sand in Denmark show that the accumulation of organic material started in early Holocene time, i.e., around or shortly after 10,000 y.B.P. (e.g., Milthers 1925; compare also Iversen 1973).

A comparison of the pollen composition of the organic layer from within the Younger Cover Sand with palynological data from other localities suggests an Allerød age (i.e., 11,000 to 11,800 y. B.P.), as is also the case in the neighbouring countries (e.g., van der Hammen 1951).

A layer of bleached fine sand and loam separates the Older and the Younger Cover Sands in some localities. A similar layer is found in the same stratigraphic position in western Belgium, northern Germany, and The Netherlands, where it is called the Lower Loamy Bed and dated to the Bølling time (12,000 to ca. 12,400 y.B.P.). It is possible that this fine-grained layer in Denmark may also be of Bølling age.

It is also possible to subdivide the Younger Cover Sand into two units in Denmark, a Younger Cover Sand II which was predominantly deposited during Late Dryas time (i.e., predominantly between 11,000 and 10,000 y.B.P.), and a Younger Cover Sand I, which was deposited before the Allerød period and possibly after the Bølling.

The pollen composition of the organic layers in the upper, undisturbed Older Cover Sand unit (three lower spectra of fig. 4) corresponds with deposits of Upper Pleniglacial age (i.e., between ca. 27,000 and ca. 13,000 y.B.P.) in The Netherlands (van der Hammen et al. 1967, Kolstrup 1980), and therefore, the Danish deposit is also thought to be of Upper Pleniglacial age.

In southern Jutland the involutions, which are locally more than 1.5 meters deep, and the frost-

wedge casts connected to them, indicate a period of cold climate. Complete Dutch sequences reveal that the deposition of Older Cover Sand was temporarily interrupted by a period with permafrost, fluvial activity, and deflation, some time between ca. 22,000 y.B.P. and ca. 14,000 y.B.P. (The Beuningen Complex: van der Hammen et al. 1967, Kolstrup 1980). Since the stratigraphic sequences in neighbouring countries and Denmark are identical, and since a cold phase is reflected in all countries at the same stratigraphic level, it seems reasonable to accept that the involutions and frost-wedge casts were formed during the same cold spell. Following the Dutch nomenclature (van der Hammen et al. 1967), the Danish Older Cover Sand is consequently divided into an upper, undisturbed, Older Cover Sand II, deposited after the cold period, and a lower, involuted (cryoturbated) Older Cover Sand I, deposited before the period of maximum cold.

The local name of Frøslev Complex is introduced here for the Danish deposits and phenomena which are probably equivalent to the Beuningen Complex. The layer of wind-polished and faceted pebbles and stones forming the top layer of the Frøslev Complex is accordingly termed the Frøslev gravel bed.

Within the area glaciated during the Weichselian the Older Cover Sand II rests upon a diamicton with wind-polished and faceted stones on top.

A comparison between the stratigraphies of the two types of areas in Denmark (fig. 5) suggests a parallel development from the time of wind-polishing and onward, whereas before that time, the northern part was glaciated while periglacial processes were active in the southern, unglaciated area.

ORIGIN OF COVER SAND

As long as cover sands have been known in north-western Europe the environmental conditions for their formation, especially those of the Older Cover Sand, have been a puzzle which has not been solved yet.

Significant studies describing eolian deposits of a similar appearance in northern latitudes where accumulation is taking place today have been made by e.g., Pissart et al. (1977) and Trainer (1961).

Source Area and Appearance

It has been suggested that the exposed sea floors of the North Sea and the Channel were the source areas for the sands and silts (loesses) in Europe (e.g., Vink 1949). This suggestion has been queried by, among others, Crommelin (1964) who advocated the idea of a more "local" origin based upon three Dutch heavy mineral provinces being closely related to the mineralogy of the underlying sediments.

It might be suggested that the alternating grain sizes in the Older Cover Sand represent winds blowing from different directions, thus representing different source areas, but the investigations by Pissart et al. (1977) and Trainer (1961), and also, indirectly, that of Crommelin (1964) show that this is not a necessary requirement.

The alternation of grain sizes in the Older

Cover Sand has been explained as being the result of transportation and deposition by snow, possibly reflecting differences in mode of deposition during summers and winters (van der Hammen 1951). Others, e.g., Krumbein (1937) attribute the formation of interbedded eolian sand and silt to the transportation of sand by traction and dust in suspension. On the other hand, investigations by de Ploey (1977) reveal that both silt and fine sand may be transported as a basal flow along the ground surface, and he suggested that the two fractions may be deposited by simultaneous dumping.

Following Trainer's (1961) investigations and considerations, it may be suggested that the fine-grained layers were deposited during slackened deposition and/or were transported over a longer distance than the coarser fraction. Trainer believes that the characteristics of the eolian sediment in Alaska can be related to changes in the character of the source area of the eolian material and puts forward an elegant solution. He suggests that the changes may be related to formation and destruction of stabilized flood-plain surfaces and "it is apparent that any considerable change in stream regimen must be dependant upon changes in the glacier, in sea level, or in both, and hence ultimately upon changes in climate" (Trainer 1961, p. 30).

The periods during which the cover sands were deposited in northwestern Europe (i.e., some time before and some time after, but not during, the maximum ice extension) were periods of changing climate, with fluctuations of ice caps and glaciers and accompanying changes of sea level. Sea level changes may therefore have altered the stream regimen of northwest European watercourses, thus giving rise to incisions and floodings which in turn might have resulted in the exposure of unvegetated deposits of sand and silt. The changes in stream regimen may also, together with changes in temperature and precipitation, have altered the moisture balance of higher ground. Although the drying out of the surface sediment is not a necessary requirement for the start of deflation (de Ploey 1977), changes in sea level may thus indirectly have contributed to the erosional effect of the wind, so that sand could relatively easily be picked up in sparsely vegetated regions and become deposited in neighbouring areas.

Vegetation

Both Pissart et al. (1977) and Trainer (1961) consider vegetation cover an important factor for catching and retaining the wind-blown sands which come from neighbouring barren, sandy areas, particularly flood plains.

The pollen content of the organic layers in the cover sands in The Netherlands (Kolstrup 1980) and Denmark show that parts of the landscape were, at least periodically, covered by vegetation during the deposition of the sands. It may therefore be proposed that vegetation, in parts of the north-west European cover-sand areas, acted as a trap for the wind-blown sands and silts as well as a protection against erosion. It is difficult to envisage the extension of vegetation during the cover-sand accumulation. It was probably much more extensive than the scattered findings in north-

western Europe suggest, but since the accumulation and preservation of organic material is dependant on a non-aerated, non-oxidized environment, organic remains have only become preserved in a few places with favourable conditions.

Furthermore, the presence of pollen from perennial plants within single, thin, organic layers of the Older Cover Sand may suggest that deposition of sand and silt only took place occasionally, thus yielding a relatively slow accumulation rate of the sand sheets.

Air Temperature

The air temperature conditions during the deposition of the cover sands in northwestern Europe may be deduced from palynological records.

The presence of pollen of *Armeria maritima* var. *planifolia* found in the Older Cover Sand I and II in The Netherlands (Kolstrup 1980), in the Older Cover Sand II in Denmark, and in Late-Glacial deposits (e.g., Iversen 1954, 1973) point to a mean January temperature, at least periodically, of -8°C or warmer (Iversen 1954). The mean July temperature may have been different during the deposition of the various units, but generally speaking, it may have been on the order of $+8^{\circ}\text{C}$ to $+13^{\circ}\text{C}$ (Kolstrup 1980) during the deposition of some of the layers in the Older Cover Sand, and between ca. $+12^{\circ}\text{C}$ and $+15^{\circ}\text{C}$ (Iversen 1954, 1973, Kolstrup 1982) during the deposition of the Younger Cover Sand.

Relief

Within the area glaciated during the Weichselian in Jutland, it can sometimes be seen that the layering of the cover sand conforms with underlying undulations of the diamicton, and in some sites the horizontal layers of the Younger Cover Sand can be followed laterally into more than 2-meters-thick eolian deposits with steep foresets. This change is thought to reflect a change in the depositional environment caused by a change from a flat, or gently undulating area, to a more accentuated relief. It is, however, unknown whether the relief alone could account for the change or whether it was caused by a combination of steeper relief, associated hydrological change, and an accompanying change in vegetation.

CONCLUSIONS

The present investigation demonstrates that parts of Denmark belong to the northwest European cover-sand area and that the sequence of changes in environmental conditions have been similar within the region. Observations within and outside the area glaciated during the Weichselian make it possible to establish a probable link between the glacial and the periglacial stratigraphies.

The environmental conditions for the formation of the cover sands are still insufficiently known, but further investigations in northern areas where similar deposits accumulate today will undoubtedly add information.

ACKNOWLEDGEMENTS

The author wants to thank J. Stockmarr (Copenhagen) and I. Sørensen (Århus) for their valuable criticism of the manuscript, D. Blom (Kolding) for the correction of the English text, and I. and C. Torres (Copenhagen) for their help with the photographic work. The Danish Oil and Natural Gas Company A/S (D.O.N.G. A/S) kindly gave permission to follow the trenching. The Geological Survey of Denmark, The Danish Natural Science Research Council (S.N.F.), and The Natural Agency for the Protection of Nature, Monuments, and Sites (Fredningsstyrelsen) financed the investigation.

RECOVERY OF PLANT COMMUNITIES AND SUMMER THAW AT THE 1949
FISH CREEK TEST WELL 1, ARCTIC ALASKA

Vera Komarkova

Institute of Arctic and Alpine Research
and Department of Environmental, Organismic, and Population Biology,
University of Colorado, Boulder, Colorado 80309 USA

The Fish Creek Test Well 1 site on the Arctic Coastal Plain (70°18'36"N, 151°52'40"W) has been abandoned since its construction in 1949. The plant communities that developed on the disturbed site are all successional. The degree of community recovery has differed with the habitat/vegetation type and corresponds to the degree of recovery of the habitat. The average depth of thaw was greater in recovering than in undisturbed habitats, particularly in mesic uplands. Marshes have recovered much faster than mesic uplands. Mesic uplands are more resistant to surface disturbance, are less resilient, and show less fluctuation and narrower ecological range on some environmental gradients, such as depth of thaw. The time of recovery of mesic upland ecosystems at the Fish Creek site is estimated to be 600-800 years and that of marshes, 100-200 years. In most general features the resulting communities will probably resemble the surrounding undisturbed complex communities.

Like other test oil well sites in arctic Alaska from the 1944-1953 oil and gas exploration period, the Fish Creek Test Well 1 site is an excellent subject for studies of arctic tundra recovery because it has been relatively undisturbed since its construction in 1949. The site was initially studied in 1977 after 28 years of recovery (Lawson et al. 1978). This paper examines the hypothesis that in permafrost areas in arctic Alaska the degree of plant community recovery after surface disturbances is closely related to the degree of recovery of the disturbed physical environment, particularly its thermal regime.

Fish Creek Test Well 1 is located at 70°18'36"N and 151°52'40"W on the Arctic Coastal Plain in the region of continuous permafrost. The landforms, soils (Everett 1979), and vegetation are characteristic of the landscape of oriented lake basins and streams active in consolidated dunes (Carter 1981). The original vegetation habitats at the site included wet polygon troughs, ponds and marshes, elevated dry ridges, snow patches, mesic uplands, and marshy lowlands; today the site is surrounded by vegetation that is probably very similar to that which was originally disturbed (Lawson et al. 1978).

During the construction and operation of the test well in 1949, vegetation and much of the surface organic soil layer on the site were removed. In 1979, solid waste was removed from the site by the U.S. Geological Survey under contract with Husky Oil NPR Operations, Inc. (Husky Oil 1981). The recovery of the vegetation cover at Fish Creek is almost complete, but ground subsidence, thermo-karsting, thermal erosion, and drainage modification caused by the disturbance may still be continuing (Lawson 1982). The new vegetation is composed of 30-40 successional plant communities that developed during primary and secondary succession. The diversity of the successional communities is high, but the taxa diversity is lower on the disturbed site

than in undisturbed tundra; almost all colonizing taxa occur in the undisturbed area surrounding the site (Lawson et al. 1978).

METHODS

Vegetation recovery is defined here as a gradual process of colonization and composition changes leading to the reestablishment of a vegetation cover and, at a later stage, to a mature plant community, which may be similar or dissimilar to the original community.

For the overall study, 339 plots were sampled according to the Braun-Blanquet method of vegetation analysis (Westhoff and van der Maarel 1978). The environmental characteristics of each plot, including disturbance, were estimated on subjective gradient scales, and soils were collected and analyzed. Several depth-of-thaw measurements were taken at each plot and averaged. The thaw data (Table 1) were collected in the summers of 1978, 1979, and 1980, in June and early July at the beginning of the growing season, and in August at the end of the growing season.

The samples selected for this analysis were collected on topographically equivalent sites within each habitat/vegetation category; for example, both the recovering and undisturbed snow patches were well-drained depressions with late-melting snowcover. One to three representative samples were selected for both undisturbed and recovering vegetation at the main disturbed site in each of the following common habitat/vegetation categories: upland, snow patch, lowland, marsh, and ridge. Two pairs of ridge samples were included to test the validity of the categories for floristically different communities. Vascular plant data averaged for each category were analyzed by numerical methods, including ordination and numerical classification.

TABLE 1 Means and standard errors of thaw for the investigated habitat/vegetation categories, in cm.

	Beginning of growing season				End of growing season			
	Undisturbed		Recovering		Undisturbed		Recovering	
	Mean	Standard error	Mean	Standard error	Mean	Standard error	Mean	Standard error
Upland	4.6	0.39	14.9	0.90	25.7	2.19	40.1	2.43
Snow patch	11.7	2.72	23.0	4.78	48.0	0	55.8	8.42
Lowland	16.0	2.97	15.5	2.45	44.8	5.57	46.0	5.38
Marsh	14.0	1.89	17.9	1.88	47.0	5.41	61.6	6.47
Ridge	36.4	3.12	34.4	3.53	84.4	6.07	69.4	3.83
Average	16.4		21.1		50.0		54.6	

Recovery habitats show deeper thaw in all categories except for ridges, where further differentiation and recovery will result in deeper thaw depths. Shallower thaw depths will result during further differentiation and recovery in all other habitat categories.

FIGURE 1 Polythetic, hierarchical dendrogram of composite plant community samples representing the selected habitat/vegetation categories. Based on percent-cover taxa data and constructed by the average linkage method using Pearson's product-moment correlation coefficient as the clustering criterion. Each category includes both undisturbed and recovering communities. The level of similarity at which the undisturbed and recovering communities were paired decreases in the following order: marsh (82%), lowland (52%), snow patch (26%), ridge 1 (16%), ridge 2 (14%), and upland (14%).

RESULTS

The degree of recovery of the original plant communities at the Fish Creek site was determined by computing the floristic similarities between undisturbed and recovering communities. The average similarity of recovering communities (22%) was slightly lower than the average similarity of undisturbed communities (25%), but they are not clearly separated in the dendrogram (Figure 1). Undisturbed and recovering communities in marshes and lowlands

FIGURE 2 Detrended correspondence analysis ordination of quantitative vascular taxa data for the same plant communities as in Figure 1. Undisturbed and recovering plant communities were paired in the outlined habitat/vegetation categories (solid line). A group of undisturbed communities was formed in the center of the ordination space (dashed line), indicating that disturbance is one of the principal factors ordering the communities on the ordination planes. Moisture, duration of snow cover, and depth of thaw were other important environmental factors ordering the communities.

were highly similar, but the pairs of upland and ridge communities clustered at very low levels of similarity. These results are consistent with field observations and indicate that the rate of community recovery at Fish Creek differs with the habitat/vegetation type (cf. Billings 1973, Hernandez 1973).

In the ordination space (Figure 2), communities were ordered according to both human disturbance and the most important natural environmental factors controlling community composition, including moisture, duration of snow cover, and possibly depth of

thaw. The relationship of these factors with the ordination axes was not linear. Undisturbed and recovering communities that belonged to the same habitat/vegetation category usually appeared close to each other. A group of undisturbed communities formed in the center and appeared on all the first three ordination planes (only the first plane is shown); marshes were the only category not included in this group. The distance between the undisturbed and recovering communities in the ordination space represents the environmental differences between their habitats. This distance is well correlated with the preceding results as it is longest between undisturbed and recovering ridges and uplands and shortest between marshes.

The degree of recovery of the original plant communities and the degree of recovery of their habitats thus appear to correspond, just as the degree of uniformity of communities undisturbed by humans and the degree of uniformity of their habitats correspond (Komarkova 1980). Given the original vegetation type, it should be possible to predict the degree of vegetation recovery from the degree of physical environment recovery, and vice versa. The distance between the undisturbed and recovering communities in the ordination space will decrease as recovery progresses.

Brown et al. (1969) reported that human surface disturbances, especially those that result in removal of the surface organic layer, significantly affect the thermal regime in permafrost terrain. Lawson et al. (1978) and Lawson (1982) related the recovery of a disturbed site on permafrost to the recovery of the thermal regime. The average depth of thaw at the Fish Creek site was greater at recovering sites than at undisturbed ones, particularly toward the end of the growing season (Table 1). The greatest difference was in the uplands, which also had the least seasonal thaw increases. The average depth of thaw was 33 cm for all the undisturbed habitats and 37 cm for all the recovering habitats, indicating that most of the disturbed site at Fish Creek is still thermally dissimilar, but that thermal recovery is taking place in some habitats. While the overall mean thaw depth was greater for recovering habitats, the extremes were greatest in some of the undisturbed habitats. This indicates that the development of specialized thaw depth conditions on the Fish Creek site takes more than 34 years (since 1949). Except for marshes, the differences in thaw between undisturbed and recovering habitats correlated positively with the degree of floristic difference between undisturbed and recovering communities.

DISCUSSION

Intensity, type and frequency of disturbance, and ecosystem resistance (ability to remain unaffected by disturbances) and resilience (ability to recover to a more or less persistent state) determine the speed, degree, and direction of recovery from partial or total disturbance (Boesch and Rosenberg 1981).

In the Alaskan arctic tundra, marshes appear to be more responsive and resilient and less resistant to partial surface disturbance than mesic uplands. Although the same vehicle will cause more severe

damage in a marsh, where the surface organic matter is considerably more compressed, than in a well-drained environment where the resistance to compression is higher (Bliss and Wein 1972, Walker et al. 1980), recovery is faster in a marsh where, under saturated conditions, compressed fibrous organic material regains its original structure faster (Abele et al., 1983).

Marshes are also more resilient after total surface disturbance. A major man-inflicted surface disturbance overcomes the resistance threshold beyond which the ecosystem does not resist displacement from its initial state. At Fish Creek, the initial disturbance resulted in a new, relatively homogeneous, bladed surface that was later differentiated by newly triggered disturbance processes such as the continuing thaw of ground ice, thermokarsting, and erosion; some live plant propagules may have been preserved at the site. Colonizing plants and successional communities slowed the new disturbance processes, contributing to the differentiation of the newly forming landforms and habitats. A few sloping, eroding sites may never recover. In 30 years marshes that resemble undisturbed marshes have developed in thermokarst depressions, but the uplands on elevated sites between the depressions do not resemble undisturbed uplands. Nevertheless, the resilience thresholds (at which the ecosystem returns to a different persistent state, characterized by altered taxa composition) of the disturbed uplands have probably not been exceeded; they may only be recovering at a very slow rate.

The resilience of the marshes at Fish Creek after the total surface disturbance is greater due to both abiotic and biotic circumstances. On disturbed sites, rapid differentiation of marshes is aided when organic matter and sediments from thawing ice wedges are deposited on thermokarsting surfaces (Lawson 1982). Marshes are strongly controlled by local natural disturbance factors, water, and the freeze-thaw cycle; in particular, water makes the pre- and post-disturbance environments similar, which may speed up colonization by the dominants of undisturbed marshes. It also speeds up colonization of organic matter left after the disturbance, which under dry conditions does not conduct enough moisture for plant establishment (Deneke et al. 1975).

The dominants of undisturbed marshes, *Carex aquatilis* Wg. ssp. *stans* (Drejer) Hultén and *Eriophorum angustifolium* Honck. ssp. *subarcticum* (V. Vassil.) Hultén, colonize and dominate newly available marsh habitats at Fish Creek. As observed in small patches bared by the 1979 cleanup, both taxa spread rapidly by rhizomes and, at a slower rate, by seedlings. The recovering marsh communities are similar to the undisturbed ones, but they lack a number of floristically important taxa that would be present were the community fully recovered. On naturally disturbed surfaces, such as wet stabilizing dunes and natural thermokarst, developing marsh communities with similar composition are common.

Alaskan arctic uplands recovering after surface disturbance contain no ice; due to compression, soil pore space and moisture content are generally reduced, and the soil bulk density is increased (Lawson 1982). Changes in soil characteristics, particularly decreased moisture, may hinder germination and establishment of *Eriophorum vaginatum* L.

ssp. spissum (Fern.) Hultén, which dominates the undisturbed mesic upland habitats but has failed to colonize the small upland patches bared by the 1979 cleanup, nor does it dominate the successional upland communities that developed at Fish Creek.

As on many human and natural disturbances throughout the Arctic, the successional upland communities at Fish Creek are formed primarily by grasses (Arctagrostis and Poa spp.) that disperse, grow, and reproduce rapidly. These grasses represent a very low percentage of undisturbed upland vegetation, but they occur even on very small disturbed patches (a few m²) and persist wherever they are periodically disturbed. Along with willows, these taxa may be enrichment opportunists, and their dominance may be promoted by the greater availability of nutrients in disturbed habitats (Chapin and Shaver 1981). Nutrients are released when permafrost containing organic matter thaws in both marsh and upland habitats (Brown et al. 1969), which is what happened at Fish Creek. On sites where the top organic layer is underlain by mineral matter, the removal of the surface depletes the nutrient capital (Van Cleve 1977).

Another factor contributing to the success of grasses over Eriophorum vaginatum during the colonization stage at Fish Creek may be their rapid advance into newly available bare surfaces by rhizomes; Eriophorum vaginatum reproduces only by seeds, and the seedlings have a high mortality rate (Gartner 1982). Eriophorum vaginatum appears to be less well adapted for both colonization and dominance than the dominants of both recovering and undisturbed marshes: Carex aquatilis ssp. stans and Eriophorum angustifolium ssp. subarcticum, which spread rapidly by rhizomes. Carex aquatilis also has larger below-ground storage reserves and slower root turnover than Eriophorum vaginatum (Chapin and Slack 1979).

Eriophorum tussocks accumulate organic matter, which insulates the ground, holds moisture, and raises the permafrost table to shallower depths that change very little throughout the growing season. In marshes, fluctuations in the depth of thaw are considerably greater, which may contribute to the better colonizing abilities of the marsh dominants. In fluctuating environments in general, taxa adapted for rapid dispersal, growth, and reproduction predominate and make the community highly resilient, while in nonfluctuating environments, taxa adapted for high competitive ability are dominant and make the community less resilient (Grime 1979).

Eriophorum vaginatum is a successful colonizer elsewhere, such as in wet, 5- to 10-year-old disturbed sites along the forested parts of the Yukon River-Prudhoe Bay road. Chapin and Chapin (1980) observed that within 5 years of a disturbance, Eriophorum vaginatum revegetated an organic disturbed site in interior Alaska that had been successfully seeded with commercially available non-native grasses. This taxon also colonizes frost boils at Cape Thompson and on the Seward Peninsula (Hopkins and Sigafos 1951, Johnson et al. 1966), and Gartner (1982) observed its good colonizing ability and early dominance in the Toolik Lake area. These sites are all south of Fish Creek, however; Eriophorum vaginatum may be less efficient at the northern limits of its occurrence and dominance.

At Fish Creek, the change from successional grasses and sedges to Eriophorum vaginatum will be

very slow. Permanent plots established in successional communities in 1980 showed no noticeable composition changes by 1982, although there is some indication that the replacement is beginning: Eriophorum tussocks appear in several places on the disturbed site, including a few ripped trenches. The development of tussock communities at Fish Creek is apparently inhibited by the Arctagrostis, Poa, and Carex communities that precede them in the successional sequence; introduced grasses delay invasion by relatively slow-growing native taxa (Johnson and Van Cleve 1976). No such inhibition exists in marshes: once the dominant achieves high cover, the subordinate taxa establish themselves more easily, even in different tussock communities (Hopkins and Sigafos 1951, Chapin and Chapin 1980).

On the Arctic Coastal Plain, complex Eriophorum vaginatum communities grow on river meanders that are 600-800 years old (Everett 1979, 1980; Komarkova and Webber 1980). The development of complex Eriophorum vaginatum communities at the Fish Creek site may take at least that long. Propagule availability, organic-rich substrate, and moisture conditions are more favorable in the small disturbed patch at Fish Creek, but the development of the tussock community is hindered by the successional upland community of grasses and sedges.

Marsh communities appear on somewhat younger, 400-600-year-old meanders and in relatively young drained lakes; in 100-200 years they may develop on thermokarsting sites where man has disturbed the surface. During the several thousand years between large landscape disturbances, the complexity of both marsh and tussock upland communities gradually increases, particularly through the development of complex microtopography; this can be seen on a series of old river meanders at Atkasook, Alaska.

Most of the communities resulting from the recovery of the Fish Creek site will probably resemble the current, undisturbed complex communities in most general features. It is likely that the Eriophorum vaginatum tussock communities are in equilibrium with the present climate and will recover once disturbed, contrary to Webber and Ives (1978) and Lawson et al. (1978). Tussock communities can be seen developing on relatively young surfaces in the Fish Creek area and after recent disturbances in southern locations in arctic Alaska. However, very recent climate change could have lowered the recovery potential of Eriophorum vaginatum communities at their northern distribution limit.

Human surface disturbances, such as the Fish Creek Test Well 1 site, represent a relatively small patch, and landscape changes triggered by the original disturbance are very localized compared to the natural landscape changes caused by the thaw lake cycle, meandering streams, and wind. Because these natural disturbances overwork most surfaces on the Arctic Coastal Plain in cycles of several thousand years, it can be expected that the small sites disturbed by humans will eventually enter this disturbance-and-recovery cycle and disappear.

CONCEPTUAL MODEL

Figure 3 shows a conceptual model of the recovery of upland and marsh communities at Fish Creek. Mesic uplands have a narrower ecological range, show less fluctuation in environmental

FIGURE 3 Conceptual model of recovery rates of Fish Creek communities related to community resistance and to the intensity of human surface disturbance. Community resistance is independent of disturbance. More resilient communities have higher overall recovery rates, which decrease slower than in less resilient communities. In highly resilient communities, such as marshes, the rate of recovery decreases with the increasing intensity of disturbance until it reaches the threshold of community resistance, and then increases when the accumulated organic matter is removed. In less resilient communities, such as upland tundra, the rate of recovery drops considerably once the community resistance threshold is passed, and the space is occupied by a successional community composed of successful colonizers, which are slowly replaced by the dominants of undisturbed communities. The communities are presumed to be at their ecological optimum, i.e. at the most favorable conditions under which they occur.

factors such as depth of thaw, and recover more slowly. This is consistent with the hypotheses that (1) complex, mature, local-climate-controlled systems are stable (resistant and resilient) only within a comparatively narrow range of conditions, whereas simple, pioneer systems controlled by factors other than local climate are stable in a wider range of environmental conditions (May 1973, Goodman 1975); and (2) frequently disturbed communities or fluctuating environments are more resilient after catastrophic disturbance than similar communities in less fluctuating environments. According to Haber (1979), the persistent, resistant, diverse ecosystems occur in relatively constant environments and can develop a rich and constant assemblage of taxa; the dynamic, resilient, simple ecosystems occur in fluctuating environments and can only develop a poor and fluctuating assemblage of taxa (van der Maarel 1980).

The tundra on the Alaskan Arctic Coastal Plain is strongly controlled by low temperature and ground moisture and by periodic disturbances of the thaw-lake cycle, rivers, and wind. It represents an "azonal" ecosystem that is taxa-poorer and has a higher degree of dominance than less-stressed ecosystems. Because these ecosystems have evolved under drastic periodic landscape changes, they are

probably well equipped to cope with small-scale human surface disturbances such as occurred at Fish Creek, and they may be more resilient to disturbance than less-stressed ecosystems. Because of the slow dynamics of the system, however, the recovery times of complex communities may be very slow.

ACKNOWLEDGMENT

This study was funded primarily by the U.S. Geological Survey's National Petroleum Reserve, Alaska program through the U.S. Army Cold Regions Research and Engineering Laboratory. I would like to thank the reviewers for valuable comments.

GEOCRYOLOGICAL MONITORING OF PIPELINES

V. G. Kondratyev

The Chita Polytechnical Institute
Chita, USSR

Long-term geocryological-geological investigations along the route of an arctic pipeline revealed environmental disturbances during both construction and operation and also corresponding changes in the permafrost condition. The impact of cryogenic processes on pipeline operation was studied; causes of breakdowns were revealed; and possible ways of improving operation were pinpointed. The conclusion was reached that geocryological monitoring must be included in the design construction and operation of pipelines in permafrost zones, as well as permafrost surveys and forecasts. The term monitoring implies systematic field observations of the dynamics of permafrost conditions along the route of the pipeline as the natural environment evolves under the technogenic influences imposed on it. The scientific and procedural aspects of geocryological monitoring are described. Its aims and practical applications at the various stages of exploration, construction and operation are defined. It is noted that the monitoring data are necessary for revealing trends in the formation and development of permafrost conditions along the pipeline, and for developing, checking and streamlining forecasts of changes and means of modifying permafrost conditions to ensure optimum conditions for pipeline operation consistent with environmental protection.

In modern literature devoted to the problems of environmental protection the term "monitoring" is more and more often used. It means, according to the Merriam-Webster Dictionary (1974), "watching or observing for a special purpose." However, in some scientific literature this term includes a broader sense, though different authors use it in various meanings. Thus, in the booklet "Global environmental monitoring", published in 1971 by a special committee of the Scientific Commission on Problems of the Environment of the International Council of Scientific Unions the comment is made that a system of monitoring includes systematic observations on the state of the environment, determination of possible changes (especially due to human influence), control of such changes, and measures to regulate (control) the environment (Ananichev 1974). In a similar definition Gerasimov (1975) describes it as "monitoring is a system of observations, control and environment conduction, which are carried out on different scales and on a global one as well." Israel (1974) says, "it is more correct to call the system of observations which helps to distinguish changes of the biosphere state under the influence of the human activity—monitoring." Mann (1973) considers monitoring an estimation of repeated observations of one or some more elements of environment; in space and time, with the definite aims and program prepared beforehand. Thus the environment observations should be considered as the main thing in monitoring, though some authors also include in it the environment estimation and control.

Many countries have set about creating a global environment monitoring system on the initiative of the United Nations. In the USSR this is carried out by the State Service of Observation and Control over the pollution level of the environment.

Recently the question arose about the necessity of environmental monitoring as a consistent of a global one. In particular, Konoplyantsev and other authors (1982) suggest organizing an observation system that would watch all processes arising with respect to underground water under the influence of the anthropogenic changes, to accumulate necessary series of comparable information, to evaluate the present situation, and to carry out the prediction of the regime, resources of the underground water and their quality for far and near perspective (underground water monitoring). There are also suggestions about organizing hydrogeological monitoring during exploitation of mineral resources (Korobeynikov et al. 1982). Grave (1980) has reported on the monitoring of the cryolithozone and the control of development in the geocryological environment as related to natural factors and technogenic operations.

Frozen rocks (Kudryavtsev 1978) are closely interrelated with the complex of the geological-geographical factors of the natural environment. Their changes cause natural changes of the permafrost conditions in the course of natural evolution and especially under technogenic operations. They are expressed in terms of the changes of temperature of the rock regime, rate and depth of their seasonal freezing or melting, the development of the cryogenic processes and phenomena. In this connection essential change of the engineering geological conditions of the territory are possible and may have an unfavorable influence on the stability of structures. For example, pipelines, being linear structures with variable heat regimes, can exert considerable influence (mechanical and thermal) upon the environment. Consequently, the permafrost situation can be changed considerably along the pipeline. The latter, in turn, acting

on the pipeline may cause additional stresses and deformations, which may result in its destruction.

Thus, because of the specific characteristics of the permafrost situation which is constantly developed and if taking into account its functional interconnection with the complex of natural factors changing both in natural conditions and during the pipeline construction and operation, along with the permafrost survey and forecast geocryological monitoring prototype systematic observations of changes of permafrost conditions along the pipeline in the course of natural evolution and under the technogenic influence should be fulfilled. It is necessary to do monitoring constantly from the moment of prospecting, during construction and after operation of the pipeline, because of the continuous changes of permafrost conditions along the pipeline.

During prospecting, prototype observations are carried out, together with the permafrost survey, and should be aimed at solving the main task of exposing general and specific regularities of forming and developing seasonal rocks and permafrost, cryogenic processes and phenomena connecting with them. Geocryological monitoring is organized in the early stages of the technological and economic calculations of the pipeline construction. For this purpose observation areas are designated in all types of terrain, for studying the temperature regime of soils, their seasonal freezing and melting, development of cryogenic processes and phenomena depending upon the main geological-geographical factors and their natural dynamics. In the subsequent site selection, monitoring should be continued on the chosen variant of the pipeline. Essential increase of the number of the observation areas and the regime observation program becomes more complicated. In addition to more detailed observations of natural permafrost situations at control areas, observations at experimental areas, with different types of technogenic operations, i.e. at "technogenic" areas are organized. These are, for example, areas with the vegetative cover taken off, areas kept free of snow, drained ponds, etc. The monitoring data during engineering prospecting along the pipeline are used for the engineering-geological estimation and making recommendations concerning the control of the permafrost situation to ensure optimum conditions for the pipeline construction, operation and environment protection.

In connection with the possibility of unfavorable development of cryogenic processes along the pipeline during construction, it is advisable to create special geocryological services (geocryological monitoring service, geocryological station, etc.) attached to the management of the pipeline under construction (or to some research institution). Such groups would carry out: (1) constant permafrost control during the pipeline construction and (2) operation of the fulfillment of measures ensuring its stability and geocryological environment protection; (3) regime observations of changes of permafrost conditions in the course of natural evolution and in connection with the disturbance of the complex of natural conditions during the pipeline construction and its heat influence during the pipeline operation; and (4) systematic study of the influence of the cryogenic processes on the pipeline operation and working out effective measures,

ensuring better geocryological conditions for its operation and environmental protection.

During the pipeline construction the fulfillment of all measures concerning the control of the permafrost situation suggested in the project are controlled, with the purpose of ensuring stability of construction and environment protection. Special attention should be paid to the quality of the earthwork, surface planning, maximum preservation of the turf-mantle of soil and to the fulfillment of measures concerning earth recultivation and decreasing the development of undesirable cryogenic processes. During this period geocryological monitoring continues at the areas equipped during prospecting (they characterize, mainly, natural conditions of work) and at additional areas which are made along the pipeline during its construction. Observation areas should characterize every type of locality, at the most complicated parts of the pipeline, for example, in areas crossing the valleys of large rivers. Observations are also made at locations where the pipeline laying, structural peculiarities (diameter, thermal insulation, etc.) and the operational regimes differ. Regime observations of the temperature dynamics, seasonal freezing and melting of soil, development of the cryogenic processes are conducted in natural conditions (undisturbed), along the construction area (in disturbed conditions) and near the pipe directly. All disturbances of the complex of natural factors occurring as the result of construction operations are fixed to maximum details. Systematic observations of the relaxation of these disturbances and regeneration of the vegetative cover are carried out; simultaneously, conditions of snow accumulation and surface structure of the radiation-thermal balance and, hence, the permafrost situation along the pipeline will change.

During pipeline operation observations are carried out at the areas equipped during construction and at those left after prospecting. They are: (1) near the pipe—observations of the temperature field change, the aureole formation of seasonal soil melting and freezing, the vertical displacement and stressed state of the structure, the thermoerosion development, winter-killing, cracking, and other cryogenic processes; (2) within the construction zone, and (3) in natural conditions—of the temperature field changes, soil dynamics of seasonal freezing and melting, new formation of permafrost and freezing or, on the contrary, of the formation of non-confluent permafrost areas, development of cryogenic processes and phenomena. Special attention should be paid to the study of influence of the cryogenic processes on the pipeline operation, efficiency of the project measures for the construction stability and environment protection. All cases of pipeline ruptures should be thoroughly analyzed from the point of view of the influence of the cryogenic processes. Based upon the regime observations it is necessary to test and to improve the accuracy of geocryological forecasting. In accordance with this to make new recommendations for improvement of the geocryological conditions of the pipeline operation. During this period it is necessary to carry out systematic and strict control over fulfillment of the measures ensuring the pipeline stability and environment protection, particularly over

limitations of the movement of crawler tractors near the pipeline and in the adjacent area.

Scientific and procedural aspects of the geocryologic pipeline monitoring described above may be illustrated by the long-term data of the geocryological-geological investigations conducted by the Geocryological Department of Moscow University at one of the northern gas pipelines (Poltev et al. 1979, Kondratyev et al. 1979). Experimental investigations were made at the most complicated and important section of the pipeline; the part of the pipeline crossing a large river valley.

With respect to climate this region is characterized by a low average annual air temperature (-10.6°C), a large amplitude of annual fluctuation (44.3°C), and 44.3 cm of precipitation annually. Due to snow-storm winds thickness of snow cover often is irregular in valleys, at the foot of the slopes and in areas covered with thick shrubs it reaches $1.5\text{--}3\text{ m}$ and more, while in elevated areas, especially from the bare ones, snow is blown off and its thickness is $0\text{ to }0.5\text{ m}$. In this connection the river valley and the adjacent areas of the alluvial plain are characterized by the very complicated permafrost situation. The areas of continuous (low flood plain, first terrace above the flood plain, watershed surface), discontinuous permafrost (high flood plain), and also the areas without permafrost (river-bed, bottom of large lakes) are observed. Thickness of the permafrost mass varies from $3\text{--}10\text{ m}$ at the bottoms of the drained lake potholes to one hundred metres at the water divide surface. The upper $10\text{--}15\text{ m}$ layer of the permafrost consists of rocks of the Middle and Upper Pleistocene and also Holocene, mainly, of loamy and sandy composition. The development of the epigenetic as well as syngenetic and polygenetic permafrost is marked. In accordance with the genesis of the permafrost masses, and their composition, the character of the cryogenic texture and their ice-content is changed. Stratified and reticulate structures prevail. At some areas the ice-content in the soil is 50% and more. Average annual temperature of soils at the depth of annual zero amplitudes varies from $3\text{ to }4^{\circ}\text{C}$ under large lakes to $-4\text{ to }-6^{\circ}\text{C}$ on the watershed surface. Typical temperatures of the soils in the river valley range from $-0.2\text{ to }2^{\circ}\text{C}$. The temperature regime in rocks is influenced considerably by the snow cover, increasing the average annual temperature of soils by $2\text{--}12^{\circ}\text{C}$. Ponds (by $0.1\text{--}6^{\circ}\text{C}$), bog formation (by $0.1\text{--}1^{\circ}\text{C}$) and summer precipitation infiltration ($0.1\text{--}0.5$) give heat effect as well. Vegetation cools soils by $0.1\text{ to }1.5^{\circ}\text{C}$, however, retaining the snow (especially in shrubs) increases the temperature of rocks. Temperature shift in annual thawed layer reduces temperature by $0.2\text{--}1.1^{\circ}\text{C}$. Thermal influences by other factors is not significant. In the territory under study seasonal melting as well as seasonal freezing of soils is observed, the former process spreading much wider than the latter one. Thickness of annual thawed layer ranges, depending on the complex of natural factors, from $0.6\text{ to }0.75\text{ m}$ to $1.8\text{--}2.5\text{ m}$ and that of an active layer from $0.4\text{--}0.5\text{ to }1.3\text{--}1.5\text{ m}$.

In natural conditions practically all main geocryological-geological processes and phenomena take place here, however, the degree of their development is very different. Solifluction,

heaving, thermokarst are widespread. Such processes as frost cracking and ice wedge formation are not common. Spreading the geocryological processes and phenomena along the area is not constant. High flood plain (heaving, thermokarst) and right-bank valley side (solifluction, ice formation) are subjected to their influence to a great extent. On the right bank within the lake-alluvial plain different age forms of the thermokarst and heaving hillocks are also met. Trench-laying of tunnels was made because of the danger of the pipeline destruction by the spring ice drift in the river floodplain. During the pipeline construction natural conditions were considerably disturbed. So, under each tunnel in the floodplain a strip from $30\text{ to }50\text{ m}$ wide was cleared away by bulldozers and then the trench from $1\text{ to }5\text{ m}$ deep and from $1.5\text{ to }10\text{ m}$ wide, was dug by excavating machines (with the preliminary ripping of soil by blasting). It was accompanied by partial change of microrelief, shrub destruction, considerable moss-herbage disturbance and also by changes of the runoff conditions of the surface, intrapermafrost and subpermafrost water, partial or complete drainage of some swamps or lakes. Later on ($2\text{--}3$ years) recovery of herbage took place within the construction strip and in $5\text{--}6$ years, cuttings were covered with meadow herbage $0.2\text{ to }0.8\text{ m}$ in height of different density. In some areas even small thin willow shrubs (to $0.2\text{--}0.4\text{ m}$) appeared. However, in the areas of the intensive thermoerosion development, e.g. on the slope of the terrace above the floodplain, herbage did not recover. Shrub felling changed considerably the conditions of the snow cover formation. Thus, in the high flood-plain area the depth of snow decreased from $2\text{ to }2.5\text{ m}$ (density, $0.25\text{ to }0.35\text{ g/cm}^3$) to $0.12\text{ to }0.90\text{ m}$ (density, $0.3\text{ to }0.4\text{ g/cm}^3$).

Everything mentioned above, together with the variable pipeline thermal regime, caused great changes in permafrost conditions along the pipeline, in comparison with natural situation. Experimental studies of the dynamics of the permafrost situation, in connection with the pipeline construction and operation, was made on 18 specially equipped observation areas which made it possible to carry on investigations, in practically all micro-districts of the territory having different operation regimes of the pipeline (Kondratyev et al. 1976). Observations of the soil temperature dynamics, using response thermometers and thermistors, in holes of $7\text{ to }11\text{ m}$ in depth, proved that the considerable changes within the construction strip occurred in areas where shrubs were destroyed and the depth of the snow cover essentially decreased. Thus, average annual temperature of soils at the base of the annual thawed layer decreased by $2\text{--}5^{\circ}\text{C}$ in high floodplain areas and, at the depth of the annual zero amplitudes, by $0.3\text{ to }2.5^{\circ}\text{C}$. In areas where the disturbance of the complex of natural conditions was not critical or it recovered rapidly (low floodplain), the soil temperature within the construction strip did not change significantly. As the average annual temperature of gas at the starting point of the underground area is almost the same as the air temperature and the temperature of rocks changes from $0^{\circ}\text{ to }-4^{\circ}\text{C}$, the pipe during the average annual cycle causes a cooling effect on the pipeline

section to the riverbed equal to 9°C at the pipe entrance into the soil; 3.5°C at the 0.5 km distance, and only 2.5°C at the 1.5 km distance. Thermal effect on the pipe occurs beyond the river, the riverbed being 2.5 km wide there. The pipeline thermal influence zone decreases rapidly downwards and laterally from the pipe. When the pipeline operates all year round, and is buried at a depth of 1.0 to 1.5 m, the thermal influence of the pipe downwards is not more than 8 to 10 m, and to the side only 3 to 4 m.

Changes in temperature regime of soils and their thermophysical properties caused the depth changes of their annual thawing. The greatest increase in the depth of the annual thawed layer (by 25-50%) occurs within the construction zone in areas such as the high floodplain and on the terrace cusp, where the shrub and the moss cover were destroyed. In the areas where there were no essential vegetative changes, such as low floodplains and the bottom of the lake basin, the depth of annual thawing of soils did not, for practical purposes, change. Due to the high moisture content of soils in the river floodplain and the decreased average annual temperature within the construction zone, because of the reduced snow cover, there was a comparatively small increase in the depth of annual thawing within the construction zone, in comparison with natural conditions away from the pipeline. A sharp increase in the depth of freezing was observed in the areas of non-confluent permafrost, where linking of the new permafrost layer with the permafrost table at greater depths took place during the first 1-3 years.

The deepest layer of soils with depths of 1.2 to 2.5 m thaw in the trench. Such deep thawing takes place both because of the day-surface and the pipe in which gas transporting in summer has a positive temperature. Thawing of soils under the pipe in the river valley varies from 0.6 m at the lake basin bottom to 1.6 m on the terrace slope, the increase being connected in the latter case mostly with the greatest thermal effect of the pipeline, since this area is the nearest one to the point of the pipe entrance into the soil and also to the suprazone water run-off along the trench. The least waste of heat on the phase water transition is observed there, as ice content of sandy loam in the trench is not essential. The least thawing layer is formed in those areas with shallow burial of the pipe at the lake basin bottom, where the soils are characterized by large ice content and low average annual temperature at the base of the annual thawed layer.

Destruction of the vegetative cover, and the sod-mantle of soil, changes in the temperature soil regime, depth and rate of their annual thawing and freezing caused considerable active geocryological-geological processes. Thus, it stimulates soil solifluction on the slopes. On many slopes and ravines, thermoerosive rain rills and gullies (Figure 1) are intensively developed because of the sod cover destruction and the formation of the concentrated run off along the technogenic micro-recesses, as a rule, along the crawler tractor tracks. Their formation rate is rather great with gullies 3 to 4 m deep and 5 to 20 m wide, forming 1-2 years after construction. Especially intensive growth of gullies occurred during rainfalls. The

increase in depth of the annual thawed layer, as well as the change of its moisture regime causes an increase in seasonal heaving and settlement of soils within the construction zone 1.1 to 2.0 times as great (up to 4-12 cm), in the trench 2 to 5 times as great (up to 8-30 cm).

The variety of permafrost conditions of the region under study causes rather dissimilar effect of the permafrost on the pipeline. This effect becomes sharply complicated by the changes of the permafrost conditions because of the destruction of the natural situation in the course of the pipeline construction and its subsequent thermal effect during operation. Everything said above together with variable thermal regime of the pipeline causes the development of pipe tensions of different values that often result in the breaking of the pipe (Kondratyev et al. 1979). It is characteristic that the overwhelming number of breaks occurred in the river valley, during the period from November until February in contact zones of permafrost and thawed rocks (Figure 2) and in places of large curves as well (Poltev et al. 1979).

The analysis of the permafrost situation of soils in places of the pipeline breaks and of the dynamics of freezing of aureoles of seasonal thawing of soils around the pipe in the areas of the permafrost development and of new formation of permafrost masses, temperature observations of the pipeline sides helped to explain the pipe breakdowns. Soil in the aureoles of seasonal thawing around the pipe in November-December and sometimes later because of the cold gas transportation freezing over, causes the pipe in the permafrost to be squeezed. In the areas of thawed rocks (under fluvial, under lakebed taliks, and in regions of non-confluent permafrost) during the whole winter, new formation of permafrost takes place under the pipeline with the intensive ice formation and soil heaving. Thus, the pipe section squeezed at the ends in permafrost masses, undergoes the ever-growing pressure on the freezing soils. Curved pipeline sections, with a small radius of bend and large temperature amplitudes at the pipe wall, causes severe stresses in the pipe. Everything mentioned above results in breaking the pipe at the weakest points, as a rule, along welded joints. That is why the following precautions should be taken into consideration: (1) avoid, if possible, laying the pipe in taliks; (2) decreasing the size and unevenness of soil heaving in a trench; (3) preventing the pipe squeezing and permitting its movement under the influence of heaving, temperature, and other tensions; (4) utilize insulation of the pipe at certain areas, with the purpose of decreasing the amplitude of temperature fluctuations, and (5) laying the pipe, if possible, without curves.

On the right-bank area of the river crossing pipeline breakdowns were not encountered. However, the development of solifluction and thermoerosive processes is of great danger for the pipeline stability (Figure 1).

Thus, the research carried out shows that rather essential changes of permafrost conditions along the pipelines take place. These changes may be quite different in various sections of the pipelines depending on the complex of the geological-geographical factors. Together with variable

thermal regimes of the pipeline they cause the pipe tensions, often resulting in its breakage. In this connection geocryological monitoring should be constantly carried out with the purpose of studying the dynamics of permafrost situation, in natural conditions, and under the influence of the pipeline construction and operation. Thus, it is possible to work out effective measures concerning the control of the permafrost situation along the pipeline construction with the purpose of ensuring its stability and environmental protection.

THE CRYOGENIC EVOLUTION OF MINERAL MATTER
(AN EXPERIMENTAL MODEL)

V. N. Konishchev and V. V. Rogov

Geography Department
Moscow State University, Moscow, USSR

An analysis of existing hypotheses as to the interaction between water and minerals in connection with their crystal and chemical properties allows one to present a theoretical model for the existence of minerals in the zone of cryogenic weathering. According to this model, the destruction threshold depends on the peculiarities of the surface energy of the minerals, which is a function of the crystallo-chemical properties of the surface, the characteristics of the ground solution, and the degree of dispersion. The threshold of cryogenic destruction was established experimentally for different groups of minerals and for different temperature regimes. It was established that the degree of mineral disintegration was two to three times higher in the case of temperature oscillations across the 0°C threshold than in the case of oscillations entirely beneath that threshold.

One of the main processes of the transformation of mineral matter in the zone of cryolithogenesis is that of destruction of primary minerals and rocks in the course of water↔ice phase transitions. By its mineralogical essence, this process is the simplest out of the known forms of hypergenesis. The mechanism of cryogenic disintegration, however, is of a rather complicated nature and refers to the physical-chemical type. The latter statement is based on the assumption that in fine-grained cryogenic crushing of minerals, their specific surface energy (SSE) has a determining role. The concrete form of the SSE effect on the process of cryogenic disintegration is realized through the protective function of the film of unfrozen water. Thus the different categories of bound water of dispersed systems play a dialectically contradictory part in the process of their freezing-thawing with respect to the resistance of mineral particles. The metastable thermoactive film of bound water inserts a destructive effect, in the main, and the stable film of unfrozen water, on the contrary, raises particle resistance, since the whole range of the outer effects on them occurs mediately, through the film of water unfrozen at the given concrete temperatures. Thus, the resistance of mineral grains is not only determined by their strength, but also depends on the thickness and properties of the adsorbed unfrozen water.

The above-given considerations were assumed as a basis of a theoretical model of cryogenic resistance of different, mainly rock-forming minerals, or rather of their relative correlations, and, in the end, of an ideal scheme of the mineralogical composition of cryogenic eluvium (Konishchev, 1977; Konishchev & Rogov, 1978).

A theoretical study of the process of cryogenic disintegration has resulted in the conclusion on the reverse distribution, over the granulometric spectrum, of the maxima of contents of individual rock-forming minerals in the deposits of the zone of cryolithogenesis, as compared with dispersed

deposits formed under the conditions of the warm and temperate climatic zones. One of the particular corollaries of this general proposition has been an inference of the fact that quartz grains in the zone of cryolithogenesis are less resistant than feldspar grains unchanged previously by some other processes.

The need for evaluation of cryogenic resistance in the "particle + unfrozen water film" system is a fundamentally important aspect in substantiating the theoretical model of cryogenic resistance of particles of different mineralogical composition. Thus it follows that in order to verify the validity of the proposed theoretical scheme of cryogenic eluvium, possibilities should be sought that would allow determining not only the total volume of unfrozen water in a dispersed system, but also its real structural correlations with the mineral skeleton. Unfortunately, the widely accepted methods of estimating the amount of unfrozen water do not give a direct answer to the question of its protective functions for different components of the skeleton of frozen ground.

One of the promising approaches to the solution of this complicated problem is related to the microscopic investigation into the structure of frozen dispersed systems.

Studies of the microstructure of mineral suspensions frozen and cooled to low temperatures with the use of electronic microscopy have shown that basal cement-ice that originates with the freezing of suspensions subdivides clearly into two types. One of these, named volumetric, forms from free and loosely bound water, and the other, the near-contact type, forms from firmly bound water. In frozen suspensions consisting of particles of different mineralogical composition with the sizes of >0.1 mm, it was recorded that the volume of the near-contact ice around feldspar grains exceeded that of quartz particles by many times. The value of the volume of the near-contact cement-ice can serve as a measure of SSE of particles of different mineral composition, and it reflects the thickness

of unfrozen water films on particles at higher negative temperatures real for the natural environmental conditions. Therefore, the correlation between the volumes of the near-contact cement-ice on quartz and feldspar grains demonstrates quite objectively and obviously the higher resistance of feldspar grains than those of quartz with respect to the factors of the outer cryogenic effect on the ground system.

The laboratory modelling of cryogenic destruction of different minerals with dimensions of the granulometric fractions widely used in the USSR, viz., 1 to 0.5 mm, 0.5 to 0.25 mm, 0.25 to 0.1 mm, 0.1 to 0.05 mm, and 0.05 to 0.01 mm, has made it possible to determine the cryogenic resistance of each of the monomineral fractions. The cryogenic resistance was estimated by a simple index of:

$$H_{cr} = \frac{a-b}{a \times n},$$

where a = the amount of granulometric monomineral fraction in the specimen prior to the effect of the cryogenic factor on it;
 b = the amount of the same fraction after this effect; and
 n = the number of cycles of freezing and thawing.

The lower the value of H_{cr} , the higher is the resistance of fraction. The index suggested is very convenient to generalize the data on laboratory modelling of cryogenic crushing and allows proceeding from the theoretical scheme to an experimental model of cryogenic disintegration. An analysis of the experimental data has shown that cryogenic resistance is a function of the mineralogical composition, degree of dispersion, humidity, and temperature conditions.

A series of cryogenic resistance of minerals was obtained for different conditions, which turned out to be most original. Thus, for example, the following sequence was observed for 1 to 0.5 mm-fraction with complete moisture saturation and the temperature conditions of freezing-thawing at $t^0 = -10; +20^\circ\text{C}$: apatite < chlorite < quartz < limestone < limonite < magnetite < garnet < microcline < muscovite (the resistance grows from left to right).

A system of such a series has made it possible to assert that quartz grains in all the fractions proved to be less resistant than feldspar grains. We also succeeded in establishing experimentally the limits of cryogenic disintegration of the most widespread minerals. This limit for quartz, amphiboles and pyroxenes corresponds to grain sizes of 0.05 to 0.01 mm, and for fresh feldspars, 0.1 to 0.05 mm.

The dependence of cryogenic stability of minerals on the degree of their erosion and freshness of grains is also clearly traced. Resistance of quartz grains may vary by several times depending on their prehistory, eg., grains from a pegmatite vein are four times more resistant than quartz grains from alluvial sand that underwent several cycles of lithogenesis.

As for feldspars, their grains, even with a low degree of pelitization, reveal a fundamentally different trend in their behaviour as compared with fresh grains, viz., they are characterized

by a high degree of disintegration in fine fractions.

The effect of humidity on cryogenic destruction of different minerals is not simple-valued. Grains of minerals with low surface energy (quartz, feldspars, amphiboles, pyroxenes, magnetite and apatite) disintegrate more intensively in a humid medium than in an air-dry state.

The degree of dispersion of minerals with high surface energy (muscovite, biotite and limonite) change fundamentally in a different way depending on the degree of humidity. Fine grains (0.1 to 0.05 mm) of biotite and muscovite are considerably less resistant in an air-dry state than with full saturation with water. These facts illustrate convincingly the protective role of adsorbed water films with respect to the factors of cryogenic influence, although the degree of the protective effect and the grain sizes with which this effect starts playing the leading role are different for different minerals.

The character of changes in the cryogenic destruction depending on dispersion is also most specific for individual minerals. For quartz, increasing resistance of grains is rather clearly traced as their sizes diminish right to the ultimate 0.05 to 0.01 mm.

The same character of dependence is also inherent in other groups of minerals, such as feldspars, amphiboles and pyroxenes. As for the grains of magnetite, apatite and carbonate, their resistance as a whole lowers, though with some divergences, as grain sizes diminish. The dependence of resistance on dispersion for minerals with high surface energy is more complicated, as there is usually a definite size of grains with maximum resistance, while particles coarser and finer than this size disintegrate. Thus, for example, maximum resistance for limonite is observed with its particles of 0.5 to 0.25 mm and 0.25 to 0.1 mm which aggregate under moderate temperature conditions of the experiment ($t^0 = -10^\circ; +20^\circ\text{C}$) coarser and finer particles of limonite disintegrate markedly. For biotite, maximum resistance is found with 0.25 to 0.1 mm grains; and for muscovite, two maxima of resistance are revealed, viz., 0.1 to 0.05 mm and 1 to 0.5 mm.

Under natural environmental conditions, cryogenic disintegration proceeds at different temperature parameters of freezing and thawing of the ground systems and temperature variation amplitudes. Two series of experiments were carried out to study the influence of temperature conditions on the cryogenic transformation of dispersed systems of different mineral compositions.

In the first series, granulometric monomineral fractions of standard sizes and of different minerals were subjected to cyclic freezing and thawing under four regimes ($t^0 = -5^\circ, +5^\circ\text{C}$; $t^0 = -10^\circ, +20^\circ\text{C}$; $t^0 = -20^\circ, +20^\circ\text{C}$; $t^0 = -40^\circ, +20^\circ\text{C}$). A factor common for these regimes was that of transition of temperature through 0°C .

Minerals are rather clearly divided into two groups with respect to these freezing-thawing regimes. The first group is composed of minerals with high surface energy (biotite and limonite). The cryogenic resistance of these minerals is minimal under the most rigorous regime ($t^0 = -40^\circ, +20^\circ\text{C}$).

The second group is comprised of minerals with relatively low surface energy (quartz, magnetite and apatite). The maximum destruction of grains of this group occurs under the conditions of complete moisture saturation and under the optimum regime of freezing and thawing ($t^0 = -10^\circ$ to -20° , $+20^\circ\text{C}$). The resistance of grains of these minerals grows under milder and more rigorous regimes. The groups of minerals that differ in cryogenic resistance with respect to the regimes of freezing-thawing correspond fully to the mineral groups singled out above depending on the influence of the degree of humidity on changes in their dispersion.

In the second series of the experiments, a spectrum of granulometric fractions of different minerals in the moistened state was frozen and then subjected to the cyclic effects of temperature variations ($t^0 = -1^\circ$, -20°C). The results of this series were to answer the question whether cryogenic transformation did take place and to what degree with the phase transitions of unfrozen water and with temperature variations within the negative spectrum of temperatures. Such methods helped to achieve reduction, to a possible minimum, of the effect of the disjoining action of ice on the particle destruction. This series of experiments simulates the conditions of cryogenic transformation of matter in the cold period of the year, after the layer of seasonal thawing freezes, and the upper layer of soil-eluvium can also change its temperature rather sharply due to temperature variations at the surface during the winter period.

The most important and general result of this series of experiments is the inference that the cryogenic disintegration of all the minerals, with the exception of hornblende and magnetite, is considerably lower with temperature variations within the spectrum of negative temperatures than with temperature variations involving the transition through 0°C .

The difference is particularly great for coarse fractions (1 mm to 0.25 mm), viz., cryogenic resistance for these differs by 2 to 3 orders. In finer fractions (0.1 mm to 0.05 mm), the values of cryogenic disintegration of different minerals have considerably lower variations. At the same time, it is necessary to emphasize that the disintegration of minerals with variations of temperatures within the spectrum of their negative values does nevertheless take place, though with lower intensity than under the regime involving the transition through 0°C . And individual minerals disintegrate within the spectrum of negative temperature values even more intensively than with the transition through 0°C . A theoretically important result of this experiment is that of ascertaining the dependence of the degree of destruction on the degree of dispersion. Under the temperature regime of $t^0 = -1^\circ$, -20°C , the cryogenic disintegration of minerals tends rather clearly to grow with the diminishing of the sizes of their grains. This dependence is contrary to the pattern that was revealed under the freezing-thawing regimes with the transition through 0°C . A comparison with the first group of experiments shows that the destructive effect of the cleaving action of ice is the highest for coarse fractions, while the cryohydrational weathering is the most

effective for finer fractions, with the former factor being absolutely far more intensive.

Under the temperature regimes of $t^0 = -1^\circ$, -20°C (as under other regimes), different minerals are characterized by individual features according to the nature of disintegration. The general reduction of the resistance of mineral grains as their sizes diminish can be asserted to be only a tendency. The concrete curves of resistance of separate minerals depending on the degree of dispersion under the given regime of temperature variations have a more complicated character. At the same time, the fundamental difference between the most widespread rock-forming minerals of quartz and feldspars with respect to the limits of cryogenic destruction takes place also under the regime of $t^0 = -1^\circ$, -20°C . And it can be seen here that in the fine-dispersed portion of the granulometric spectrum, quartz grains of 0.05 mm to 0.01 mm sizes are distinguished by maximum resistance. This maximum for feldspars is found to be shifted to the area of coarser particles.

The results of the experiments carried out allow understanding rather comprehensively the role of different factors and mechanisms of the cryogenic transformations of mineral matter. The different behaviour of the basic groups of minerals under different regimes of humidity and freezing-thawing is based on the fundamental differences in their structure and crystallochemical properties which are expressed in different values of the surface energy.

The process of cryogenic destruction of minerals occurs most actively under temperature variations involving the transition of temperature through 0°C , when the major part of water \leftrightarrow ice phase transitions takes place. In this case, the disjoining effect of ice and the cryohydrational destruction act simultaneously. Under temperature variations within the negative spectrum of its values, the degree of destruction of minerals due to the reducing of the cleaving action of ice decreases, as a whole, by more than one order, though it is not extinguished. Hence it follows that under such conditions, it is the disjoining action of water that is displayed most fully. This process manifests itself most vividly in fine-dispersed particles for which a tendency to intensification of the cryohydrational destruction begins to show.

FROST SUSCEPTIBILITY OF SOILS IN TERMS OF THEIR SEGREGATION POTENTIAL

J. M. Konrad¹ and N. R. Morgenstern

Department of Civil Engineering, University of Alberta, Edmonton, Alberta, Canada T6G 2G7

¹Presently at the Division of Building Research, National Research Council Canada, Ottawa, Canada K1A 0R6

Recent studies have shown that the segregation potential, which is the ratio of water intake velocity to temperature gradient near the frost front, provides a basis for coupling mass flow with heat flow in a freezing soil. Since the segregation potential depends upon the composition of the soil system and the externally applied load, it appears to be an effective parameter for classifying frost susceptible soils. Moreover, it can be obtained readily for various applied pressures from a one-dimensional freezing test and can be used directly to estimate frost heave in the field versus time, provided that the solution to the corresponding thermal problem can be obtained. Data is presented and practical cases are described that illustrate the use of the segregation potential for determining frost susceptibility with respect to various project requirements.

FROST ACTION IN SOILS

The problem of frost action damage is widespread; it occurs in all temperate zones wherever there is seasonal soil freezing as well as in the active layer of more northerly permafrost regions. Moreover, recent resource development in arctic environments have brought up novel freezing situations such as long-term freezing induced by chilled buried gas pipelines. For unheated buildings, cold-storage facilities, and other structures, deformation of the structure by heaving rather than by thaw softening is the principal frost problem. Usually most of these structures do not heave uniformly, nor do they settle to the original elevation after the thawing period. Thus uplift due to cyclic freezing and thawing tends to be cumulative. When a chilled pipeline is buried in discontinuous permafrost, differential frost heave will occur that could lead to unacceptable strains in the pipe. Dams constructed in a northern environment may be subjected to severe frost action, and ice lensing may develop in the upper part of the impervious core. Upon thawing, preferential seepage paths may lead to serious internal erosion problems in the crest of the dam.

This paper presents the concept of segregation potential, which provides a new basis for evaluating the degree of frost susceptibility. The concept is tested on various case histories, illustrating the different types of problems associated with frost action in soils.

PHYSICAL PROCESSES ASSOCIATED WITH FREEZING OF SOILS

When wet soil is subjected to freezing, frost heave occurs as a result of two simultaneous processes: pore water in the soil freezes in situ and water supplied from the unfrozen soil, or possibly an external source, is sucked to the freezing front where it freezes, thereby leading to the development of ice lenses. The amount of heave

by ice lensing depends on the frost susceptibility characteristics of the soil.

As the frost front progresses, ice nucleates in water-filled pores, but some water remains unfrozen as adsorbed films on the surface of soil particles. Water from the unfrozen soil migrates through the unfrozen water films into the frozen zone under the action of a temperature-induced suction gradient. Since the thickness of the unfrozen water films decreases as the temperature of the frozen soil decreases, the migratory water will be essentially stopped in a zone of extremely low permeability within the frozen soil where it freezes. When sufficient water accumulates, an ice lens forms (see Figure 1).

The zone between the frost front corresponding to the warmest isotherm at which ice exists in the soil pores and the segregation front where the ice lens is growing has been referred to as the frozen fringe (Miller 1972). Direct experimental evidence for the existence of the frozen fringe has been given by Konrad and Morgenstern (1982b).

Moisture transfer in the frozen soil behind the warmest ice lens is strongly reduced owing to very low frozen soil permeabilities and the presence of continuous ice. The contribution to the final heave from this region has been found to be negligible under both laboratory (Hoekstra 1969) and field conditions, at least over several years (Slusarchuk et al. 1978).

From a phenomenological point of view, the mechanics of frost heave can be regarded as a problem of impeded drainage to an ice-water interface at the segregation front. Substantial suctions are generated at this interface, but the reduced permeability of the frozen fringe impedes the flow of water to the segregation front, particularly for fully saturated soils. Thus, it appears that the frost heave characteristics or the frost susceptibility of freezing soils are related to the characteristics of the frozen fringe that, in turn, depend on the unfrozen water content. It is well known that the relationship between unfrozen water content (and hence frost susceptibility) and

temperature for soils of different textures depends mainly on (1) specific surface of the soil, (2) gradation, grain size, amount of fines, type of minerals, (3) quantity and type of exchangeable cations, (4) pressure in ice and water phase, (5) solute concentration, and (6) density of the unfrozen soil.

LIMITATIONS OF EXISTING FROST SUSCEPTIBILITY CRITERIA

Once the physical processes associated with the freezing of wet soils are understood, the relevance of the criteria commonly utilized in existing frost susceptibility classifications can be evaluated.

The survey by Chamberlain et al. (1982) identified in general 3 levels of sophistication in estimating the frost susceptibility of soils used in roads and airfield construction. The first level, type I, is primarily based on the percent of soil finer than a specified particle size, commonly 0.074 mm or 0.02 mm. In some cases, a uniformity designation is an added requirement. Since its criterion is based on a single particle size, it cannot directly assess frost susceptibility because the controlling factors of the unfrozen water content are not addressed solely by the particle size. In addition, it is too conservative because non-frost susceptible soils are frequently classified as frost susceptible.

The second level, type II, is generally based on soil type or classification of particle size curves, and supplementary tests for Atterberg limits, capillarity, pore size distribution, or permeability of unfrozen soil. Type II methods, although more time consuming and costly, have limitations as well, since the parameters, which solely characterize the unfrozen soil, do not address the main factors affecting the frozen fringe.

The third level, type III, requires a laboratory freezing test and observations of frost heave and/or thaw weakening. However, the time required for most specified freezing tests, about 10 days, imposes serious restraints on their use. Freezing test procedures tend to differ from agency to agency; as a result, it is not always possible to compare their results directly. Moreover, existing classification work using a type III approach has been hampered by a lack of clear transfer to field conditions. In general, two freezing modes are used either with a constant cold plate temperature or a constant rate of frost penetration and often only one freeze-thaw cycle. Cold plate temperatures vary significantly, ranging between -3 and -20 °C and even -25 °C. This results in substantial temperature gradient variations in the various tests and thus affects significantly the water migration rate as shown by Konrad and Morgenstern (1980, 1981). Hence, freezing a given soil sample with different thermal boundary conditions may result in different degrees of frost susceptibility, which in turn may create an inadequate basis for decision making for a variety of field conditions.

SEGREGATION POTENTIAL OF FREEZING SOILS

If one considers that water migration occurs through a layered medium composed of saturated unfrozen soil and the frozen fringe, the freezing soil would be best characterized by suction at the segregation-freezing front and permeability of the frozen fringe (Figure 1). Both parameters are temperature and pressure dependent. Although these parameters provide a better insight into the physical processes involved during freezing, from a practical point of view they are difficult to measure.

As discussed by Konrad and Morgenstern (1980, 1981, 1982a, b) the characteristics of a freezing soil can also be represented by the segregation potential, SP, defined as the ratio of the rate of water migration, v , and the overall temperature gradient in the frozen fringe, $\text{grad } T_{f_f}$. The use of SP is advantageous because it can be determined directly from a freezing test in which water intake rate and temperature profile with time are measured. Since the physical size of the frozen fringe is relatively small, its temperature gradient is approximated by the measured overall temperature gradient in the frozen soil near the 0 °C isotherm, $\text{grad } T_f$.

Both theoretical analyses and experimental results reported by Konrad and Morgenstern (op.cit.) indicate that SP is dependent on the suction at the frost front, P_u , the pressure applied on the warmest ice lens, P_e , and the rate of cooling of the frozen fringe, T_f . T_f includes both geometrical and thermal boundary conditions and is defined as the change in average temperature of the frozen fringe per unit time. Its value can be approximated by the change of temperature at the 0 °C isotherm per unit time from:

$$\dot{T}_f = \text{grad } T_f \cdot \dot{X} \quad (1)$$

where \dot{X} is the rate of frost advance.

The rate of segregation frost heave, \dot{h}_s , in a freezing soil can therefore be expressed as:

$$\dot{h}_s = 1.09 \cdot v = SP(P_u, P_e, T_f) \cdot \text{grad } T_f \quad (2)$$

To successfully predict frost heave in the field using equation (2), SP must be determined from laboratory tests using representative values of P_u , P_e and T_f .

For field conditions, frost penetration rates are usually small (for example, in Figure 3 they are only about 0.07 cm/h), and the average temperature gradients in the frozen zone are also small, say approximately 0.07 °C/cm. Because equation (1) results in an extremely small \dot{T}_f (field), about 0.005 °C/h, it is argued that \dot{h}_s (field) may be approximated by SP obtained at the formation of the final ice lens using freezing tests with constant temperature boundary conditions. For these conditions, T_f as the final ice lens is initiated is of the order of 0.01 °C/h.

In many field conditions, it may be safely assumed that P_u will be small enough to ignore owing

mainly to high mass permeability of the unfrozen soil and small migration rates. Consequently, equation (2) reduces simply to:

$$h_s (\text{field}) = 1.09 SP (P_e) \text{ grad } T_f \quad (3)$$

The relationship between the segregation potential and applied pressure is best expressed as (Konrad and Morgenstern, 1982b):

$$SP = SP_0 e^{-aP_e} \quad (4)$$

where SP_0 corresponds to the formation of the final ice lens for zero applied load and for P_u close to atmospheric pressure, and "a" is a constant determined from tests for various P_e .

Finally the change in water content, (ΔWC), with depth due to moisture migration is evaluated from:

$$\Delta WC(\%) = 100 \frac{V}{X} \frac{\gamma_w}{\gamma_d} \quad (5)$$

where γ_w and γ_d are the unit weight of water and soil, respectively.

The results of a literature survey on well-documented cases of frost heave data are shown in Figure 2. The segregation potential for various applied pressures can be expressed by using equation (4) for many soils ranging from sandy silts to clays, thereby giving strong support for the general validity of this relationship to characterize any freezing soil.

Figure 2 also reveals the importance of including the overburden pressure in any frost susceptibility classification. In general, the segregation potential of soils with low unfrozen water contents (silty sands) will be very sensitive to small changes in overburden pressures; this is not the case for soils with higher unfrozen water contents such as clays.

In conclusion, it appears that only a limited number of well-controlled freezing tests may be required to characterize adequately the segregation potential of any soil for field freezing conditions over a wide range of overburden pressures. In practice, these freezing tests are performed with constant temperature boundary conditions (the warm end at +1 °C) and different applied surcharges covering the expected stress range in the field. Using a cold end temperature of about -5°C to -8°C and 10 cm high samples shortens the time required to reach the maximum frost penetration, and hence the growth of the final ice lens, to less than 1 day.

A NEW APPROACH FOR FROST SUSCEPTIBILITY EVALUATION

The existing frost susceptibility criteria, either index tests or empirical relationships relating laboratory investigations to field performance, are usually effective for regional seasonal freezing problems only. Extension of these criteria to new types of problems such as sustained freezing beneath a chilled gas pipeline is therefore very limited. Furthermore, these criteria lead only to the acceptance or rejection of soils without specifying the degree of damage resulting from the freeze-thaw cycles.

The authors are suggesting a new approach for determining the relative frost susceptibility of soils. This method considers that the freezing conditions, the soil properties, the project requirements, and the acceptable risks should be taken into account in assessing the degree of frost susceptibility. Frost heave and water content changes in the field during seasonal or long-term freezing can be estimated by using the segregation potential measured in the laboratory as specified in the previous section. Frost susceptibility is then evaluated by comparing these parameters with allowable parameters that ensure adequate safety of the project.

It is proposed to distinguish between problems where the thaw weakening effect is of prime importance (class I), problems where frost heave and/or differential frost heave can lead to damage (class II), and problems where the combined effects of frost action (i.e., lensing and thaw weakening) is a concern (class III).

Class I Problems

These problems are generally associated with the performance of roads and airstrips. Surface heave due to ice lensing does not usually affect trafficability during the freezing period. However, the loss of strength by thaw weakening is of paramount importance, particularly for cases where dynamic loading is involved.

Class I problems, (e.g., evaluating the adequacy of a particular soil for construction purposes) can be dealt with as follows. According to climatologic factors at a given locality, the depth of frost is determined either from a geothermal analysis with appropriate boundary conditions or from existing solutions for relevant problems. The amount of heaving and change in water content with depth are then calculated under the most adverse conditions by using equations (3) to (5). The relationships between the change in water content and the loss of strength upon thawing should be obtained from laboratory and/or field tests. These tests are not standard practice to date, but efforts are being made in this direction (Chamberlain 1982). From such relationships, a thaw weakening factor could be obtained for a given soil subjected to given freezing conditions, and an allowable increase in water content could be determined for adequate safety.

The following situation illustrates frost susceptibility evaluation for a class I problem. The till at the La Grande hydro electric project in northern Quebec (James Bay) is a well-graded, gravelly, silty sand (60-80% passing #4 sieve, 20-40% passing #200 sieve) (Paré et al. 1978). Both the Casagrande and Beskow frost susceptibility criteria classify the till as being frost susceptible. Townsend and Csathy (1963), using the concept of limiting pore-size ratio, also classified similar tills as frost susceptible. Cyclic freeze-thaw tests were performed for various surcharges on the matrix material from the till by the U.S. Army Cold Regions Research and Engineering Laboratory (USA CRREL) and reported by Paré et al. (1978). The results of these tests have been reanalysed in terms of segregation potential and are presented in Figure 2. Frost penetration, segregational frost

heave and increase in water content have been calculated for this till at two different locations characterized by freezing indexes of 1000 °C days and 2800 °C days using the suggested segregation potential relationship. These climatic conditions are representative of the Montreal-Ottawa and James Bay areas, respectively. The results of the analysis are presented in Figure 3 and compare relatively well with field observations reported by Paré et al. (1978) for the James Bay area and by Penner (1976) for the Ottawa area. Penner indicated that frost heaving in Leda clay (70% clay size and 30% silt size) is approximately 9 to 12 cm during most winters in snow-cleared areas. It should be noted that Leda clay has higher SP values than James Bay till (Figure 2).

The analysis reveals that a significant increase in water content due to moisture migration will occur in the Montreal-Ottawa region at shallow depths. Furthermore, because the frost front remains almost stationary for about one month, a discrete ice lens may grow approximately 0.6 m below ground surface, resulting in serious road damage when it thaws. At James Bay, frost penetrates much deeper and the increase in water content per unit depth is smaller than for the warmer Montreal-Ottawa area. Moreover, the overburden pressure reduces significantly the moisture migration at larger depths, hence reducing the occurrence of ice lenses as the frost front becomes stationary.

This analysis clearly shows that the degree of frost susceptibility of the till at James Bay is significantly smaller than for the same till in Montreal or Ottawa. For specific projects, the design requirements will determine the suitability of the till with respect to performance associated with varying degrees of frost action.

Class II Problems

These problems are associated with projects such as building a pipeline, that involve soils subjected to long-term freezing (more than one season). Two important new design considerations arise. First, how much frost heave (restrained or unrestrained) will occur over the lifetime of the project? In addition, where the pipeline crosses from permafrost to unfrozen ground and back to permafrost, how much differential heave will occur and will it lead to unacceptable strains in the pipe? Konrad and Morgenstern (1983) describe a procedure for calculating the amount of heave under a chilled gas pipeline based on a finite difference formulation of the heat and mass transfer in saturated soils and on the segregation potential concept. Good agreement is found between the predictions of heave obtained with this procedure and that of long-term, full-scale experiments at a test site in Calgary, Canada. Figure 4 shows the predictions of frost heave and frost penetration over 20 years for a hypothetical pipeline with a temperature of -8 °C, buried in soil with an initial ground temperature of +2 °C at a nominal depth of about 2 m below ground surface. The frost heave characteristics, i.e., the SP versus P_e relationship, were assumed to be those of the Calgary silt shown in Figure 2. The maximum pipe heave after 20 years is nearly 0.8 m, and the frost penetration below the original position of the

pipeline is about 6 m. The combined influence of small temperature gradient and significant overburden pressure at depths greater than 4 m explains why the heave rate is only 0.012 m/yr after 10 years of operation. The maximum differential heave that might occur after 20 years is a function of the depth of the shallow permafrost. Deciding whether this soil is considered acceptable with respect to frost susceptibility will mainly depend on the allowable strains for the pipeline. If no remedial measures are considered during operation of the pipeline, two approaches can be used. A maximum differential heave could be specified for adequate safety or, alternatively, a more sophisticated analysis of frost heave pipeline interaction may be performed such as that presented by Nixon et al. (1983). A pipeline situated in the warmer discontinuous permafrost could present a problem of differential heave if variable soil conditions are encountered. In these conditions, for a ground temperature of about +5 °C, the maximum differential heave would be approximately 1.0 m, which would occur for a layer of nonheaving soil thicker than 4 m. The previous example illustrates clearly that the degree of frost susceptibility of a given soil depends essentially on the project requirements that can be expressed in terms of maximum total and/or differential heave and related allowable pipe strains.

Class III Problems

Problems associated with dam construction in colder areas (such as James Bay) fall into this category. When frost penetrates into the till core of an embankment, ice lensing may occur in its upper part. The thawing of the ice lenses may cause preferential seepage paths to form parallel to the water flow, which, in turn, may induce internal erosion and lead to the destruction of the top part of the dam.

Frost heave and water content increases with depth may be calculated for a two-layered medium composed of a top protection layer of sand and gravel (non-frost susceptible) and the till core. A simulation of frost action in a typical crest of James Bay embankments is shown in Figure 5. It is assumed that there is no frost heave in the upper sand and gravel protection and that the water table is 3 m below the crest surface. Segregational frost heave in the till core is significantly reduced owing to the effect of overburden pressure; hence the change in water content with depth is also negligible, as shown in Figure 5. These results have been confirmed by a test pit in a till embankment at the LG 3 Project, which revealed no visible ice lenses below a depth of 1.5 m (Paré, 1982). One can conclude that for James Bay freezing conditions, minor heaving without any real ice lens formation will occur in till cores placed under a sand and gravel cover of about 1.5 to 1.8 m. Since the increase in water content after freezing is negligible, damage of till core with time due to freeze-thaw cycles is therefore not likely to be expected in the dams and dykes at the La Grande complex although the accepted standards classify the till as frost susceptible.

CONCLUSIONS

Existing procedures are not very effective in distinguishing between differing degrees of frost susceptibility in soils. The segregation potential SP, defined as the ratio of the velocity of migration water and overall temperature gradient in the frozen soil adjacent to the frost front, provides a new basis for a quantitative evaluation of frost susceptibility. A standard freezing test can be devised to determine SP for different applied surcharges. SP is therefore a parameter that includes the influence of mineralogy, pore water solutes, and other compositional factors known to influence frost heave susceptibility. Furthermore, it has been established that the laboratory-based SP associated with a "quasi" stationary frost front corresponds reasonably well with values of SP deduced from field frost heave observations.

Rejection or acceptance of a given soil with respect to its frost heave potential should be determined by comparing calculated heave and ice content distribution using the SP concept with an allowable water content increase per unit depth for problems where thaw weakening is of paramount importance. Comparisons with an allowable heave and/or differential heave should be made where vertical movements could lead to structural damage. Finally, where freeze-thaw effects are of concern, the frost susceptibility should be determined with respect to both allowable parameters. Specific project requirements and acceptable risks will predicate the maximum values of frost heave and water content increase per unit depth in order to ensure adequate safety. The SP-based approach applies to any climatic or design condition and thus facilitates an extension of the experience gained on regional problems to new problems.

HYDROTHERMAL PROPERTIES OF PERMAFROST SOLONCHAKS IN
THE CENTRAL MONGOLIAN ARID-STEPPE ZONE

A. Kowalkowski

Soil and Fertilization Division, Forest Research Institute,
Raszyn, Poland

A three-layer, unstable system exists within the permanently frozen solonchak profiles of the dry-steppe zone in the southern part of the Central Gobi Peneplain. It is subject to deformation due to hydrostatic pressure and low temperature. The action of the latter factors results in the formation of characteristic continental mud boils on the lower parts of the slopes. These are perennial features and lack frost segregation.

INTRODUCTION

The well known theory of the cryostatic genesis of tundra "mottled soils," "mottled tundra," or "tundra craters" in the periglacial zone is open to criticism. These phenomena are now interpreted as resulting from gravitational processes in liquefied and thixotropic soil materials over a frozen or low permeability substrate. The studies by MacKay and MacKay (1976) and French (1977), as well as earlier studies by Jahn (1948) indicate the possibility of horizontal and vertical subsurface shifts of semi-fluid materials under periodically increased hydrostatic pressure within the soil profiles. These processes are initiated after the saturated layers immediately above the permafrost table have thawed. The processes in question result in diapiric up-lifts and open muddy craters.

AIMS AND METHODS

During the period of 5-7 July 1978, in the vicinity of Augutuin (Nuur) Lake, the author observed a cluster of mud boils (frost scars, non-sorted circles) in permafrost turf solonchaks composed of rhyolite-granite debris with a basalt admixture. Similar boil clusters were observed in the semi-desert permafrost solonchaks composed of basalt debris with a volcanic-ash admixture in the vicinity of Shagshuraga (Nuur) Lake (Figure 1). These two saline lakes are in the northern part of the Central Gobi Peneplain (Korzhev 1982) in the southern reaches of the insular Central Asian permafrost region (Gavrilova 1981).

Data recorded at the nearby physico-geographical Gurvan Turuu Station (lat. 47°03'N, long. 07°38'E, elevation = 1371 m) indicate that the winter period, with temperatures lower than 0°C, lasts for 187 days, while summer, with temperatures higher than 15°C, lasts for only 22 days. January is the coldest month with temperatures averaging -24°C, while July is the warmest with average temperatures of +16°C; the mean annual temperature is -2.7°C. Mean precipitation totals 250 mm, of which 43% falls in July (Hess et al. 1980). Groundwater flow and precipitation usually result in the formation of intermittent lakes in summer in thermokarst-

ablation alluvia filled basins. Soils of these depressions are takyr solonchaks (sorovyi solonchak) according to Nogina et al. (1977) with permafrost.

As a result of the arid climate, the subsurface waters are highly mineralized, with dissolved solids ranging from 0.1 to 0.7 g/l. Chemically these waters are included in the calcium bicarbonate and potassium bicarbonate category (Chelmicki and Tserev 1980).

Low snowfall results in the freezing of soil to depths greater than 3.5 m and in the formation of discontinuous, insular permafrost. In permafrost solonchaks, an active layer 0.4 to 4.5 m thick is usually underlain by permafrost in which temperatures range from -0.1°C to -0.4°C (Kowalkowski et al. 1981).

Soil samples taken from mud boils and from soil profiles excavated at distances of 0.5-1.0 m from the boils were analyzed granulometrically using a combination of sieve methods. Bulk density (BD) was determined by the pycnometric method *in vacuo*, volumetric density (VD), actual humidity (AH), maximal capillary water capacity (MCWC), and field water capacity (FWC) were determined for 100 cm³ samples with the natural structure preserved.

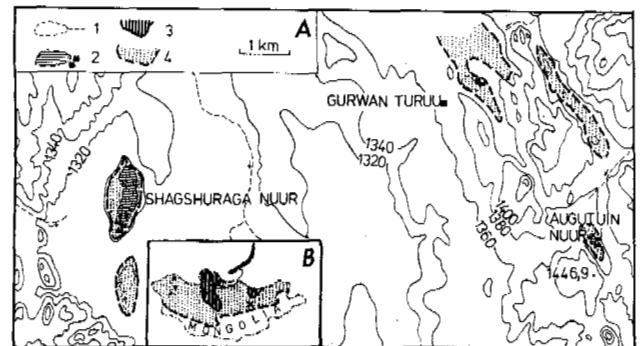

FIGURE 1 Location and topography of the solonchaks under study and of the Physico-Geographical Gurvan Turuu Station. 1 - ephemeral (intermittent) saline lakes and streams; 2 - ephemeral saline lakes with takyr solonchaks and fields of mud boils under study; 3 - southern boundary of discontinuous permafrost; 4 - southern boundary of sporadic and insular permafrost.

Wilting moisture (WM) was determined by multiplying the maximum hygroscopicity by the coefficient of 1.34 determined for Mongolian dry-steppe soils by Umarov and Yakushkina (1978). Total porosity (TP) was calculated from both the specific and the volumetric density. Soil temperature was measured under field conditions with an accuracy of 0.1°C.

RESULTS

In the basins of two permafrost solonchaks located 9.5 km apart, there were accumulated slightly segregated alluvia of different origin and grain size (Figure 2). These alluvia determined the forms of the mud boils (Figures 3 and 4). The frost boils form irregular clusters along the eastern, south-eastern, and southern banks of the intermittent lakes that occur on the lower parts of slopes inclined 0.5° to 2.5° and underlain by permafrost at depths of 0.6-1.4 m (Figure 5).

Within the areas of mud boils the soil surface is characterized by a great variety of morphogenetic forms. On turf solonchaks, among the turf tussocks, the soil surface has patches of salt crusts 0.2-0.4 cm thick in the form of polygons

(Figure 3). The surface of semidesert solonchaks, which have a vegetation cover of 2 to 4%, is mosaic of deflation-pavement on a thin desert crust with salt efflorescence (Figure 6), cracked silt alluvia (Figure 3), and forms of eolian accumulation and surface and furrow flushing. The upper parts of the slopes, which are underlain by permafrost at depths of 0.4-0.6 m are dominated by fields of recent cryogenic peat thufurs, which are saturated, particularly during the rainy season.

Materials that comprise the profiles of the soils under study form an unstable layered system where hydrostatic pressure is the main factor that stimulates disturbances, without, however, the frost segregation processes that are typical of the periglacial environment. The stratigraphy consists of three units of different density (Figure 7) and satisfies the conditions defined by Cegła and Dzhulynski (1970) for a geologically unstable layered system. The respective layers have the following characteristics:

(1) Compact soil layer VD 1.73-1.28 g/cm³, TP 37-54%.

(2) Thixotropic layer, periodically liquified, VD approximately 0.35 g/cm³, TP approximately 85%.

(3) Permafrost layer, with lamellar ice, VD

approximately 0.65 g/cm^3 , TP approximately 75%.

The above layers have high water contents ranging from 72% to 100% (by volume) in the compact soil layer and 98% to 100% in the thixotropic layer, in the mud-boil craters, and in the underlying permafrost (Figure 8).

The formation of peat thufurs and mud boils depends upon increased hydrostatic pressure in the 20-40-cm-thick cryogenic thixotropic layer that extends along the slopes above the permafrost. This pressure increases during spring thaw on adjacent plateaus and mountain ridges and in the rainy season. The pressure magnitude depends on four factors: the distance between the point of water inflow and the support of the thixotropic layer by compact materials of takyr solonchaks, the thickness of compact soil above the thixotropic layer, the slope length and inclination (Figure 5), and the geological origin of the soil material (Figures 3 and 4).

If most of the permafrost water exists in the form of horizontal, 1-4-mm-thick ice lamellae, then in the thixotropic layer or in the mud-boil craters it will form highly durable coagulation structures

that are resistant to the action of mechanical factors. Within this structure, two directions of capillary motion predominate--toward the cold front of the permafrost at the bottom, and toward the warm soil surface, especially in the open mud-boil craters (Figure 9).

Transition of water into ice lamellae and the resulting increase in permafrost volume is usually accompanied by liquefaction of the thixotropic mass immediately above the permafrost table. By contrast, within the mud-boil craters, a dense suspension, high-molecular gel forms, containing permanently suspended rock and mineral fragments up to 4 cm in diameter. Water is lost by evaporation into the atmosphere through a cracked dry crust less than 5 cm thick (Figure 9). As a result of this process a coagulation structure is formed that remains static under uniformly changing pressure and undergoes syneresis. At the same time the freezing point of the soil structure is depressed and, consequently, ice can aggrade but not veins or lamellae.

The ascending capillary motion of water above the permafrost table and the loss of heat through evaporation result in a temperature drop within the

crater. One consequence of this process is the growth of a permafrost cone over 100 cm high in the crater. In some cases, the cone apex is 10-15 cm lower than the slope surface. In general, however, it occurs at a depth of 40-80 cm beneath the top of the mud boil. There is also an increase in crater diameter of up to 2.5 m as a result of liquefaction of soil material under the influence of the aggrading permafrost cone.

The most important factors responsible for deformation and transformation of the unstable layered system are the dynamics of temperature change with time and local temperature variation in the vertical and horizontal soil planes (Figure 9). From the temperature depth profiles shown in Figure 10, it can be concluded that the greatest vertical temperature range within the thixotropic layer occurs above the apexes of permafrost cones. Here, temperature differences of 15-20°C occur in the 50-75 cm thick layer. Between the permafrost cones, the thixotropic layer is 20-30 cm thick and the vertical temperature range is 7°C. The degree of exposure influences both the temperature distribution in the boils as well as the form of the permafrost cones (Figure 9).

Figure 10 illustrates the characteristic decrease in the temperature jump with the depth of the contact between the thixotropic layer and the permafrost layer.

SUMMARY

The feature that distinguishes the islands of permafrost solonchaks in the northern dry-steppe area of the Central Gobi Peneplain is a system of layers with variable density. The basic deformation conditions determined by Cegła and Dzhulynski (1970) include the difference in volumetric mass between the upper and lower layer, the degree of soil water saturation, and the soil liquefaction characteristics. In addition, the hydrostatic pressure and low temperature conditions are major factors stimulating disturbance of the unstable system. These two factors, modified by slope length and inclination, extent of the thixotropic layer, and thickness of the compact soil layer, determine the formation on the lower parts of slopes of the characteristic clusters of mud boils. Variation in height and diameter of these forms, between the respective solonchaks, is a function of the geological origin of the soil parent material. The occurrence of similar forms in Iceland has been described by Stingl and Herrmann (1976).

The mud boils in question come into being as a consequence of local liquefaction of the compact soil-cover in vertical channels and the pressing through of these channels onto the surface of the thixotropic layer remaining constantly under hydrostatic pressure. Mud boils in this area constitute perennially active forms, in contrast to the periodically repeated outflows of mud in the polygon systems of periglacial tundra, which also occur under the influence of hydrostatic pressure (Jahn 1948, Mackay and Mackay 1978, French 1979, Wojcik 1981). This major contrast reflects the continental Central-Asiatic peculiarity of hydrothermal conditions of the permafrost solonchaks that contain fields of cryogenic mud boils.

ERODIBILITY OF UNCONSOLIDATED MATERIALS IN PERMAFROST

E. Z. Kuchukov and D. V. Malinovsky

Geology Department,
Moscow State University, Moscow, USSR

Mechanisms and laws governing the erosion of unconsolidated rocks in permafrost are examined. Four types of erosion, distinguished on the basis of the interaction of water flow with the rock, are identified. The most typical for the erosion of frozen rocks are the thermoerosional and extreme-thermoerosional types. It was established that the intensity of erosion increases with increasing stream discharge (in the case of the erosional and thermoerosional types) and with increasing water temperature (in the case of the extreme-thermoerosional type). It was shown that the composition, cryogenic structure, ice content, and density of the rocks are basic factors in dictating their erodibility.

Indices of erodibility of permafrost materials, which reflect the mechanical, thermal, and physical aspects of erosion as well as methods of determining them are proposed. A scheme is developed for subdividing permafrost materials on the basis of erodibility, which might be used for assessing and mapping permafrost and seasonally-frozen materials within the Yamal Peninsula. Much of the peninsula is composed of deposits susceptible to catastrophic and rapid erosion with the percentage area of such deposits increasing from south to north.

Stream activity in permafrost conditions emerges as one of the most important factors of cryolithogenesis and is essential for the development of surface denudation, transportation and accumulation of weathering products. The specific nature of this process, also called thermoerosion, is the simultaneous thermal and mechanical effects of streams on permafrost. The present work, carried out under the guidance of Professor E. Yershov at the University's Permafrost Studies Department, limits itself to discussing the scouring of permafrost dispersed rocks by intermittent streams, as the most hazardous effects of man's economic activity, and of scourability of permafrost reflecting its sensitivity to concurrent thermal and mechanical impact of flowing water. As a result, the degree of scouring is dependent on the thermal-physical and stability properties of permafrost (Yershov, Kuchukov et al., 1980). The former determine the speed of rock thawing, and the latter determines the destruction intensity and the follow-up material removal, i.e., the scouring intensity (I), which may be defined as a rock amount carried off with flow from a unit area in a unit time, or, for the flat flow, as a rock layer scoured in a unit time.

Laboratory and field studies have shown that permafrost is scoured while removing individual particles (for sandy rocks) and microaggregates and aggregates (for clay). Basically, the character and size of jointings torn off are specified by the cryogenic texture.

Three essentially differing patterns of this process may be ascertained with regard to the correlation of the thermal and mechanical factors, and accordingly, the scouring types identified by the stream-rock relationship.

1) Scouring of permafrost proper, when erosion capacity of a stream surpasses the scouring resist-

ance of permafrost is the permafrost-erosional type (Fig. 1, curve 1). The pivotal point here is the high strength of permafrost rocks, and their scouring forestalls their thawing. Under natural conditions this type of scouring is improbable since actual streams in permafrost areas do not possess adequate mechanical energy to destroy frozen rocks. Therefore, many specialists have difficulty depicting the whole permafrost area (except for its most southern part) on many gully-erosion maps as gullyless and not prone to erosion.

2) Thawing of permafrost and instantaneous removal of thawed material while the stream is in contact with a permafrost basement is the maximum-thermoerosional type (Fig. 1, curve 2). It is characterized by an equal intensity of thawing and scouring; while the flow rate reaches its critical point (N_{KR1}), the erosion front inevitably catches up with the thawing line. The scouring intensity then becomes a function of the thawing speed, and more important, of a water temperature, dispersity and thermal-physical properties of thawing rocks. The linear relationship was traced between the critical scouring intensity (N_{KR1}) for permafrost rocks at a given temperature, and the stream temperature (Fig. 2). The scouring of clear ice goes on slower than that of sand but much quicker than of clay. And loamy sand is more easily scoured than loam. What is important here is that the ice content of permafrost determines the heat level at phase transitions and the cryogenic texture determines movement of the scouring front. The scouring of clay having a laminated or reticulate texture develops in two ways. If the size of mineral aggregates is smaller than the geometrical parameters (depth and width) of jet-type water flow, then the scouring acquires a discrete nature because mineral aggregates, due to their scouring resistance, are removed only after they thaw. If the size of

mineral aggregates is comparable to the water flow parameters (e.g., at scouring of mineral aggregates over 3 cm in size), then scouring proceeds through selective erosion along ice schlierens. In this case the removal of frozen aggregates is possible. The critical scouring intensity may be calculated as follows:

$$I_{Kr} = K_{tp} t_w \quad \text{m/s}, \quad (1)$$

where t_w = water temperature, °C;
 K_{tp} = temperature index of scouring, m/s·degree, describing an increment of the critical scouring intensity per one degree Centigrade. It is determined by resolving the problem of a thawing line movement for the case of a complete "instant" removal of any thawed rock:

$$K_{tp} = \frac{\delta + \Delta}{\sigma [L_{vol} \cdot \delta \left(\frac{\delta}{2\lambda} + \frac{1}{\alpha_0} \right) + \frac{\Delta}{\alpha}} \quad \text{m/s} \cdot \text{degree}, \quad (2)$$

where δ and Δ = the sizes of mineral and ice layers, respectively, m;
 σ = the ice-thawing heat, J;
 L_{vol} = the ice volume in mineral interbeds;
 α_0 and α = coefficients of a turbulent exchange between water and permafrost rock, water and ice, J/sq.m·degree;
 λ = the thermal conductivity of a mineral interbed, J/m.s·degree.

This solution is valid only for the condition when the temperature of a permafrost rock series is close to zero. Observations of the rock temperature in a one-meter layer and under a stream bed, carried out at permanent stations in the north of Western Siberia show that it does not drop below -3°C in the spring-summer period. But taking into account the heat amount used for heating permafrost rocks under the stream bed, the proposed relationship (2) may be employed with adequate reliability.

3) Forestalled rock thawing and a stream contact with thawing or thawed deposits: Two types of scouring are found here: a) thermoerosional (Fig. 1, curve 3)—erosion of thawing rocks having a post-cryogenic structure and a low mechanical strength due to the increased humidity and structural linkages not fully restored during thawing; b) erosional (Fig. 1, curve 4)—scouring of thawed deposits, not differing from the traditional erosion of non-frozen rocks. In both cases, when scouring is done by a jet-type flow, the relationship between the scouring intensity and the water flow power may be described as follows:

$$I = K_{sc} N \quad \text{m/s}, \quad (3)$$

where K_{sc} = the scouring resistance factor, cu.m/J, being equal to the scouring intensity at a unit water flow power,

calculated by the formula:

$$N = 0.5\rho \cdot V^3 \quad \text{W/sq m}, \quad (4)$$

where ρ = water density, kg/cu.m;
 V = flow velocity, m/s.

The value of the resistance factor and, correspondingly, the scouring intensity, is determined by the stability of thawing rocks. We have established a close correlation (a correlation factor being 0.95) between the scouring resistance factor and the maximum rock displacement stress measured by micropenetrator MB-3 (Yershov, Malinovsky et al. 1982) for multiple dispersed thawing rocks of various composition, found in the north of Western and Eastern Siberia. The relationship obtained may be presented as follows:

$$K_{sc} = 10^{-15} \frac{1}{R} \quad \text{cu.m/J} \quad (5)$$

where r = the maximum displacement stress, Pa. Research has indicated that there is actually no relationship between the maximum displacement stress and the angle of internal friction. On the other hand, a close relationship was traced between the R value and cohesion, taking up a linear form for non-frozen rocks and a parabolic form for thawing rocks. Using equation 3, it may be easily stated that the admissible non-scouring velocity (ANV) for sands does not exceed 0.1 m/s, while for clays with a laminated or reticulate texture it ranges from 0.1 to 1.0 m/s and exceeds 1.0 m/s for rocks with a cryogenic texture. The established relationship between the scourability of permafrost rocks and the stability of thawing rocks is quite reliable and in accord with the data of Ts. Ye. Mirtskhulava (1970), ascertained the dependence of ANV on cohesion of water-saturated rocks.

Thus, we may define the likely type and intensity of permafrost scouring relying upon the scouring indices, when external conditions (N and t_w) are known. If the potential scouring intensity exceeds the critical value, then the maximum-thermoerosional type of scouring is to be anticipated, and if below critical, then thermoerosional or erosional. Usually deposits having the maximum displacement stress less than 0.03 MPa are subject to thermoerosional scouring.

The likely intensity of scouring of a thermoerosional type is of utmost importance for erosion forecasts in permafrost. This is so because the resistance factor may change by two orders depending on the rock structure and texture, while temperatures, although different in different rocks studied, are still rather close to each other. Besides, since many varieties of dispersed permafrost show high stability to the effects of natural stream erosion (e.g., heavy clays), the maximum-thermoerosional type of scouring cannot be obtained. Then the subdivision of permafrost rocks by scouring is done using the resistance factor with regard to their composition, ice content, cryogenic composition and stability (Table 1). The first three categories differ by the ice content and the cryogenic rock texture. The fourth and fifth categories comprise ice-rich rocks, having differing

cryogenic texture and low stability at thawing. The increased dispersion generally results in the diminished scouring in view of the growing cohesion. Should the structure of permafrost rocks be disturbed, their susceptibility to scouring grows; readily thawing rocks are easy to scour. But this is not always valid because of differences in thawing and scouring patterns. Hence the data on the speed and character of thawing may be taken (conventionally) to describe the scouring intensity. The presence of plant roots in permafrost rocks is very essential for diminishing the rock scouring.

The scouring assessment of major geological-genetical types of rocks on the Yamal Peninsula was carried out making use of the described classification of permafrost rocks by scouring. It is based on the analysis of permafrost-engineering geological peculiarities of upper horizons (to a depth of 5 m) within the Peninsula. The results obtained have indicated that the rocks of the fourth category (highly susceptible to scouring) are most widely spread over the Peninsula; and the scouring here is of the maximum-thermoerosional type because in most typical conditions their potential scouring intensity goes beyond $1 \cdot 10^{-4}$ m/s. These are syn- and epigenetic ice-rich sands of a marine, lagoon-marine and alluvial geneses possessing low structural stability in a water-saturated state. The scouring resistance factor ranges within $(0.3-10) 10^{-6}$ cu.m/J. Widely met also are rocks of the fifth category, including syngenetic alluvial ice-rich clay with an ataxitic cryogenic texture of disastrous scouring, behaving in this respect as clear ice. They are scoured by the maximum-thermoerosional type. Their stability after thawing is nearing zero. Their scouring resistance factor is always above 10^{-7} cu.m/J. Many researchers (Kosov and Konstantinova 1969) claim that it is the presence of deposits of the fourth and fifth categories that are conducive to a disastrously rapid scouring. Less developed on the Yamal Peninsula are deposits of the third and second categories, in which scouring intensity is equal to $(0.1 \text{ to } 1.0) 10^{-4}$ m/s following the thermoerosional type. These rocks are distinguished by the lack of cohesion between aggregates and, usually, the post-cryogenic structure at scouring. The third category includes syngenetic clay of the marine, lagoon-marine and alluvial geneses. They are given to thixotropy and have low stability (not more than 0.01 MPa) after thawing. In typical conditions the scouring may sometimes be of the maximum-thermoerosional type. The scouring resistance factor makes up $(0.1 \text{ to } 0.3) 10^{-6}$ cu.m/J which refer them to easily-scoured rocks. The second category encompasses medium-scoured syngenetic clay of the marine, lagoon-marine and glacial-marine origin. What set them apart is the fact that the tearing of particles is attributable not only to textural but structural peculiarities which emanate from lithological, physical, chemical, biological and other factors. Their stability when thawing varies from 0.01 to 0.03 MPa and, in typical conditions, the scouring is of the thermoerosional, and more seldom, erosional type. The resistance factor is estimated to be $(0.03 \text{ to } 0.10) 10^{-6}$

cu.m/J. The first category of slightly scourable rocks includes epigenetic clay deposits in which scouring (erosional type) intensity is less than $0.1 \cdot 10^{-4}$ m/s. These rocks are characterized by specific scouring along schlierens, but, in general, erosion tends to decrease. Stability of mineral aggregates does not exceed 0.03 MPa and the scouring resistance factor is not more than $0.03 \cdot 10^{-6}$ cu.m/J.

Slope-type deposits (alluvial, deluvial, solifluctious, proluvial) may enter any of the above categories with regard to their composition and structure (Yershov, Malinovsky et al. 1982).

Studies of permafrost dispersed rock scouring have indicated that syngenetic permafrost series which area increases northward, are characterized by less resistance to scouring. This explains, in our view, the tendency to intensified gully development to the north of the so-called gullyless belt in the USSR, which is dwelt on in many publications (Kosov and Konstantinova 1969). This belt is confined to the southern part of the permafrost zone typical for which are a maximum depth of seasonal freezing and thawing and a lack of syngenetic permafrost. It is the latter that, in view of their high ice content and, mainly, due to the development of small-meshed and thinly-laminated cryogenic textures, show the lowest erosion resistance.

Generally the scouring properties of permafrost rocks tend to decrease in the following order: syngenetic alluvial-marine-lagoon-marine-epigenetic lacustrine-marine-lacustrine-glacial-water-glacial. Therefore, the genesis of permafrost series (the freezing type being inclusive) gives an idea about the deposits' scouring.

The results obtained laid the basis for zoning the scour potential of Yamal Peninsula at a scale 1:5,000,000 (Yershov, Malinovsky et al. 1982). Identified on the map were regions, microregions, etc. of deposits having similar factors contributing to permafrost scouring. Permafrost surveys, providing ample material for ascertaining these factors, were used. For the purposes of zoning, taxonomic units distinguished for the West-Siberian map by V. T. Trofimov in 1977 were employed. Reflecting the changeability of engineering-geological rock properties in space, they are also helpful in tracing the scouring variability in particular. Indeed, while dividing a region into provinces on the basis of rock classes (with or without cementation), there are distinguished, first of all, areas composed of practically unscoured and scoured (dispersed) rocks. The thermal effect of streams on rock scouring (thermoerosion or traditional erosion) becomes clear when subdividing the provinces into zones and subzones by the present state of rocks.

Most important for scientific and practical purposes is zoning of territories (for assessing rock scouring) composed, firstly, of deposits without cementation and, secondly, rocks in a permafrost state. This somehow narrows the problem and allows application of the zoning pattern, described for the Yamal Peninsula, to predominantly permafrost areas.

The zoning of the Yamal Peninsula was carried out using the system of taxonomic units inherent in the engineering-geological zoning. The largest

taxonomic units—districts—are identified by the morphological specifics of a territory and the genesis of the upper horizons in permafrost series: (1) district of predominantly Late Quaternary and modern lagoon-marine, marine, lacustrine and alluvial terraces, with a surface layer of syngenetic permafrost; (2) district of predominant Middle and Late Quaternary marine, glacio-marine, glacio-lacustrine and glacial plains in which the surface is epigenetic permafrost. The next taxonomic unit, in a decreasing order, is a region or a part of a district distinguished by bedrock in the upper part of a profile. Subregions are differing by the cryogenic structure of deposits. A definite rock category for scouring corresponds to each subregion. Disregarding composition and structure, deposits with well-developed ice wedges are referred to the fifth category. The assessment undertaken on Yamal Peninsula has indicated that much of the territory is composed of disastrously and rapidly scoured deposits, and their area increases northward.

DILATOMETER TESTING IN THICK CYLINDERS OF FROZEN SAND

B. Ladanyi¹ and H. Eckardt²

¹Northern Engineering Centre, Ecole Polytechnique, Montréal, H3C 3A7, Canada
²Züblin AG, Stuttgart, West Germany

The borehole dilatometer method for in situ determination of creep properties of frozen soils, introduced initially by Ladanyi and Johnston (1973), has since that time been used with reasonable success in several field investigations in frozen soils and ice, the results of which have been reported in several previous papers. However, since, the method has not yet been tested under controlled laboratory conditions, it was decided to carry out a series of dilatometer creep tests in confined thick cylinders of frozen sand, using the conventional field equipment. This paper presents and discusses the results of a series of stage-loaded medium- and long-term creep tests carried out in these cylinders with the Menard pressuremeter and gives the whole theoretical interpretation of such tests, which appear to be an interesting alternative method for the determination of creep parameters of frozen soils under plane strain conditions.

INTRODUCTION

After the first experience with field testing of creep properties of frozen soils, the results of which were published by Ladanyi and Johnston (1973), several additional field studies have been carried out in the North, both in frozen soils and in sea ice. Most of these studies were designed to improve the understanding of the borehole expansion testing method, in which two kinds of borehole dilatometers were used for performing short- and long-term borehole creep and relaxation tests (Ladanyi 1982).

This paper presents some results from a recent study of borehole expansion testing in frozen sand, in which the tests were performed with the conventional field equipment but under cold room conditions (Eckardt 1981). Such a study, carried out in thick cylinders of frozen sand under controlled temperature and lateral stress conditions, was considered necessary to be able to better evaluate and understand the effects of stress level and time on the creep behavior of frozen soil. Although the main purpose of this investigation was to simulate the field testing, the thick cylinder expansion method has proved to be an interesting alternative to other types of laboratory tests with frozen soils, especially when large scale plane strain information is required.

Special problems discussed in this paper are the interpretation of such thick-cylinder tests, the shape of stress-strain curves deduced from short-term tests, the different creep behavior of the soil at low and high stress levels, the extrapolation of creep curves to longer times, and the effect of stress redistribution on the observed creep behavior in stage-loaded borehole creep tests.

TEST EQUIPMENT

Although Eckardt (1981) used both the Menard pressuremeter and the CSM cell for performing borehole creep and relaxation tests, because of the space limitation only the results obtained with the

pressuremeter will be described in this paper. The pressuremeter used in the tests was a Menard type GC with a volume capacity of about 800 cm³ and a pressure range of up to 10 MPa. The probe had a minimum diameter of 7.1 cm, and its total length was 45.5 cm.

A sketch of the test chamber, specially constructed for sample preparation and test performance, is shown in Figure 1. The chamber, a steel tank with an outer diameter of 90 cm and a height of 50 cm, was designed to contain cylindrical hollow samples of frozen soil that were about 50 cm in diameter and up to 45.5 cm long. A rigid construction of the bottom and the top of the tank furnished essentially plane strain conditions for the sample. The bottom of the tank was perforated with 16 holes connected by plastic tubes to a water container for saturating the samples. The lateral confinement of the sample was supplied by two superimposed air-filled rubber cushions (actually inner tubes of large truck tires) placed between the sample and the steel tank wall, making it possible to apply a confining pressure of up to 0.3 MPa.

The test chamber was located in a cold room in which the temperature was controlled with an accuracy of $\pm 1^\circ\text{C}$. In general, the temperature measured within the chamber and on the sample did not show much variation, remaining around -2.5°C in all the tests.

TEST MATERIAL

A natural medium-grain-size sand was used in all the tests. Its grain size distribution obtained by a periodic check of different batches, was about 90% between 0.1 and 1.0 mm, with less than 2% below 0.1 mm and less than 1% above 2 mm; giving a coefficient of uniformity of about 3.0. The maximum and minimum dry densities of the sand, determined by the ASTM standard method, were 1,810 and 1,510 kg/m³, respectively. Constant-cell-pressure triaxial tests on the dry sand gave peak strength angles of internal friction of 45° at the maximum density, and 39° at a medium density of 1,680 kg/m³.

The residual friction angle was about 35° at both densities.

FIGURE 1 Thick-cylinder test setup for pressurimeter tests in frozen sand. (a) steel tank, (b) sample, (c) central tube during sample preparation, (d) steel strips for sample preparation, (e) rubber cushions for lateral confining pressure, (f) saturation water supply line, (g) reinforced lid, (h) lateral pressure gages, (i) auxiliary frame.

PREPARATION OF SAMPLES

Before each sample preparation, the bottom of the steel tank was greased with a cold-resistant lubricant and then covered with a plastic sheet, perforated to permit sample saturation. Next, the rubber cushions for lateral pressure application were inserted and slightly inflated. Then 16 steel strips, each 13 cm wide and 45.5 cm long, were installed vertically against the inner side of the cushions, to form the outer sample envelope. The hole for the test was provided by installing in advance a central steel tube with a 7.4 cm diameter. The tube, which was greased and covered with a plastic sheet, was extracted after the sample was frozen. Lateral steel sheets and the central tube were fixed in the empty container by an auxiliary mobile frame, as shown in Figure 1. During the

filling of the dry sand into the tank, this frame was pulled continuously upward. The sand was compacted by a vibrator to a medium density by moving the vibrator around the sample and inserting it in four different cycles. After the whole sample was prepared, the chamber was closed with a reinforced lid. Then the rubber cushions were inflated up to 100 kPa lateral pressure, and the sand was saturated from the bottom up with distilled and deaerated water.

The sample was frozen at a cold room temperature of -10°C . During freezing, the steel tank was insulated on the top and the sides to force the freezing front to move upward, which minimized freezing strains and stresses. After 3 days, the sample was frozen, and the room temperature was increased to the desired test level of -2.5°C . The sample was allowed to attain a homogeneous temperature distribution for three more days without insulation. Thus, altogether, the preparation of each sample took between 6 and 8 days.

The densities and water contents of the test samples were determined by taking six specimens after each tests, two from the top, two from the bottom, and two from the center.

THEORY OF DILATOMETER TESTS IN THICK-WALLED CYLINDERS

Short Term Tests

In the borehole dilatometer and pressuremeter practice (e.g., Ladanyi and Johnston 1973, 1978), the results of a short-term borehole expansion test are usually first plotted as a corrected pressure-expansion curve. The "true pressure-expansion curve" used for interpretation is obtained by shifting the pressure origin of that first curve to p_0 , which denotes the average original ground pressure acting normally to the borehole axis. The "true pressure-expansion curve" represents then a relationship of the form $\Delta V = f(p)$, where $p = p_c - p_0$ is the net pressure acting on the borehole wall, and ΔV is the corresponding volume increase of the measuring section of the borehole, whose underformed volume was V_0 .

For evaluation of test results, it is still more convenient to plot, instead of ΔV , the dimensionless quantity $\Delta V/V_0$, which represents in fact the shear distortion strain γ at the cavity wall. Here $V = V_0 + \Delta V$ denotes the current borehole volume at a net pressure p .

As shown by Ladanyi (1982), the classical theory of an expanding elastic thick cylinder in plane strain, enables to determine from the initial slope of the true pressure-expansion curve the value of the shear modulus of the soil.

$$G = \frac{E}{2(1+\nu)} = \lambda \frac{\Delta p}{\Delta \gamma} \quad (1)$$

where E and ν denote the Young's modulus and the Poisson's ratio of the soil, respectively, $\gamma = \Delta V/V_0$, and,

$$\lambda = \frac{1 + (1 - 2\nu) \alpha^2}{1 - \alpha^2} \quad (2)$$

where $\alpha = r_i/r_e$ is the ratio between the inner and the outer radius of the cylinder.

As far as the short-term strength is concerned, a method enabling one to deduce the whole stress-strain curve from a pressure-borehole expansion curve, developed originally by Ladanyi (1972), can easily be modified to include the tests performed in thick cylinders. It can be shown that in such a case, from any two consecutive points $i, i+1$ on the pressure-expansion curve, the value of the corresponding principal stress difference $q_{i, i+1} = (\sigma_1 - \sigma_3)$, can be calculated from

$$q_{i, i+1} = \frac{2(p_i - p_{i+1})}{\ln(\gamma_i/\gamma_{i+1}) - (\alpha^2/\gamma_f)(\gamma_i - \gamma_{i+1})}, \quad (3)$$

where $\gamma_f = q_f/2G$ is the shear strain at failure of the soil and q_f is its unconfined compression strength, all valid for a plane strain case.

For the same interval, the average value of shear strain is

$$\gamma_{i, i+1} = (\epsilon_1 - \epsilon_3) = \frac{1}{2}(\gamma_i + \gamma_{i+1}). \quad (4)$$

All these formulas remain valid only until radial cracking of the cylinder occurs. It follows from Lamé's theory that in a linear-elastic material, radial fissures start to appear as soon as the internal pressure p_c in the borehole attains the value

$$p_c = \frac{2p_o + |T_s|(1 - \alpha^2)}{1 + \alpha^2}, \quad (5)$$

where p_o is the external pressure applied to the cylinder at $r = r_e$ and $|T_s|$ is the absolute value of the tensile strength of the material.

Creep Tests

For an ice-rich frozen soil or ice, the total strain attained after a given time under a constant stress is given by

$$\epsilon_e = \epsilon_e^{(i)} + \epsilon_e^{(c)}, \quad (6)$$

where $\epsilon_e^{(i)}$ is the instantaneous (elastic and plastic) portion of the total strain and $\epsilon_e^{(c)}$ is the creep strain, which may be expressed by a power law equation

$$\epsilon_e^{(c)} = (\dot{\epsilon}_c/B)^B (\sigma_e/\sigma_c)^n t^B. \quad (7)$$

Here the subscript e denotes the von Mises equivalent stress and strain, σ_c is the reference stress at the reference strain rate $\dot{\epsilon}_c$, t is the time, and B and n are creep exponents.

Following Ladanyi and Johnston (1973, 1978) and Ladanyi (1982), it will be seen that the creep portion of the borehole expansion in a thick cylinder at a constant stress $p = p_c - p_o > 0$, applied during stage 1, is given by the equation

$$\ln(V/V_{i-1}) \approx (\Delta V_c/V) \approx \gamma_c = 2D_n p^n t^B, \quad (8)$$

where V is the current volume of the cavity, $V_c = V - V_{i-1}$ is its creep increment with respect to the volume V_{i-1} attained in the preceding stage, and D_n is defined by

$$D_n = (\sqrt{3}/2)(\dot{\epsilon}_c/B)^B (\sqrt{3}/n \bar{\sigma}_c)^n, \quad (9)$$

with

$$\bar{\sigma}_c = m \sigma_c, \quad \text{and } m = 1 - \alpha^{2/n}. \quad (10)$$

As shown in the above-mentioned references, the values of creep parameters B , n , and $\bar{\sigma}_c$ can be obtained from a series of borehole creep tests or from one multistage creep test, by plotting the results in a double-log plot, first the creep strain γ_c versus time and then $(2D_n p^n)$ versus the applied pressure p . The value of creep parameters deduced from such tests is, however, subject to a certain error which is due to the apparent primary creep, resulting from the stress redistribution around the hole, as shown later.

TEST RESULTS

As mentioned before, only some typical results of tests carried out with the Menard pressuremeter will be presented here. A more complete report on these tests and on the CSM cell tests performed in this investigation can be found in Eckardt (1981) and in a companion paper by Eckardt and Ladanyi (1983).

Altogether 15 pressuremeter tests were carried out for determining the short- and long-term parameters of frozen sand in this study. Eight of these tests were conducted as stage-loaded tests with eight to ten 30-min-long stages at constant load. The results of these tests were used not only for determining the deformation modulus G and the short-term strength parameters of the soil but also for calculating its medium-term creep parameters. The remaining seven tests, designed to study long-term behavior of frozen sand, were conducted with two to three creep stages, one of which was at a low stress level. The longest creep time reached in one of the tests was about 8 days. The tests were performed at different confining pressures ($p_o = 0, 0.1, 0.2$, and 0.3 MPa) and at an average soil temperature of -2.4° (-2.2° to -2.6°C).

Short-Term Parameters

The short-term parameters of the frozen sand were determined from the results of pressuremeter tests by the usual method, described before (e.g., Ladanyi 1972), but by using equations (1)-(5), valid for the tests in thick-walled cylinders. The procedure consisted in calculating the corrected pressuremeter curve $\Delta V/V = f(p)$ for the end-of-stage (30 min) readings of each test, and in determining the corresponding stress-strain curves. Five of such stress-strain curves, relating the principal stress difference $q = \sigma_1 - \sigma_3$ to the shear strain $\gamma = \sigma_1 - \sigma_3$ are shown in Figure 2. As they represent a plane strain information, the corresponding axial symmetry curves can be obtained through the von Mises relationships:

$q_{ax} = (\sqrt{3}/2)q_{ps}$ and $\epsilon_{1ax} = (\sqrt{3}/3)\gamma_{ps}$. The slope through the origin of these curves gives the value of the shear modulus $G = \frac{1}{2} \Delta q / \Delta \gamma$.

FIGURE 2 Stress-strain curves from 30-min-per-stage creep tests.

In addition, a set of Mohr circles was also plotted for each test (Eckardt 1981), from which the minimum value of the tensile strength T_s of the soil was determined. Although the tests were conducted at external confining pressures varying from 0 to 0.3 MPa, no systematic effect of that pressure on test results could be detected. In general, in spite of the great care in preparing the tests, the results were rather variable, which may be due to the great sensitivity of the sand behavior to small variations of its density and ice saturation.

Table 1 shows the main data of the six most consistent short-term tests 3-8.

The rather variable shape of the stress-strain curves in Figure 2, some with two peaks and others showing strain hardening, may be explained by the fact that, on one hand, radial tensile cracks started propagating from the central hole rather early in the tests, which might have caused the first peak, while, on the other hand, the ever-increasing strain rate, which is typical in such stage-loaded tests, combined with the mobilization of friction, resulted in an apparent strain hardening.

Theoretically, according to equation (5), with $|T_s| \approx 1$ MPa and $\alpha^2 \approx 0.02$, the radial tensile cracks should have started propagating at $p_c \geq 1$ MPa

with $p_0 = 0$, and at $p_c \geq 1.6$ with $p_0 = 0.3$ MPa. In fact, they were observed only at nearly 4 times higher p_c values, which may be explained by the non-linearity of stress-strain behavior of frozen sand due to creep (Ladanyi and Gill 1981). In other words, although the tests invariably finished with a complete failure of the cylinders, during the major portion of the tests the radial cracks were insignificant and did not affect seriously the creep behavior.

TABLE 1 Results of Short-Term (30 min/stage) Tests.

Test	ρ_d (kg/m ³)	w (%)	S (%)	T (°C)	p_0 (MPa)	$ T_s $ (MPa)	q_{ps} (MPa)	γ_f (%)	G (MPa)
3	-	-	-	-2.5	0.1	1.5	3.7	2.5	90
4	1,560	17.5	66.8	-2.1	0.2	0.9	2.8	4.0	70
5	1,540	18.1	66.5	-2.5	0.3	0.8	3.7	3.0	70
6	1,590	17.9	70.6	-2.3	0	1.0	2.8	3.0	70
7	1,640	15.1	65.0	-2.5	0.3	1.0	2.4	3.0	50
8	1,590	17.6	70.1	-2.3	0	0.8	3.6	3.2	60
Average	1,584	17.3	67.8	-2.37	-	1.0	3.17	3.1	68.3

Note: ρ_d = dry density; w = water content; S = degree of saturation; q_{ps} = plane strain compression strength; γ_f = shear strain at failure.

Creep Behavior: Medium Term

As described by Ladanyi and Johnston (1973), the medium term creep parameters can be determined from a stage-loaded pressuremeter test by plotting the successive creep curves in a log-log plot of creep strain $\gamma \approx \ln(V/V_{i-1}) \approx \Delta V/V$ versus time t, such as shown in Figure 3 for test 4. However, as noted by Ladanyi and Johnston (1978), a disadvantage of such a plot is to include not only the creep strains, but also the instantaneous plastic strains, which makes its use for parameter determination difficult and inaccurate, especially at low pressures. At higher pressures, i.e., at $p > 2$ MPa, it was nevertheless possible to determine from the tests 3-8 average values of creep parameters B, n, and σ_c in equation (7). These values and their ranges were $B = 0.80$ (0.72 - 0.84), $n = 2.40$ (1.80 - 3.60), and $\sigma_c = 1.23$ MPa (0.82 - 2.00) at $\dot{\epsilon}_c = 10^{-5}/\text{min}$. In particular, for test 4 (Figure 3), the values were $B = 0.81$ (0.5 - 1.1), $n = 2.26$, and $\sigma_c = 0.94$ MPa.

A better way of interpreting the same creep data is to subtract from the measured strains the pseudo-instantaneous ones read from the first plot at a given short time interval, say, 1 min, and replot the remaining strains, as suggested by Ladanyi and Johnston (1978).

The plot in Figure 4 is the result of such a manipulation of data for test 4, where the intercepts at 1 min in Fig. 3 were subtracted from the total strains and the rest was replotted at the times reduced by 1 min. It will be seen that a much more regular plot is obtained in such a manner. In addition, two distinct regions of creep behavior can clearly be discerned: one at low stresses, in which B strongly increases with stress, and

FIGURE 3 Test 4: Total strain versus time curves.

FIGURE 4 Test 4: Creep strain versus time, and $(2D_n p^n)$ versus pressure curves.

another at high stress, where B remains practically constant. In test 4, for $t > 15$ min, these values were $B = 0.34 - 0.77$ (average 0.52) for p between 0.8 and 2.8 MPa, and $B = 0.8 - 1.0$ (average 0.90) for $p > 2.8$ MPa. Using the average B values, the corresponding n and σ_c values obtained for the two regions were $n = 1$, $\sigma_c = 11.63$ MPa for $p \leq 2.8$ MPa, and $n = 3.2$, $\sigma_c = 0.878$ MPa for $p > 2.8$ MPa (all at $\dot{\epsilon}_c = 10^{-5}/\text{min}$). In addition, by treating the cumulative 1 min pseudo-instantaneous strains in a manner similar to the creep strains, it was possible to determine also the first term in equation (6) for both regions.

The final result of such interpretation were the following two complete stress-strain-time equations, describing the behavior of frozen sand during a medium-term creep at -2.1°C : (1) for $p \leq 2.8$ MPa,

$$\epsilon_e = \sigma_e (0.00117 + 0.00030 t^{0.52})$$

and (2) for $p > 2.8$ MPa,

$$\epsilon_e = 0.000874 \sigma_e^{1.5} + 5.277 \times 10^{-5} \sigma_e^{3.2} t^{0.90}$$

where the stresses are in MPa and the time in minutes.

Creep Behavior: Long Term

As creep time intervals of more than 24 hours have been difficult to realize in the field, one of the main tasks of this study was to see whether the creep rate remains unchanged after longer periods of time. Several tests were made for that purpose with two to three loading stages, the first one being up to 10 days long. The results of two of such tests are shown in Figure 5. The figure shows the creep curves from which the 1 min portion of strains has already been subtracted.

In Figure 5, for test 10, it appears that B remained constant during the first 4 hours but increased with the stress level from 0.38 at 0.9 MPa to 0.64 at 3.0 MPa. There was some decrease in slope after 4 hours, which could have been caused by small variations in the soil temperature and in the confining pressure during this test.

A similar trend of B increasing with pressure was observed in test 12 (Figure 5), as well as in several other similar tests not shown here. In test 12, the first stage at $p = 0.92$ MPa was held for 8 days and showed a fairly constant average slope of $B = 0.32$. The second stage at 3.96 MPa manifested a much faster creep rate with $B = 0.82$, ending with the cylinder failure after 3.5 hours.

The variation of the time exponent B with pressure is considered to be quite an important phenomenon, which should be taken into account when using the pressuremeter-determined creep data for the design of structures in permafrost. Based on the results of pressuremeter tests performed in this study, it was found that for the frozen sand at about -2.5°C , the variation of B could be described on the average by $B = 0.45p^{0.5}$, with an upper bound of $B = 0.52p^{0.4}$ and a lower bound of $B = 0.38p^{0.6}$, valid for $0.8 < p < 5.0$ MPa.

It is noted that the values of creep exponents n and B , reported in the literature for various frozen sands, $1.28 < n < 2.63$ and $0.45 < B < 0.63$, do not differ much from those found here (Sayles 1968).

CONCLUSIONS

FIGURE 5 Test 10: 24 h creep curves.
Test 12: a two-stage creep test, the first stage being 8 days long.

Stress Redistribution Time

In a stage-loaded dilatometer test, a certain time is necessary after load application for the stresses to redistribute from the initial linear-elastic state to that corresponding to the nonlinear stationary creep. As during this time the measured creep parameters may be in error, it is interesting to see how long this time would be under the conditions prevailing in this study. While the problem of stress redistribution in such a case can be solved only numerically, an approximate answer may be found by using the method proposed by Calladine (1969). Using that approach, the authors have developed the following equation, valid for a thick-walled cylinder in plane strain under a stage load p .

$$\tau_R = t_R^B = \frac{(m \sigma_c)^n \ln R}{G n \sqrt{3} (\sqrt{3}/n)^n (\dot{\epsilon}_c/B)^B p^{n-1}} \quad (11)$$

Here, τ_R denotes the "time" to achieve redistribution of stress to within a fraction $1/R$ of the stationary state, or for the creep strain to become equal to $(1/n) \ln R$ times the elastic strain.

Substituting in equation (11) the average values of creep parameters found in tests 3-8, i.e., $B = 0.80$, $n = 2.40$, $G = 70$ MPa, $\sigma_c = 1.23$ MPa at $\dot{\epsilon}_c = 10^{-5}/\text{min}$, and $m = 0.80$, it is found that the redistribution time is given by $\tau_R = 476.4/p^{1.75}$, with τ_R in minutes and p in MPa. This equation gives for τ_R about 27 hours at 0.5 MPa, 8 hours at 1 MPa, over 2 hours at 2 MPa, and about 1/2 hour at 5 MPa. Although these times vary with the values of creep parameters, it is interesting to note that stress redistribution times are much longer at low stresses than at high stresses.

An independent Finite Element Method study, designed for checking these predictions, is presently under way.

This cold-room study of the pressuremeter test as a means for determining certain basic stress-strain and creep parameters of frozen soil has revealed the potential of such a test, not only as a field test, but also as an alternative method for large-scale testing of frozen soils under plane strain conditions. In particular, this study, carried out in large thick cylinders of frozen sand, has made it possible to attain creep times much longer than under field conditions. The results show that the assumed power law formulation for the creep behavior of frozen sand can be retained and used for long-term extrapolation, provided one takes into account the fact that the creep parameters n and B both tend to decrease with decreasing deviatoric stress.

THE EXTENSION OF PERMAFROST IN WESTERN EUROPE IN THE PERIOD
BETWEEN 18,000 AND 10,000 YEARS B.P. (TARDIGLACIAL) :
INFORMATION FROM SOIL STUDIES

R. LANGOHR

Department of General Pedology, State University of Ghent
Krijgslaan 281, 9000 Ghent, Belgium

Soils developed since the beginning, or during the Tardiglacial (+18,000 to 10,000 years B.P.), are compared with "Holocene" soils. The area covers the loess and coversand belts of NW France, Middle Belgium, and The Netherlands. Eight major kinds of Tardiglacial soils are recognized. All of these except one have a consolidated horizon which is present regardless of the texture and drainage class. This horizon has a particular structure and porosity fabric, shows relict pseudogley properties, and is not observed in the Holocene soils. The formation of the consolidated horizon either by freeze-thaw cycles or by permafrost is discussed. It is concluded that only the permafrost hypothesis can explain the complete set of properties. Consequently, permafrost would have been at least once continuous during the Tardiglacial in the studied area.

INTRODUCTION

There is no agreement whether permafrost conditions occurred in NW France, Belgium, and The Netherlands during the Weichsel Tardiglacial age (+18,000 to 10,000 years B.P.). Many authors mention traces of periglacial processes like cryoturbations and small frost wedges but do not specify whether permafrost was present or not (e.g., Zagewijn and Paepe 1968, Paepe 1969, Paepe and Sommé 1970). Others mention permafrost (e.g., Haesaerts and Bastin 1977, Haesaerts and Van Vliet 1981). Our purpose is to investigate this controversy on the basis of the surface soil characteristics (upper 2-3 m of the regolith).

SELECTION OF THE AREAS AND FIELD SURVEY

In studying the traces left in the surface soils by the Tardiglacial environment the areas of interest are severely reduced because of the following requirements.

1. The soils must be formed in sediments deposited just before or during the Tardiglacial. For this reason the investigation is limited to (1) the upper meters of the Weichsel Pleniglacial B loess and coversands, deposited after 23,000 years B.P. and probably before 18,000 years B.P. (Haesaerts et al. 1981) and (2) the recent coversands deposited during some of the colder periods of the Tardiglacial. The loess deposits are dominant in NW France and Middle Belgium, the coversands occur mainly in N. Belgium and in The Netherlands.

2. The influence of man on the soil characteristics must be avoided as much as possible. Consequently, the field survey is limited to only those forested areas which as verified by historical data have not been cleared and plowed since at least the eleventh or twelfth century.

3. For the study of complete toposequences, including the water divide, the slope, and the val-

ley bottom positions, only the large forests are suitable.

4. Only those toposequences are selected where soils are developed in thick (more than 1 m) sediments of the same litho-chronostratigraphic unit.

The above mentioned requirements reduced the area of interest for this investigation to less than 3% of the loess belt and less than 15% of the coversand belt.

The soil descriptions were made using a methodology developed by the author, combining procedures from the soil survey as well as the archeology and the field survey made for lithostratigraphy. Special attention was paid to the combination of both vertical and horizontal sections of the soil profile and to the relative position of each soil feature. When useful, samples were collected for physicochemical analysis or for the preparation of thin sections.

In total, some 60 profiles have been described in loess and coversands. These data have been compared with those from soils developed in Holocene sediments, particularly sand dunes, marine and alluvial deposits, and colluvial sediments in areas under cultivation.

RESULTS

For reasons of simplicity the soils developed since +10,000-18,000 years will be called "Tardiglacial soils" and the younger soils will be called "Holocene soils". Figure 1 represents the main soil kinds (SK) observed. SK1-SK6 are Tardiglacial soils developed in the upper meters of Pleniglacial B loess and coversands. SK7 and SK8 are the most common Tardiglacial soils in the recent coversands. SK9-SK11 represent the most common types of Holocene soils.

A striking feature of Tardiglacial soils (SK2 up to SK8) is the presence of a particular consolida-

FIGURE 1 Main soil kinds (SK) developed in sediments deposited within the last 23,000 years. SK1 indicates soil kind 1. 1 : abundance of roots, n, no; vf, very few; f, few; c, common; a, abundant; va, very abundant. 2 : soil horizon symbols, mainly after Soil Survey Staff (1975), except c (consolidated horizon). In B'2t'g'c', the accents stand for all the processes that are thought not to be active any more. 3 : texture classes, after Soil Survey Staff (1975), SiL, silt loam; L, loam; SaL, sandy loam; LSa, loamy sand; Sa, sand. 4 : D = drainage class, after Soil Survey Staff (1951), E, excessively; W, well; MW, moderately well; I, imperfectly; SP, somewhat poorly; P, poorly; VP, very poorly. 5 : with these drainage classes, the symbol g (active gleying) should be added to the horizon symbols. 6 : biologically most active part of the profile. 7 : total thickness of the consolidated horizon.

ted horizon or pan indicated in Figure 1 by the horizon symbol c and by the thick black line on the lefthand side of the profiles. This layer was neither observed in the Holocene soils nor in SK1 of the Tardiglacial soils. In latter soils a calcareous C horizon is observed relatively close to the soil surface (mostly at 1.5-2.2 m depth). These soils are formed in particular landscape positions of the loess belt, namely (1) relatively steep slopes (gradient mostly of more than 30%) and (2) in some poorly drained smooth upland depressions.

The main characteristics of the consolidated horizon are the following.

1. The upper limit of the compact horizon always represents an abrupt increase in bulk density (see Table 1). The density remains more or less constant throughout the pan and drops slightly in the underlying B3.

TABLE 1 Average Bulk Density in Soils Developed in Pleniglacial B Loess (Ring Samples Collected at Field Capacity)

Horizon	Depth of samples (cm)	Average Bulk density	Number of horizons analyzed
Root-active (B)	10-25	1.25	11
Consolidated A'2g'c'	25-35	1.59	7
Consolidated B'2t'g'c'	40-110	1.60	19
Root-active B3t	130-180	1.53	10

2. All the consolidated horizons, regardless of the texture and drainage class, have a particularly high penetration resistance. Field measurements made at field capacity always indicate a penetration resistance of more than 50 Newton/cm² (upper limit of many field instruments). These high values are obtained in all parts of the horizon, including the bleached vertical streaks and the porous central part of the prisms. In the underlying nonconsolidated B3 horizon the resistance drops to values ranging mostly between 10 and 20 Newton/cm².

3. No evidences of recent or present-day activity of burrowing animals such as earthworms or larvae of beetles is seen.

4. Few if any roots pass through the pan. Where they do, they are always oriented downwards and situated along the faces of a coarse prismatic structure (see point 10 below). The only biological activity inside these prisms is limited to hyphae of fungus along some pores and secondary ped faces.

5. The upper boundary is at 20-50 cm depth and is abrupt and roughly parallel to the soil surface. Its topography is in places smooth, but commonly the overlying much more porous earth tongues down to several decimeters depth. The lower limit is mostly at a depth of 80-150 cm, yet depths up to 180-230 cm have been observed (mainly in the sandy

soils), this boundary is gradual and smooth to wavy.

6. The soil material is not cemented, and air dried fragments slake in water.

7. The consolidated layer overlaps different soil genetic horizons such as bleached clay-eluvial horizons (A'2g'c' of SK3 and SK4), brown clay-illuvial horizons (B'2t'g'c' of SK2-SK6), color and/or structure B horizons (B'g'c' of SK7b and SK8b) and even C horizons (Cc' of SK7a and SK8a). In the B'2t'g'c' horizons most of the pores and ped faces are devoid of clay coatings. However, thin sections show numerous disrupted fragments of clay-illuvial bodies in the interior of the peds. In contrast, below the compact horizon (B3t) the clay coatings are covering pore walls and ped faces.

8. The present-day drainage class of these soils ranges from excessively drained up to poorly drained. In the loamy and silt loamy soils with a fluctuating groundwater table, the water saturation is in fact limited to the bleached streaks in between the prisms (see point 11 below); because of the low hydraulic conductivity of the prism border, the large pores inside the prisms remain empty of water, even when the whole horizon is below the groundwater table level.

9. All soils show at least in the upper part of the pan morphological evidences of a fluctuating groundwater table. Bleached and iron oxide enriched mottles occur along the pores and ped faces; the manganese oxide enriched areas are found mainly inside the aggregates. In at least the excessively-, the well- and the moderately well-drained soils (the latter two soils represent more than 50% of the studied area), this hydromorphic characteristic is relict. In fact, all the observed soils with compact horizon have pseudogley characteristics, as the most intense mottling is situated in the upper part of the pan, whereas it decreases in the lower part. In the soils without a groundwater table today, the mottling disappears completely in the underlying B3. On the other hand, in soils with a fluctuating groundwater table the mottling increases again in depth.

In some profiles the lower limit of the pseudogley is abrupt and contains a few centimeter thick layer with, successively from top to bottom, an accumulation of iron and manganese oxides. These profiles are mainly found in very flat plateau positions or in depressions. In the latter profiles the accumulation horizon is situated deeper in the profile (80-130 cm versus 35-60 cm).

10. Where the compact horizon starts nearest to the soil surface (around 20 cm, SK3 and SK4 in Figure 1, and Figure 2) the following structures sequence is observed. (1) The structure is composed of very thin plates (1-3 mm thick) in the upper 5-10 cm of the pan. The packing density of the plates is very high, and no roots pass in-between the peds. Yet discontinuous pores and fissures occur in-between the plates. (2) At a depth of 30-40 cm the structure becomes gradually coarser and lenticular. (3) From 25-35 cm depth this structure type overlaps with the upper part of coarse prisms. These prisms vanish toward the lower limit of the consolidated horizon. The prisms are largest (up to 4-5 m) in the excessively and in the well-drained sandy soils of SK7a and

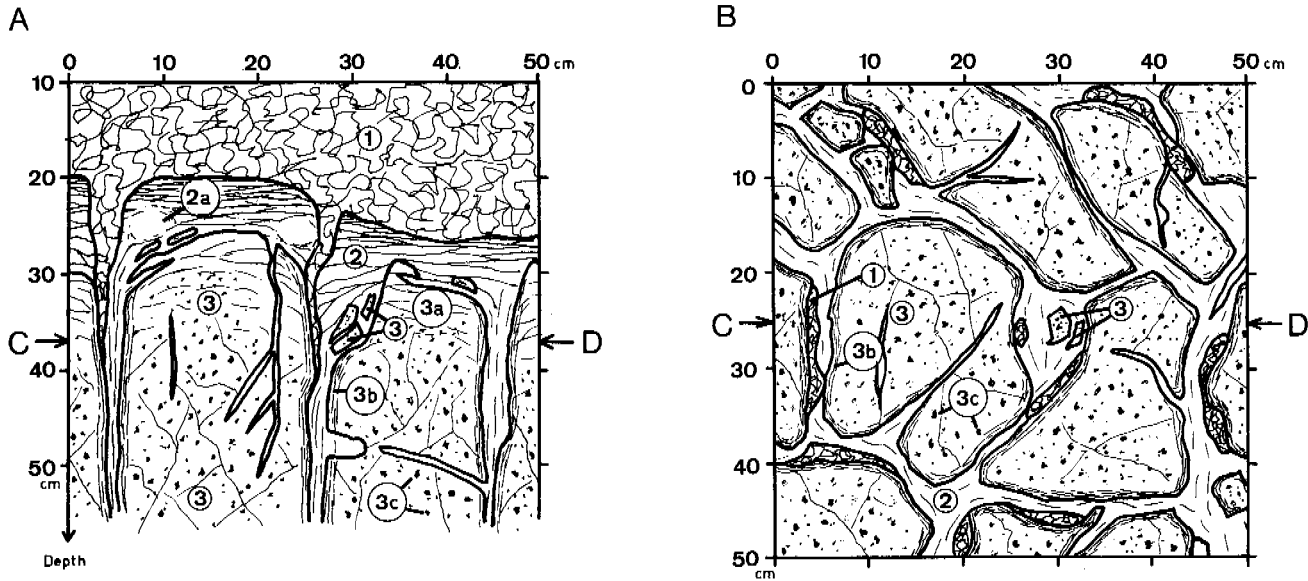

FIGURE 2 Detail of the upper part of a consolidated horizon in an imperfectly drained soil that was under forest and developed in a +20,000 year old loess (SK3 of Figure 1). A : Vertical section-- 1 : biologically very active (B) horizon, with downward tongues; 2 : consolidated bleached A'2g'c' horizon with platy to lenticular structure and tonguing down along continuous vertical streaks, (2a, very compact massive earth nodules). 3 : consolidated B'2t'g'c' horizon with coarse prismatic structure, (3a, upper part of the prisms, with a coarse lenticular structure; 3b, particularly compact rim of the prisms, with weak vertical platy structure; 3c, coarse irregular discontinuous pores inside the prisms). B : Horizontal section at 37 m depth-- 1 : vertical tongues with material of the (B) horizon, all roots are situated here; 2 : vertical streaks with consolidated material similar to the one of the A'2g'c' horizon; 3, 3b, 3c : see A; CD : line of intersection between A and B.

SK8a. They are smallest (5-10 cm) in the somewhat poorly and the poorly drained silt loamy soils. Present-day well-drained soils located in depression also can have relatively small prisms. The outer rim of the prisms, with a width of 0.5-2 cm, has only pores smaller than 0.2 cm and has a weak vertical platy structure oriented parallel to the prism walls. The structure inside the prisms varies from profile to profile and can even vary within the same profile. The most common types are (1) structureless (the stratification of the sediment is still present in SK7 and SK8). (2) moderately fine to coarse angular blocky, and (3) weak very irregularly fine up to coarse prismatic. The in-ped porosity of the prisms is also variable; in the sandy soils few or no pores are visible with a lens; in the medium textured soils, 0.5 up to 2 pores of 0.5-3 mm diameter are present per square centimeter. These relatively large pores have an irregular shape and are discontinuous.

11. A particular feature of most compact horizons is the presence of bleached streaks from a few millimeters up to 5-8 cm wide in-between the prisms (see point 8). They are widest in the upper part of the horizon and gradually become thinner with depth; the largest ones reach a depth of 150-230 cm. The material in these streaks is the same as that in the overlying A'2g'c', whenever this horizon is still present. This was confirmed in at least two soil kinds, (1) in soils where only the A'2g'c' and the streaks contained small charcoal fragments and (2) in sandy loam soils with a graded texture becoming more silty downward and where the

streaks contained the same coarser material as that in the upper part of the pan. The soil material in the streaks is also rather compact, particularly in the upper part of the horizon, where close examination shows only very few pores larger than 0.5 mm and very locally a weak vertical platy structure. The lower part of the streaks can contain larger pores which are irregularly shaped and discontinuous. When roots pass through the consolidated horizon, they do so at the contact between the streaks and prism walls. The largest roots are flat shaped.

12. Locally angular fragments of the brown B'2t'g'c' are included in the bleached A'2g'c' (Figure 2). Inversely, intrusions of the A'2g'c' and of the bleached streaks penetrate along fine fissures into the brown prisms of the B'2t'g'c'.

13. Chemical analysis, total analysis, and clay mineralogy do not show any significant difference between profiles with a consolidated horizon as in SK2 and very similar soils without this horizon (SK1) (Lozet and Herbillon 1971, Guidotti Pena 1976, Van Ranst 1981).

DISCUSSION

Among the Tardiglacial soils, only those of soil kind 1 (SK1 in Figure 1) have no consolidated horizon. In these SK1 soils the presence, relatively close to the soil surface, of a still calcareous parent material is probably not a coincidence and the absence of a consolidated horizon can be explained by the following mechanism. When the upper

part of the soil became compacted, the soil at that depth was still calcareous; as during further pedogenesis the calcium carbonate was gradually leached, the compaction disappeared, and biological activity and roots could easily penetrate; consequently the consolidated horizon was not conserved (Langohr and Van Vliet 1981).

From the data described previously it can be concluded that the formation of the consolidated horizon was mainly a physical process, creating a particular aggregate and porosity fabric associated with or immediately followed by a perched groundwater table. The process had a gradient parallel to the soil surface and was active in all soils, regardless of texture, drainage, and previous profile development conditions. However, parallel to these three soil attributes, differences in morphology of the compact horizon are observed. The process was not active during the Holocene or during the beginning of the Tardiglacial. The latter statement is concluded from the fact that the compact horizon formed after the development of other pedogenetic soil horizons.

Also, the high packing density of the platy and lenticular aggregates in the upper part of the horizon indicate a pedogenetic process that has been active in a period when there were no roots and no worm activity at these depths (+ 20-50 cm). Such an environment does not correspond to what we know of the Holocene in Western Europe.

The question arises whether this consolidation developed during freeze-thaw cycles or whether it is indicative of permafrost conditions.

In soil science literature, more or less similar compact horizons have often been called "fragipan". The author previously used this term (Langohr and Van Vliet 1981). However, in view of the data described in previous chapter, he prefers not to use this term any more. Indeed, as it is defined in USDA Soil Taxonomy (Soil Survey Staff 1975), fragipans are restricted to compact horizons situated below an eluvial horizon. Several of the compact horizons represented in Figure 1, or part of some of these horizons, do not fit in this definition.

Fragipan horizons have been described in many countries (Van Vliet and Langohr 1981). There is no general agreement concerning the genesis of this horizon, and it is impossible to summarize here all the theories that have been proposed. Literature reviews have been made by Grossman and Carlisle (1969) and recently by Smalley and Davin (1982). The latter authors recorded five approaches to fragipan formation. One of these is by periglacial processes. In western Europe, unspecified periglacial processes have been proposed as the cause for the formation of this compact horizon in The Netherlands by Sevink and Vink (1969-1970), and Vink and Sevink (1971) and in Belgium by Lozet and Herbillon (1971). For Scotland, Fitzpatrick (1956) has proposed a link with permafrost conditions and so have Langohr and Van Vliet (1981) for Belgium and northern France.

Ice segregation in lenses, creating a platy or lenticular structure has frequently been observed in active layers (e.g., Pissart 1975, Mackay and MacKay 1976) and in soils with annual freeze-thaw cycles (open system) (e.g., Allan et al. 1969,

Fedorova and Yarilova 1972, Bunting and Fedoroff 1974). Prismatic and blocky structures, on the other hand, are more often described at the level of permafrost layers (e.g., Kuznecova 1973, Svenson 1964, Mackay 1974). The smallest prisms and blocks are mainly observed where permafrost developed in clayey and water saturated sediments.

Several authors mention the particular consolidation of the aggregates as a result of freezing (Mackay and MacKay 1976, Mackay 1974, Pissart 1970). This consolidation, which remains after thawing, seems to be associated with the extreme desiccation and consequent collapsing of the pores during the freezing process.

CONCLUSIONS

The observations from areas with active permafrost today permit to explain the very particular set of characteristics of the consolidated horizons.

1. The thin plates in the upper part of the horizon can correspond to the lower part of the active layer, and the prismatic and blocky aggregates below would then coincide with the upper part of the permafrost.

2. The compact spherical nodules in the bleached A'2g'c' probably are those cores of the lower part of the active layer that freeze last in autumn. From such spots, water can be extracted toward the downward and upward freezing fronts starting from the soil surface and from the permafrost table respectively. This water extraction can promote the consolidation of the soil (Mackay and MacKay 1976).

3. The locally observed thin layer of iron and manganese oxide accumulation is very similar to the layer described by Black (1976) as one of the soil properties indicative of the limit between the active layer and the permafrost.

4. Permafrost conditions can explain the presence, starting from a depth of a few decimeters, of wedge shaped cracks which reach a depth of 1-2 m and a final width of several centimeters in the upper part. Whether these cracks were filled with ice or with soil material, is not yet known. The local presence of a weak vertical platy structure is an argument for a soil wedge; the presence of coarse pores in the lower part of the streaks and the compaction of the outer rim of the prisms points more to ice segregation. Possibly both, soil material and ice, were present.

5. The hydromorphic mottling, coinciding with at least the upper part of the compact horizon, even in landscape positions where today no groundwater table occurs, can be explained by the water saturated layer perched on top of the permafrost table. When the permafrost gradually thawed, this water saturated layer gradually moved downward until the whole frozen layer vanished. This mechanism permits to understand why this mottling occurs along the pores and aggregate faces of the compact horizon.

Considering that the consolidated subsurface horizon is observed in all those Tardiglacial soils where no biological, chemical or physical turbation occurred at that soil depth during the Holocene, we can conclude that in the Tardiglacial, at least

once, permafrost was continuous in NW France, Middle and N Belgium, and The Netherlands.

NUIQSUT AIRPORT DREDGE PROJECT

Craig C. LaVielle, Scott C. Gladden, Alvin R. Zeman

Rittenhouse-Zeman & Associates, Inc.
Anchorage, Alaska

The unique Nuiqsut Airport Dredge Project is the first dredged fill placed over permafrost on the Alaska North Slope. The specially designed 45.7 cm diameter suction dredge capable of being air or truck transported, was used to unify the steps of mining, transporting and placement of the runway embankment fill material. This technique has the advantage of minimizing damage to the fragile tundra and ice-rich permafrost. The need for large on-shore borrow pits and long haul roads was eliminated. Approximately 152,911 cubic meters of sand and gravel was hydraulically placed along the 1554.0 meter long runway right-of-way. The predicted depth of thaw beneath the fill and the amount of thaw consolidation in the natural soils compared well with measured values. The direct placement of dredged fill material on permafrost with controlled and limited thawing of the subgrade has proved to be a rapid, ecologically sound, and cost-effective technique.

Design and construction of the Nuiqsut, Alaska runway was completed in the spring and summer of 1981. This unique project used the direct placement of pumped dredged fill to construct a 1.8 m to 3.66 m (6- to 12-foot) thick runway embankment on an ice-rich permafrost subgrade. Direct dredged-fill placement on permafrost is a new technique to the North Slope. The process had previously been considered too risky for use on thaw-sensitive, ice-rich permafrost because of the large volume of relatively warm river water that is required. However, preliminary analysis indicated that, depending on the thermal regime of the specific site, dredge placement procedures may not only be feasible, but cost-effective in comparison to conventional dragline mining and pit excavations.

Our involvement in the project as geotechnical consultants for the North Slope Borough, included conducting exploration for submerged fill material source areas and detailed sampling of permafrost soils along the proposed runway alignment. In addition, engineering studies were undertaken including a complete thermal analysis concerning the effects that a pumped hydraulic fill would have on thaw-sensitive permafrost. Periodic construction monitoring was maintained throughout the construction process.

PROJECT DESCRIPTION

The Inupiaq Village of Nuiqsut, Alaska is located on the North Slope of the Brooks Range near the head of the Colville River Delta. This isolated village is approximately 402 km (250 miles) east of Barrow and 129 km (80 miles) west of Prudhoe Bay (Deadhorse) Alaska. Air access to Nuiqsut in the past has been limited to a small 457 m (1500-foot) gravel runway and temporary winter landing strip on the ice of Nechelik Channel. During breakup, the runway in the channel is lost. In addition, breakup in the channel often results in the short gravel runway being flooded by the river which may rise 12 m (40 feet) or more above normal channel levels. During the month of June, and at times into July, access to the village is limited to helicopter and light aircraft which are forced to land on the main streets of the village. Even when the small strip is repaired, it is far too short to accommodate fully loaded large cargo aircraft

such as the Hercules C-130 transport planes. For this reason, a large permanent runway located close to the village was deemed necessary. Such a runway would allow transportation of needed construction materials and fuel to the village at any time during the year.

The Nuiqsut runway as planned would be 1554.5 m (5100 feet) long, 45.7 m (150 feet) wide, consisting of approximately 152,911 m³ (200,000 cubic yards) of material. The runway would also have a taxiway, parking apron and a shipping/receiving terminal building. The runway core embankment would have to be constructed of high-quality NFS (non-frost susceptible) fill of sufficient thickness to protect the ice-rich subgrade. The surface course of the runway would also have to be designed for easy maintenance and not be subjected to extensive frost-heave and rutting. In addition, construction of the runway should take place within the short Arctic summer when thawed fill soils could be placed and properly compacted.

Existing borrow sources in the village contained large amounts of silt and could not be considered as non-frost susceptible. In order to construct the runway from locally available sand and gravel, a system was needed for excavation, washing, transportation and placement of clean fill material. Equipment to complete this project must be minimal, since transportation of equipment to the village would be costly, having to be done during the winter across a temporary ice road from Prudhoe Bay. For this reason, the decision was made to utilize a suction-dredge system. The dredge unifies all the steps for mining, transportation and placement of fill along the runway alignment, along with the help of two locally available bulldozers and a grader. Costly haul-roads and trucking equipment would not be needed. In addition, a specially designed dredge could be disassembled into easily transported units and then carried to the site by truck or Hercules C-130 air transport.

Our involvement in the Nuiqsut Runway Project included conducting an exploration for suitable submerged sites of high-quality sand and gravel which were thawed. This material would have to be within

the Nechelik Channel of the Colville River and within a two-mile radius of the runway alignment to allow for pumping. In addition, subsurface sampling must be conducted along the runway alignment in order to determine the nature of the underlying permafrost. This information in turn would be utilized for the thermal analysis of the site to determine the thaw-sensitive nature of the permafrost. Finally, during construction phases of the runway, we would monitor fill procedures to insure quality control. At this time, temperature probes would be installed both in the center of the runway and along its perimeter to monitor thaw depths during construction and to determine the long-term outcome of dredge-placed fills of this size.

SUBSURFACE EXPLORATION

Material Source:

A subsurface exploration for suitable submerged high-quality sand and gravel for the Nuiqsut Runway was conducted during the summer of 1980 and winter of 1981. As previously discussed, the dredge system together with its booster pump, had a practical discharge limit of two miles. For this reason, material had to be located within these limitations and in sufficient quantities to complete the project.

The first phase of exploration was to conduct a summer surface-deposit reconnaissance within the Nechelik Channel. This was done in order to observe fluvial deposition characteristics of the channel as well as locating strand and bar deposits of sand and gravel. Likely areas of accumulation were denoted on a topographic map of the area. These locations were then used to delineate areas for subsurface sampling. The subsurface exploration within the Nechelik Channel took place during the winter of 1981. The frozen condition of the channel and upland tundra allowed access to sites of expected sand and gravel accumulation delineated during the summer reconnaissance.

In general, the ice thickness at the time of exploration on the channel ranged from 1.8 m to 2.4 m (6 to 8 feet) underlain by approximately 3 m (10 feet) of water followed by thawed sediments in the thalweg of the channel. Where the channel water was less than 1.8 m (6 feet) deep, the water and sediment were completely frozen except for remnant talik zones within the sediments at depth. In order to cut through the ice for bottom sampling, a 15.2 cm (6-inch) solid-stem auger was advanced as a pilot hole, utilizing a Nodwell-mounted Acker Mark IV drill rig. Once the pilot hole was completed, an 8-inch hollow-stem auger was attached and advanced down through the pilot hole and underlying water to the thawed sediments below. At this stage, samples were taken of the thawed sediments through the hollow-stem auger at selected intervals. These samples were used to determine quality and quantity of the deposit as well as to detect the permafrost boundary if encountered. This procedure proved useful for acquiring relatively undisturbed soil samples. However, at temperatures below -40°C (-40°F), freezing of water within the hollow-stem auger caused a slowdown in production. These problems were not encountered when ambient air temperatures were above -32°C (-25°F). Exploration of the channel was successfully completed

upon delineating approximately 49,699 cubic meters (65,000 cubic yards), pit-run grade sand and gravel and 168,212 cubic meters (220,000 cubic yards) of fine to medium sand, (see Figure 1 for range in grain size distribution).

Runway Alignment:

The second phase of exploration involved taking continuous core samples at 61 m (200-foot) intervals down the proposed runway alignment. This was done in order to determine the subsurface soil and ice conditions to facilitate thermal analysis of the thaw-sensitive permafrost. Each test boring location was cored to a depth of at least 1.5 m (5 feet). These samples were extruded on-site, classified, photographed, and returned undisturbed to our Anchorage laboratory for thaw consolidation tests. Drilling fluids were not used for this coring procedure.

Typically, the subsurface soils along the runway alignment consisted of a 15 cm (6-inch) tundra mat over sandy, ice-rich organic silts to a depth of .61 m to 1.5 m (2 to 5 feet). Underlying the silts were generally found silty medium sands having a high ice content. Ice formations generally occurred as pore ice, veins, lenses, and in massive formations.

DREDGE, HYDRAULIC FILLING PROCESS and RUNWAY CONSTRUCTION

The technique of direct placement of pumped dredged fill was used to construct the airport runway embankment at Nuiqsut, Alaska. The direct placement technique has several distinct advantages over more traditional techniques of fill embankment construction. The advantages include unifying the project operations of mining, transporting, placing, washing and compacting the fill material. By unifying these operations, significant construction cost savings are realized. The direct placement technique also proved to be more environmentally acceptable than the traditional open-pit mining and trucking techniques.

The Nuiqsut Airport project used an 946 cm (18-inch) suction dredge to mine the thawed sands and gravels from the sources located in the river channel (see Figure 2). The special unitized dredge, designed by Dredging Consultant, Michael Weston, is approximately 12.8 m (42-feet) long. A 9.1 m (30-foot) ladder with the suction pipe and a revolving cutter head allowed material to be mined from as deep as 7.9 m (26 feet) below the water surface. Two large pumps, one onboard the dredge and a second acting as a booster pump at the half-way point, pumped the sands and gravels up a 6.1 m (20-foot) rise and out onto the alignment. Sand and gravel was pumped 3.2 km (2 miles) to the farthest end of the runway alignment utilizing a 46 cm (18-inch) diameter, 4.45 cm (1.75 inch) thick polyethelene pipe as a discharge line. Approximately 3823 cm (5000 cubic yards) per shift was delivered to the site.

The excavation and transportation of the sand and gravel to the site required only two dredging pumps, as opposed to the traditional fleet of loaders and trucks. For this reason, no haul-roads were needed from the borrow source area. Therefore, all fill material could be used on the project itself. The

traditional maintenance headaches of pit operations in the arctic such as frozen stockpiles, thawing and draining stockpiles, pit drainage, and blasting were avoided.

The construction of the Nuiqsut Airfield required some 152,920 cubic meters (200,000 cubic yards) of select fill with frost-susceptible silt and clay materials removed. Once staking of the runway limits was finished, a small dike approximately .91 m (3 feet) high and 3.65 m (12 feet) wide was constructed around the perimeter of the proposed runway (see Figure 3). These dikes as well as the parking apron and taxiway were constructed of silty sand scraped and truck-hauled from small channel bar deposits. The dredge located approximately two miles distant in the Nechelik Channel of the Colville River, was maneuvered over a known, submerged sand and gravel deposit.

As the saturated dredged material was deposited at the end of the outfall line, two small bulldozers (Caterpillar D5 and D7) graded the fill across the runway alignment building up the dikes as needed see Figure 4. The winch-equipped dozers could move the flexible discharge line laterally across the runway. When enough material had been deposited at any one spot, sections of the plastic pipeline were quickly cut and removed, shortening the line. If extension of the pipe was required, a small portable fusion weld machine was used. As the water settled out of the fill material, consolidation of the soil took place, leaving a well-compacted NFS material averaging 90 to 95 percent of the laboratory maximum density (ASTM:D-1557). The millions of gallons of water used to carry the sand and gravel was allowed to drain from the fill to a settling pond at the middle of the runway and then pumped back to the river. The rapid draining of the water acted to wash the sands and gravels and carry the silt and clay fines down to the settling pond. In addition, the washed fill material was densified due to active water settlement. For this reason, no compaction equipment was required for the embankment core to meet compaction specifications.

The above described filling process was continued until the eastern third and western third of the runway was completed. At this point, a large stockpile of material was collected on the borders of the settling pond located in the middle of the runway. The return pump was dismantled and frost-susceptible silt accumulation removed. The stockpiled fill was then placed into the location of the excavated silt pond completing the core embankment of the runway. The entire fill project was completed within 75 days during the short Arctic summer. The following summer, stockpiles of substantial quantities of gravel for other village improvement programs and for the gravel topping course of the runway was collected and crushed. At this time, the 1555 m (5100-foot) runway can support a fully loaded C-130 Hercules transport aircraft. The permanent runway surfacing consisting of approximately 25 cm (10 inches) of compacted crushed gravel will allow all-season operation and is currently being installed.

By combining the mining transporting, washing, placing and compacting operations, significant

construction cost savings was achieved. The savings came as a result of reductions in the required fuel, labor and capital costs.

CONSTRUCTION MONITORING

Thawing beneath the fill as a result of the hydraulic filling process was monitored at five points in the runway alignment. Monitoring points were placed at center line STNs 14+50, (feet) 23+50, 31+50, 38+50 and 45+00. The temperature of the soil was measured by means of thermistors placed at depths ranging from 0.3 to 2.1 m (1 to 7 feet) below the top of the tundra. Measurements were made at random intervals not exceeding two weeks, throughout the construction period. A plot of the temperature beneath the fill from July 1981 through October 1983 are shown in Figure 5.

Maintaining the monitoring stations and thermistor wires proved to be difficult. Construction equipment moving along the containment dikes while moving the discharge pipe frequently cut the wires. In addition, ground squirrels chewed through several of the buried wires.

Thirty-three compaction tests, using a nuclear densometer were also taken along the full-length of the runway near the top of the completed fill surface. The test results ranged from 90-95 percent of the laboratory maximum using ASTM:D-1557 as the standard. Observation wells were installed in early September at five locations along the right-of-way; STNs 25+00, 30+00, 35+00, 40+00 and 45+00. The reading obtained during the early September period indicate water depths averaging just over 1 m (3 feet) below the finished runway surface. The compaction test results and the temperature readings over a one-year period show the fill is performing very well and that a total freeze-back was achieved and a second-season thawing did not penetrate the base of the fill.

A significant benefit of suction dredging versus open-pit mining was that washing of the sand and gravel fill material occurred during placement. Grain size analysis of the source materials prior to dredging indicated a silt and clay content of up to 10 or 12 percent finer than .07 mm. Samples obtained of the completed runway showed that 90 percent of the silt had been removed. A technically non-frost susceptible (NFS) material with less than 1 percent finer than .02 mm was produced without expensive screening.

LABORATORY TESTING

The laboratory phase of our thermal study included a series of tests designed to determine the material parameters pertinent to this project. These material parameters included grain size distribution, total moisture content and dry unit weight. The thermal properties of soil thermal conductivity and heat capacity which are used in the thermal analyses could be derived from these parameters.

The results of our laboratory testing program, have shown that the natural soils along the runway alignment tend to display high ice contents and low dry unit weights. Moisture contents of the tundra ranged from 41% to 237% and averaged 172%.

Moisture values for the silt unit ranged from 46% to 368% and averaged 127%. Moisture values for the sand unit ranged from 19% to 188% and averaged 42.5% by weight. Dry unit weights averaged 309 kg/m (19.3 pcf), 637.5 kg/m (39.8 pcf), and 1401.8 kg/m (87.6 pcf) for the tundra, silt and sand units respectively.

In addition, a series of thaw consolidation tests were performed on the frozen, undisturbed core samples taken from the runway alignment. The thaw consolidation tests consisted of cutting 5 cm (2-inch) long sections from the 6.4 cm (2-1/2 inch) diameter, undisturbed core samples, and loading the thawing sample with 147 to 295 kg per square meter (720 to 1440 psf for 48 hours). This surcharge is approximately equivalent to the load which would be expected to be imposed by the completed runway fill. The samples were kept saturated and confined within a bronze ring 6.4 cm (2-1/2 inch) in diameter during consolidation. Sample drainage was allowed through both top and bottom of the sample, by means of filter paper and porous stones. The mean percent consolidation for tundra unit and the silt unit was 36 and 23 respectively. The range of consolidation values was 15% to 55% for the tundra and 17% to 32.5% for the silt unit.

Although only three basic soil types were involved in our study, a wide range of soil thermal conductivities were found to apply. Thermal conductivities were determined from curves published by Kersten (1949). It was noted that soil thermal conductivities can change significantly with changes in moisture content, soil dry unit weight, soil temperature and changes from the frozen to the thawed state. Of the variables mentioned above, all were expected to effect the soils in the runway alignment. The greatest variations in thermal conductivity would be due to the wide variation in soil moisture content. As previously mentioned, the moisture contents in the tundra unit varied from 41% to 237% by weight. According to the charts published by Kersten for peat, this variation in moisture content represents a variation in soil thermal conductivity of .1038 to 1.038 W/(m°C) (0.06 to 0.6 BTU/hr ft °F) in frozen peat and .086 to .43 W/(m°C) (.05 to .25 BTU/hr ft °F) in frozen peat. Conductivity values for the silt unit and sand unit averaged 1.21 W/(m°C) (0.7 BTU/hr ft °F and 3.07 W/(m°C) (1.78 BTU/hr ft °F) respectively.

The variations in thermal conductivity caused by temperature and the changes from the frozen to the thawed state were dealt with by averaging the frozen conductivity with the thaw conductivity ($k_u+k_f/2$).

In order to perform a meaningful thermal analysis of the entire runway alignment, it was necessary to assume mean soil properties. By taking this approach in our analyses, we realized we would lose some accuracy in our depth-of-thaw estimates in localized areas. However, a large overall view of the scale of potential thawing was produced and, therefore, the project's feasibility could be presented. An accounting of the possible consequences of deeper thawing in areas where the deviation from our mean soil properties occurred was also made. The deviation

was then used along with experience to temper the estimates presented.

THERMAL ANALYSES

The thermal analyses consisted of determining by mathematical methods the estimated depth of thaw to be expected in the natural frozen ground as a result of the hydraulic filling operation; the estimated time required for freeze-back of the thawed natural soils and the fill itself. These estimates are based upon the assumed conditions and parameters of an undisturbed tundra mat, subsurface soils, the mean Nuiqsut area climatic conditions, and thermal conditions imposed by the hydraulic filling operation. The soil parameters were determined experimentally.

The climatic condition assumptions were obtained from data published by the Environmental Atlas of Alaska, U of A, Fairbanks. The conditions assumed for this study are listed below.

<u>Nuiqsut Townsite Area</u>	<u>Parameters</u>
Thawing Index	500 degree-days
Length of Thaw Season	95 days
Freezing Index	8500 degree-days

The length of the thaw season has been defined as the number of days that have a mean daily air temperature (M.A.T.) above 0°C (32°F). Typically, the months of June, July, August, compose the thaw season, at Nuiqsut, although a variation of one-half month on either end is possible. The initial part of our thermal analysis consisted of constructing as complete a picture as possible, of the events, time tables and temperatures anticipated for the filling operation.

The model of the hydraulic filling operation consisted of millions of gallons of a sand and gravel slurry being quickly placed on the frozen soil. The sand and gravel slurry pumped from the river would tend to initially act as a constant temperature heat source. The temperature of the slurry was estimated at 7°C to 10°C (45°F to 50°F). This constant temperature heat source would allow heat to flow into the soil causing melting and thaw consolidation. The temperature of the slurry fill presumably then would tend to cool near it's base as heat was lost to the frozen soil. The surface of the slurry/ fill would either warm or cool in response to changes in air temperature and solar radiation. The rate of temperature change in the slurry/fill would depend strongly on how quickly the fill drained. The drained fill would tend to reach an equilibrium more rapidly with the frozen subgrade and the air.

The heat capacity of the river water is far greater than the soil particles. Therefore, the water in the fill was acting as the constant heat source. By draining the water away, thawing could be limited. If the water could be drained away quickly, only the climatic influences of air temperature, wind speed, and solar radiation on the dark fill surface would promote thawing. The completed thickness would tend to insulate the natural soils from the climatic influences and limit thawing beneath the fill.

Our analysis assumed a maximum of two days would be required to place the full thickness of fill

over the new area. The surface of the fill was expected to drain within hours. The base of the fill, however, was anticipated to require three months or more to drain. Complete drainage of the fill would not be required and would not be advantageous. Additional insulation against climatic influences would be available if most of the fill retained a moisture content equivalent to 10 percent of the dry soil weight and the lower 15 cm (6 inches) of fill remained saturated.

Our study of the subsurface thermal aspects of the placement of hydraulic fill indicated the project was feasible if proper drainage could be maintained. Our conclusions covering potential thawing and thaw consolidation are presented below with a discussion of what actually occurred.

The estimated average depth-of-thaw beneath the existing tundra surface was 1.1 to 1.2 m (3½ feet to 4 feet). Variations in the depth of thaw were of as much as ± 0.3 m (1 foot) could be expected depending on local conditions. This estimate was based again on a 95-day filling period. In actuality, approximately 75 days were required to complete the runway fill. Measured depths-of-thaw averaged 0.76 m (2½ feet) with as little as 0.6 m (2 feet) of thaw occurring in some areas and as much as 1.5 m (5 feet) of thaw occurring in a small localized area. The maximum depth of thaw that actually occurred (0.76 m) was within the range anticipated. The total filling period was approximately 25% shorter than assumed and a proportionately reduced amount of thawing were found to have occurred.

The total percent consolidation of the thawed soils was estimated at 25% of the newly thawed thickness or approximately 0.3 m (1 foot) of the estimated 1 to 1.2 m (3½ feet to 4 feet) thaw depth. Considering the wide range of ice and soil conditions, actual ground settlements were expected to range from 0.23 to 0.46 m (¾ to 1½ feet). The actual thaw consolidation that occurred averaged approximately 0.30 m (1 foot). The range of settlement that occurred at the points measured was as much as 0.46 m (1½ feet) and as little as 0.15 m (½ foot). The correlation between the estimated and the actual consolidation are good. Actual consolidation was slightly overestimated, possibly because lesser amounts of ice were present than assumed. The estimated date of freeze-back of the total thickness of fill and thawed natural soil was mid-February. A frozen thickness sufficient to allow for heavy aircraft traffic was estimated to exist by mid-October. Actual total freeze-back of the fill and the natural ground was complete by early January. Our estimate proved to be conservative but within an acceptable range. Although sufficient data is not available for any theoretical analysis, we do expect that the raised profile of the fill mass allowed greater exposure to the wind and more rapid cooling than initially were anticipated.

SUMMARY

Until quite recently, sand and gravel for construction purposes has been mined from large upland pits. These huge pits become a permanent feature in the Arctic landscape along with their attendant haul roads. Even so, at many locations

across the North Slope of Alaska there is a lack of quality sand and gravel which could be considered as a suitable Arctic construction material. Where present, these sands and gravels contain high percentages of silt or clay which renders them marginally suitable at best for use in roads, pads and runways. Other methods of mining and improving the quality of the borrow material, such as by washing or screening, have normally not been considered economically feasible in the short construction season.

As an alternative to pit mining and truck hauling, the runway at Nuiqsut represents the first major use of a pumped dredge fill on upland permafrost. A special 46 cm (18-inch) suction dredge, capable of being broken down into truckable units, was designed and constructed for this project as well as future projects planned by the North Slope Borough. The use of a dredge for this major fill allowed for the mining, washing, transportation and placement of the material by essentially a single piece of equipment.

The use of a dredge for mining and placing fill material has been hampered in the past by concerns about thawing and thermal degradation of ice-rich permafrost. This project has demonstrated that with proper engineering and construction techniques, the use of a dredge for material extraction and placement offers a viable option to open-pit mining for sand and gravel. In the future, we expect to see dredges such as this used for the extraction and placement of materials for the many proposed offshore oil drilling islands.

Aside from the advantages associated with extracting and placing fill materials, the use of a dredge can have important advantages from an environmental standpoint. Rather than being left with the scars of an open-pit, the deepened channel in this case study is expected to provide an improved overwintering habitat for fish in the river. At the same time, there has been little or no damage to the surrounding tundra or beaded streams since an extensive system of haul roads was not required.

ACKNOWLEDGMENTS

We wish to acknowledge the important participation of Michael Weston, Dredging Consultant, on this project. Mr. Weston performed the early feasibility studies as well as being in charge of the design, construction and operation of the dredge. Our studies were sponsored by the North Slope Borough, the governmental unit responsible for dredge funding and runway construction. Particular credit is due Mayor Eugene Brower and Public Works Director, Irving Igtanloc, who actively supported this innovative construction technique.

GROUND ICE IN PERENNIALY FROZEN SEDIMENTS, NORTHERN ALASKA

D. E. Lawson

U.S. Army Cold Regions Research and Engineering Laboratory
Hanover, New Hampshire 03755 USA

The distribution and volume of ice in perennially frozen sediments beneath three unglaciated sites in northern Alaska vary with the grain size and depositional origins of the sediment, thermal history (permafrost aggradation and degradation), and age of the terrain and deposits. Substantial lateral variation in near-surface ice volume exists between and within each site, but reasonably consistent trends in ice content with depth were measured beneath individual landforms. Primary deposits, those deposited and frozen without postdepositional thermal or sedimentologic modification, contain the highest volume of ice at each locality. Sediments that have undergone thawing or resedimentation typically contain much less excess ice. Thaw lake, slope, or fluvial processes modify ice contents and produce sedimentary sequences with a spatial distribution of ice determined by these depositional processes and the subsequent thermal history.

The volume, distribution, and configuration of ice in perennially frozen ground are extremely important parameters that affect its physical response to disturbance as well as its geotechnical properties (e.g. Muller 1947, Terzaghi 1952, Ferrians et al. 1969, Mackay 1970, French 1975, Johnston 1981, Lawson 1982). Although knowledge of the occurrence and types of ground ice has substantially increased (e.g. Mackay and Black 1973, Mackay et al. 1978), few studies have analyzed the volume and distribution of ground ice in North America in relation to geologic parameters. There are few published measurements or estimates of ice volume for North American regions or sites (e.g. Livingstone et al. 1958; Carson and Hussey 1962; Black 1964; Hussey and Michelson 1966; Brown and Sellmann 1973; Williams and Yeend 1979; Pollard and French 1980).

From 1978 to 1981, I examined ground ice in perennially frozen sediments at three unglaciated localities in northern Alaska: Oumalik, East Oumalik, and Fish Creek (Figure 1). Each site is the location of an exploratory well drilled about 30 years ago by the U.S. Navy in Naval Petroleum Reserve No. 4 (now designated National Petroleum Reserve, Alaska) (Reed 1958). This paper summarizes the data on ice volume and its relationship to each site's physical attributes and recent sedimentary history. A paper in preparation will discuss the results of the analyses in detail.

METHODS

The geology and occurrence of ground ice were defined by drilling and coring 375 holes ranging in depth from about 2.5-40 m. An additional 450 holes were augered to depths of 1.5-11 m. Drill holes were generally located along transects across the primary landforms at each site.

After logging the geology of each drill hole, frozen samples were selected, usually at an interval of 1 m or less (max. 2-m spacing), for laboratory analyses that included grain size distribution, moisture content by weight, ice content by volume, organic content by loss-on-ignition, and bulk/dry density following standard techniques. The undisturbed frozen cores were 7.5 cm in diameter, with samples cut to a 5-cm length. Degree of saturation, porosity, void ratio, and textural statistics were calculated from the analytical data.

GROUND ICE OCCURRENCE

Fish Creek

The Fish Creek site lies on the Arctic Coastal Plain in a region of gently rolling terrain with low relief and numerous oriented lakes and drained lake basins that are commonly separated by ridges of inactive eolian dunes (Sellmann et al. 1975, Williams

FIGURE 1 Location of Oumalik, East Oumalik, and Fish Creek in northern Alaska.

et al. 1977). Sediments beneath Fish Creek, as well as at Oumalik and East Oumalik, are part of the Gubik formation of the Quaternary Age (Black 1964). They range from about 10-20 m thick over bedrock at this site. The landforms examined were drained lake basins, an intervening upland surface between those basins, and stream valley floodplains and slopes (Figure 2).

The upland surface is composed of 8-14 m of eolian sand that overlies a second sand that is of fluvial, or possibly marine, origin. The eolian deposits are stratified to massive, well-sorted, fine-grained sand, with some layers of medium-grained or silty sand. Some sections exhibit high angle cross-bedding. Organics are generally sparse (1-3%), but stringers of peaty material are interspersed randomly throughout. The underlying sands are medium- to fine-grained and stratified, with horizons rich in polished pebbles, shell fragments, and disseminated organic materials mixed with silt. Radiocarbon analysis of six in situ peats in the upper 3 m yielded ages ranging from 2200-3500 yr B.P., while an organic-rich horizon at the approximate contact of the two sand units yielded an age of 22,750 \pm 1700 yr B.P. These dates suggest deposition of the eolian sands in late Wisconsinan time; they are correlative with sand sea deposits described by Carter (1981).

Ground ice is mainly interstitial, filling voids between sand grains. Less frequently, irregular lenses (5-10 mm across) and thin veins (0.1-3 mm thick) are present. Ice volume was fairly consistent to depths of 15-18 m, ranging generally from 40-50%, with volumes of up to 68% measured in strata containing silt or organic material (Figure 3a). Ice volume was most variable near the contact of the two sand units. Most samples were unsaturated.

Wedge ice was encountered only near the ground surface in association with irregular, polygonal

troughs of 5-15 m spacing. Wedges range from 1.5-2.4 m in width at the top and extend 2.3-3.2 m below the surface. They compose about 10-15% of the upper 10 m of sediment.

Lacustrine deposits in the drained lake basins consist of interstratified silt, sandy silt, and fine sand, with peaty horizons (40-60% organics by weight), organic-rich zones, and shelly zones common. Alternating light silt and dark sandy silt layers (2-3 mm thick) commonly form a varve-like stratification. These deposits average 3-4 m thick in the large basin east of the upland (5.5 m in a mound near basin center), and 1-1.5 m thick in the smaller basin to the west (Figure 2). Radiocarbon analyses of peat horizons indicate deposition in the eastern basin began about 10,700 \pm 230 yr B.P. and ended near 8900 \pm 180 yr B.P., while activity in the western basin took place after 3500 yr B.P.

The lacustrine deposits are underlain by two stratified sands that appear laterally continuous with upland deposits. The physical properties of these sands are the same as the upland sand, except that the upper unit is only 3-6 m thick and both units contain much less ice in veins and lenses.

Ice volume of basin sediments is a highly variable 50-90% in the lacustrine deposits but drops sharply to a consistent 30-40% in the lower sands (Figure 3b). A comparable downhole trend in ice volume was measured by Hussey and Michelson (1966) in sediments beneath drained lake basins near Barrow. Ice in the lake deposits occurs as lenses (2-30 mm thick), veins (0.1-3 mm thick, of vertical to horizontal orientation), and thin layers (10-15 mm). Ice wedges in the eastern basin are similar in dimension to those of the upland, while those in the western basin are smaller (1.5-2.4 m deep, 1.1-1.7 m wide). Larger segregated ice bodies (up to 15 cm thick) form mounds located near the center of the basins (Figure 3b). Whereas lake deposits are generally saturated or oversaturated, underlying sands are unsaturated. Further, these sands are less saturated with ice than those of the upland and have a higher bulk density and lower void ratio.

The trend in ice volume with depth can be explained as the direct result of the thaw lake cycle (Britton 1967), with the lower ice volume of the sand a result of its thaw during lake formation and expansion. Thawing of sediments beneath lakes that are more than 2 m deep will melt the ground ice, thereby inducing thaw subsidence and consolidation. The higher density and lower void ratios of the sand in comparison to upland deposits suggest that compaction has taken place. Refreezing after lake drainage then "resets" the content and distribution of ice in the sand. During freezeback, water may migrate toward the freezing front, particularly into the lacustrine deposits, but ice in the underlying sand would be derived mainly from interstitial water present in its unfrozen state.

Indirect support for this process is that upland sands, which thawed because of disturbance by activities on the old drill site, then subsequently refroze, show a similar change in physical properties, with ice volume decreasing to a relatively consistent 35-40% (Lawson 1982). In addition, similar ice contents are found in the colluvial deposits mantling valley slopes and the sand underlying the alluvium in the stream valley, which also presumably thawed during fluvial activity (Figure 3c).

FIGURE 2 Aerial photograph of Fish Creek (BAR 741-030, 7/10/48). Lines indicate general position of drilling transects. Landforms examined include (1) upland sand surfaces, (2) drained lake basins, and (3) stream valley floodplain (scale 1:20,000). North to top.

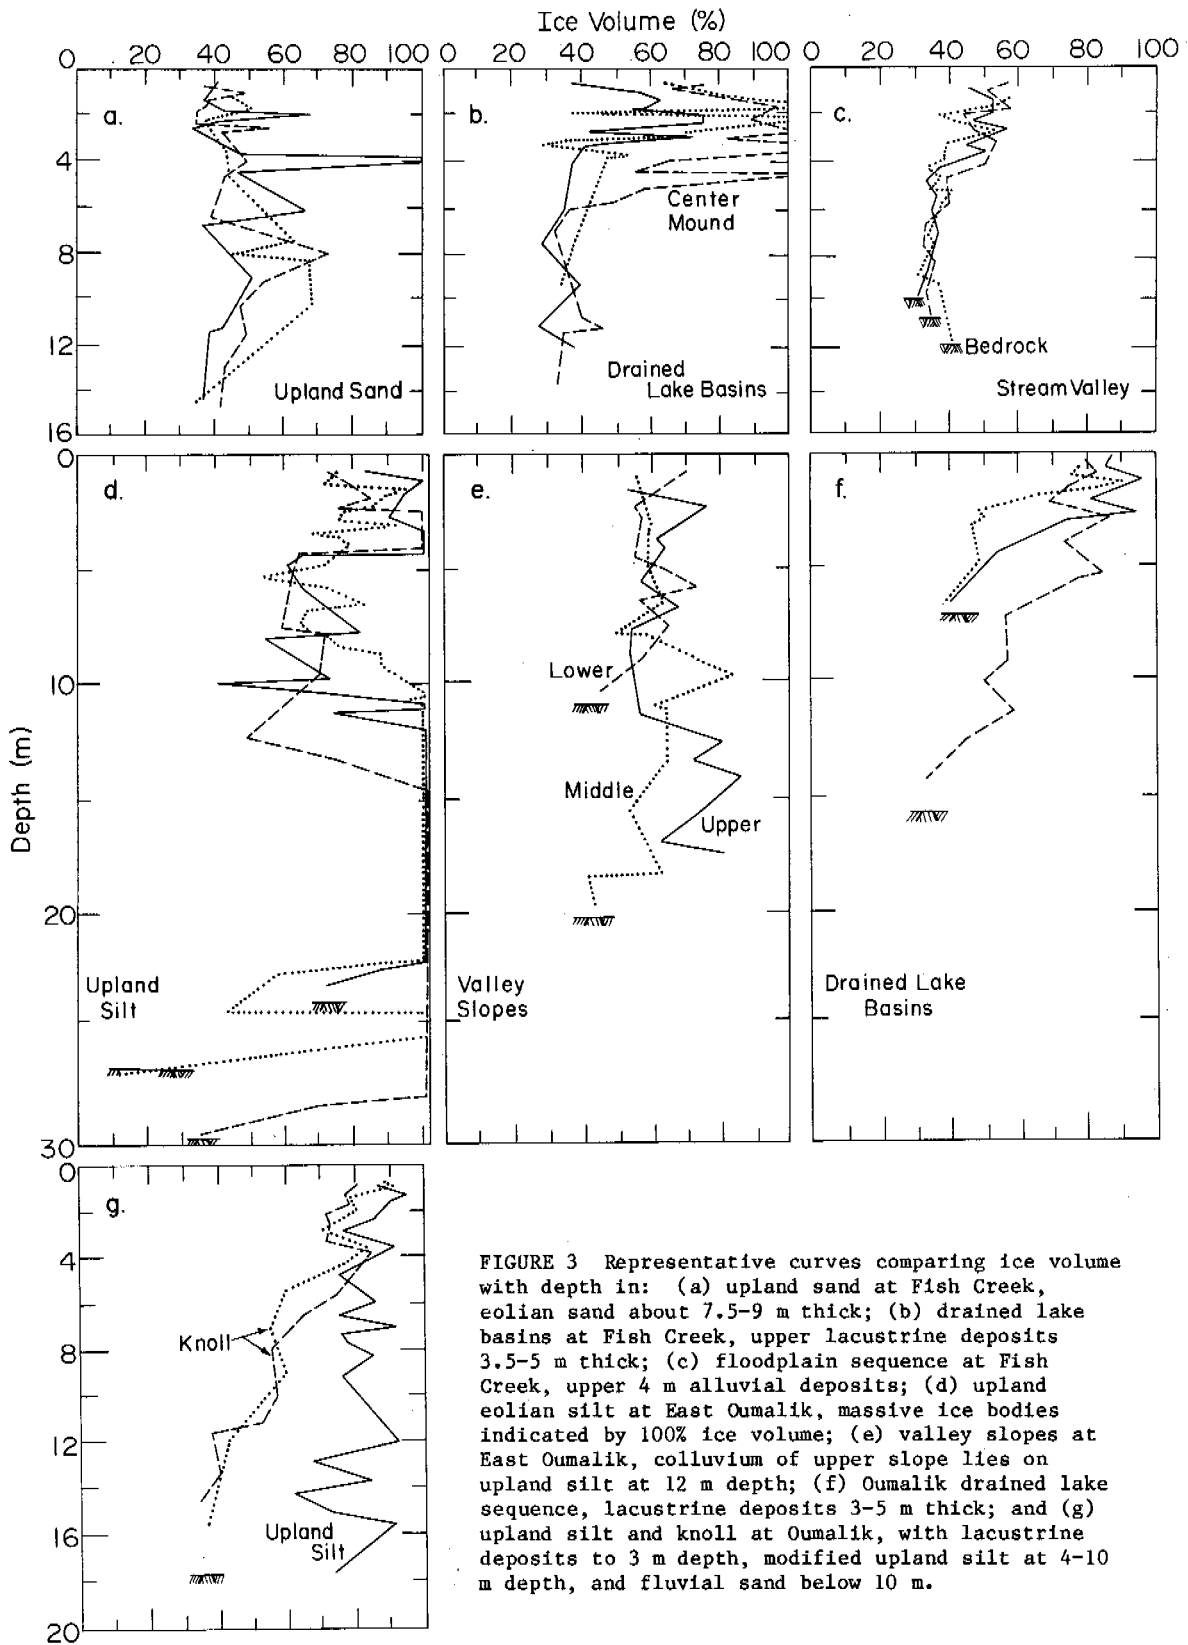

FIGURE 3 Representative curves comparing ice volume with depth in: (a) upland sand at Fish Creek, eolian sand about 7.5-9 m thick; (b) drained lake basins at Fish Creek, upper lacustrine deposits 3.5-5 m thick; (c) floodplain sequence at Fish Creek, upper 4 m alluvial deposits; (d) upland eolian silt at East Oumalik, massive ice bodies indicated by 100% ice volume; (e) valley slopes at East Oumalik, colluvium of upper slope lies on upland silt at 12 m depth; (f) Oumalik drained lake sequence, lacustrine deposits 3-5 m thick; and (g) upland silt and knoll at Oumalik, with lacustrine deposits to 3 m depth, modified upland silt at 4-10 m depth, and fluvial sand below 10 m.

East Oumalik

East Oumalik, which lies near the southern boundary of the Arctic Coastal Plain, is located in an area of upland surfaces cut by meandering streams and active, often deeply incised, thaw lakes (Figure 4). The maximum relief is about 20 m.

The upland at East Oumalik (Figure 4) is composed of relatively homogeneous silt that overlies sedimentary bedrock at a depth of 24-39 m. Approximately 80% or more of the upland silt ranges in size from 0.01-0.06 mm. It is structurally massive or faintly to strongly laminated, with occasional strata of fine sandy silt. Some strata exhibit low angle cross-bedding. Organics are sparse, with organic-rich horizons (10-30%) limited to the upper 2-3 m, and only small fragments of wood (2-3 mm) or fibrous material randomly disseminated at depth.

The upland silt is interpreted as eolian in origin. Its age is not well defined. Twelve radiocarbon analyses of organics within 2-3 m of the surface yielded ages ranging from $10,550 \pm 150$ to 5980 ± 115 yr B.P., while fibrous material and wood at depths of 6 and 12 m were older than 37,000 yr B.P.

Extreme variability in ice volume, with rapid shifts from 50-100%, characterizes all holes in the upland (Figure 3d). Ice occurs as irregular lenses (0.1-20 cm thick), discontinuous layers (generally 5-10 cm thick, but exceptionally to 2 m), veins in near-horizontal or near-vertical orientation (0.1-5 mm thick), and a massive sill (tabular body).

The ice sill ranges from 11-13 m thick and may compose up to 50% of a vertical section above bedrock. It is laterally continuous over at least

8 km², occurring in the lower part of each upland hole and separated from bedrock by a 0.5-3.5-m-thick layer of silt and weathered rock. Debris may be suspended randomly within the ice, or it may occur in veins that parallel or cross-cut ice foliation. Fracture fillings are also common. Alternating bubble-rich and bubble-poor ice in bands of varying thickness (1-10 cm) contain mostly spheroidal bubbles. Analyses of the ice sill data are continuing, but the similarity of the ice to the segregation ice of Mackay (1971) and Gell (1976) suggest that it is also of a segregated origin.

Downhole variability in ice volume and form does not relate to changes in grain size distribution or other sedimentary features, suggesting cryogenic processes were more important in determining ice occurrence. The increase in the ice content of sediments just above the ice sill, and the decrease below it, may relate to these processes.

Ice wedges in the upland are from 5-10 m wide at the top and extend to a depth of 7-15 m. Wedge ice may compose up to 60-70% of the upper 10 m of the upland. Two sets of ice wedges, one without surficial expression and apparently inactive, are present. The top surface of the "inactive" wedges occurs at a depth of about 0.9-1.2 m, whereas the other wedges lie at 0.3-0.7 m. The present active layer thickness of the upland is 0.3-0.6 m.

Colluvial sediments of the stream valley slopes, the lower parts of which have been reworked by solifluction, show less spatial variability in ice volume, generally in the range of 50-70% (Figure 3e). Thin veins (2.1-5 mm thick) or small, irregular lenses (1-10 mm thick) are common, but larger bodies of ice are not. These deposits form a wedge that mantles valley slopes to a thickness of more than 15 m at some locations.

FIGURE 4 Aerial photograph of East Oumalik (BAR 124-147, 9/6/48). Lines indicate general location of drilling transects. Valley slope (1) and upland silt (2) are located (scale 1:20,000). North to top.

Oumalik

Oumalik, located about 18 km west of East Oumalik (Figure 1), is an area principally of coalesced, drained thaw lake basins, many of which contain or are separated by remnants of uplands like those at East Oumalik (Figure 5). The lake basins are poorly drained and are covered by polygonal ground.

Silt beneath the uplands at Oumalik (Figure 5) is physically and mineralogically similar to that at East Oumalik. The radiocarbon ages of near-surface peat horizons (upper 5 m) are correlative. The silt is therefore believed to be contemporaneous wind-blown material derived from the same source. The distribution and volume of ground ice are the same as at East Oumalik (Figure 3g), except that an ice sill was not encountered.

The upper lacustrine deposits beneath drained lake basins consist of 4-6 m of silt or silty clay, with occasional strata of fine sand. They possess a well-defined horizontal stratification (0.5-2 cm thick) including varve-like couplets. Sedimentary structures, including flame structures, load casts, and graded bedding, occur within some strata. Organic material is disseminated throughout the deposits, with peat and woody horizons common in the upper 3 m. The lake deposits lie directly on bedrock or on a thin layer (<2 m) of fine to medium sand over bedrock. Radiocarbon dating of six peat samples suggests lake activity was established by

FIGURE 5 Aerial photograph of Oumalik (BAR 106-117, 9/4/48). Lines indicate general position of drilling transects. Upland (1), drained lake basins (2), and knoll (3) are located (scale 1:20,000). North to top.

7500 yr B.P. and continued for at least another 1500 years.

Ice occurs as small lenses, veins, and irregular layers (max. 20 mm thick) within the lake deposits, composing 60-90% of the upper 4 m (Figure 3f). Within basinal slopes, lake deposits overlies silt, like that of the uplands, but with an ice content of from 50-60%. Melting of excess ice in the silt during thawing beneath the active lake accounts for the lower ice content. Ice occurs as sporadic, small lenses (1 mm) or thin veins (1-3 mm thick) in this modified silt.

The small knoll adjacent to the drained lake basin (Figure 5) is an upland remnant that has been modified by lacustrine and subaerial slope processes. The uppermost 3 m are laminated lacustrine deposits that contain substantial amounts of ice (Figure 3g). They are comparable in age to lake deposits in the adjacent basin. Beneath these deposits is silt of a composition similar to that of the uplands but containing distinctly less excess ice (Figure 3g). Stratified, medium sands with pebbly horizons and cross-bedding indicative of fluvial deposition lie at the base of the sequence (lower 4 m). The ice volume of the sand is comparable to the thawed and refrozen sand at Fish Creek (Figure 3c). The ice content of the middle eolian silt and lower fluvial sand reflects thaw and refreezing during thaw lake activity and drainage. Colluvial silt on the knoll slopes contains 50-65% ice, lacks structure, and forms a basinward thickening wedge onto the adjacent lake deposits.

DISCUSSION

The total ice volume of perennially frozen sediments at each locality results from the combined effects of geological and cryogenic depositional and postdepositional processes. Stratigraphic variability in ice occurrence relates to the origin and composition of the sedimentary sequence and thermal events that accompanied sedimentary activity. Trends in volume with increasing depth as well as lateral near-surface variability at each site reflect this sedimentary and thermal history. Shifts in ice volume are thus indirectly correlated with the relative age of deposits and landforms at a given site.

Primary deposits--those not reworked by post-depositional processes, which are fine-grained or organic-rich--contain significantly more ice than coarse-grained deposits and possess the greatest downhole variability in ice volume. This relationship is not necessarily valid if sediments subsequently thaw; ice content then depends upon the processes of resedimentation or refreezing events that follow.

This concept is illustrated by the effects of thaw lake processes. Thawing and reworking of sediments during lake formation and expansion mixes and concentrates fine-grained sediments and organic material in deposits on the lake bed. Following drainage, freezing of the lacustrine deposits results in ice segregation, with moisture migrating from the underlying, still-thawed sediments. Their ice content equals or exceeds surrounding primary deposits. Sediments that are thawed by lake activity refreeze to an ice content lower than before lake formation, with segregated ice less common. Ice wedge dimensions are smallest in basins drained most recently.

Additional detailed analyses of ground ice occurrence in relation to geologic parameters are clearly needed to examine further the relationships of spatial variability found in this study. An ability to predict the general distribution and volume of ice based upon limited borehole data, for example, would be particularly useful in selecting sites that are least susceptible to disturbance, or in assessing the variability in geotechnical properties of frozen ground during presiting studies.

ACKNOWLEDGMENT

This study was supported by the U.S. Geological Survey's National Petroleum Reserve, Alaska, program. I thank Bruce Brockett for working with me on the sampling program and Drs. Max Brewer and Jerry Brown for encouraging and supporting this research.

EROSION BY OVERLAND FLOW, CENTRAL BANKS ISLAND, WESTERN CANADIAN ARCTIC

Antoni G. Lewkowicz

Department of Geography, University of Toronto
Toronto, Ontario, Canada, M5S 1A1

Process studies carried out at runoff plots on Banks Island emphasize the importance of solute erosion by overland flow, rather than suspended sediment removal. Rates are low, despite the influence of permafrost in promoting surface runoff. Observations of feedback within the slopewash system suggest that these trends may not be universal. In tundra zones, vegetation is thought to be more protective than in the transitional zone of Banks Island. In semidesert and polar desert zones, where vegetation cover in snowbed locations is limited, removal of sediment particles by overland flow may be more significant.

INTRODUCTION

Overland flow (i.e. surface wash) is an azonal process not restricted to permafrost regions. The presence of permafrost, however, favours saturation of the active layer by preventing deep percolation of water, while the rapidity of snowmelt in early summer further increases the probability of overland flow (Washburn 1980 p. 244). The role played by overland flow in eroding and transporting material in permafrost regions is speculative. French (1976 pp. 141-142) hypothesizes that erosion by overland flow is most effective in areas transitional between tundra and polar desert. On Spitsbergen, Jahn (1961) measured rates of erosion due to overland flow of up to $16 \text{ g/m}^2/\text{yr}$. Apart from these, and more limited observations by Wilkinson and Bunting (1975), there is an absence of data available on the erosional capability of surface wash.

This paper summarizes data collected during 3 years of direct field observations of overland flow in the Western Canadian Arctic. Measurements were made in the Thomsen River lowlands of north central Banks Island (Figure 1; latitude $73^{\circ}14'N$, longitude $119^{\circ}32'W$), an area regarded as transitional between the tundra and semidesert and polar desert zones. Four instrumented runoff plots ($67\text{--}525 \text{ m}^2$) were located on typical low angled slopes, and standard hydrologic and geomorphic monitoring techniques were employed to collect data (Lewkowicz 1981). Earlier papers provide descriptions of the frequency and magnitude of overland and subsurface flow, and the relevance of hillslope hydrologic theory to this part of the Arctic (Lewkowicz and French 1982a, 1982b). This paper deals with the erosional capability of overland flow and consequently with the rapidity and nature of slope evolution under periglacial conditions (see French 1976 pp. 165-166).

METHODS

The methodology of the study involved independent measurements of overland flow volume,

FIGURE 1 Location of study: A (inset)--Banks Island, N.W.T., Canada, showing Early Wisconsin glacial limit (after Vincent 1982); B--Air photograph of study area (part of A-17379-40).

solute concentration, and suspended sediment concentration. These data were then used to calculate net rates of erosion. Standard procedures were used to monitor overland flow and other hydrologic parameters at the runoff plots (see Figures 2 and 3). A full description is presented in Lewkowicz and French (1982b). Samples of overland flow were taken manually at the runoff collectors. Solute concentrations were estimated by field titration for total, calcium and magnesium hardness (Schwarzenbach method) and/or by a measurement of specific conductance.

FIGURE 2 Runoff plot 1, the interfluvial site, June 3, 1977. Note small hummocks, sparse vegetation cover and breakup of thin snowpack into discrete pieces.

Conductance values in $\mu\text{S}/\text{cm}$ were multiplied by 0.65 (the middle of the range given by Rainwater and Thatcher (1960)) to obtain solute concentrations in mg/l . One litre samples for suspended sediment were filtered through predried and preweighed filter papers using an Østrem filter pump, and were reweighed in a laboratory after drying at the end of the field season. Control experiments revealed an accuracy of approximately $\pm 4 \text{ mg}/\text{l}$.

SOLUTES

A wide range of solute concentrations was determined in overland flow samples collected at the runoff plots (Table 1). Minimum values of 2 mg/l were recorded in the vicinity of the snow edge, but concentrations increased as the water moved downslope. The low values confirm that basal ice (e.g. Lewkowicz 1981 p. 197, Woo et al. 1982) prevents meltwater from coming into contact with the ground prior to leaving the snowbank. Consequently, no wash erosion takes place beneath the snow.

Variability in solute concentrations can largely be explained by (1) the distance between the snow edge and the collector and (2) the

FIGURE 3 Runoff plot 2, a snowbank site, June 30, 1978. Note tricycle for scale at top of plot, widespread overland flow, and extensive vegetation cover. Weir and water-level recorder provide a continuous record of overland flow.

overland flow discharge. These are related to the residence time and the degree of mixing of the flow, and can be considered at diurnal and seasonal time scales.

On any particular day, changes in solute concentrations (Figure 4) relate mainly to velocity variations associated with diurnal hydrographs. The relationship between discharge and solute concentration is inverse and best described for plots 3 and 4 by semilogarithmic curves. Hysteresis, thought to be the result of snow edge retreat (0.5 m at plot 3 and 0.9 m at plot 4 on July 4-5, 1978), is also present. On a longer time scale, solute concentrations increase as the melt season progresses. This is partly the result of higher flow temperatures and vegetation growth (linked to biogenic CO_2 production (Woo and Marsh 1977)), but is mostly due to the greater distances between the snow and the collector, the result of snowbank ablation.

TABLE 1 Variability of Solute Concentration in Overland Flow and Best Fit Multiple Regression Equations

Plot No.	Years	Number of samples	Mean solute concentration in samples (mg/l)	Standard deviation (mg/l)	Regression Equation ^a	r
1	1977 & 1979	46	217	95	$C=122.1-14.0Q+12.3D$	+0.90

3	1977-1979	121	93	86	$C=64.4-37.4 \ln Q+8.2D$	+0.87
4	1978-1979	28	52	32	$C=13.2-10.6 \ln Q+9.0D$	+0.98

^a Symbols in regression equation: C is solute concentration (mg/l); Q is overland flow (l/min); D is distance between the snow edge and overland flow collector (m).

FIGURE 4 Diurnal variation of solute concentration in overland flow, plots 3 and 4, July 4-5, 1978.

Multiple regression of solute concentration against overland flow discharge and distance travelled by the flow gives correlation coefficients (r) between +0.87 and +0.98 for the four plots (Table 1). Since these values are high, the multiple regression equations in Table 1 can be used as predictive rating curves for their respective plots. The total weight of dissolved solids can be calculated by multiplying concentrations derived for each 30-min period of the discharge record, by the discharge over that time. The only case where it is not possible to derive totals in this way, is plot 1 for 1977. The breakup of the snow cover into a number of irregular masses during that year prevented assessment of the distance to the snow edge. A sufficient number of conductivity measurements exist, however, for direct use to be made of the solute concentration data. Since the regression equations provide imperfect explanation of the

data variation, the totals produced should be regarded as "best estimates".

The mean solute concentration at the interfluvial site (plot 1) is considerably higher than those at the snowbank sites (plots 2, 3, and 4) (Table 2). This may be the result of contact between water and the ground surface within the snow-covered area due to a poorly developed basal ice layer in the thin snowpack. Best estimates of solute erosion vary by 2 orders of magnitude, from a 3-year average of $1.3 \text{ g/m}^2/\text{yr}$ at plot 2 to $49.6 \text{ g/m}^2/\text{yr}$ at plot 3. The average for the interfluvial is higher than that for plot 2, primarily because the mean solute concentration is 4 times greater. These rates represent erosion averaged over the complete plot. Because of the presence of basal ice, however, the true picture is one of zero erosion over that portion of the plot upslope of the final runoff-producing position of the snowbank, and enhanced erosion on the lower portion of the plot - the "affected area". The latter constitutes between 30 and 54 % of the total plot area (calculated from snow edge retreat records). If weight losses are distributed over the affected areas, rates increase 2-3 times, reaching a maximum of $165 \text{ g/m}^2/\text{yr}$ at plot 3 (Table 2).

The values of weight loss by solution can be converted into denudation rates using a bulk density factor for the eroding surface of 0.67 Mg/m^3 (from Pearce 1976) (Table 2). Average rates for the plots range from 2 to $74 \text{ mm}/1,000 \text{ yr}$, and for the affected areas from 6 to $246 \text{ mm}/1,000 \text{ yr}$. Data available for comparison with these figures are extremely limited, since most measurements of net solution loss have been made by examination of the stream solute load. One of the few comparable measurement rates was obtained by Thorn (1974), working in the alpine environment of the Colorado Front Range. A denudation value of $6.7 \text{ mm}/1,000 \text{ yr}$ was attributed to solution by overland flow downslope of a large snowbank. This value falls within the range measured at the Thomsen River runoff plots but is an order of magnitude less than the maximum recorded.

TABLE 2 Best Estimate Rates of Solute Erosion by Overland Flow

SUSPENDED SEDIMENT

Suspended sediment concentrations in overland flow were lower and less variable than solute concentrations. A total of 78 samples were collected at the plots in 1979, and more than half of these possessed concentrations less than 4 mg/l. Moreover, with one exception, no diurnal or seasonal cycles in concentrations were identified. Since the transport capacity of the overland flow varied on an hourly basis, these observations suggest that the concentrations were limited by the availability of sediment ("weathering limited").

The single exception to the lack of concentration variation occurred at plot 1 on June 30, 1979. More than half of the total season's overland flow was generated in 14 hours, and a maximum discharge of 10.7 l/min was recorded. The concentration of suspended sediment reached 70 mg/l, but peaked prior to the maximum flow (Figure 5). Similar cycles of sediment concentrations in overland flow have been observed in nonpermafrost areas in response to natural or simulated rainfall (e.g. Emmett 1970). They indicate the removal of easily transported particles in a relatively short time. The absence of any discernible cycles at the other three plots, in spite of unit discharges greater than those at plot 1, is attributed to the stabilizing presence of vegetation downslope of the snowbanks.

Despite problems with the measurement of suspended sediment, resulting from concentrations being close to the level of discrimination of the technique, it is still possible to produce estimates of the rates of weight loss and denudation. In order to perform the calculations, a number of assumptions are necessary. First, because of variability in the weight of filter papers during drying, any concentration apparently less than 4 mg/l was assumed to be 2 mg/l. Second, values greater than 4 mg/l were used unchanged. Third, after calculation of total suspended sediment lost during the melt season by multiplying flow volumes by their appropriate concentrations, the residue of sediment trapped in the collector and weir was added. When divided by

FIGURE 5 Diurnal variation of suspended sediment concentration in overland flow, plot 1, June 30, 1979.

the flow volume, this total gave the mean concentration. It was assumed that this concentration, obtained from 1979 data, was applicable to the 1977 and 1978 field seasons.

The results of the suspended sediment calculations are given in Table 3. Best-estimate mean concentrations are less than 4 mg/l at the snowbank plots and 21 mg/l on the interfluve. Average sediment weight losses from the plots vary from 0.1 to 2/yr. These values can be compared with Jahn's (1961) measurements on unvegetated slopes on Spitsbergen. His maximum value of 16 g/m²/yr exceeds that at Thomsen River by a factor of 10, and his minimum value of 1 g/m²/yr is close to the maximum recorded in the study area. It is probable that these differences result from the absence of a relationship between sustained moisture supply and vegetation growth on the coarse regolith slopes in Spitsbergen. A further contrast between the results is the positive correlation between snowbank size and erosion rate that exists on Spitsbergen but not on Banks Island. This also indicates the protective

TABLE 3 Best Estimate Rates of Suspended Sediment Erosion by Overland Flow

^c Dry bulk density assumed to be 0.67 Mg/m³.

influence of vegetation, resulting in a lower average erosion rate at plot 2 than at the interfluvial plot (Table 3).

Conversion of the weight losses to denudation rates (Table 3) gives low values, with a maximum of 2.6 mm/1,000 yr for the whole of plot 3, and 8.6 mm/1,000 yr for the area affected by wash. These values can be compared with the global range of denudation rates by surface wash of 0.1 to >230,000 mm/1,000 yr (Young 1974 p. 69). The estimated losses from the runoff plots are among the lowest in the world and somewhat lower than those obtained by Thorn (1974) of 3.5-8.4 mm/1,000 yr.

DISCUSSION AND CONCLUSIONS

Comparison of the denudation rates shown in Tables 2 and 3 reveals that solute removal by overland flow in central Banks Island is 8 to 30 times greater than removal of sediment in suspension. This dominance is most pronounced at the site of the largest snowbank and least at the interfluvial site.

Problems arise, however, if attempts are made to extrapolate from these results to other permafrost environments. These values may not be representative of overland flow erosion in all areas north of the tree line due to variations in (1) snow amounts and distribution, (2) rates and distribution of snowmelt runoff, and (3) vegetation cover. Observations made at Thomsen River, however, do permit the formulation of a hypothesis concerning the spatial variability of overland flow erosion in permafrost areas. The details of the hypothesized trends (Figure 6) are as follows:

(1) A simple decrease in interfluvial solution may occur between the tundra zones and the semidesert and polar desert zones, resulting from decreases in overland flow runoff, flow temperature, and biogenic CO₂ production (Line A).

(2) Interfluvial suspended sediment removal may increase between the tundra zones and the semi-desert and polar desert zones because the positive erosional effects of vegetation decline outweigh the negative influences of lower runoff production (Line B).

(3) Snowbank solution may decrease between the tundra zones and the semidesert and polar desert zones as overland flow runoff, flow temperature, and biogenic CO₂ production all decline (Line C).

(4) Snowbank suspended sediment removal may be more complex, with little change expected in erosion rates between the tundra and transitional zones, since vegetation is protective in both. A substantial increase may occur between the transitional and semidesert and polar desert areas, however, as locations downslope of snowbanks are subjected to high unit discharges without the presence of a completely protective vegetation cover (mainly due to a shortened growing season) (Line D).

In conclusion, therefore, the generalization that surface wash erosion increases northward from the tree line (French 1976 p. 142) is

FIGURE 6 Inferred variation of overland flow erosion in areas of continuous permafrost.

supported by the trends summarized in Figure 6. The maximum erosion rate, however, is thought to occur in the polar desert transition zones rather than in the tundra-polar desert transition zones. On the other hand, the measurements reported in this paper suggest that rapid landscape modification by surface wash processes is unlikely, even in the polar desert regions of the High Arctic.

ACKNOWLEDGEMENTS

Fieldwork on Banks Island was supported by the Natural Sciences and Engineering Council (Grant A-8367), the University of Ottawa Northern Research Group, and the Polar Continental Shelf Project, Energy, Mines and Resources (Project 34-73). Equipment was kindly loaned by the Terrain Sciences Division, Geological Survey of Canada, Inland Waters Directorate, Environment Canada, and the Rideau Valley Conservation Authority. Use of the Terrain Sciences Division's tundra hut at Thomsen River is gratefully acknowledged. Excellent field assistance was provided by G. Champagne, T. Colosimo, J. M. C. Lalonde, A. LeHenaff and R. Spencer. Illustrations were drawn by B. Nakrosius using financial aid from a University of Toronto grant. Helpful comments on draft of this paper were provided by H. M. French and J. M. C. Lalonde.

People's Republic of China

Field investigation, laboratory experiments, and engineering practice during the past 30 years has given China a great deal of information on railroad construction in permafrost regions. The thermal and mechanical properties of soils both in frozen and thawed states were determined, several formulas for predicting the natural and artificial permafrost tables were developed, four distribution maps of permafrost at different scales were compiled, and a principle for selecting railroad routes was presented. In the field of foundation design for railroads, bridges, and culverts, methods for constructing foundations in sectors of thick-layer ground ice have been studied, along with measures to prevent freezing of blind drain outlets and avoid thaw damage to embankment foundations. Raft and wood-reinforced culvert foundations were successfully used in the permafrost regions of the Great Hinggan Mountains, reinforced concrete pile foundations were tested, and a method of rapid construction of foundation pits for small bridges and culverts was developed. In tunnel design and construction, a sluiceway drainage system was used. A set of design principles and methods has been developed for buildings, pipelines, and pavements. In addition, two kinds of low-temperature construction materials have been developed for reinforced concrete-poured pile foundations and culverts.

In the mid-1950s, with the development of our socialist economic construction, railroad survey and design crews entered the Great Hinggan Mountains to exploit forest resources. The permafrost regions there presented unfamiliar geological, geographical, and climatic conditions. As neither the nature nor the distribution of permafrost were known, conventional methods of railroad design and construction were used. A number of problems inevitably resulted, emphasizing the need to study railroad survey, design, construction, and maintenance in cold regions. This was the beginning of our research into permafrost and its effect on railroad engineering.

Gradually, through research, testing, and more than 20 years of practical experience, we have mastered some aspects of building railroads in permafrost areas. So far, the railroad built through the Great Hinggan Mountains of northeast China is more than 2000 km long, of which nearly 450 km runs through continuous permafrost. To meet the needs of China's economic development and to establish the prerequisites for building the Qinghai-Xizang Railroad in the near future, some essential experiments and studies have been conducted in the permafrost region of the Qinghai-Xizang Plateau.

The following is a brief introduction to various aspects of our research and experience.

ENGINEERING GEOLOGY IN PERMAFROST AREAS

In cold regions, the controlling factor for construction projects is engineering geology; this

is especially true for railroad construction in permafrost areas. For this reason, much effort has been concentrated on this problem, and the Lanzhou Institute of Glaciology and Cryopedology of the Academia Sinica has made a major contribution.

The subjects under study are: (1) the essential properties of permafrost, (2) the classification of permafrost for engineering purposes, (3) permafrost distribution, (4) physical and geological phenomena in permafrost areas, (5) special features of surveying and mapping the engineering geology of permafrost areas, and (6) principles for route selection in permafrost areas.

Satisfactory results have been achieved in both field and laboratory work. The results have been incorporated into the "Railroad Design Standards" and the "Detailed Rules and Regulations of Railroad Survey and Design."

China's progress in the study of cold regions includes achievements in permafrost mechanics, the study of the thermodynamics of frozen ground, mapping of permafrost distribution, and selection of railway routes in permafrost regions.

Permafrost Mechanics

Our achievements in permafrost mechanics include developing a method for calculating permafrost bearing capacity, a distribution law of frost-heave pressures on foundations and retaining walls, and indexes of shear strength of frozen soils.

The Lanzhou Institute of Glaciology and Cryopedology has played a principal role in developing the mechanical indexes of typical soils

and calculating building stability. The indexes are the basic bearing capacity of permafrost (First Railroad Survey and Design Institute et al. 1972), tangential frost-heaving pressure on concrete and wooden foundations from seasonally thawing or freezing soil during freezing (Wu et al. 1979b), and the long-term adfreezing force between permafrost and concrete or wooden foundations (Wu et al. 1979a). These have all been included in "Railroad Design Standards" and "Detailed Rules and Regulations of Railroad Survey and Design."

The Third Railroad Survey and Design Institute has defined a distribution law for tangential frost-heaving pressures in the thawing-freezing layer on building foundations in the Great Hinggan Mountains, and has developed a technique for determining appropriate values for foundation design (Cui and Zhou 1981). In addition, empirical formulas to determine the thawing and compression coefficients of frozen clayey soil in the area were obtained from regression analysis of many of the experimental data (Wu et al. 1979c).

The Northwest Institute of the Chinese Academy of Railway Sciences (the Northwest Institute, for short), through analysis of L-shaped, model retaining walls at the Mt. Fenghuo test site, has defined not only the distribution law of horizontal frost-heaving pressure acting on vertical retaining structures, but the relation between horizontal frost-heaving pressure and the deformation of a retaining structure, and the maximum horizontal frost-heaving pressure (Ding 1983). Recently, the long-term resistant force of anchor rods in permafrost has been studied (Ding and Zhang 1983).

To obtain indexes of the shear strength of soil so that the stability of the slope and ground base of railroad embankments can be determined, the Northwest Institute has conducted a series of direct shear tests in the laboratory and large-scale shear tests in the field to study the nature of sandy and clayey soils in the permafrost areas of the Qinghai-Xizang Plateau. The results show that the shear strength at the freeze-thaw interface is greater than that of fully thawed soil (Tong 1983). This conclusion is valuable in computing soil stability in all permafrost areas.

Thermodynamics of Frozen Ground

Based on laboratory experiments made on peat, clayey soil, sandy soil, gravel-clayey soil, and sandy gravel along with a number of field tests, the Lanzhou Institute presents the relationships between five thermal indexes (specific heat, volumetric heat capacity, thermal conductivity, thermal diffusivity, and latent heat of fusion when thawing and freezing) and two physical indexes (dry bulk density and water content) of each of the above materials as well as a list of thermal parameters (Xu et al. 1979b). In addition, in the field of thermal engineering, the Lanzhou Institute has developed an empirical formula to determine the depth of the permafrost table at different elevations and latitudes (Xu et al. 1979a), an approximation equation to evaluate the critical height of an embankment in a permafrost area (Qinghai-Xizang Highway Research Group 1981), and a method for calculating the required thickness of the thermal insulation layer within a railroad

embankment using a one-dimensional model (Ding et al. 1979).

The Northwest Institute has studied the thermodynamics of the permafrost areas of the Qinghai-Xizang Plateau to determine burial depths for building foundations and the design of insulating layers. They have also developed a method for determining the depth of the natural and artificial permafrost tables for railroad, bridge, and culvert foundations based on:

- the seasonal freezing and thawing characteristics of soil layers in the permafrost areas of the Qinghai-Xizang Plateau,
- a method for determining the permafrost table, and its application to cut engineering,
- an empirical formula to determine the necessary thickness of the heat insulation layer in the area,
- the law of variation of the artificial table of an embankment in the area,
- an empirical formula for evaluating the artificial table of a culvert foundation and an equation to calculate the thaw depth of the ground under culvert foundations in permafrost, and
- the artificial table of a bridge foundation in permafrost.

Some of these achievements represent significant progress, e.g. evaluating the latent freezing capacity of the soil layer in view of the surplus freezing index; using the period from October to September as the calculation year, which is more precise and logical than the calendar year used previously; presenting a quantitative estimate of the variation of the natural permafrost table in sandy and clayey soil layers (1.7% when the variation in average temperature of the calculation year is 1°C), and then making a 100-year forecast (Huang 1981). The statistical equation to determine the natural permafrost table of the peat and clay soils in the Mt. Fenghuo region is based on the average August temperature in the Wudaoliang region, and is verified by data from the preceding seven years with a maximum calculation error of no more than 7%. The forecast conclusion for the first 20 years, based on the 100-year forecast, proved to be identical with the data obtained from the test observations in those 20 years (Liu 1983).

Permafrost Distribution

Our research on the distribution of permafrost is so extensive that only those achievements relevant to railroad engineering are introduced in this report.

A map "The Distribution of Permafrost in Northeast China" (1:2,000,000) was compiled by the Yakeshi Institute of Forest Survey and Design, the Lanzhou Institute, and the Third Railroad Survey and Design Institute.

A map of the distribution of permafrost along the railroad within the jurisdiction of the Qiqihar Railway Administration (1:200,000) was compiled by its regional bureau from information collected by the Third Railroad Survey and Design Institute and the Geological Bureau of Heilongjiang Province, as well as that collected by the bureau.

An abridged map "The Distribution of Permafrost in the Great and Minor Hinggan Mountain Regions"

(1:4,660,000) was compiled by the Third Railroad Survey and Design Institute from "The Distribution of Permafrost in Northeast China."

A map "The Distribution of Permafrost along the Qinghai-Xizang Highway" (1:600,000) was drawn by the Lanzhou Institute.

The Third Railroad Survey and Design Institute has studied ground temperature characteristics in the northern permafrost areas of the Great Hinggan Mountains and has determined the ground temperature curve, annual variation depths of ground temperature, factors affecting perennial ground temperature, and laws governing ground temperature variations in this area to complete the ground temperature data base for the region (Dai and Li 1981). These data will be valuable in future research and engineering.

In addition, the Institute has studied the close relationship between various plant communities and permafrost distribution and ice content in the area (Lin 1981). It offers a feasible method for speeding investigation and mapping for geological engineering.

Railway Route Selection in Permafrost Regions

This work was undertaken by the First and Third Railroad Survey and Design Institutes and the Northwest Institute, based on analysis of geological, topographical, and physical-geological phenomena as well as other geological engineering conditions for each sector of the permafrost region.

SEVERAL PROBLEMS IN THE DESIGN OF RAILROAD FOUNDATIONS

Methods for designing railroad foundations in sectors of thick layer ground ice have been studied, along with measures to prevent freezing of blind drain outlets and means to avoid settlement of embankment foundations due to thawing. The primary achievements in this area are as follows.

Designing Road Foundations in Sectors of Thick-Layer Ground Ice

In the area from the Kunlun Shan to Tanggula Shan on the Qinghai-Xizang Plateau, thick-layer ground ice is widely distributed on mountain and hill slopes as well as on the high plains, with single-layer thicknesses up to 4 m (Qinghai-Xizang Highway Research Group 1983). Road foundations in these sectors frequently subside and collapse due to thawing. Through in-situ tests (Figure 1) and laboratory experiments, the Northwest Institute and the First Railroad Survey and Design Institute have successfully addressed the following subjects as they affect the design of railroad foundations in sectors of thick-layer ground ice (Shu and Huang 1983): (1) the principles of design, (2) the sectional form of cut and engineering measures, (3) design and preparation of minimum cuts and fills and low embankments, (4) methods for calculating the thickness of the thermal insulation layer and the artificial table of an embankment, and (5) drainage system design.

FIGURE 2 Heat-preserving outlets.

FIGURE 3 Wide, shallow, large-sectioned drainage ditch.

FIGURE 4 Thermal-insulating revetment road without soil covering.

FIGURE 5 Thermal-insulating revetment road covered with soil and tatau grass.

Heat-Preserving Water-Discharge Outlets

To control the formation of ice mounds in the permafrost areas of the Great Hinggan Mountains, blind drains are often used to discharge water. Since the outlets were inevitably subject to freezing, in the past a small cabin containing a burning furnace was built as a shield. The Third Railroad Survey and Design Institute designed and built seepage blind drains with cone-shaped, heat-preserving outlets that do not freeze (Figure 2). Recently, the original design has been further improved (He and Li 1983). This achievement not only reduces project costs, but facilitates transportation and management. It has been widely and successfully used in the design of railroad foundations, tunnels, and water-supply and drainage outlets.

Comprehensive Treatment of Embankment Subsidence

Embankment subsidence is a major hazard for railroad foundations in permafrost regions, directly affecting the quality and safety of the roadbed. The Qiqihar Railway Administration built a wide, shallow, large-section drainage ditch near an embankment on the Ya-Lin Railroad (Figure 3), and constructed a thermal-insulating, single-slope revetment road covered with tatau grass between the railroad and the drainage ditch. The permafrost table under the embankment and the road isolated the water and heat sources of the thawing trough of the embankment foundation from ground water (Figures 4 and 5). This gradually reduced the thickness of the weak layers of the foundation and prevented the embankment from sinking (Wang 1980).

DESIGN AND CONSTRUCTION OF BRIDGE AND CULVERT FOUNDATIONS

In China, smaller bridges and culverts in permafrost regions are subject to damage, so the study of their design and construction is stressed. Our major achievements are described below.

Raft and Wood-Reinforced Culvert Foundations

There are many smooth valleys in the permafrost regions of the Great Hinggan Mountains that are covered by tatau grass and brush; they store water all year round. Not far beneath the ground surface

there is a layer of peat 0.4-1.0 m thick, below which is a layer of clayey soil mixed with gravel up to 5-6 m thick. Culverts built in such areas are frequently subject to such hazards as crushing of the end and side walls, staggering or pulling of pipe sections, and subsiding and bowing. To overcome these hazards, the Third Railroad Survey and Design Institute has used raft or wood-reinforced continuous foundations (Third Railroad Survey and Design Institute 1971). The raft foundation preserves the permafrost and adapts to slightly uneven subsidence, and wood-reinforced foundations can adapt to uneven subsidence if thawing ground has been allowed for in the design. The culverts constructed according to these principles have been successfully tested for 7 or 8 years.

Reinforced Concrete Pile Foundations

A pile foundation is the optimal type of foundation for bridges and buildings in permafrost regions, because it not only causes minimal damage to the frozen state of the underlying soil, overcoming frost heaving as well as deformation caused by thawing, but it also can speed construction, lower costs, and improve working conditions. Reinforced concrete pile foundations appear to suit Chinese conditions better than any other type, so the Northwest Institute, the First Railroad Survey and Design Institute, and the Low-Temperature Construction Institute of Heilongjiang Province have studied several subjects (Chen 1982): (1) the construction conditions, technology, and equipment necessary to emplace inserted, reinforced concrete, driven, and poured piles, (2) a cost-effective method of calculating a beam's capacity for use in field tests, and (3) a method for determining horizontal and vertical loads (bearing capacity and thrust) on pile foundations in permafrost (Figure 6).

Rapid Construction of Foundation Pits for Small Bridges and Culverts

To maintain the underlying soil in the frozen state, foundations for small bridges and culverts must be excavated as quickly as possible. After conducting a number of tests on various types of excavation blasts, the Railroad Construction Institute of CARS developed techniques for designing foundation excavation blasts in permafrost (Qinghai-Xizang Railroad Research Group of Testing Project 1976).

FIGURE 6 Pile foundation test site in Kunlun Shan.

FIGURE 8 Drilled pile foundation test structure.

FIGURE 7 Sluiceway blocked by ice.

FIGURE 9 Buried pile foundation test structure.

Live demolition blasts on the Qinghai-Xizang Plateau showed that the goal of rapid construction was achieved. Upon evaluation, the method was approved for use in the excavation of foundation pits for small bridges and culverts in permafrost regions.

DRAINING WATER AND MELTING ICE IN TUNNELS

A major problem of tunnel design in permafrost areas is water drainage. Ground water leaks into the tunnel and freezes, causing the liner to crack, break, and peel off, and ice accumulates on the foundation and hangs from the ceiling. This not only damages the tunnel, but also impedes and even endangers trains. The Third Railroad Survey and Design Institute has used various devices, such as deeply buried, shallowly buried, and frost-heave-protected ditches and sluiceway drainage systems to eliminate hazards to tunnels in permafrost areas (Nie 1981). The sluiceway drainage system has proved to be the most efficient. It uses a small gallery beneath the tunnel along with shafts, water-discharging borings, and natural fissures to collect and drain ground water from around the tunnel. The complete drainage system includes an inspection well and a cone-shaped, heat-preserving outlet.

In permafrost areas ground water often freezes inside sluiceways (Figure 7). For example, an emergency occurred in February 1973 in a tunnel in the Great Hinggan Mountains---freezing had blocked the sluiceway, causing freezing in the tunnel and endangering traffic. Various methods were used to try to clear the blockage---manually shaving the ice

and melting it with electricity, with locomotive steam, and by burning coal---but they were unsuccessful because of the large amount of heat required. In 1977 tests, the Qiqihar Railway Administration succeeded in melting ice by mechanical ventilation. Expanded experiments were conducted in 1978; over three separate periods of time, a cumulative ventilation of 23 days and nights successfully melted as much as 1400 m³ of ice. This has proved to be an economical and effective way to treat freezing in tunnels.

BUILDING DESIGN AND CONSTRUCTION

Subsidence due to thawing and deformation due to frost heaving frequently affect buildings constructed in permafrost areas because of poor choice of location or inappropriate design of the bases and foundation. Research has been conducted to determine the suitability of various kinds of foundations (Figures 8, 9, 10, and 11) to permafrost regions and to develop a method for determining the shape and dimension of the thawing plate beneath heated buildings (Ma and Wang 1983, Zhao and Wang 1983). On the basis of engineering practice as well as several years of testing and research, the First and Third Railroad Survey and Design Institutes, the Qiqihar Railway Administration, and the Northwest Institute offer a set of design principles and methods: (1) proper choice and layout of construction site, (2) proper base and foundation design, (3) protecting foundations from frost heaving, (4) proper design of structures above ground, and (5) proper design of aprons.

DESIGN AND CONSTRUCTION OF WATER-SUPPLY PIPELINES

FIGURE 10 High-filled, ventilated foundation test structure.

FIGURE 11 Girth foundation test structure.

FIGURE 12 Water-supply system with heat-preserving pipes on ground and outside cistern.

FIGURE 13 Joining culvert foundations.

FIGURE 14 Joining culvert box pipes.

Since the founding of the People's Republic of China, 25 railroad water stations have been established in the northeastern permafrost region. More than half of these are located in discontinuous and continuous permafrost areas. At first, varying degrees of freezing or pipeline breakage occurred at almost every station. So as early as the mid-1960's, the Third Railroad Survey and Design Institute began to search for a new method of constructing water-supply pipelines by using pipes of various materials, various heat preservation materials, and various methods of laying pipelines (Figure 12) (He 1983). After 20 years of continuous engineering practice, testing, and research, the problem of design and construction of water-supply pipelines in permafrost areas of the Great Hinggan Mountains has been solved.

LOW-TEMPERATURE CONSTRUCTION MATERIAL

The success of trial production of low-temperature, early-strengthened concrete makes it possible to adapt reinforced poured-concrete pile foundations to permafrost regions.

Many methods for producing low-temperature and negative-temperature concrete have been used in China, but there is little complete or systematic information, especially about freeze- and thaw-resistant indexes. The Railroad Construction Institute of CARS has succeeded in developing three types of low-temperature early-strengthened concrete, whose low-temperature and negative-temperature strength, compared with those of ordinary concrete, are 30-67% stronger over the same time using the same amount of cement; cement consumption can be reduced by 100 kg/m³ without reducing the strength. The freeze- and thaw-resistant indexes when the concrete is soaked in fresh water or salt water solutions of 0.1%, 1.0%, and 5.0% are all over M-200, which is 4 to 11 times those for ordinary concrete without additional chemicals. The predicted lifetime of low-temperature concrete structures is about 50 years. Another advantage of this concrete is that the temperature of the mixture can be controlled as low as 0°C so that its thawing effect on permafrost is greatly reduced (Railroad Construction Institute 1979, Shi 1978). This concrete is suited for use in regions where ground temperatures range from 0 to 3°C, so it may be used in frigid zones as well as in permafrost regions. It has been recommended that the technical construction specification be incorporated into the "Standards of Construction of Railroad Engineering Concrete and Reinforced Concrete."

An inexpensive and easy-to-use negative-temperature cement has been developed to cement joints, so that culverts can be constructed at temperatures below -25°C (Li and Wu 1981).

One of the subjects of our research into railroad construction in frigid and permafrost areas is the use of prefabrication techniques in bridge and culvert construction (Figures 13 and 14). Constructing prefabricated, reinforced concrete structures in regions with temperatures below -25°C requires a cementing material (for joints) that has

the advantages of being fast developing, is long lasting, has strength at negative temperatures, shows little shrinkage, and has no corrosive effect on reinforcing bars. The Railroad Construction Institute of CARS was commissioned to undertake this work and has fulfilled its charge. The material has a compressive strength that approximates 300 kg/cm² in three days, it cannot be damaged even when subjected to freeze (-18 to -25°C) shortly after it is poured, and it has a freeze- and thaw-resistant strength up to M-150. Its other features are: (1) low drying shrinkage, about one-fourth that of concrete containing ordinary dry-to-harden cement, (2) no corrosive effect on reinforcing bars, (3) resistance of sulphate corrosion, (4) long-term stability and strength, and (5) cementing strength, tensile strength, and modulus of elasticity with reinforcing bars to meet the railroad design standards.

The material was first used in a test bridge in the northwestern frigid zone in August 1976, and then in two prefabricated bridges in the same zone in December 1977. The construction quality was excellent and these three bridges have been used safely for 4 and 5 years. Since 1978, the material has been used in prefabricated winter projects throughout northern China. The material has passed inspection and is approved for use in frigid-zone railroad engineering and similar projects. According to the evaluation, it is suggested that the temporary detailed construction specifications for using the material be incorporated into the next revision of the "Standards of Construction of Railroad Engineering Concrete and Reinforced Concrete."

SUMMARY

This has been a brief description of research into railroad construction in the permafrost regions of China. Some of the work has been successfully completed, but a number of technical problems remain to be studied and solved, including the prevention and treatment of frost heaving of road and building foundations, the design of light and pliable culverts, further improvement of the design of reinforced concrete pile foundations, and the design of shallow ditches with frost-heave protection for tunnels and buildings constructed on warm permafrost ground.

PERIGLACIAL SLOPEWASH AND SEDIMENTATION IN NORTHWESTERN GERMANY
 DURING THE WÜRM (WEICHSEL-) GLACIATION

Herbert Liedtke

Geographisches Institut, Ruhr-Universität Bochum,
 D-4630 Bochum, Federal Republic of Germany

The older morainic landscape of the Northwest German Lowland has a very subdued relief. This was caused by Weichsel periglacial processes, partly of a solifluidal but mostly of an abluval kind. The latter encompasses all eroding sheetwash processes on slopes and accumulation of fine sandy material in basins. Abluval and solifluction were processes during cold periods in the foreland of central European glaciations; erosion and sedimentation occurred mainly during the end of interstadial phases. The most impressive incision happened at the very end of the last interglacial.

THE SUBDUED RELIEF OF CENTRAL EUROPE'S
 OLDER MORAINIC LANDSCAPE

In the Northwest German Lowland two geomorphologically different types of glacial landscape can be distinguished: young morainic and older morainic landscape.

The young morainic landscape is characterized by fresh forms of relief which clearly bear the marks of the about 20 000 years old Weichsel glaciation and whose topography is so distinct that it is east of Kiel called "Holsteinian Switzerland"; the older morainic landscape shows, deposited during the Saale (Riss) glaciation, a totally subdued relief, which is characterized by low gradients of slope and wide, almost flat plains underlain by Pleistocene deposits (Figure 1). Large differences in altitudes like those so conspicuous in the young morainic landscape are absent, and the endmoraines originally existed are so subdued that different investigators disagree as to their positions. The boundaries of ice-marginal channels (Urstromtäler) against neighbouring terrain are also difficult to recognize. Even the boundaries of outwash plains have to be deduced and their connection with ice-marginal positions is in most cases not clear. On the whole one can speak of a terrain in which glacial deposits are still present, but glacial relief is almost completely extinguished (Liedtke 1981b).

Why have the main features of glacial relief disappeared in the older morainic landscape? Why are glacial channels and tongue-like basins no longer recognizable? Why is the landscape so extraordinarily flat? The answer is easy: it was the periglacial climate with permafrost and lack of vegetation which created these conditions and caused a flattening of relief in the region adjacent to the inland ice of the last glaciation.

STRATIGRAPHIC EVIDENCE FOR INCISION AND ABLUVAL

ACCUMULATION

In general, solifluction is made responsible for this erosional process. But, as known from areas where hard rock is underlying a thin glacial cover,

FIGURE 1 Northwestern Germany's young and older morainic landscapes and the major basins filled up by abluval sediments during the Weichsel glaciation

- Young morainic landscape (Weichsel = Würm)
- Old morainic landscape (Saale = Riß)
- Major basins filled up mainly by abluval sediments during the Weichselian
- Outcrop of hard rock
- Area of Rhine terraces
- 146 Damme Hills

the effectiveness of solifluction is limited and the main features of relief have been altered comparatively little. Apart from that there are large areas underlain by sandy-gravelly sediments which, due to their lack of fine material, were hardly liable to solifluction. The "sanding up" of areas with Saale ground moraine shows that here not only a simple transport of material occurred but also sorting: blocks and coarse sand remained, whereas finer sand, silt, and clay were carried away. Therefore, slopewash and not solifluction played the main role in flattening the glacial relief in older morainic landscapes. Fine materials such as clay, silt and fine sands were washed off the land surface and carried away during the melting period every year whereas the coarser material remained. For this process I propose the term "ablation" (from Latin "abluere", to wash off), which is understood as a periglacial aquatic process of wash on slopes, with deposition of this material at the bottom of such slopes where the inclination decreases. For northwestern Germany this process explains the filling up of wide glacial basins through which scattered small islands of ground moraine protrude. The sediments were transported in periglacial-fluvial valleys, which can be subdivided into three parts: the upper reaches with denudational ablation, the middle reaches where material was transported through, and the lower reaches and foreland with depositional ablation.

Evidence on which these statements are based, were found at the Damme Hills in Northwestern Germany southwest of Bremen, which belong to the typical older morainic landscape. These Damme Hills, 20 km long and 10 km broad, consist of probably pre-Saale pushed glacial sands and gravels (Stauchmoräne) which were formerly covered with a thin layer of Saale till or ground moraine. Due to the glacial push, the relief was very hilly and has still today a relief of about 100 m between the highest point (146 m) and the lowest (38-50 m). During the entire Weichsel glaciation, this area was exposed to a periglacial climate, which was the reason that the covering Saale ground moraine was mostly removed and only erratic boulders were left. In the push area selective erosion took place; valleys were cut in the sandy parts whilst the gravelly structures formed ridges, because they acted as a resistant layer. Geomorphological mapping shows that eroded material was transported partly along former glacial channels (Galbas, Klecker & Liedtke 1980).

These valleys with a graded longitudinal profile have a flat-floored cross-profile and show a very uniform stratigraphy:

- 0.5-0.8 m sandy-gravelly blanket, unsorted (Geschiebedecksand);
- 2.0-3.0 m well-sorted fine sands in the upper reaches, sandy-gravelly sands in the middle reaches;
- 0.5-1.0 m basal conglomerate;
- sharp unconformity;
- Saale layers;

The basal conglomerate contains flat blocks of

Bunter Sandstone up to a diameter of 0.5 m in a thalweg that is 5-10 m wide. This shows that a rapid discharge occurred during the time of incision even in the upper reaches of small valleys. All coarse clasts, bigger than the transport capacity allowed sank down and were moved only occasionally. The basal conglomerate became packed so densely that it can be exposed only by a pickaxe.

The erosion phase is followed by a sedimentary accumulation of several meters. On the top we find an unsorted sandy-stony cover, called "Geschiebedecksand", which is thought to have been formed under periglacial conditions (Kopp 1970, Lembke 1965).

The material that reached the valleys was partly sedimented in valley floors and mostly in basins of the lowlands, where often more than 5-10 m were accumulated. It is typical and remarkable that nearly always fine or medium sands were deposited, as an example in a large sand pit at Holdorf station shows. Within the uppermost 5 m of horizontally stratified sandy layers I found only three beds with scattered small gravels up to 3 cm in diameter, though the edge of the Damme Hills is nearby (1 km). Organic layers are totally lacking (Liedtke 1981a). Several syngenetic frost cracks are proving an accumulation under cold periglacial conditions (Karte 1979).

Such very common accumulation plains, consisting mostly of medium to fine sands without gravels, demonstrate an activity of water, but are not the typical deposit of a river. The slight gradient of 2-3 ‰ allowed only the transport of fine sand on the top of the permafrost during the seasonal melting of winter snow when the water ran down in a kind of sheet discharge. Coarse material was left behind, sands were deposited in the basins, and only silt and clay could reach the North Sea. According to these processes, all the basins were filled up and sediment spread more and more, drowning the adjacent flat glacial landscapes. Geologists, not recognizing these processes, mapped these sandy areas as "Talsand" (valley sands). The borders to the adjacent higher areas are often very uncertain, especially where during the end of the Weichsel cold period eolian coversands or dunes were sedimented or where Holocene low fens or raised bogs developed.

THE AGE OF THE MOST ACTIVE PROCESSES SUBDUING THE TYPICAL GEOMORPHOLOGICAL FEATURES OF THE SAALE GLACIATION

As the original constructional topography of this area was formed during the Saale (Riss or Illinoian) glaciation, we now have to solve the question whether reduction of the relief and aggradation in the basins already began during the end of the Saale glaciation. We cannot expect considerable denudation at that time, because in the young morainic landscape we find a merely changed rugged glacial relief with a lot of typically closed depressions still visible today. On the other hand, we have direct evidence that the aggradation in depressions did not start earlier than the beginning of the Weichsel glaciation, as Menke (1976) showed in

Schleswig-Holstein and Lembke et al. (1970) in Brandenburg (Figure 2).

identified by a special sign (arrow).

Why are we very sure that these depressions were filled up not earlier than during the Weichsel cold period? There are 3 indications:

1. Many of these depressions contain an interglacial Eem (Sangamon) layer at their bottom (Figure 2).
2. The Eem layer covers the typical late Saalean "G geschiebedecksand", a kind of sediment which we can find on all young morainic deposits as well.
3. The upper parts of the aggradated sands in some of the depressions contain Weichsel interstadial layers. They allow to fix the time of aggradation closely, and they demonstrate that about 80 % of the filling up happened during the early Weichsel (Figure 3).

So we can fix two processes very accurately: The dominant aggradation happened during the cold stages of early Weichsel by abluval sheetwash and was preceded by strong erosive incision. Without any doubt, it was the geographical milieu that offered the best conditions for these two processes: it was the transitional phase from the last interglacial to the last glacial. At that time everywhere in central Europe an erosion phase took place and was connected or immediately followed by aggradation in basins and lowlands. It is now proved by recent research in periglacially formed areas of central Europe (Menke 1976) that this erosive phase introduced the beginning of the Weichsel cold period. This idea can also be applied to former cold periods of the Quaternary, although no stratigraphic evidence has been found that would demonstrate this.

We now know that the filling up of depressions

Figure 2 Schematic representation of Weichsel abluval filling-up of closed depressions.

For in the older morainic landscape nearly all glacial lakes have disappeared and most areas have become drained by valleys, it is surprising that thousands of former kettle holes have survived. There are more than 1000 of them on the Fläming (south of Berlin, Liedtke 1960), and a special mapping showed that in Lower Saxony more than 10 000 closed depressions are still existing; partly they were explained as pingos (Garleff 1968). Most of them are glacial depressions that were not totally filled up by post-Saale or Weichsel periglacial processes. They are recognizable in the landscape as depressions with a depth of 1-2 m and a diameter of up to 250 m. Sometimes they are filled with water. On topographical large-scale maps they are

Figure 3 Vegetation succession during the early Weichsel.

began with the first cold forest climate. That means that the main erosive phase took place during the very end of the Eem interglacial, and we can conclude:

The very end of an interglacial or a warm interstadial started strong erosion in hilly areas and accumulation in basins.

During a stadial, accumulation filled up the valley bottoms according to solifluction and (or) slope wash.

During every end of the early Weichsel interstadials, after the vegetation had returned and the area was reforested, a phase of steady erosion occurred. To cause this erosion a special fluvial process is needed: a seasonal sudden heavy discharge produced by melting of winter snow and favored by winter frost in the surface layers. There was no continuous permafrost needed, but it was in formation and expansion; and there was still a thick mollisol that together with a large amount of running water allowed erosive incision, which was increased by the eroded material as an attacking weapon. Big blocks remained more or less stationary at the bottom; they were only projected downwards to form the basal conglomerate.

During the cold tundra periods accumulation took place in valleys and basins. The material came from the slopes; on sandy-gravelly slopes ablation prevailed, on sandy-silty slopes solifluction was usual. Both of the processes supplied the valleys with fine or coarse material. The wetter the conditions were the more material reached the valleys. During the extremely dry High (Main) Weichsel the loess cover could develop.

Unfortunately, sand pits with interglacial or interstadial layers are very rare. Here was shown the ablation filling up of a glacial depression during the begin of the early Weichsel. But also during the middle Weichsel ablation proceeded, and sandy material was ablationally deposited in the basins. A temporary sand pit at Lemförde, 8 km southeast of the Damme Hills, showed more than 8 m of horizontally stratified sandy layers with four cryoturbated beds. Two of these beds were recently C^{14} -dated (Nr. 11770, 11771 by Niedersächsisches Landesamt für Bodenforschung, Hannover, April 6, 1983); their age of $35\ 060 \pm 870$ B. P. and $36\ 030 \pm 650$ B. P. lies between the Hengelo and Denekamp interstadials and indicates that also during the middle Weichsel ablation processes were active under periglacial conditions with permafrost.

So, ablation processes happened under full periglacial permafrost conditions as well as under conditions when the formation of permafrost began and a long duration of seasonal frost existed.

We must keep in mind that during the very end of the Eem interglacial, erosion took place, which was accompanied and followed by a mighty accumulation during the first tundra periods of the early Weichsel. There were only about 10 000 years of tundra climate in which this accumulation occurred during early Weichsel (Liedtke 1981b) and filled up nearly most closed depressions, left from the Saale glaci-

ation; at that time also began a mighty sedimentation in the lower parts of Saale-aged glacial basins.

A COLLOCATION ANALYSIS FOR SOLVING PERIODIC THAWING AND FREEZING
PROCESSES IN ACTIVE LAYERS OF PERMAFROST

Sui Lin and Shimao Ni

Department of Mechanical Engineering, Concordia University
Montreal, Quebec, Canada H3G 1M8

The periodic variation of the ground surface temperature causes alternative thawing and freezing processes in the active layer of the permafrost. The ground surface is an important location of the present problem, which is selected as the collocation point of the analysis. Analytical results are compared with those obtained from the zeroth-order and the first-order quasi-steady approximations, and the first-order perturbation method. The accuracy of the collocation analysis is not less than that obtained from the first-order perturbation approximation.

INTRODUCTION

MATHEMATICAL FORMULATION AND
ANALYTICAL APPROXIMATION

Due to the seasonal variation of temperature, alternating thawing and freezing processes take place in the active layer of permafrost. When the ambient temperature increases above the melting point of the permafrost, melting starts at the ground surface and propagates downward into the permafrost. There co-exist two phase regions: liquid and solid. When the ambient temperature decreases to below the melting point of the permafrost, the liquid phase solidifies starting also from the ground surface and propagates downward. There co-exist three phase regions: solid, liquid, and solid. When the solidification process reaches the end of the liquid phase, the liquid region disappears, and it becomes one solid phase region again.

Consider a permafrost region having its melting point T_m . Initially the active layer is at the melting temperature and in solid state. After a definite time the surface at $x = 0$ is subject to a periodic temperature variation, $T_{x=0} = A_0 \sin \omega t + T_m$, where A_0 is the amplitude and ω is the frequency. We wish to find the response of the active layer to this periodic temperature disturbance for large values of time, that is, the steady periodic solution of the problem, for which the initial condition may be ignored. During the time period

$$\frac{2n\pi}{\omega} < t < \frac{(2n+1)\pi}{\omega} \quad (n = 1, 2, 3, \dots)$$

because the surface temperature is higher than the melting temperature of the permafrost, a melting process propagates from the surface downward into the active layer of the permafrost. In this case, there co-exist two phase regions: liquid and solid. During the time period

$$\frac{(2n+1)\pi}{\omega} < t < \frac{(2n+2)\pi}{\omega}$$

because the surface temperature is lower than the melting temperature of the permafrost, a solidification process propagates from the surface downward into the liquid phase of the active layer of the permafrost. There co-exist therefore three phase regions: solid, liquid, and solid. When the solidification process reaches the end of the liquid phase, the active layer becomes solid. At that time the three phase regions disappear and return to one phase region.

The prime characteristic of the melting and solidification processes is the existence of moving boundaries between the solid and liquid phases, whose locations are unknown and which are to be determined as a part of the solution. The moving boundary problem is nonlinear and solutions involve considerable mathematical difficulties. Exact solutions to such problems are presently restricted to only a few idealized situations [1]. With regard to the nonlinear problem, solutions have been obtained by analytical approximations and numerical methods (see, for example, [2] and [3]).

For the periodic thawing and freezing processes, we consider that the ground surface is subject to a temperature variation with a harmonic function varying around the melting temperature of the permafrost. The surface temperature variation causes steady periodic thawing and freezing processes in the active layer of the permafrost. For solving such a nonlinear problem, the first-order perturbation approximation and a numerical analysis were conducted by Lock et al. [4], the zeroth-order quasi-steady approximation was used by Seban [5], and the first-order quasi-steady approximation was used by Lunardini [1]. In the present paper, an approximate analysis utilizing the method of collocation is developed for solving the steady thawing and freezing processes in the active layer of the permafrost. The result is compared with results obtained by Lock et al., Seban, and Lunardini.

For mathematical formulation of the problem, we designate the initial complete solid phase as region 0, the liquid phase formed during the melting process as region 1, and the solid phase formed during the freezing process as region 2. As described above, after the liquid phase disappears, region 2 becomes region 0 as shown in Figure 1, where s_1 , s_2 represent the locations of the phase boundaries between regions 0 and 1, and between regions 1 and 2, respectively. To simplify the

problem, it is assumed that material properties in each phase are constant, but they may be different in different phases and that density change across the phase boundary may be neglected. Furthermore, it is assumed that the latent heat of fusion of the permafrost is much larger than its sensible heat. Under this assumption, the following approximations may be made:

1. After the time, $t = t^*$, when the liquid phase disappears, or when $s_2 = s_1 = s^*$, it is assumed that the temperature at the position $x = s^*$ is maintained at the melting point.
2. The heat flux in the solid phase during the melting process, and the heat flux in the liquid phase during the solidification process, may be ignored.

The following is the system of equations describing the one-dimensional periodic melting and freezing processes with the melting temperature of the permafrost as a reference temperature, that is,

$$T_m = 0:$$

$$\frac{\partial T_i}{\partial t} = a_i \frac{\partial^2 T_i}{\partial x^2} \quad (1)$$

$$T_i(0, t) = A_0 \sin \omega t \quad (2)$$

$$T_i(s_i, t) = 0 \quad (3)$$

$$\rho L \frac{ds_i}{dt} = (-1)^i k_i \frac{\partial T_i(s_i, t)}{\partial x} \quad (4)$$

where $i = 1$ refers to the melting process for the time period

$$\frac{2n\pi}{\omega} < t < \frac{(2n+1)\pi}{\omega}$$

for $n = 0, 1, 2, \dots$, and $i = 2$ refers to the freezing process for the time period

$$\frac{(2n+1)\pi}{\omega} < t < \frac{(2n+2)\pi}{\omega}$$

For solving the problem, the method of collocation will be used [6], in which the heat conduction differential equations are satisfied only at preselected points (collocation points). For the present problem, the periodic melting and solidification processes are caused by the periodic variation of the surface temperature. Therefore the most important location of the present problem is at the surface $x = 0$. Hence, we select the point $x = 0$ as the collocation point.

The temperature profile is assumed as

$$T_i = A_i e^{-\lambda_i x / \sqrt{2}} \sin(a_i \lambda_i^2 t - \lambda_i x / \sqrt{2}) + B_i x \quad (5)$$

which satisfies the differential equation, Equation (1), at the collocation point $x = 0$, where A_i and

λ_i are constant, and B_i is a function of time. By making use of the boundary conditions, Equations (2) and (3), A_i , λ_i , and B_i can be determined as follows:

$$A_i = A_0 \quad (6)$$

$$\lambda_i = \sqrt{\frac{\omega}{a_i}} \quad (7)$$

$$B_i = -\frac{1}{s_i} A_0 e^{-\lambda_i s_i / \sqrt{2}} \sin(a_i \lambda_i^2 t - \lambda_i s_i / \sqrt{2}) \quad (8)$$

The temperature profile can then be written as

$$T_i = A_0 \left[\exp\left(-\sqrt{\frac{\omega}{2a_i}} x\right) \sin\left(\omega t - \sqrt{\frac{\omega}{2a_i}} x - \frac{x}{s_i} \exp\left(-\sqrt{\frac{\omega}{2a_i}} s_i\right) \cdot \sin\left(\omega t - \sqrt{\frac{\omega}{2a_i}} s_i\right)\right] \quad (9)$$

The derivation of the temperature T_i , at the position $x = s_i$, can be expressed by

$$\begin{aligned} \frac{dT_i}{dx} \Big|_{x=s_i} &= -A_0 \exp\left(-\sqrt{\frac{\omega}{2a_i}} s_i\right) \left[\left(\sqrt{\frac{\omega}{2a_i}} + \frac{1}{s_i}\right) \sin\left(\omega t - \sqrt{\frac{\omega}{2a_i}} s_i\right) + \sqrt{\frac{\omega}{2a_i}} \cos\left(\omega t - \sqrt{\frac{\omega}{2a_i}} s_i\right) \right] \quad (10) \end{aligned}$$

Substitution of Equation (10) into Equation (4) yields

$$\begin{aligned} \frac{ds_i}{d\tau} &= (-1)^{i+1} \frac{St_i}{2} \frac{\exp(-\bar{s}_i)}{\bar{s}_i} \left[(\bar{s}_i + 1) \sin(\tau - \bar{s}_i) + \bar{s}_i \cos(\tau - \bar{s}_i) \right] \quad (11) \end{aligned}$$

$$\text{where } \bar{s}_i = \sqrt{\frac{\omega}{2a_i}} s_i \quad (12)$$

$$\tau = \omega t \quad (13)$$

$$St_i = \frac{A_0 c_i}{L} \quad (14)$$

For a seasonal temperature variation, the value of ω and, in turn, the value of s_i are very small. For a small value of s_i , Equation (11) may be approximated, after the expansion of the functions $\exp(-\bar{s}_i)$, $\sin(\tau - \bar{s}_i)$, and $\cos(\tau - \bar{s}_i)$, by neglecting the terms having s_i of order higher than two, as follows:

$$\frac{ds_i}{d\tau} = \frac{St_i \sin \tau}{2 \bar{s}_i} \quad (15)$$

Integration of Equation (15) yields

$$\bar{s}_i = \sqrt{2 St_i} \sin \frac{\tau}{2} \quad (16)$$

RESULTS AND DISCUSSION

In order to compare the location of the moving phase boundary obtained from Equations (11) and (16) with those obtained by Lock et al. [4], Seban [5], and Lunardini [2], the coordinates of the moving boundary must have the same scale for all cases. With the following transformation,

$$\bar{s}_i = \sqrt{\frac{St_i}{2}} \xi_i \quad (17)$$

Equations (11) and (16) become

$$\frac{ds_i}{d\tau} = (-1)^{i+1} \exp\left(-\sqrt{\frac{St_i}{2}} \xi_i\right) \left[\left(\sqrt{\frac{St_i}{2}} \xi_i + 1 \right) \sin\left(\tau - \sqrt{\frac{St_i}{2}} \xi_i\right) + \sqrt{\frac{St_i}{2}} \xi_i \cos\left(\tau - \sqrt{\frac{St_i}{2}} \xi_i\right) \right] \quad (18)$$

and

$$\xi_i = 2 \sin \frac{\tau}{2} \quad (19)$$

The results obtained in [4], [5], and [2] are, respectively, as follows:

$$\xi_i = 2 \sin \frac{\tau}{2} - \frac{St_i}{3} \sin \frac{\tau}{2} \sin \tau \quad (20)$$

$$\xi_i = 2 \sin \frac{\tau}{2} \quad (21)$$

and

$$\xi_i = 2 \sin \frac{\tau}{2} - \frac{St_i}{2} \left[\frac{2}{3} + 2 \cos \frac{\tau}{2} - \frac{8}{3} \cos^3 \frac{\tau}{2} \right] \quad (22)$$

It is seen that the simplified Equation (19) is identical with Equation (21) obtained from the zeroth-order quasi-steady approximation. By using the fourth-order Runge-Kutta method, Equation (18) can be integrated. Figures 2-4 show the comparison of the results calculated from the collocation method (Equation (18)), the first-order perturbation approximation (Equation (20)), the zeroth-order quasi-steady method (Equation (21)), and the first-order quasi-steady approximation (Equation (22)) with St_i as a parameter. For a small Stefan number, $St_i = 0.01$, there is practically no difference among these results as shown in Figure 2. However, deviations among these results increase with an increase of the Stefan number as shown in Figures 3 and 4. From the comparison, it can be concluded that the accuracy of the collocation analysis is between those obtained by the first-order perturbation approximation and the first-order quasi-steady method.

EFFECT OF SURFACE-APPLIED PRUDHOE BAY CRUDE OIL ON VEGETATION AND
SOIL PROCESSES IN TUSSOCK TUNDRA

A. E. Linkins¹ and N. Fetcher²

¹Biology Department, Virginia Polytechnic Institute and State University,
Blacksburg, Virginia 24061 USA

²Duke Phytotron, Department of Botany, Duke University, Durham,
North Carolina 27706 USA

Prudhoe Bay crude oil was applied as a 20 liter m⁻² surface spray on Eriophorum vaginatum tussock tundra at Eagle Summit, Alaska, in August 1979. Oil caused a significant reduction in mycorrhizal root numbers and root respiration rates in Betula nana, but not in Eriophorum vaginatum root tips which had grown through the 5- to 15-cm-deep oil-contaminated soil. Significant changes did occur in leaf senescence patterns of B. nana and the tillering index of E. vaginatum. Soil cellulase and phosphatase enzyme activities both declined in the oiled soil horizons but were unaffected in horizons immediately below visibly contaminated organic matter.

INTRODUCTION

The impact of oil on soils and vegetation in arctic and subarctic regions has been studied in association with the development of oil exploitation and transportation in these areas. The effect of oil on soils and vegetation has recently been reviewed by Linkins et al. (1983). This review points out that the toxic effects of direct oil-vegetation contact are relatively straightforward (leaf death occurring from direct oil contact, with regrowth from protected buds (Walker et al. 1978, Wein and Bliss 1973) and vigorous regrowth occurring where the soil is water saturated and oil does not penetrate the soil.) However, where oil penetrates the soil into the plant rooting zone, the plant responses are more complex, ranging from rapid death, or gradual losses in growth and reproduction capability, to complete or limited revegetation (Deneke et al. 1975, Johnson 1981, Johnson et al. 1980, Linkins et al. 1978, Linkins and Antibus 1978). All these responses must be due to oil-related altered soil water potential, structure, cation exchange capacity, aeration, as well as direct toxic effects of the oil (Everett 1978, Johnson, et al 1980, Pesek 1981, Sparrow et al. 1978). The complexity of these oil-soil-plant interactions makes it quite difficult to establish a successful revegetation/restoration plan in oil-contaminated arctic-subarctic soils (Linkins et al. 1983).

It is the purpose of this paper to present information on the responses of two plant types to a surface oil spill of 20 liters m⁻²--Eriophorum vaginatum and Betula nana. The decomposition of cellulose and organic phosphorous is also discussed as it relates to overall site recovery potential.

MATERIALS AND METHODS

Oil Application

Prudhoe Bay crude oil was applied as a uniform

surface spray to give a final coverage volume of 20 liters m⁻² as a uniform surface spray (Everett 1978) on a 3 x 20 m plot of E. vaginatum tussock tundra at Eagle Creek, Alaska, on August 14, 1979. Oil was applied at ambient temperature. A control plot of 3 x 20 m was delineated adjacent and upslope of the oil spill plot.

Plant Studies:

Xylem pressure potential was measured on a clear day (July 16, 1980) at midday for five species of tussock plants, Eriophorum vaginatum, Carex biglowei, Rubus chamaemorus, Betula nana, and Vaccinium uliginosum. Measurements were taken on unshaded stems or blades following the recommendations of Ritchie and Hinckley (1975). Readings were taken using nonoiled current year's vegetation from plants in the oiled plot. Similar vegetation was used from plants in the control plot. Data were analyzed using a two-way analysis of variance.

Plant demography studies were conducted with E. vaginatum. Demographic analysis of new tillers (Vo), 1-year tillers (V1), and mature tillers (Vm) was done according to Goodman and Perkins (1968). Demographic analysis was conducted using two to three tussocks per sample, with all tillers in a harvested tussock categorized.

Viable root tips from the above tussocks were suspended immediately upon harvesting in a 5 mM CaCl₂ solution. Respiration rates of these root tips were measured at 10°C using an Orbisphere polarographic electrode (Model 2709).

Leaves of the deciduous shrub B. nana were categorized as follows: live, dark green and turgid; senescent, light green colored and turgid; or dead, brown or dull red and dry. Determinations were made on a minimum of five main stems of at least three separate plant clumps.

Ectomycorrhizal root tips from the above plant clumps were harvested and quantified on a soil volume basis as described by Antibus and Linkins (1978). Root tip respiration rates were measured as described above.

Soil Studies

Potential for cellulose hydrolysis in oiled and control soils was measured by the exocellulase and endocellulase assays as described by Linkins et al. (1978). Potential for organic phosphomonoester hydrolysis in the soil was measured using the phosphomonoesterase enzyme assay with p-nitrophenylphosphate (PNPP) (Sigma) substrate as described by Tabatabai and Bremner (1969) and modified to 0.3M PNPP as described by Herbein (1981). All enzyme assays were conducted at 20°C with appropriate controls as described by Linkins and Neal (1982) and Herbein (1981).

RESULTS AND DISCUSSION

The effect of crude oil on the water potential of representative plants in tussock tundra is shown in Figure 1.

FIGURE 1 Water potential in megapascals for *E. vaginatum* (E.V.), *C. biglowei* (C.B.), *Rubus chamaemorus*, *B. nana* (B.N.), and *Vaccinium uliginosum* (V.U.) in control 0 and 20 liter m⁻² oil spill 0 plots. Data are given as means with standard deviation.

In no case was there any significant difference in the water potential of any plants tested. This was even true for plants which have the majority of their root biomass in the 1-15 cm soil layer visibly contaminated with the oil (e.g. *B. nana*, *V. uliginosum*, *C. biglowei* (Miller et al. 1982)). There were not even any water potential differences for known ectomycorrhizal plants (*B. nana*), even though Antibus and Linkins (1978) and Linkins and Antibus (1978) showed significant structural and functional changes in oil contaminated ectomycorrhizal roots of *Salix rotundifolia* at Barrow, Alaska.

The ectomycorrhizal roots of *B. nana*, many of which were found to reside in the 1- to 15-cm oil contaminated soil depth, did show a significant reduction in both numbers and the respiration rates of those remaining (Table 1). These responses were similar to those noted for *S. rotundifolia* at Barrow following a 5- or 12-liter m⁻² Prudhoe Bay oil spill (Antibus and Linkins 1978, Linkins and Antibus 1978).

This reduction in mycorrhizal root biomass and activity seemed to be balanced by a reduction in the number of leaves per stem (Table 2). There was a trend in the reduction of leaves per stem during the season for plants in oiled soils, although it was not always significant. This concomitant reduction in both absorptive root surface and leaf surface area could explain the lack of observed water stress in these plants (Figure 1).

However, there are other differences in the leaves on the stems of oiled and nonoiled plants. There is a significant shift in the proportion of leaves which are green, senescing, or dead. For 3 years there was a significant increase in the proportion of leaves in a senescing or dead class for oiled plants (Table 2). This shift was independent of the time of the growing season. These data suggest that there is an effect of oil on these plants which continues to cause not only an overall reduction in viable roots and leaves but also an accelerated aging and death in leaves.

TABLE 1 Effect of Prudhoe Bay crude oil (20 liters m⁻²) on Root Tip Numbers (cm⁻³ soil) and Respiration Rates ($\mu\text{l O}_2 \text{ h}^{-1} \text{ g dry wt root}^{-1}$) of the Mycorrhizal Root Tips of *B. nana* and on Root Tip Respiration ($\mu\text{l O}_2 \text{ h}^{-1} \text{ g dry wt root}^{-1}$) of *E. vaginatum* in *E. vaginatum* tussock tundra at Eagle Creek, Alaska.

Regardless, it will be important to understand the nature of this oil/*E. vaginatum* interaction as it may undermine long-term restoration of oil-contaminated tussock tundra by *E. vaginatum*.

Soil Enzymes

The enzyme complex cellulose hydrolyzes cellulose and similar 14 linked polymers into soluble carbohydrates which can be assimilated by soil microorganisms (Eriksson 1978, Linkins et al. 1978, Linkins and Neal 1982, Reese 1977). Two major functional groups of this complex are the endocellulases, which hydrolyze internal bonds in the cellulose chain, and exocellulases, which hydrolyze bonds from the nonreducing end of the

cellulose chain (Eriksson 1978, Reese 1977). This latter group is most directly associated with the production of soluble molecules for microbial uptake.

A ratio of the exocellulase to endocellulase activity has been shown in natural ecosystems to be related to the quantity (degree of lignification) or availability of cellulose in plant litter (Linkins et al. 1978, Linkins and Neal 1982, Linkins et al. 1980, Shaver et al. 1983, Sinsabaugh et al. 1981). The higher the ratio the more cellulose is hydrolyzed for microbial uptake and oxidation. Data in Table 4 show that oil-contaminated soils lose their ability to support the hydrolysis of cellulose to products taken up by microorganisms.

Endocellulase activity is given as unit h⁻¹ g dry wt soil⁻¹; Exocellulase activity is given as µg glucose equivalents released h⁻¹ g dry wt soil⁻¹. N = 18. Activities given as means. Value in an enzyme type followed by a different superscript are significantly different at the 0.05 level.

The loss in cellulase activity is initially in the exocellulase component, but eventually both components' activities are reduced. In addition to an absolute loss in cellulase activities there is a reduction in the efficiency of the enzyme complex to produce microbially utilized products. The exocellulase to endocellulase ratio shifts from the 0.50-0.62 range in control soils to 0.27-0.16 in 1982 oiled soil horizons. These patterns are similar to those seen for cellulase activities in oil-contaminated soils at Barrow, Alaska, where cellulose was lost as an energy source in oiled soils (Linkins et al. 1978).

Acid phosphomonoesterase is an enzyme that hydrolyzes inorganic phosphorous off organic phosphomonoesters. In soils, these enzymes, like most other extracellular soil hydrolases, are physically adsorbed to soil particles (Spier and Ross 1978). The effect of oil on acid phosphomonoesterase activity in the oil contaminated soil Oi-Oe horizons is given in Table 5. Unlike the exocellulase activity, phosphatase

activity did not show a significant reduction in activity until the third season, 1981. This reduction remained through the following season. Thus, the potential for generation of inorganic phosphorous, if organic phosphorous was available to the enzyme in these oiled soils, was unaffected for 2 years after the oil spill. This maintenance of activity could be due to the tolerance of the extant enzyme or production of the extracellular enzyme by oil tolerant organisms. The ultimate decline in activity is probably due to loss of the enzyme as a result of loss of suitable available substrate and/or enzyme binding sites in the oil-coated soil material (Everett 1978, Linkins et al. 1978, Pesek 1981).

The influence of oil in a particular soil horizon (Oe-Oi in this study) seems to primarily be limited to that horizon. Tables 5 and 6 show that soil enzyme activity in the Oe-Oa soils material immediately under the visibly contaminated Oi-Oe horizons was unaffected. These data suggest that those oil components, if any,

that leach down in the soil do not adversely effect certain enzymatic aspects of decomposition.

CONCLUSIONS

Limited observations on the water potential of plants in oiled soils suggest that oil in the soil may not induce significant water stress in plants. The concomitant reductions in both leaf area and absorptive root surface area in B. nana (a plant with the bulk of its roots in the oiled soil horizon) undoubtedly played a role in the maintenance of observed plant water potentials (Oberbauer and Miller 1982). The consistent premature senescing of leaves in B. nana and reduction in mycorrhizal root tips (Antibus and Linkins 1978, Linkins and Antibus 1978), plus the altered tillering index in E. vaginatum, suggest that the persistence of crude oil in the soil significantly alters plant growth and carbon-nutrient allocation patterns. These changes which

were observed for 3 years after a 20 liter m^{-2} crude oil spill, provide useful additional information in planning cleanup and revegetation/restoration efforts in tussock tundra. Johnson (1981) and Linkins et al. (1983) suggest that an important option for consideration in planning cleanup and revegetation/restoration efforts should be no action (passive). However, the plant response data in this paper show that even after 3 years the presence of oil still alters growth and nutrient allocation patterns such that successful regrowth and restoration may not occur, or at least be very slow. Perhaps a passive approach should occur only on small or contained spills where acceptable revegetation can occur by invasion from adjacent tundra by plants with some porportion of their root system in uncontaminated tundra.

Data on soil processes in this paper show that the effect of oil is limited to areas visibly contaminated by the oil. The organic soils immediately adjacent to or below the contaminated area are unaffected. McGraw and Shaver (1982) and Shaver et al. (1983) have shown that the organic mat is an important natural seed source for seedling establishment of many tussock tundra plants. Therefore, in oil spills with limited vertical movement where some uncontaminated organic material remains, removal of only the contaminated soil may leave organic material with normal nutrient cycling and decomposition potential (enzyme activity) and a viable native seed source. This may promote the most acceptable long-term cost-effective restoration of the site.

CALCULATION OF FROST-HEAVING FORCES IN SEASONALLY FROZEN SUBSOILS

Liu Hongxu

Heilongjiang Provincial Low-Temperature Construction Research Institute
People's Republic of China

The mechanical properties of frozen soil differ considerably from those of unfrozen soil. The author proposes that the soil beneath foundations on seasonally frozen ground be considered as a double layer, composed of a layer of frozen soil and a layer of unfrozen soil. Based on the linear elastic theory, the author proposes a method for calculating stress distribution at the freeze/thaw interface in soils under foundations. Analyzing the characteristics of stress distribution during the frost process in a double-layer subsoil, the author has presented a method for estimating the normal and horizontal frost-heaving forces in frost-susceptible subsoils. According to field test results, a nomograph for determining normal and horizontal frost-heaving forces in various frost-susceptible soils is also presented. To demonstrate the application of double-layer calculations to foundation design, several examples for examining foundation stability are given.

Ordinary foundation soil is of one layer in seasonal frozen soil districts. With the freezing and expansion of the foundation soil, its stress state gradually and finally changes to that of the two-layer soil. When thawing takes place in the spring, the mechanical properties of the thawing soil are much less than those of frozen soil, thus forming a three-layer foundation soil. This paper analyzes the force imposed on building foundations during the process of frost heaving by frost-heaving soil using the calculation result of the two-layer soil.

Based on the relation curve of normal frost-heaving with respect to freezing depths actually measured at the frozen soil observation station, by using a finite element method under a principle of non-linearity during a certain load history, we can obtain the frost-heaving stress distribution in different depths of the foundation soil.

When the stress is comparatively small, numerical calculation should be done by the finite element method based on the linearity concept. Similarly, the shearing frost-heaving force can also be developed by using the calculation of frost-heaving for a two-layer soil.

Using the non-linear analyses of the force imposed on two-layer foundation soil, the bearing capacity of the frozen soil can also be calculated.

The strength of a frost-heaving soil usually becomes lower when it is thawing. By using an analysis of the stress for a three-layer foundation soil, the stability of a foundation during thawing process can be checked.

CALCULATION OF NORMAL FROST-HEAVING FORCE

Before freezing, the distribution of additional stress induced by loading is uniform (in a single layer) in the foundation soil. When freezing develops to a depth under the base of the foundation, the foundation soil will turn into two layers because of the difference of mechanical properties between the frozen soil and the unfrozen soil. If the foundation soil is not expansive in freezing, distribution of stress in the soil also remains uniform, although the foundation soil has turned into two layers. But if the foundation soil is of frost-heaving soil, then the stress in it will undergo a series of changes or redistributions as frost-heaving force occurs and increases continuously. If the additional stress is σ_z at the intersecting point of freezing interface, depth of which is h counted from the foundation base, and the symmetric axis (z -axis) of the foundation base is n , considering the foundation soil as two layers, and the heaving stress on the interface σ_z is m , the additional load $\frac{m}{n}$ on the foundation will be equal to the stress in the two-layer foundation soil, when $m < n$, while the remaining part $(1 - \frac{m}{n})$, is equal to the stress in the unchanged one-layer foundation soil. When $m = n$, the stress state of the foundation soil becomes that of two-layer soil completely. If the soil expands only a little during freezing, its stress state may not attain that of the two-layer soil at all.

Loads on buildings with their foundations buried within the range of freezing

are comparatively small. The stress in the soil, as a homogeneous body linearly deformed, is usually calculated by using the elastic theory. After the soil is frozen, its mechanical properties will be greatly improved. It is reasonable to analyze the stress in foundation soil as a linearly deformed body in a two-layer semi-infinite space.

Deformation modulus of the frozen soil is closely related to temperature. In winter, distribution of temperature in the seasonal frozen layer along its depth can be taken as linear, when the thickness of the frozen layer does not exceed $3/4$ of the maximum frozen depth, i.e. when the temperature increases again. According to actual measurements in Northeast China, where the frozen depth is about 2m (about in the region of 46° N, 120° E), the mean vertical temperature drop in the soil is 0.1° c/cm. Temperature at various points under the ground surface could be calculated by the following formula:

$$t = f(z) = -0.1(h-z) \quad (1)$$

where h is thickness of the frozen layer counted from the base of the foundation, in cm; and z is the vertical coordinate of a certain point in the frozen layer under the base of the foundation. The relation between the deformation modulus of the frozen soil and the soil temperature is

$$E_1 = f(t) = E_0 + Kt^{\alpha} = 100 + 430t^{0.865} \quad (2)$$

Where E_0 is the deformation modulus of frozen soil at 0° C. Substituting eq1 into eq2, we have

$$E_1 = 100 + 59(h-z)^{0.865} \quad (3)$$

Figure 1 shows a schematic diagram for the calculation of two-layer foundation soil. For foundations in the form of circular disc with diameter of 50 cm, calculation is made by computer with parameters somewhat different from those in Figure 1, before freezing and at different frozen depth respectively. Results are listed in Table 1. When h is 25 cm, the stress coefficient σ_{zx} at the point a reduces from the original value, before freezing 0.6659 to 0.3313, i.e. 50% lowered. When h reaches 50 cm, σ_{zx} reduces from the value before freezing 0.2835, to 0.770, i.e. 73% lowered. It is evident that within the range of bearing, layer stress after freezing is much lower than before freezing, indicating that during the process of freezing and subsequent expansion, stress attenuates continuously, and the smaller the foundation disc and thicker the frozen layer, the larger the attenuation. When h is 25 cm, the stress reduces to 50%. If part of the foundation soil expands non-uniformly during freezing and stiffness of the whole building is comparatively good, then internal stress in the building will

FIGURE 1 Schematic diagram showing calculation for two-layer foundation soil.

TABLE 1 Stress coefficient on interface between two layers and that of one layer.

Thickness of frozen layer(cm)	Foundation in form of circular Disc (50 cm dia.)	
	Homogeneous Single Layer	Frozen Interface between Two Layers
25	0.6659	0.3313
50	0.2835	0.0770
75	0.1380	0.0299
100	0.0799	0.0116
125	0.0536	0.0061
150	0.0349	0.0033

redistribute as frost heaving occurs. The soil near the foundation will unload to the foundation. At that time, if the load increases twice the compression stress in the interface is just equal to that before freezing. At this moment, ordinary buildings with lower stiffness and strength will crack essentially. When h is 50 cm, the compression stress on the interface will be equal to that of one-layer foundation soil before freezing, only when load on the foundation increases 4 times approximately. Therefore, in the process of frost heaving, no compression will apply to the underlying unfrozen soil.

Measurement of foundation models located on ground surface and at different depths under ground surface has been performed for many years at the Yanjiagang Observation Station in Harbin (frost heaving soil of type IV), and at the Longfeng Observation Station in Daqing (frozen heaving soil of type III and type II). Anchored load cell was used in the measurement. Stress distribution on the frozen interface was obtained, using the measured frost heaving force at different frozen depths by foundation models of different shapes and sizes. The maximum value on the symmetrical points will be the frost heave force on the frozen interface at the given depth.

Frost heaving stress is the upward expanding force per unit area while frost-

FIGURE 2 Relation curve between diameter of circular foundation D and stress coefficient σ_{zx} .

FIGURE 3 Relation curve between length of square foundation A and stress coefficient σ_{zx} .

FIGURE 4 Relation curve between width of strip foundation B and stress coefficient σ_{zx} .

heaving occurs at various depths. It is the inherent mechanical property of the frost heaving foundation soil, independent of the foundation itself. In finding the frost heaving stress, when the contact pressure on the base of the foundation is very great, the plastic-viscous property of frozen soil under higher stress should be considered based on the concept that non-linearity exists during a certain load history. If the contact pressure is too great, the frost heaving force should be revised by stress relaxation. When the stress is comparatively small, numerical calculation should be done by the finite element method based on the linearity concept.

Figures 2, 3, and 4 show the calculated stress coefficient σ_{zx} on the frozen interface between two layers for circular, square and strip foundations, using the parameters shown in Figure 1. Relation of the frost heave stress versus frozen depth curve, based on experimental data, and the mean frost heaving rate η for different frozen depths is shown in Figure 5.

The mean frost heaving rate η is defined as the ratio of the amount of frost heave to the thickness of frozen layer. In the calculation of frost heave force, the external load imposed on the foundation should be used as the actual load during the long winter period in which frost heave develops. Live loads, which do not always exist, must not be included in the calculation. For example, during the

FIGURE 5 Relation curve between mean frost heaving rate η and frost heaving stress σ_t in soil.

season of acute frost heaving, there would be no snow load or only a thin layer of snow on the roof; the live load on the floor of a school classroom during winter vacation is practically zero; though there are activities in meeting rooms and clubs usually, there will be no live load in the spare time. Under these conditions, it is unsafe if these buildings are considered to have full loads in the calculation for balancing the frost heaving force.

Example 1. Consider a square independent foundation of 100 cm \times 100 cm, buried depth of foundation 100cm, additional load (permanent load in winter) on the foundation $p = 2.0$ kg/cm², the foundation soil is of type IV frost heaving soil, frost heave rate $\eta = 10\%$. Maximum frozen depth 200 cm. Tangential frost heave force on the lateral wall of the foundation has been removed.

When the frozen depth reaches 150 cm, the thickness of the frozen layer under the foundation h is 50 cm. From Figure 3, the vertical downward additional stress $\bar{\sigma}_z$ is $0.255 \times 2 = 0.53$ kg/cm². From Figure 5, when $h = 150$ cm, the upward frost heaving

stress of soil $\bar{\sigma}_t$ is 0.16 kg/cm² (while finding the frost heaving stress in soil, the weight of the foundation itself has been considered already). Because $\bar{\sigma}_z > \bar{\sigma}_t$, the foundation is stable. At a frozen depth of 200cm, $\bar{\sigma}_z$ is 0.06 kg/cm², $\bar{\sigma}_t$ is 0.05 kg/cm², $\bar{\sigma}_z$ is still larger than $\bar{\sigma}_t$, the foundation is safe.

CALCULATION OF TANGENTIAL FROST HEAVING FORCE

For pile or column foundations and the like, before freezing of the foundation soil, the load (not for supporting piles) is balanced mainly by friction and stress-induced distributions in one layer. As soil freezes, frozen strength is produced by the freezing of soil on the lateral surface of the foundation. If the foundation soil is not of frost heaving soil, distribution of stress at different locations after freezing remains the same as in one-layer soil, despite the foundation soil becomes two-layer soil for the frost heaving soil, with the freezing and expansion of soil, internal force undergoes redistribution, i.e. freezing force gradually replaces friction. As result of redistribution, the component of stress in the two-layer foundation soil gradually and finally replaces that of the single layer soil at all. Therefore, the calculation method of two-layer foundation can be applied to tangential frost heave also.

At present, it is more convenient and practical to use average tangential frost heave force per unit area along the frozen depth in calculation for engineering purpose. The relation between average tangential frost heave force per unit area and the frost heave rate, according to the result of measurement at two Frozen Soil Stations, is shown by the dotted line in Figure 5. In calculation, if the actual frost heave rate of the local foundation soil is given, its corresponding tangential frost heave force per unit area will be obtained. Multiply this force by the lateral surface area of the foundation in frozen soil layer, and the product is the tangential frost heave force.

Example 2: Consider an independent square foundation of 100 cm \times 100 cm, buried depth of the foundation is 100 cm, additional load on the foundation $p = 2.0$ kg/cm², the foundation soil is of type IV frost heaving soil, frost heave rate $\eta = 10\%$, maximum frozen depth is 200 cm, measures are taken to eliminate normal frost heave force on the base of foundation and maintain the bearing force.

When the frozen depth reaches the base of the foundation, the frost heave force of soil $\bar{\sigma}_t$ at this depth is 0.335 kg/cm², lateral surface area is 40,0000 cm² mean height of lateral surface from the frozen surface is 50 cm. From Table 2 the stress coefficient for a square foundation

with side length 100 cm and frozen depth 50 cm is 0.27. Take the force acting on the lateral surface as that acting on the lateral side of the cross-section at the mean height, the force on such assumed area is $0.335 / 0.270 \times 10.000 \text{ kg} = 12407 \text{ kg}$ force per lateral unit area is $12,407 / 40,000 = 0.310 \text{ kg/cm}^2$.

When the frozen depth reaches 150 cm, the frost heave force of soil $\sigma_t = 0.16 \text{ kg/cm}^2$, the distance between the lateral surface and the frozen surface is 100 cm, stress coefficient $\sigma_{zx} = 0.03$, the maximum tangential frost heave force developed at this moment is $0.16 / 0.03 \times 10.000 \text{ kg} = 53,333 \text{ kg}$. According to actual measured data of foundation model, it can be approximately taken as the maximum unit tangential frost heave force as shown by dotted line in Figure 5, or the frozen strength between soil and lateral surface of foundation. When frost heaving rate is 10%, the maximum tangential frost heave force is 1.13 kg/cm^2 . Because of restriction by the maximum unit tangential frost heave force, the actual value is only $1.13 \times 40,000 = 45,200 \text{ kg}$, while the remaining force induces shear displacement between the soil and lateral side of the foundation. Because the existing load is only 20,000 kg and the tangential frost heave force could not be balanced, this foundation would be raised by frost heaving and lose its stability.

According to the roughness shown by the dotted line in Figure 5, the lateral surface of the foundation is an ordinary plane. For especially smooth or especially rough ones, it should be multiplied by a modified coefficient either smaller than 1 or larger than 1.

CALCULATION OF COUPLED ACTION OF NORMAL AND TANGENTIAL FROST-HEAVE FORCES

When the normal frost heave force and the tangential frost heave force act simultaneously, the resulting force is not a simple superposition of such two individual forces. When the frozen depth is h , either the tangential frost heave force sustained by the lateral surface of the foundation or the normal frost heave force sustained by the base of the foundation is induced by the frost-heaving stress acting on the frozen interface.

Example 3: Consider a strip foundation of width $b=100 \text{ cm}$, buried depth of foundation is 50 cm, additional load $p=2.0 \text{ kg/cm}^2$, the foundation soil is of type IV frost heaving soil, frost heave rate is 10%, maximum frozen depth is 200 cm.

When frozen depth reaches 100 cm, the depth of the frozen layer under the base of the foundation is 50 cm, the distance between the centre of the lateral surface of the foundation and the frozen interface is 75 cm. At the depth of 100 cm, the frost heaving stress of soil σ_t is 0.335 kg/cm^2 .

From Figure 5, the unit tangential frost heave force is 1.13 kg/cm^2 and the total tangential frost heave force is $50 \times 100 \times 1.13 \text{ kg} = 11,300 \text{ kg}$. From Figure 4, the stress coefficient for the cross-section at the centre of the lateral surface of the foundation to the frozen interface is 0.255 kg/cm^2 , the stress on the cross-section is 1.13 kg/cm^2 , the frost heave stress of soil consumed in the generation of $11,300 \text{ kg}$ of tangential frost heave force is $0.255 \times 1.13 = 0.288 \text{ kg/cm}^2$, the remaining frost heave stress of soil on the frozen interface is $0.335 - 0.288 = 0.047 \text{ kg/cm}^2$. From Figure 4, the stress coefficient for a frozen layer of 50 cm thickness is 0.45. At the same time, the existing normal frost heave force is $0.047 / 0.45 = 0.1044 \text{ kg/cm}^2$, and the resultant normal frost heave force is 1044 kg . The total sustained frost heave force is $11,300 + 1044 = 12,344 \text{ kg}$, smaller than external load 20,000. So it is safe. If the frozen depth increases to 150 cm, the distance from the centre of the lateral surface of the foundation to the frozen interface is 125 cm, its stress coefficient is 0.085. When the distance from the bottom of the foundation to the frozen interface is 100 cm, its stress coefficient is 0.135, the frost heave stress of soil at the depth is 0.16 kg/cm^2 . The frost heave stress consumed in the generation of tangential frost heave force is $0.085 \times 1.13 = 0.096 \text{ kg/cm}^2$, the normal frost heave force generated from the remaining frost heave stress is $0.064 / 0.135 = 0.474 \text{ kg/cm}^2$, and the resultant force is $0.474 \text{ kg/cm}^2 \times 10,000 = 4,740 \text{ kg}$, and the total sustained frost heave force is $11,300 \text{ kg} + 4,740 \text{ kg} = 16,040 \text{ kg}$, smaller than 20,000 kg. The foundation is safe. At frozen depth of 200 cm, using the same way of calculation, the frost heave force obtained is still smaller than the external load, and the foundation is safe.

The above calculations are not the stability of foundations, i.e. whether it would be raised in the process of frost heaving, and as long as the frost heave force is not larger than the external load, stability is guaranteed. But if frost heave force exceeds the external load not too much, it is also allowable, because each building is allowed to sustain certain deformation according to its stiffness, except redistribution of internal force. Within the range of allowable deformation, no crack or failure would occur. With the occurrence of frost heave deformation, the frost heave force attenuates continuously. Further studies will be needed for the relation between frost heave force and deformation, as well as the calculation of frost force from soil deformation. At present, testing data in these respects are not too much, so data accumulation should be carried on.

CHECK OF FOUNDATION
STABILITY DURING THAWING

If deformation occurs in the frozen foundation soil during thawing, a series of changes (redistribution of internal force) also occur in its interior, which could be found through the analysis of internal force of the linearly deformed body in the three-layer semi-infinite space.

Ordinary foundation soil is of one layer. With the freezing and expansion of the foundation soil, its stress state gradually and finally changes to that of the two-layer soil. When thawing takes place in the spring, the upper part of the soil mass begins to thaw. The mechanical properties of the thawing soil are much less than those of frozen soil, thus forming a three-layer foundation soil. Since the stiffness of the frozen soil in the second layer is great and its compressibility is relatively small, the concentration of stress appears in the first layer, i.e. the stress in the thawing soil suddenly increases. The larger the foundation and the thinner the thawing layer, the more obvious is the concentration of stress. Under loading, the frost heaving foundation soil freezes first and then melts; change of its stress is shown in Table 2.

Taking the soil of the Longfeng Frozen Soil Station as an example, when the water content in the upper part of the soil layer increased 5% during freezing, the plastic state of the soil will change to the soft plastic state, thus lowering 10% of its allowable bearing strength. During thawing in spring, stress concentrates on the thawing interface, concentration is more serious, generally increasing more than 20%, especially when the thawing depth is within the range of the radius of the foundation. For foundation, the strength of which is just enough

for use, it is necessary to check whether it is in an allowable condition during thawing.

For piles located in the range of frozen layer, when the foundation soil is of a strong frost heaving soil, relative sliding generally occurs between the soil and the lateral side of the foundation. For soil subjected sliding during thawing, the bearing capacity owing to friction before freezing turns into negative friction, which plays the role of bearing during thawing. At this time, it is also necessary to check the bearing capacity of the pile.

CALCULATION OF THE BEARING
CAPACITY OF FROZEN SOIL

When seasonal frozen layer freezes to a certain depth, it has a much higher bearing capacity than that before freezing. With the increase of frozen depth and the decrease of soil temperature in the upper part, its bearing capacity still increases. Before weather becomes warm and the soil temperature increases, it is quite possible to utilize such bearing capacity in this short period, for instance, in the emergent repairing of bridges, framework foundation construction for engineering practice, roads construction for heavy trucks in war time, runway construction for airplane, etc. during winter.

Bearing capacity of the frozen soil is calculated according to the nonlinearity of the two-layer foundation soil. Based on the assumed load, find out the stress and also the soil temperature at each point according to the distribution of soil temperature at different depths. Then, from soil temperature, find out the corresponding allowable compressive strength. It would be safe when the calculated compressive stress is not greater than the allowable value, but it would be unsafe if the compressive stress exceeds the allowable value.

TABLE 2 Variation of Stress in Foundation Soil During Freezing and Thawing.

Depth (cm)	Circular foundation of (50 cm diameter, $q=1 \text{ kg/cm}^2$)			
	Single homogeneous layer	At the frozen interface of two layers soil	The thawed interface of three-layer soil	Increment during thawing %
25	0.6659	0.3313	0.8042	21
50	0.2835	0.0770	0.3556	25
75	0.1380	0.0299	0.1782	29
100	0.0799	0.0116	0.1240	55
125	0.0536	0.0061	0.0766	45

Remarks: The 2nd interface located at depth of 200 cm.

CONCLUSION

This calculating method is based on the theoretical analysis of layered deformed body in semi-infinite space. The physical meaning of this method is quite explicit, and the stress state obtained is very clear. In this method, using the finite element program, numerical computation can be made by electronic computer, and a lot of diagrams, graphs, and tables can be compiled to make calculations easy and convenient.

FROST SUSCEPTIBILITY OF SOILS

C. W. Lovell

School of Civil Engineering, Purdue University
West Lafayette, Indiana 47907 U.S.A.

The fabric of soil significantly influences all aspects of its behavior including frost susceptibility. While the arrangement of solids in a soil is very difficult to quantify, the size distribution of pores may be simply accomplished by techniques of mercury intrusion porosimetry. The resulting frequency distribution may be characterized in any convenient statistical manner, and related quantitatively to other variables. A conventional technique of relating frost susceptibility to grain size distribution has a serious intrinsic deficiency in that a soil has a single grain size distribution, but a multitude of pore size distributions. It is, of course, the pore size distribution which controls the movement of fluids under all gradients. This has been demonstrated experimentally by producing a wide variety of frost heaving rates for a single soil; in all cases, the heaving rates were related to the pore size distributions in the soil. Pore size distribution has also been related to suction and hydraulic conductivity values. It is an appropriate substitution for (1) direct determination of the water characteristics curve and (2) measurement of permeability, in fine grained soils, since it requires but a fraction of the time required for these tests. Examples of all correlations cited above are contained in the paper.

INTRODUCTION

The fabric of soil significantly influences all aspects of its behavior, including frost susceptibility. This fact is illustrated by Figure 1, where such characteristics as grain size and shape, density, and total porosity are constant between the two parts of the picture. Fabric is seen to be strongly contrasting, whether evaluated in terms of the distribution of solids, or in terms of the size distribution of pores. Many susceptibility ratings would predict identical effects of frost action for the two soil conditions, although such can obviously not be true with strong differences in fabric.

The author supports the use of pore size distribution to quantitatively characterize fabric and differences in fabric. These characterizations have been successfully related to soil stress-strain (Ahmed et al. 1974), to hydraulic conductivity (Garcia-Bengochea et al. 1979), to name but a few responses.

PORE SIZE DISTRIBUTION

Successful application of mercury intrusion porosimetry to characterize soil and rock fabric required several research studies, culminating in the reports by Ahmed (1971) and Bhasin (1975). Limited and largely unsuccessful experience with the method prior to this time is summarized by Ahmed and Bhasin. A major stumbling block was the need to dry specimens, prior to pore size measurements, without change in the fabric. Two techniques were identified for fine-grained soils,

viz., critical region drying and freeze drying. The latter is much more simple and less expensive than the former, and is the preferred technique. Freeze drying can be accomplished within a working day (Reed 1977). Porosimetry for soils and rocks has been sufficiently debugged to be the subject of a draft standard in Committee D18 of the American Society for Testing and Materials. Laboratory porosimeters are available "off the shelf" from a number of commercial equipment companies.

In the pore size distribution determinations, the nonwetting fluid (mercury) is forced into the pores by pressure. The absolute pressure (p) - pore diameter (d) relationship is given by the capillary equation,

$$p = - \frac{4 \sigma_m \cos \theta}{d}$$

where σ = surface tension of mercury and θ = contact angle of mercury with the intruded material.

As the pressure is increased, smaller pore diameters are intruded. By precisely measuring the volume of mercury pushed into the pores by an increase in pressure, a cumulative curve of pore space vs. pressure (pore size) is generated. The intrusion and all calculations can be accomplished within a working day.

The evidence of a great number of experimental measurements on soil is that all (or essentially all) of the pore spaces can be intruded by mercury, which means that these spaces are interconnected (Bhasin 1975, Garcia-Bengochea 1978,

Reed et al 1980). These same measurements provide explicit proof that the total porosity of the soil is unchanged by the mercury penetration, and implicit evidence that the pore size distribution is also unchanged. In addition, it has been shown (Reed et al. 1979, Garcia-Bengochea et al 1979, Juang 1981) that the coarser portions of the porosity control the engineering properties of greatest interest. These spaces are penetrated at modest values of pressure.

Figure 2 shows both cumulative and differential representations of the pore size distribution of a compacted sand-clay mixture. The bimodal distribution is commonly observed with clayey soils. The larger mode is interpreted to represent the pores between grains or aggregations of particles (Garcia-Bengochea et al. 1979). The magnitude of the small pore mode is likely a "signature" of the clay minerals present, while the large one varies with the details of soil placement. For example, both the magnitude and frequency of the large pore mode can be changed by varying the compaction water content and the roller used.

Frost Heaving Rate

The importance of fabric to rate of frost heaving has been clearly demonstrated by Reed et al (1979). Figure 3 shows a wide range in frost heave rates for a single soil (90% silt-10% clay). The two compaction pressures are represented by three water contents each. The lower and upper values of water content represent equal porosities (densities) on the dry side and on the wet side of optimum, respectively. The dry side samples have a fabric more conducive to frost heaving than the wet side ones. Lower compaction pressures also allow a more open fabric in the fine-grained soil, and result in a higher frost heave rate.

Using the rating scale shown in Table 1, Reed (1977) clearly showed that any of three silt-clay test mixtures could be prepared to produce any level of frost susceptibility, simply by varying the compaction energy and water content. Reed also produced statistical equations which related frost heaving rates to pore size distributions of the compacted soils. These relationships are available in the open literature (Reed et al. 1979 and 1980) and are too lengthy to be presented and explained here. The statistical credentials of these regressions are excellent...statistical equations of course require statistical input, as opposed to single values input, to produce reliable values.

Determination in Sands

Juang (1981) extended the porosimetry techniques to sandy soils, including clean sands. He accomplished the retention of fabric in cohesionless soils by mixing in a trace of thermally sensitive polymer prior to sample preparation. A subsequent heating of the sample melted the polymer and achieved a sufficient cohesion to allow handling and pore size distribution determination. The amount of polymer was insufficient to change the total sample porosity.

Changes in fabric are more subtle in sands than in fine-grained soil, but porosimetry is a feasible way of detecting these. Thus, the effects of sand fabric on frost susceptibility can be experimentally determined. Juang (1981) did not accomplish this, although he did produce excellent correlations between pore size distributions and hydraulic conductivity, for a range of soil textures from clay to sand. The analytical techniques developed to relate pore size distribution and hydraulic conductivity included: the Kozeny hydraulic radius model, a variable diameter capillary approach, and a simple (Marshall) probabilistic model (Garcia-Bengochea 1978, Garcia-Bengochea et al. 1979 and 1980, Garcia-Bengochea and Lovell 1981). The model ultimately used by Juang (1981) is a reasonably versatile probabilistic one, and its statistical reliability is illustrated in Figure 4. When the time and expense of direct permeability measurements are considered, the potential value of pore size distribution correlations becomes more obvious.

It is unlikely that the mercury intrusion porosimetry technique can be employed for soils of coarser texture than sands. There are two major reasons for this (Juang 1981): sample size must be rather small (approximately 1 cm cube), and penetration of pores larger than about 300 micrometers is difficult to control. Other techniques (e.g., optical) are needed to quantify the distribution of such macro-porosity in both intergranular and extended forms.

Determination of Moisture Characteristics

Wood et al. (1982) report that pore-size distribution data can be used to produce a soil moisture characteristic curve. This curve relates the water content and its associated capillary pressure.

The capillary pressure (p_w) equation for water has the same form as that previously stated for mercury, viz.,

$$p_w = \frac{4 \sigma_w \cos \theta_w}{d}$$

$$d = \frac{-4 \sigma_m \cos \theta}{p} = \frac{4 \sigma_w \cos \theta_w}{p_w}$$

and

$$p_w = \frac{+ \sigma_w \cos \theta_w p}{- \sigma_m \cos \theta}$$

where σ_w = surface tension of water, θ_w = contact angle of water with the soil, and the other terms have been previously defined.

The water content (w) for the partially saturated condition which matches this p_w may be calculated from

$$w = \frac{V_w \gamma_w}{W_s}$$

where V_w = volume of water, γ_w = unit weight of water, and W_s = weight of dry solids, and

$$V_w = V_v - V_{vm}$$

where V_v = total volume of voids and V_{vm} = volume of voids intruded by mercury at absolute pressure (p).

Direct determination of the soil moisture characteristics curve would normally require much more time than that required to define the pore size distribution. Therefore, the above correlations have important practical value.

Use as a Susceptibility Index

In his comprehensive review of the subject, Chamberlain (1982) identified several tests which are particularly promising for the prediction of frost susceptibility. These include grain size distribution, moisture-tension, hydraulic conductivity, and frost heave tests. Limited experimentation with pore size distribution on soil textures from clay to sand indicate that it too has great promise as an indicator test. To date, experiments have:

- (1) illustrated the intrinsic limitations of the grain size criteria (Reed et al. 1979);
- (2) shown that the frost heave is statistically related to pore size distribution (Reed et al. 1979);
- (3) defined the relationships between hydraulic conductivity and pore size distribution (Garcia-Bengochea et al. 1979, Juang 1981); and
- (4) demonstrated the determinations of moisture tension curves from pore size measurements (Wood et al. 1982).

In many cases, the pore size determination is less time consuming than direct determination of the index property with which it is correlated.

CONCLUSIONS

The mercury intrusion method of determination of pore size distribution in soils and rocks has been developed and improved over the past decade. The procedure is presently being standardized in Committee D18 (Soils and Rocks) of the American Society for Testing and Materials.

The pore size relations generated by this technique for soil textures from clay to sand have been statistically correlated with the following

frost susceptibility indices: frost heaving rate, hydraulic conductivity, and moisture-tension relationships. In each case the pore size determination is expected to be less time consuming than the cited index quantity. The author concludes that the pore size method deserves more attention and application for definition of frost susceptibility than it has received in the past.

BASIC CHARACTERISTICS OF PERMAFROST IN NORTHEAST CHINA

Lu Guowei¹, Guo Dongxin², and Dai Jingbo³

¹ Yakeshi Survey and Design Institute of Nei Monggol Ministry of Forestry

² Lanzhou Institute of Glaciology and Cryopedology, Academia Sinica

³ Third Survey and Design Institute, Ministry of Railways
People's Republic of China

There are two kinds of permafrost in northeast China: high-latitude permafrost and alpine (high-altitude) permafrost. The high-latitude permafrost is distributed mainly in the Da-Xiao Hinggan Ling and occupies an area of about 38,000 km², while the alpine permafrost is only sporadic. From south to north in Northeast China, the mean annual air temperature drops from 0°-1°C down to -5° or -6°C, and the landscape changes from forest-steppe, through mixed coniferous and broad-leaf forest, to coniferous forest, and the permafrost varies correspondingly in continuity, temperature, and thickness. In the south, there is insular permafrost, 5-10 m thick, with a mean annual ground temperature of 0°C. In the north, the large-patch continuous permafrost has a mean annual ground temperature of 0° to -2.5°C (and in some places even lower than -4.2°C) and is 80-100 m thick. Between these two extremes there is a transitional permafrost zone with insular taliks. The southern limit of permafrost descended to the upper course of the Liao He River during the last glacial period. The existing permafrost is the sum of relic permafrost formed in the Late Pleistocene and younger permafrost formed in the last 3000 years.

There are two types of permafrost in Northeast China, i.e. high-latitude and alpine permafrost. The former mainly occurs in the Da and Xiao Hinggan Ling and occupies an area of about 380,000-390,000 km². The alpine permafrost is scattered in Changpai Shan Mountain and Huanggang Liang Mountain situated in the southern end of Da Hinggan Ling.

HIGH-LATITUDE PERMAFROST

Natural Conditions Forming High-Latitude Permafrost

Both the Da and Xiao Hinggan Ling are in the northernmost part of China, and stretch northeastward and northwestward through the eastern and western parts of the region respectively, separated by the Nen Jiang Valley. Thus, the landforms of the region are higher in the eastern and western parts, but lower in the middle. The Da and Xiao Hinggan Ling form the shape of "λ" on a plane. The elevation in the middle section of Da Hinggan Ling is 1000-1400 m and descends gradually to the north to 500-600 m northward. Da Hinggan Ling is an asymmetrical mountain. The west-facing slope consists of undulating hills, but the east-facing slope is steep and is deeply cut by numerous river valleys. However, the Xiao Hinggan Ling has more gentle slopes with dendritic type of valleys. The mean elevation of this mountain is 500-600 m with some peaks reaching up to 800 m.

Since the Late Tertiary, the Da Hinggan Ling Mountain has risen unevenly parallel to an old tectonic system undergoing planation and denudation for a long time. On the top and along the slope of the mountains, 1-2 m of colluvium, eluvium and slope wash occur consisting of crushed stones, angular clasts or silty clay with crushed stones. The loose deposits in pediments, intermontane valleys and basins are relatively thicker and consist mainly of the solifluction, slope wash, and pluvial sediments with peat and humus soil above them, and clayey silt, silty clay with crushed stones, sand, and gravel below them, usually with a total thickness of less than 10 m.

The climate in this region belongs to the continental monsoon of the cold-temperate zone. From south to north and southeast to northwest, the mean annual air temperature (MAAT) drops from 1°-0°C to -5° or -6°C, the annual precipitation decreases from 500-600 mm to less than 200 mm, while the amplitude of mean daily air temperature increases from 35°C to 50°C.

The main feature of climate in the region is severe cold, especially in winter, because of the influence of the high pressure over Siberia and Mongolia. The strong cold air mass current often intrudes into this region, greatly lowering the air temperature, so that in January the mean air temperature is 5°-10°C lower than that in Xinjiang at the same latitude.

In summer, this region is affected by the Pacific high pressure cell. The

southeast monsoon is strengthened, warm air with moisture from south meets the cold air from north in this region, producing heavy rains so that 80-90% of the annual precipitation is concentrated in the summer. The associated cloud keeps the air temperature cool, so that the air temperature in summer is 1-3°C lower than that in Xinjiang at the same latitude. Thus, the low mean annual air temperature constitutes not only the basic condition for the existence and growth of permafrost, but also one of the main causes of the southern boundary of Eurasian permafrost protruding southward in this region.

Under the control and influence of Siberian and Mongolian high pressures, the winter temperature inversions are widespread and stable, and have an important effect on both the regional differences of permafrost and the process of permafrost development.

Comparison and analysis of the air temperature at the 850 mb (1500 m) elevation indicate that this region is located in the southern margin of the inversion layer controlled by Siberian high pressure. In the Middle Siberian Mountains the thickness of the inversion layer is 1200-1500 m, the inversion gradient is 1.5-2.0°C/100 m (Fotiyer, S. M. et al. 1974), but in China the former is 500-1000 m, and the latter is 1.0°C/100 m in Mohe, 0.8°C/100 m in Nunjiang, and 0.5°C/100 m in Hailar.

Most of the region is covered with forest, shrub and sedge, and is known as the "green ocean". The northern part belongs to the cold-temperate montane coniferous forest consisting of Hinggan larches, and southward it gradually becomes coniferous-broad leaf mixed forest and forest-steppe. To the southern edge of the region, crops can be planted.

Distribution, Temperature and Thickness of High-Latitude Permafrost

The formation of frozen ground is the result of heat exchange between the atmosphere and the lithosphere. The above mentioned natural factors, which act jointly on heat exchange, exert great influence on the features of permafrost. Therefore, the latitudinal zonation of natural conditions from south to north and from southeast to northwest as mentioned above should surely reappear in the features of permafrost (distribution, temperature, thickness, ground ice, etc.). Along the directions mentioned above, from south to north, the area of permafrost increases from 5-20% to 70-80%; the ground temperature drops from 0° -1.0°C to -2.0°C with the lowest being -4.2°C. The average thickness of permafrost increases from 5-20 m to 70-80 m, with extreme cases with more than 100 m (Guo Dongxin 1981). The type of permafrost changes gradually from insular permafrost into insular talik and large patch continuous permafrost (Figure 1).

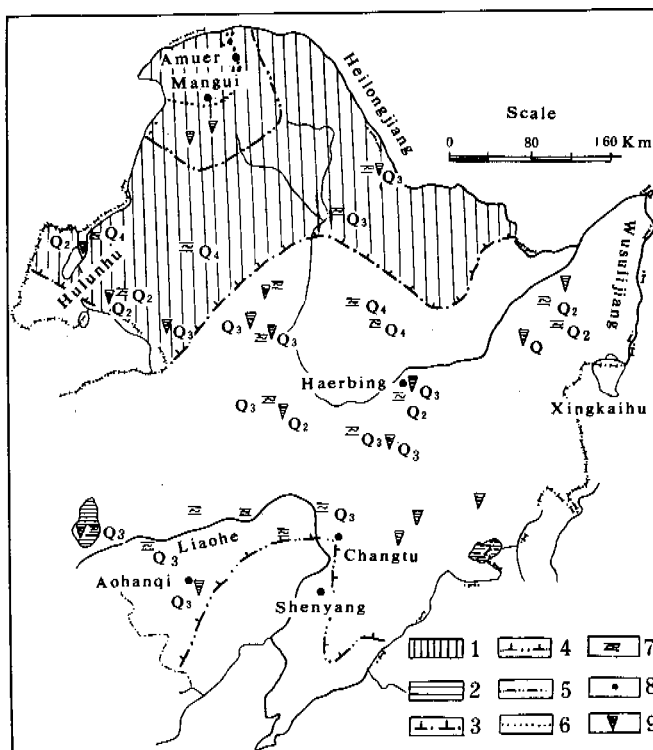

FIGURE 1 The distribution and south boundary change of permafrost from late Pleistocene to now in north-east China. 1) existing high latitude permafrost, 2) island alpine permafrost, 3) existing south boundary of permafrost, 4) south boundary of permafrost during late Pleistocene, 5) existing south boundary of continuous permafrost with patch taliks, 6) inferring south boundary of permafrost during Hypsithermal interval, 7) involution layers, 8) town, 9) sand wedge.

Because of the differences in landform, temperature inversion, vegetation and thickness of loose deposits, and of the combined influence of various natural factors, such as surface water, the above-mentioned principal regularities of the permafrost features are made less obvious and on the background of latitudinal zonation, the distribution of permafrost also shows the regional and local differences.

Because of the influences of landform and elevation (Figure 1), the permafrost southern boundary does not trend parallel to the latitude, but presents a "W" shape. The southern boundary of permafrost obviously stretches out southward along the limbs of the Da and Xiao Hinggan Ling but extends northward in the Nunjiang plain. The difference of latitude between them is nearly two degrees. Besides, as mentioned above, the lower mean annual air temperature in this region due to the influences of Siberian and Mongolian high pressure cells is another important boundary of Eurasian permafrost to be extended southward.

The northern part of the region belongs

to the large patch continuous permafrost zone. The distribution, temperature, and the thickness of permafrost, as well as the growth of ground ice at different landform units of the same region are quite different owing to the influences of the above mentioned factors.

In the shady intermontane valleys, in marshlands and lower terraces covered with dense moss and lichen, as well as beneath thick loose deposits (8-10 m), the permafrost develops very well and is up to 60-80 m thick, occasionally reaching more than 100 m in places, with ground temperatures of -2° to -4.2°C and layered ground ice. In contrast, on sunny and semi-sunny slopes with sparse trees and thinner loose cover, generally the permafrost develops less well and may be absent, its thickness is less than 20 m with ground temperatures of 0° to -1.0°C , and there is no ground ice. According to the data of adjacent region, when the slope is 20° - 22° , the value of direct solar radiation is $92 \text{ kcal/cm}^2\text{.yr}$, on the sunny slope, but $42.6 \text{ kcal/cm}^2\text{.yr}$ on the shady slope (Shpelynskaya, N. A., 1978). The thickness of loose deposits on the shady and semi-shady slopes is as large as that on the sunny slope, but the shady slope has more dense vegetation and less solar radiation than sunny one. Therefore, the growth of permafrost on shady slope is interposed between the valley bottom, depression, low terrace and sunny slope.

In the northern part of the region, under large river beds and within 10-30 m on either side of a large river, the permafrost is usually absent and open talik exists. Under smaller river beds, the permafrost table generally descends and closed talik forms.

The southern part of the region belongs to the insular permafrost region. The permafrost features vary according to the natural environment also. In the high plain of Hulun Buir, the intermittent marsh zone evolved from paleochannels, and the pools in the centre of this marsh are the outstanding characteristics of the landscape. Marsh and pool are closely related to island permafrost. Generally speaking, in the margin of marsh and pool, there is always scattered insular permafrost with its area less than 10% of total area, its thickness 3-5 m to 10-15 m and its temperature 0° to -1°C . In the undulating ground on the east-facing and west-facing slopes of Da Hinggan Ling in the southern part of the region, the permafrost islands are distributed along the flood plains and low terraces in intermittent bands. Northward from the southern boundary the permafrost increases from several dozens of meters and 100-200 m to several hundred meters in size, covering 10% to 30% in area. The dominant permafrost thickness is 5-10 m with a ground temperature of 0° to -1°C . In Xiao Hinggan Ling Mountains, the permafrost islands

occur only in the intermontane valleys, flood plains land and low terraces with dense vegetation and marsh. The area of permafrost is about 20% of the total area, with permafrost thicknesses of 5-10 m, ground temperature colder than -1.0°C . In the southern part of the region, the permafrost in profile is quite complex (some connected, some disconnected, and some multi-layered.) due to different soil types and the influence of ground water.

On the whole, either in the south or in the north of the region, the distribution and growth of permafrost is better in the low land than in the high land, having greater thickness and lower temperature, and is obviously different from the permafrost existing in the western mountains and plateau, so it is called "Hinggan Ling-type permafrost". The characteristics of this type of permafrost are not only reflected in the distribution and growth, but also exert an influence on the process of permafrost degradation. As early as the 1960's, it was found that the permafrost degradation occur first on the south-facing slopes, high land and mountains, and only later on the north-facing slope, low lands and valley bottom. Although the formation of such a characteristic of Hinggan type permafrost is the result of comprehensive action of various natural factors, the wide and stable inversion in winter, thick unconsolidated deposits, and dense vegetation in the valley bottom and depression exert a dominant control.

ALPINE PERMAFROST

The permafrost found south of the southern boundary of contemporary permafrost in the Da and Xiao Hinggan Ling and above a designated elevation is called alpine permafrost. This type of permafrost mainly occurs in the Changpai Shan Mountain and Huanggang Ling Mountain which is located in the southern part of Da Hinggan Ling. The natural conditions for growing permafrost and the lower limit in these two mountains are also different.

Huanggang Ling Mountain situated in the western part of Songliao plain and the eastern part of Nei Monggol high plain, is the highest mountain at the southern end of Da Hinggan Ling, with elevations exceeding 1400-1500 m. The climate in this region is semi-arid continental and is influenced by the Mongolia high pressure cell. The mean annual air temperature at an elevation of 1500 m is -2.9°C . The landscape has an obvious vertical zonation with the semi-arid steppe and desert zone below 1500 m; sparse coniferous-broad leaf mixed forest above 1500 m, and marshes on the gentle hill top and north-facing slope. The lower limit of permafrost on the mountain is 1600 m. The permafrost islands mainly occur on the gently sloping hill

top and in the wet, marsh areas. The permafrost thickness is less than 10 m and most of it is 3-5 m thick.

Changpai Shan is the highest mountain in Northeast China. There are 16 peaks all over 2500 m high. The montane climate and landscape possess an obvious vertical zonation: coniferous-broad leaf mixed forest occurring below 1000 m, montane dark coniferous forest at 1000-1600 m, dark coniferous forest at 1600-1800 m, birch forest at 1800-2000 m, and alpine tundra above 2000 m. The mean annual air temperature at an elevation of 2670 m is -7.3°C .

Up to now there have been no studies of location of the lower limit of permafrost. Taking the 0°C mean annual ground surface temperature as a criterion for existing permafrost and considering the higher value of geothermal heat flow in this region, we suggest that the lower limit of alpine permafrost should be at an elevation of 1800 m (mean annual air temperature of -3° to -4°C), roughly coincident with the upper limit of dark coniferous forest.

HISTORY OF PERMAFROST SINCE THE LATE PLEISTOCENE

During the Quaternary Period, there were several occurrences of aggradation and degradation of permafrost with cold climate alternating with warm. According to the periglacial remnants and other evidence, the history of permafrost since the Late Pleistocene may be divided into three parts (Guo and Li 1981).

The Periglacial Conditions in the Late Pleistocene

The large number and wide extent of periglacial remains belonging to this stage indicate that permafrost was much more extensive. According to the paleo-air temperature calculated from fossil plant and pollen, it is estimated that within the Liao He Plain, the 0°C isotherm of mean annual ground surface temperature at that time stretched roughly along the northern part of Aohanqi and Changtu, and coincided with the southern boundary of relic permafrost at that time. Moreover, both of them roughly coincided with the 7° - 8°C isotherm of the present mean annual air temperature. Therefore, we have estimated the southern boundary of permafrost in the Late Pleistocene in regions

lacking relic permafrost as having lain at the present 7° - 8°C isotherm.

The Hypsithermal Interval

During the Hypsithermal warm period lasted from 3000-7000 years B.P. According to the paleo-air temperature calculated from spore-pollen analysis, it is estimated that the air temperature at that time was about 0°C in the northern part of the existing large patch continuous permafrost zone (the region to the north of Mangui). On the other hand, the analyses of light and heavy minerals of unconsolidated sediments in drill hole No. 50 at Armer indicate that humid and warm climate was absent there at the Hypsithermal Interval. According to this, it is suggested that the permafrost in the northern half part of existing large patch continuous permafrost zone might not have been entirely destroyed during the Hypsithermal Interval.

Post-Hypsithermal Permafrost

Beginning around 3000 years B.P., the thawed permafrost regenerated as the temperature dropped. In the northern part of the existing large patch continuous permafrost region, the ground temperature of relic permafrost formed during the Late Pleistocene decreased, its thickness increased and the permafrost has been developing to present state. In the southern part, new permafrost formed. In the 17-18th century, the young permafrost reached its maximum. The alpine insular permafrost in Huanggang Ling Mountain above 1600 m and Changpai Shan Mountain above 1800-2000 m is the product of that stage.

PERMAFROST ON MARS: POLYGONALLY FRACTURED GROUND

Baerbel K. Lucchitta

U.S. Geological Survey, 2255 North Gemini Drive, Flagstaff, Arizona 86001 USA

Newly discovered martian polygons of 50-300 m diameter have random orthogonal patterns and are similar in size and shape to terrestrial unsorted polygons in permafrost terrain. The martian polygons occur at lat 47°N, long 346°W, where conditions are favorable for ice-related fracturing processes; ice is in equilibrium with the atmosphere and could remain in the ground for extended periods. Desiccation of ground ice due to astronomically forced climatic cycles, or thermal contraction due to seasonal cycles could have fractured the ground. The desiccation hypothesis has uncertainties concerning the temperature regime and the exchange of water between the atmosphere and the ground. An origin by seasonal thermal contraction, however, is compatible with the size and shape of the polygons, with a seasonal cooling of -60°C, and with the availability of seasonal frost. Both sand wedges and ice wedges could have filled the polygonal fractures. Crispness of the fractures suggests that they are only slightly degraded and thus relatively young, but local ground collapse indicates that they are probably not forming actively today.

INTRODUCTION

Mars is the only explored body in our Solar System that has many landforms similar to terrestrial ones, especially those associated with permafrost or cold climate. Permafrost, 1-3 km thick, probably occurs over the entire planet because the mean temperature is -80°C (Fanale 1976). Rossbacher and Judson (1981) calculated this thickness, assuming the heat flow values of Toksöz and Hsui (1978) and a surface layer composed of hard-frozen limonitic soil with a high (60%) ice content. Near the equator, midday temperatures may reach 15°C (Michaux and Newburn 1972), but nighttime temperatures remain far below 0°C, and, even though freeze-thaw processes are possible, the formation of a thick active layer is unlikely. Although liquid water cannot exist at the surface because of the thin (6.1 mbar) atmosphere, the presence of fluvial features, such as channels, implies that water once flowed on the surface of Mars. Remote-sensing measurements suggest that water presently exists in the atmosphere and in the polar caps (Kieffer et al. 1977, Farmer and Doms 1979). At the Viking landing sites water in the soil was detected from instrumental readings (Anderson and Tice 1978), and in late winter a thin frost layer was observed by the cameras on the Viking 2 Lander (Wall 1981). Ground ice would be in equilibrium with the atmosphere north and south of lat 40° (Farmer and Doms 1979), and even in the equatorial areas, ice could remain in the ground if blanketed by fine debris (Smoluchowski 1968). Thus, conditions on Mars are conducive to permafrost processes, and permafrost features can be expected on its surface. Such features were illustrated in the summary reports by Carr and Schaber (1977) and Lucchitta (1981).

LARGE POLYGONS

Polygonal-fracture patterns on the martian surface were discovered on Viking Orbiter images; these patterns are abundant throughout the northern latitudes. The polygons are 2-20 km in diameter, much larger than those of known patterned ground on Earth (Washburn 1980). That martian polygonal ground may be related to thermal contraction was suggested by Carr and Schaber (1977), but Black (1978) objected because the size of the polygons is incompatible with the thermal-contraction process as observed on the Earth. Alternative hypotheses include contraction by cooling lava (Morris and Underwood 1978) or tensional tectonism (Pechmann 1980). Lava cooling, however, should form small polygons, and the tensional tectonism should not be restricted to northern latitudes.

Helpenstein and Mougini-Mark (1980) pointed out that thermal-contraction polygons 2-3 times the size of terrestrial ones could have formed under Martian lithostatic stresses and suggested that desiccation later preferentially enlarged and coalesced some polygons to form the network presently observed. Also, cooling cycles on Mars may be 10^5 - 10^6 years long and related to changes in the obliquity and eccentricity of Mars' orbit rather than seasonal. Using secular cycles of 1.2×10^5 years, Coradini and Flamini (1979) calculated that Mars would have an "active layer" of 100 m; isotropic tensile horizontal stresses penetrating to such depths could form polygons of kilometer size (Helpenstein 1980). Nevertheless, the origin of the 3-7-km diameter polygons, most common in the northern plains of Mars, remains enigmatic.

SMALL POLYGONS

Several new observations show that some patterned ground on Mars has polygon diameters similar to those of ice-wedge polygons on Earth (generally a few meters to more than 100 m, Washburn 1980). Evans and Rossbacher (1980) noticed networks of polygons outlined by ridges in the smooth plains material of Lunae Planum (lat 17°N, long 56°W). These polygons range in diameter size from 400-1,000 m; considering martian conditions, those dimensions are comparable to those of ice-wedge polygons on the Earth. Brook (1982) has discovered light-colored polygonal networks on a layered tableland (lat 23°N, long 35°W). The polygons range from 100-1,000 m in diameter and are concentrated near the rims of several flat-floored, steep-walled depressions that were previously interpreted as alases (thermokarst collapse depressions) by Carr and Schaber (1977) and Lucchitta (1981). Brook hypothesized that the association of polygons and alases indicates ground ice and that the network is composed of ice-wedge polygons.

A recently discovered area underlain by polygonal ground occurs on a platform in Deuteronilus Mensae, near lat 47°N, long 346°W (figs. 1,2). The polygons measure 50-300 m in diameter, but smaller ones may also exist locally; faint networks can be detected down to the limit of resolution of the pictures. The interiors of these polygons are dark, similar to the polygons observed by Brook (1982). The polygons occur mostly on level ground but are also found on the sloping rim of a crater (8 km diam.), where the light-toned network can be clearly identified as linear depressions or cracks. Fractures parallel to the slope are emphasized, similar to what is observed on some terrestrial polygons (Washburn 1980). No upturned margins are visible; it appears that most of the polygons are flat or high centered. Apparent influence on the shape of the polygons by subparallel linear structures resulted in a network pattern most compatible with Lachenbruch's (1962) random-orthogonal class. Even though some small (about 500 m diam.), subdued old craters have polygonal fractures on their rims, most other small craters and their ejecta are devoid of cracks. The absence of such features may indicate that the craters are superposed and thus younger than the polygonal ground, or that the craters are older and the ejecta have physical properties which do not support formation of polygons. Some craters are, indeed, older than the polygons because they are surrounded by light radial lines that appear to merge with the polygonal ground pattern; these polygons apparently developed along preexisting radial impact fractures. Other radial lines may be rays. Figure 2a shows that polygons become less well defined northeastward; the light-toned networks widen, the dark centers shrink, and the polygonal patterns are more difficult to trace. Eventually, the patterned ground dissolves into a field of dark spots or low hummocks on a lighter-toned background.

Terrestrial patterned ground may be sorted or unsorted (Washburn 1980). Sorted patterned ground has circles, polygons, or nets that would be below the resolution of available images on Mars. Most large polygons on the Earth are unsorted; they may be more than 100 m in diameter, have cracks as much as 30 m deep, and occur in well-sorted fines, sand, gravel, or poorly sorted glacial deposits (Washburn 1980). Patterns may be dominated by orthogonal intersections (random or oriented orthogonal systems) or by triradial 120° intersections (nonorthogonal system) (Lachenbruch 1962). Orthogonal systems, which are common, develop mostly in nonhomogeneous or plastic media, or wherever loci of low strength or high stress predisposed certain areas to cracking; and some fractures predate others. Pure nonorthogonal systems are rare (Kerfoot 1972); they develop in homogeneous materials under isotropic tensional-stress regimes, and cracks propagate from point sources simultaneously. Kerfoot's study showed that on close inspection, most apparent triradial 120° intersections are orthogonal or at 60°. The polygons on Mars are similar in shape to unsorted random-orthogonal polygons on the Earth. Figures 1 and 2 show predominantly random-orthogonal systems that locally appear to be influenced by structural lines of weakness; these lines include fractures radial to craters, on slopes, and in subparallel sets of unknown origin.

ORIGIN OF POLYGONS

Unsorted polygons can be formed by desiccation, thermal contraction, or phase changes (Lachenbruch 1962, Washburn 1980). Desiccation polygons, for example, occur in mud and are generally less than 1 m in diameter (Washburn 1980). Phase-change polygons occur in cooling lava and thermal-contraction polygons in ice or salt. Salt polygons, on the Earth, are restricted to a few hot deserts. Polygons due to thermal contraction of ice are common at high latitudes, where they are known as tundra polygons or ice-wedge polygons. Fundamental to their formation are ice-rich ground, temperatures below -6°C (Péwé 1973), and rapid cooling with a large temperature differential. The fractures that form when the ground cools and contracts become filled with ice (ice-wedge polygons), or with dirt (sand-wedge polygons) where moisture is scarce. The polygons are not restricted to the active layer, but form within the permafrost layer, owing to seasonal temperature changes. Active polygons (low centered) have upturned edges caused by expansion of material during the warm season; inactive polygons (high centered) are surrounded by troughs from melting of ice wedges. Upon further degradation of wedges and ground ice, troughs widen, polygon centers slump into troughs, fields of hills (baydjarakhs) develop, and eventually the terrain disintegrates into thermokarst depressions.

An origin of the martian polygons by contraction of cooling volcanic materials is

implausible because of the age relations of cracks and impact craters. Lavas or ash flows would develop cracks immediately upon cooling, and all ensuing impact craters would be superposed on the cracks. However, the pictures show that some polygons developed on the rims of small craters and that, locally, crater and polygon fractures apparently interacted. Therefore, it is more likely that some time elapsed between the cooling of possible flows and the formation of polygons.

An origin by desiccation, though possible for the martian polygons, presents some difficulties. On the Earth, desiccation polygons are commonly small, whereas the polygons on Mars are large. However, the common occurrence of desiccation polygons on the Earth in thin layers of mud predisposes cracks to be limited to shallow depths and polygons to small sizes. By contrast, desiccation on Mars may have affected materials to considerable depth, the desiccation being caused by seasonal or secular climatic cycles. Since thick layers may thus have been affected by desiccation on Mars, the polygons might have grown commensurately larger than those on the Earth.

The areas on Mars most severely desiccated lie in the equatorial zone between lat $\pm 40^\circ$ where water is in disequilibrium with the atmosphere and depleted from the ground (Fanale 1976). A wealth of very high resolution images fail to show polygonal ground in those regions. The fracture patterns observed by Evans and Rossbacher (1980) lie in the equatorial area, but the patterns are composed of ridges rather than fractures, and so contraction due to desiccation may not be the appropriate mechanism. The pattern detected by Brook (1982) is a better candidate for desiccation: It also lies equatorward of lat 40° and the polygons are associated with well-developed thermokarst depressions (Lucchitta 1981). Brook has interpreted this relation to indicate disintegration of ice wedges, although the loss of ice could also have been by pervasive desiccation of the ground. The distinction between polygons formed by desiccation or by thermal contraction may be difficult on Mars on the basis of observational evidence alone because both processes require the existence of ice-rich ground, which in both processes may generate features of ground collapse.

Recent seasonal desiccation to the depths required to form polygons 50-300 m in diameter is unlikely at the latitude of Deuteronilus Mensae, where the newly discovered patterned ground is situated, because water there is in equilibrium with the atmosphere year round and may remain in the ground below about 1 m depth (Farmer and Doms 1979). During astronomic cycles of 10^5 - 10^6 years, however, resulting in a temporary high obliquity of Mars' rotational axis, the ground might have possibly warmed to sufficient depth for large-scale desiccation. Fanale and Jakosky (1982), however, have considered that water exchanged between the regolith and the atmosphere would be greatly inhibited by carbon dioxide pore gas and surface absorption, so that the depth of desiccation

should not exceed a few meters. Helfenstein (1980) calculated that these climatic cycles have large effects near the poles but only negligible effects near lat 45° , and so fractured ground near and equatorward of this latitude would probably not be affected much by secular climatic cycles. These considerations indicate that, near the poles, desiccation due to climatic cycles may have created polygons there, but also indicate that secular desiccation is not a likely mechanism for the origin of the patterned ground in the latitudes discussed here and by Brook (1982).

An origin of the martian polygons as thermal-contraction cracks in ice-rich ground appears to be most compatible with the observations. Ground ice is a prerequisite for thermal-contraction polygons. As pointed out above, theoretical considerations suggest that ice is currently stable in the martian ground below about 1 m depth at the latitudes of the patterned ground here discussed. According to Coradini and Flamini (1979), only water ice would be able to withstand the seasonal thermal wave into the ground; clathrates and carbon dioxide ice would evaporate too quickly.

Observational evidence also suggests that ice exists in the martian ground. As Figure 2 shows, the polygonal network appears to disintegrate into a field of hummocks northeastward across the picture. This feature is similar to the collapse of ice-rich ground on the Earth, where polygons disintegrate into fields of baydjarakhs. The destruction process on Mars, however, is more difficult to explain. As discussed above, evaporation would not occur under present climatic conditions below about 1 m depth, but ice at the surface could be seasonally depleted, and any disturbance, such as slumping, could initiate exposure of deeper ice to the atmosphere and trigger progressive loss of ice and collapse. Also, desiccation to a few meters depth during a past warmer period of the secular climatic cycle, as proposed by Fanale and Jakosky (1982), may have caused loss of ice and partial disintegration of the terrain. This process, however, as mentioned above, is less likely.

The seasonal temperature change in the area discussed is substantial. The mean diurnal temperature ranges from -50°C in the summer to -110°C in the winter during a martian year, a drop of 60°C (Kieffer et al. 1977). The amount of this drop is more than adequate to initiate thermal contraction in ice-rich ground. A decrease in the linear coefficient of expansion of ice with decreasing temperature (from $40 \times 10^{-6}/^\circ\text{C}$ at -50°C to $30 \times 10^{-6}/^\circ\text{C}$ at -110°C ; Hobbs 1974) would lessen the thermal contraction at the lower temperatures but would not prohibit the formation of thermal-contraction polygons at the cold temperatures of the martian surface.

If the polygons on Mars are, indeed, thermal ice-contraction cracks, the question remains whether the fractures are filled by ice wedges or sand wedges. The climate on Mars is extremely dry; only very few to about 30 precipitable microns of water exist at this

latitude on Mars in winter and summer, respectively (Jakosky and Farmer 1982). Wind-driven material, however, is ubiquitous on Mars and would readily fill cracks. The lighter tone of the polygonal network also is compatible with infilling by drift: sand wedges, therefore, are plausible. On the other hand, as seen at the Viking 2 Lander site, waterfrost is precipitated in winter on Mars (Wall 1981), and crystals may grow in cracks. On the Earth, ice wedges form mostly by percolation of meltwater into previously opened cracks (Leffingwell 1919, p. 205-214), although windborne snow may also contribute (Black 1976). Windblown movement of frost is possible on Mars in winter and could contribute to the infilling of cracks and the growth of ice wedges. Furthermore, the polygonal ground observed is transitional with the hummocky ground. This observation suggests that disintegration occurred along the polygonal-fracture lines, which, in turn, suggest that ice was contained in the fractures. Overall, the evidence is compatible with ice-wedge polygons, although sand-wedge polygons cannot be ruled out; the fractures probably contain a mixture of dirt and ice.

It is difficult to ascertain whether the polygons are actively forming today or are relics from the past. The crispness of some cracks suggests a recent origin, but the absence of recognizable upturned edges (indicating actively forming ice wedges), the locally disintegrating ground, and the possible superposition of some rayed craters suggest that the polygons may be old. The polygons may belong to a former part of the climatic cycle, when the temperatures were colder or when air currents favored supply of moisture to the region.

The composition of the material in which the polygons are developed is not known; it could be regolith on old volcanic surfaces, windblown deposits, or other sediment. The proximity of several channels, including a previously unknown outflow channel, suggests that the surface might be covered by fluvial or glacial (Lucchitta et al. 1981, Lucchitta 1982) materials. Corte (1963) noted that the largest and best developed ice-wedge polygons occur on somewhat elevated, relatively well-drained and coarse outwash from glaciers. Deposition of similar sediment in this area on Mars may have enabled the polygonal ground to become exceptionally well developed there.

CONCLUSIONS

Newly discovered polygonal ground on Mars occurs in Deuteronilus Mensae at lat 47°N, long 346°W, near the northern margin of the martian highlands. The polygons measure 50-300 m in diameter and form cracks in random orthogonal patterns. The size and shape of these polygons are analogous to those of unsorted polygons on the Earth, which are most common at high latitudes and form by thermal contraction of ice-rich ground. On Mars, ice is in equilibrium with the atmosphere at the latitudes of this

patterned ground, and ice may remain in the ground for extended periods. The presence of ice is also indicated by the disintegration of some polygonal patterns to fields of hummocks, which suggests loss of material. Therefore, the polygons on Mars are probably related to the presence of ground ice in this region.

Both desiccation due to climatic cycles and thermal contraction due to seasonal cycles could have formed the polygonal fractures. The desiccation hypothesis has uncertainties concerning the temperature regime and atmospheric exchange of water during climatic cycles. The thermal-contraction hypothesis is favored because it is compatible with the size and shape of the polygons, with theoretical and observational evidence for ground ice, with seasonal cooling of -60°C, adequate to initiate thermal contraction of ice-rich ground, and with the availability of seasonal water vapor or frost. The fractures may be filled by sand wedges or ice wedges, or, most likely, by a combination of the two. The dry martian climate and abundant supply of windblown materials favor the formation of sand wedges, whereas the disintegration of the ground along polygonal patterns favors the formation of ice wedges. The crispness of some fractures suggests that they are little degraded and thus relatively young, although local destruction of the ground indicates that presently they are not forming actively.

THAWING BENEATH INSULATED STRUCTURES ON PERMAFROST

V.J. Lunardini

U.S. Army Cold Regions Research and Engineering Laboratory
Hanover, New Hampshire 03755 USA

The problem of thawing beneath heated structures on permafrost (or cooled structures in nonpermafrost zones) must be addressed if safe engineering designs are to be conceived. In general there are no exact solutions to the problem of conduction heat transfer with phase change for practical geometries. The quasi-steady approximation is used to solve the phase-change problem for insulated geometries, including infinite strips, rectangular buildings, and circular storage tanks. Analytical solutions are presented and graphed for a range of parameters with practical importance.

Large-scale exploration and development of the high latitudes of the northern hemisphere have stimulated interest in a number of thermal problems. Not the least of these is the effect of heated structures on underlying or surrounding permafrost. This involves the study of conduction heat transfer in media that can undergo freezing or thawing. Lachenbruch (1957a,b, 1959) and Jumikis (1978) applied linear conduction theory to the effect of heating on permafrost since no phase change was considered. However, the phase change conduction problem is nonlinear and few exact solutions exist (Lunardini 1981a).

Geometries of practical interest do not allow exact solutions of the thermal problem. Closed form solutions, as opposed to numerical evaluations, have relied on approximate methods such as the heat balance integral method and the quasi-steady method. The heat balance integral method gives excellent accuracy and has been applied successfully to simple geometries such as semi-infinite systems (Goodman 1958, Lunardini 1981c, Lunardini and Varotta 1981, Yuen 1980) and pipes buried at infinite depth (Lunardini 1980, Bell 1978).

The quasi-steady method is not as rigorous as the heat balance integral method, but it can be applied to a wide variety of geometries. Applications have included uninsulated buried pipes (Hwang 1977, Thornton 1976, Porkhayev 1963), insulated buried pipes (Lunardini 1981b,d; Seshadri and Krishnayya 1980), and three-dimensional structures (Porkhayev 1970). Probably the most widely used calculated results are those of Porkhayev (1970). New quasi-steady relations are derived and applied to insulated geometries including semi-infinite strips (roads, rivers), rectangular buildings, and circular storage tanks.

QUASI-STEADY METHOD

The quasi-steady approximation assumes that the temperature field changes slowly from one steady state to another. Consider an infinite strip, as shown in Figure 1, with different properties in the thawed and frozen zones. Initially, the temperature is uniform at T_0 and the insulated surface of the strip jumps suddenly to T_p . The equations for the thawed and frozen regions are

FIGURE 1 Phase change beneath center of an uninsulated infinite strip.

$$\frac{\partial^2 \phi_1}{\partial \zeta^2} + \frac{\partial^2 \phi_1}{\partial \xi^2} = \frac{2}{\pi} S \frac{\partial \phi_1}{\partial \tau} \quad (1)$$

$$\phi_1(\zeta, 0, \tau) = 1 \quad -1 \leq \zeta \leq +1 \quad (1a)$$

$$\phi_1(\zeta_0, \xi_0, \tau) = 0 \quad (1b)$$

$$\frac{\partial^2 \phi_2}{\partial \zeta^2} + \frac{\partial^2 \phi_2}{\partial \xi^2} = \frac{2S_T}{\pi \kappa_{21}} \frac{\partial \phi_2}{\partial \tau} \quad (2)$$

$$\phi_2(\zeta, 0, \tau) = 0 \quad \zeta < -1 \text{ or } \zeta > +1 \quad (2a)$$

$$\phi_2(\zeta, \xi, 0) = 0 \quad (2b)$$

$$\phi_2(\zeta_0, \xi_0, \tau) = 1 \quad (2c)$$

$$\lim_{\zeta, \xi \rightarrow \infty} \phi_2(\zeta, \xi, \tau) = 0 \quad (2d)$$

The energy balance over the surface S' separating the frozen and thawed zones is

$$\int_{S'} \left(\frac{\bar{T} - T_p}{T_p - T_f} \frac{\partial \phi_1}{\partial m'} - \beta \frac{\partial \phi_2}{\partial m'} \right) ds' = - \frac{2}{\pi} \frac{dV'}{d\tau} \quad (3)$$

Equations 1 through 3 cannot be solved exactly, but if S_T is small then the diffusion equations reduce to the steady-state case that is more easily

solved. If the properties of the frozen and thawed media are identical, then the quasi-steady system is

$$\frac{\partial^2 \phi}{\partial \zeta^2} + \frac{\partial^2 \phi}{\partial \xi^2} = 0 \quad (4)$$

$$\phi(\zeta, 0) = \begin{cases} 1 & -1 \leq \zeta \leq 1 \\ 0 & \zeta > 1 \text{ or } \zeta < -1 \end{cases} \quad (4a)$$

$$\lim_{\zeta, \xi \rightarrow \infty} \phi(\zeta, \xi) = 0 \quad (4b)$$

Notice that the energy boundary equation is solved by merely using the quasi-steady solution for ϕ . Lunardini (1981a) showed that Equations 4 through 4b are the zeroth order of a perturbation solution of Equations 1 and 2. The quasi-steady method consists of solving the steady-state problem and locating the phase change boundary with an equation similar to Equation 3. The accuracy of the method depends upon the magnitude of the Stefan number. For systems with a large latent heat relative to the sensible heat, the approximation will be reasonably good. This includes soil systems and many latent heat storage materials.

GENERAL QUASI-STEADY RELATIONS

General equations can be derived that will be valid for a class of important phase change problems. Assume that the solutions to the quasi-steady forms of Equations 1 and 2 are

$$\phi_1 = A_1(\tau) + B_1(\tau) f(\zeta, \xi) \quad (5)$$

$$\phi_2 = A_2(\tau) + B_2(\tau) f(\zeta, \xi) \quad (6)$$

When combined with the boundary conditions, these give

$$\phi_1 = (f - f_0)/(1 - f_0) \quad (7)$$

$$\phi_2 = f/f_0 \quad (8)$$

The function f is the solution to the equivalent steady-state equations, and f_0 is its value on the phase-change surface.

The heat flow through the insulation will be equated to the heat flow from the thawed soil at $\xi = 0$, a concept used by Seshradi and Krishnayya (1980) and by Lunardini (1981b). Using Equation 7, the relation for the insulation/ground temperature is

$$\frac{T_p - T_f}{T_p - T_f} = \frac{1}{1 - \frac{2\alpha}{1 - f_0} \frac{\partial f(0,0)}{\partial \xi}} \quad (9)$$

The general interface equation, Equation 3, is now

$$\left(\frac{1}{f_0 - 1 + 2\alpha \frac{\partial f(0,0)}{\partial \xi}} + \frac{\beta}{f_0} \right) \left(\frac{\partial f}{\partial \xi} \right)_{\zeta_0, \xi_0} = \frac{2}{\pi} \frac{d\xi_0}{d\tau} \quad (10)$$

The steady-state (limiting) solution occurs when $d\xi_0/d\tau \equiv 0$. This is

$$f_{0\infty} = \frac{\beta}{1 + \beta} \left[1 - 2\alpha \frac{\partial f(0,0)}{\partial \xi} \right] \quad (11)$$

The heat flux into the thawed soil at the center of the heated surface is

$$q = \frac{-k_1(T_p - T_f)}{a \left[1 - f_0 - 2\alpha \frac{\partial f(0,0)}{\partial \xi} \right]} \frac{\partial f(0,0)}{\partial \xi} \quad (12)$$

The effect of the insulation can also be accounted for by considering an excess layer of soil, applied to the thawed zone temperature relations, with a thermal resistance equal to that of the actual insulation. The concept was introduced by Porkhayev (1963, 1970), however the method used here gives better results (Lunardini 1982).

SEMI-INFINITE STRIP

The semi-infinite strip can represent roads, shallow rivers, or very long rectangular buildings. The steady-state solution is given by Lunardini (1981a) as

$$f(\zeta, \xi) = \frac{1}{\pi} \tan^{-1} \left(\frac{2\xi}{\zeta^2 + \xi^2 - 1} \right) \quad (13)$$

Equation 10 can be integrated to obtain

$$\tau = \int_0^{\xi_0} \frac{[(\zeta^2 + u^2 - 1)^2 + 4u] du}{(\zeta^2 - u^2 - 1) \left[f(\zeta, u) - 1 - \frac{4\alpha}{\pi} + \frac{\beta}{f(\zeta, u)} \right]} \quad (14)$$

Equation 14 was evaluated numerically, along the axis of symmetry at $\zeta = 0$, with the values for $\alpha = 0$ plotted as Figure 1. Correction factors for nonzero α values are defined as

$$\gamma = \gamma(\alpha=0) - K_i \quad (15)$$

and plotted in Figures 2 and 3. The single-phase solution ($\beta = 0$) is

FIGURE 3 Insulation correction factor, infinite strip, $0.6 < \beta < 1.2$.

FIGURE 4 Phase change beneath center of rectangle, $n = 1, \alpha = 0$.

FIGURE 5 Insulation factor, $n = 1, 0 < \beta < 0.5$.

FIGURE 6 Insulation factor, $n = 1, 0.5 < \beta < 2.0$.

$$\tau = \left(1 + \frac{4\alpha}{\pi}\right) \left(\frac{\gamma^3}{3} + \gamma\right) - \frac{2}{\pi} \left\{ \left(\frac{\gamma^3}{3} + \gamma\right) \operatorname{ctn}^{-1} \gamma + \frac{1}{3} \ln(1 + \gamma^2) + \frac{1}{6} \gamma^2 \right\} \quad (16)$$

The temperatures, in the thawed and frozen zones, can be found with Equations 7 and 8.

RECTANGULAR BUILDING

The semi-infinite strip can represent a building with a very large length-to-width ratio, but solutions for small aspect ratios are needed. The general steady-state solution is given by Lunardini (1981a) and the geometric factor along the axis of symmetry, for $\zeta = \eta = 0$, can be written

$$f(\xi) = \frac{2}{\pi} \tan^{-1} \left(\frac{n}{\xi \sqrt{\xi^2 + 1 + n^2}} \right) \quad (17)$$

The phase-change interface is

$$\tau = \frac{1}{n} \int_0^{\xi_B} \frac{[u^2(u^2 + 1 + n^2) + n^2] \sqrt{u^2 + 1 + n^2} du}{(2u^2 + 1 + n^2) \left[\frac{1}{f(u) - 1 - \frac{4\alpha \sqrt{1 + n^2}}{\pi n}} + \frac{\beta}{f(u)} \right]} \quad (18)$$

The steady-state solution is

$$\xi_{B\infty}^2 = \sqrt{\left(\frac{1 + n^2}{2}\right)^2 + n^2 \cot^2 \left[\frac{\beta}{1 + \beta} \left(\frac{\pi}{2} + \frac{2\alpha \sqrt{1 + n^2}}{n} \right) \right]} - \frac{(1 + n^2)}{2} \quad (19)$$

FIGURE 7 Phase change beneath center of rectangle, $n = 2, \alpha = 0$.

FIGURE 8 Insulation factor, $n = 2, 0 < \beta < 0.5$.

FIGURE 9 Insulation factor, $n = 2, 0.5 < \beta < 2.0$.

FIGURE 10 Phase change beneath center of uninsulated circular tank.

Equation 19 is valid for the infinite strip if the limit is taken as $n \rightarrow \infty$.

Numerical quadrature of Equation 19 was carried out and a correction factor was defined as

$$\xi_B = \xi_B(\alpha=0) - K_{in} \quad (20)$$

Figures 4 through 9 can be used for rectangular structures.

CIRCULAR TANK

The transient solution for the temperature in a semi-infinite medium initially at T_0 , after a surface area S_1 is disturbed with a temperature

T_p , is given by Lachenbruch (1957). The steady-state solution is

$$\frac{T - T_0}{T_p - T_0} = \frac{z}{2\pi} \iint_{S_1} \frac{dA}{[(x-x')^2 + (y-y')^2 + z^2]^{3/2}} \quad (21)$$

Equation 21 cannot be integrated in closed form for the circle, but the temperature along the z -axis can be written immediately, and the geometric function is then

$$f(\xi) = 1 - \frac{\xi}{\sqrt{\xi^2 + 1}} \quad (22)$$

FIGURE 11 Insulation factor, $0 < \beta < 0.25$.

FIGURE 12 Insulation factor, $0.3 < \beta < 0.55$.

FIGURE 13 Insulation factor, $0.55 < \beta < 1.0$.

The phase-change interface depth along the axis of symmetry is

$$\tau = \frac{2}{\pi} \int_0^{\xi_c} \frac{(u^2+1)du}{\sqrt{\frac{1}{u+2\alpha\sqrt{u^2+1}} - \frac{\beta}{\sqrt{u^2+1}} - u}} \quad (23)$$

The limiting solution is

$$\xi_{c\infty} = \left(\left[\frac{1+\beta}{1-2\alpha\beta} \right]^2 - 1 \right)^{-1/2} \quad (24)$$

The single-phase solution can be written as

$$\tau = \frac{1}{\pi} \left\{ \frac{\xi_c^4}{2} + \xi_c^2 + \frac{\alpha}{2} \left[\xi_c (2\xi_c^2+5) \sqrt{\xi_c^2+1} + 3 \ln (\xi_c + \sqrt{\xi_c^2+1}) \right] \right\} \quad (25)$$

The circular tank correction factor is

$$\xi_c = \xi_c(\alpha=0) - K_{ic} \quad (26)$$

Numerical values are given in Figures 10 through 13.

CONCLUSIONS

The problem of conduction heat transfer with phase change has been solved approximately using the quasi-steady method. The method is expected to be more reliable than the widely used graphs of Porkhayev (1970).

The quasi-steady method is extremely useful since it can be applied quite easily to a number of practical cases, and the results can be presented in a compact form, as shown by the graphs. These graphs are felt to be acceptable for engineering estimates with maximum errors of $\pm 20\%$. For insulated systems, where the phase change is more limited, the graphs should be even more accurate.

RESULTS OF LOAD TESTS ON TEMPERATURE-CONTROLLED PILES IN PERMAFROST

Eight temperature-controlled pile load tests have been made at three sites representing typical interior Alaskan permafrost conditions. The loads were applied in increments, and accurate displacement histories were obtained for each increment. Direct results of these tests and evaluations based on primary creep and ultimate strength are presented in this paper. It is believed that these tests represent an extremely valuable data base to the profession, to evaluate the load-carrying and settlement characteristics of slurried piles in permafrost.

INTRODUCTION

This paper presents data obtained during a significant load test program on piles in permafrost. An earlier description of these pile load tests was published by Black and Thomas (1978).

As of the early 1970s, piles had been installed in Alaska at several locations, principally in connection with Air Force facilities and other national defense programs. Also, the U.S. Army's Cold Regions Research and Engineering Laboratory had tested many piles in permafrost conditions (Sanger 1969). This previous work represented the starting point for the development of the design criteria for the piles used by Alyeska Pipeline Service Company to support the elevated portion of the Trans-Alaska Pipeline System (TAPS). Alyeska was required to conduct a substantial amount of independent research and criteria development for its design purposes, because these prior projects and research differed in many important respects from the pipeline project. Basically, prior pile projects had been installed at single sites covering a small geographic area, generally on projects requiring only 100 or so piles, and most were installed in cold permafrost. Alyeska, in contrast, needed to develop criteria which were suitable for approximately 78,000 piles installed along a 1,280-km route, in soils which varied widely in composition and thermal state. In addition, the design criteria which were developed for Alyeska's purposes needed to ensure the integrity of the pile system for a 30-year useful life, with allowance only for limited maintenance. The end result was several significant differences between the piles and the criteria developed for Alyeska and the research and projects which had preceded that program. For example:

- Many of the prior projects used timber piles and mechanical refrigeration systems for initial freezeback, which were uneconomical or impractical for use by Alyeska. Alyeska used steel pipe piles, many of which were corrugated and contained self-refrigerating thermal devices.

- Most prior installations used in situ soil, which frequently was ice-rich silt, or even water, to backfill the holes around the piles. Alyeska, in contrast, engineered a carefully controlled sand-water slurry which was used to backfill the annulus around the pile and which was vibrated during placement for densification.
- While other projects had typically been designed on the basis of the exact temperature of the soils, which often were substantially below freezing, this was impractical over the long route of the pipeline. So a specific upper design temperature was established (-0.3°C for most of the line) for the pile and the adjacent frozen ground.

The pile tests discussed herein were confirmation tests, made by Alyeska as one condition of acceptance of Alyeska's pile design criteria by the federal government review agencies in late 1974. The purpose of the tests was to confirm previously established criteria, not to serve as the basis for setting new criteria. The initial design criteria for the piles had been established on the basis of earlier criteria and performance results, extensive laboratory creep tests on frozen slurries and natural soils, and thorough analytical modeling of the thermal and mechanical performance of the piles.

TEST CONDITIONS AND DETAILS

Test Plan

The basic test plan was to install and test three identical piles at each of three test sites representing different soil and permafrost characteristics. The piles were configured and installed as similar to pipeline prototype piles as was possible. Each pile was tested by applying loads in increments, at 3-day intervals, and pile top displacements were measured very accurately during the 3-day period after each incremental load application.

Special Test Conditions

Special test conditions which made these test piles different from prototype piles were as follows. The test piles were cased down to the bearing layer, a distance varying between 1.8 and 3.6 m at the three sites. The inside of the piles was filled with a temperature-controlled fluid to maintain a constant-temperature environment of -0.3°C in and near the piles during the loading phase of the test; this temperature was the highest design temperature for the prototype piles. The test loads were applied in discrete increments, which were held constant for 3 days to allow very accurate creep displacement measurements. The size of the load increments was selected to lead to failure in about 10 increments.

Further the test piles were subjected to a "thermal shock" loading (Heuer 1979) of -30°C temperature for a period of 6 hours prior to the load test, to simulate a rapid ambient temperature drop in fall.

Controls and Measurements

The test load was applied to each pile through a hydraulic ram which was furnished pressure by an air-actuated hydraulic pump. An electronic load controller was programmed to maintain the desired load within 1%. A calibrated load cell monitored the load and provided feedback to the load controller. This system provided load control well within the specified 1%.

The pile top displacement was measured by both dial gauges and displacement transducers. The displacements were measured with respect to an independently supported reference frame. A reading sensitivity of 0.0025 mm was desired, and a precision of about 0.025 mm was obtained.

The maximum prototype pile design temperature of -0.3°C was selected as the test temperature. It was considered impossible to select test sites where natural permafrost conditions would provide a constant test temperature at that level. Therefore, separate control units were provided to control the temperature of each test pile. Heat was removed by circulating a refrigerant in coils inserted within the test length of each test pile. The coils were thermally coupled to the pile wall by a glycol solution which was also circulated. The heat withdrawal was opposed by heating elements, to meet a temperature criterion of -0.3°C with plus 0°C and minus 0.1°C tolerance.

Though load transfer along the pile and end bearing will not be discussed herein, the corresponding measurement systems are noted. They included a Gloetzl load cell at the pile tip to measure end bearing, and pairs of strain gauges placed diametrically opposite each other at five locations along each pile to measure loads transferred at different depths along the pile (see Figure 2).

A 128-channel data acquisition system was used to monitor all instrumentation at each site, except for the dial gauge readings, which were manually read and recorded. Output from the data recorder included a typed tape used for hourly and daily monitoring of the results and for

adjustments to the test plan, and a computer-coded punched tape which furnished the record copy of all test data.

TESTS AND TEST RESULTS

Tests Accomplished

The planned three tests were implemented at the Glennallen and Shaw Creek sites. At the Engineer Creek site, two of the test piles were damaged during construction and were considered unsuitable for testing. Thus one of the originally designated test piles, plus the redundant test pile, were tested at this location. The latter had a steel end plate instead of a bottom load cell, otherwise it was equivalent to the other test piles.

In all cases the test length had been selected to give a design load of about 267 kN (60 kips) and anticipated failure at approximately 890-1,340 kN (200-300 kips) of applied load. Correspondingly, the reaction frame was designed for a maximum load of 1,780 kN (400 kips). The test load was applied in all cases in 89-kN (20-kip) increments up to 890 kN (200 kips) applied load and in 178-kN (40-kip) increments above that load. The maximum applied load, if no prior failure occurred, was 1,780 kN (400 kips). This load was reached in all tests except those at Engineer Creek, where the maximum applied load was 1,600 kN (360 kips).

Test Results

The results of a typical load test at the Glennallen site are presented in Figure 3, which shows a displacement-time history and a load-displacement curve for the entire test. The reported displacement is that at the top of the load-bearing portion of the pile; i.e., elastic shortening of the pile above that location was subtracted from the measured displacements. The displacement-time curve illustrates the occurrence of displacement in each of the 15 applied load increments. The load-displacement curve is similar to that of a typical pile load test.

Additional detail on the development of displacement under several selected load increments is given in Figure 4. The figure shows that even at relatively small loads an equilibrium condition was not reached within the 3-day duration of the increment; rather, the curves are indicative of increasing displacements with a decreasing creep rate. This shape, which is frequently termed "primary creep," was typical of the vast majority of the results. Only in three of the eight tests was a constant or increasing creep rate, i.e., secondary or tertiary creep, observed, and then only at the highest applied load level. These were Pile 2 at Shaw Creek at 1,780 kN (400 kips) load and both piles at Engineer Creek at 1,600 kN (360 kips) load.

Figures 3 and 4 give results for Pile 3 at the Glennallen site. This pile had intermediate strength results of the three tests at Glennallen.

FIGURE 3 Pile Test Results--Glennallen Site.

In Figure 3 the load-displacement curves of the other two tests at Glennallen are also shown. At the Shaw Creek site, Pile 1 gave the intermediate strength results of the three piles there, and the corresponding load-displacement-time results are presented in Figure 5, together with load-displacement curves for the other two tests at Shaw Creek. At Engineer Creek, the two test piles gave very similar results. The displacement-time curve of Pile 4 and the load-displacement curve for both tests are presented in Figure 6.

EVALUATION OF RESULTS

General Observations

The two or three tests at each site showed reasonable repeatability of tests, as seen in Figures 3, 5, and 6. One exception is Pile 2 at Shaw Creek, which showed a significantly greater displacement than the other two piles at the same site. On the other hand, systematic differences between the three soil types are quite marked.

The pile tests in the gravel at the Shaw Creek site had the smallest displacements and the highest ultimate loads. All three piles reached the 1,780 kN (400 kip) maximum test load, with only one showing any signs of weakening. It is believed that considerable end bearing was mobilized in addition to the resistance along the vertical sides in these tests at Shaw Creek.

The piles in the stiff Copper River basin clays at the Glennallen site showed intermediate strength. All three piles reached the 1,780 kN (400 kip) maximum load, though the displacements were considerably larger than at Shaw Creek at all loads.

The test piles at the Engineer Creek site, though they had the longest bearing length, both showed large displacements and displacement rates at 1,600 kN (360 kips) of load and accordingly were not taken to the 1,780 kN (400 kip) maximum load. These piles were relatively stiff at low loads but then showed a dramatic increase in displacements above 530 kN (120 kips).

FIGURE 4 Typical Creep Curves--Pile 3, Glennallen Site

Notes:
 The plotted displacements have been corrected for the calculated elastic deflection of the cased-off portion of the pile.
 1 kip = 4.448 kN
 20 kips = 89 kN

FIGURE 5 Pile Test Results--Shaw Creek Site

Specific Evaluations

Two evaluations of the pile load test results are presented below as examples of what can be done with these data. These include an evaluation based on primary-creep data and another based on indications of ultimate strength.

Evaluation of primary creep can be done utilizing a plotting method introduced by Sayles (1968), who suggested that primary creep is described by a creep rate power function of the form

$$D = D_1 \left(\frac{1}{t}\right)^{1/M}$$

where D is a creep rate at some time, t is time, and D_1 and M are constants for a given creep relationship. Evaluation of the data by this method is best done by plotting the displacement rate versus reciprocal of time on log-log paper. To make these plots, the time-displacement data were smoothed, and the corresponding displacement rates were calculated. The curve fitting and rate calculations were done using a simple computer program. Determination of the two constants D_1 and M from the plots (for the later times in the usual case of bilinear plots) allows calculation of the expected primary-creep settlement for the particular load at any time, for instance over a 30-year design life. These 30-year expected settlements can then be plotted versus the load (presuming that the settlement under each load increment is independent of the prior smaller loading increments), and a reasonable and conservative relationship established. This relationship allows determining, for any selected design

load, the expected 30-year primary-creep settlement as indicated by the particular test. An example of the two plots is given by Black and Thomas (1978) in their Figures 7 and 8.

This evaluation was made for all eight test piles in this program. Results from all eight tests for a 276 kN (60 kip) design load sustained for 30 years are summarized in Table 1. They show a maximum predicted 30-year primary-creep settlement of 40 mm (1.6 in.). Displacements of this magnitude could easily be accommodated by Alyeska's elevated pipeline design.

The second evaluation is analogous to load test evaluations that might be made for pile tests in

TABLE 1 Results of Evaluations

Site and File No.	Prim. Creep	Ultimate Capacity		
	30-year Settlement for 267 kN	Ultimate Capacity	Design Load (F=2.5)	Design Stress (F=2.5)
	mm	kN	kN	kPa
GA 1	38	1,250	500	77
GA 2	10	>1,780	>710	>110
GA 3	40	1,600	640	96
SC 1	<3	>1,760	>710	>134
SC 2	8	1,600	640	120
SC 3	<3	>1,760	>710	>134
EC 1	8	1,070	430	48
EC 4	8	1,070	430	48

1mm = 0.04in., 1kN = 0.22kips, 1kPa = 0.021ksf

FIGURE 6 Pile Test Results--Engineer Creek Site

unfrozen soils; it is based on the pile's ultimate capacity, as evidenced by the creep rate at the end of each load increment. Specifically, it has been suggested that the load at which a creep rate of 0.5 mm (0.02 in.) per 24 hours was occurring at the end of the 3-day duration of each load increment was a reasonable representation of the pile's ultimate capacity. The highest load increments at which the displacement rate was just below 0.5 mm/day are indicated in Figures 3, 5, and 6 for the three highlighted piles, and in Table 1 these ultimate capacities are tabulated for all eight test piles. If a factor of safety of 2.5 is used, as suggested by Crory (1974) for piles in permafrost when pile load tests have been made (3.0 without load tests), the design load and the design adfreeze stress levels are also presented in the last columns of the table. The design loads are 427 kN (96 kips) or higher for all tests, well in excess of the 267 kN (60 kips) intended design load.

Thus both types of evaluations of the tests in terms of primary-creep displacement and of ultimate load confirmed the adequacy of the previously adopted pile design criteria.

PINGO GROWTH AND SUBPINGO WATER LENSES, WESTERN ARCTIC COAST, CANADA

J. Ross Mackay

Department of Geography, University of British Columbia
Vancouver, B.C., Canada, V6T 1W5

Field surveys of hydrostatic (closed) system pingos which are growing in the bottoms of drained lakes have been carried out along the western arctic coast, Canada from 1969-1982. The water pressures beneath a pingo are derived from pore-water expulsion in saturated sandy lake-bottom sediments during permafrost aggradation. A subpingo water lens develops when the pore water pressure uplifts the pingo overburden and intrudes water beneath it. Three growth patterns have been identified for the pingos with subpingo water lenses. (1) Constant year-to-year growth suggesting a balance between water supply and freezing of the water lens; (2) decreasing year-to-year growth suggesting a freeze-through of the sub-pingo water lens; (3) erratic year-to-year growth with periods of increasing height followed by pingo rupture, water loss, and pingo subsidence. The freezing point of the water in a subpingo water lens is depressed slightly below 0°C by a combination of hydrostatic pressure and the concentration of solutes rejected during freezing.

INTRODUCTION

A pingo is an ice-cored hill which is typically conical in shape and can only grow and persist in permafrost. There are about 1,450 pingos along the western arctic coast of Canada, and of these, about 1,350 occur on Richards Island, Tuktoyaktuk Peninsula, and the coastal area just south of the Eskimo Lakes and Liverpool Bay (Figure 1). Pingos can be divided into two main types: (1) hydraulic (open) system pingos where the water is derived from a source higher in elevation than the pingo and (2) hydrostatic (closed) system pingos where the water is derived from a hydrostatic head resulting from pore water expulsion during permafrost aggradation (Mackay 1962, 1979). The pingos under discussion are of the hydrostatic type and have grown in residual ponds left by rapid lake drainage. The lake bottom sediments are sandy. The pingo cores are composed mainly of segregated ice, "injection ice" frozen from bulk water in a subpingo water lens, or any combination of the two types. Although the term "injection ice" is a misnomer, because it is the water which is injected and not the ice, the term is used here because it is well established in the permafrost literature. Field surveys have been carried out on many growing pingos (Figure 1) for the period 1969-1982. The focus of this discussion is on pingos 13, 14, and 17. The mean annual air temperature in the area is about -11°C, the mean annual ground temperature about -8°C to -9°C, and permafrost is about 500-600 m thick. The purpose of this paper is to discuss aspects of pingo growth affected by the presence of subpingo water lenses.

PINGOS 13, 14, AND 17

Pingos 13, 14, and 17 have formed in the bottom of a large lake which drained prior to 1890. The lake was about 1 km wide, 6.5 km long, and deeper than the maximum winter ice thickness over most of

its area, so that a large talik would have existed beneath the lake bottom prior to lake drainage. The tops of each of the three pingos rise to a uniform height of about 12 m above the lake bed and the position of the three tops forms the vertices of a triangle the sides of which are about 450 m long.

Pingo 14

A section across the width of the drained lake basin with pingo 14 in the center is shown in Figure 2. The 1971-1982 changes in height of a bench mark installed into permafrost on the top of the pingo, and referenced by precise survey to a stable datum beyond the former lake shore, are plotted in Figure 3. Holes were drilled through ice-bonded permafrost in the pingo down to the subpingo water lens in 1973, 1976, and 1977. All holes produced artesian flow (Figure 4). In 1973 and 1976, the holes were allowed to freeze in. In 1977, two drill holes were kept open for 2 weeks, and two pressure transducers were installed in the subpingo water lens where it was 1.2 m thick (Figure 2). Because the projections of the growth trends for the pingo top (Figure 3) were parallel for 1971-1972, 1973-1976, and 1978-1982 when there was no water loss, the rate of recharge to the subpingo water lens seems to have been constant. The water pressure in the subpingo water lens for 1977-1982 is plotted in Figure 5. Within a month following freezing of the drill holes in 1977 the pressure stabilized at 370 kPa where it has remained essentially constant ever since.

Pingos 13 and 17

Increase in elevation of the tops of pingos 13 and 17 is plotted in Figure 6. Although pingos 13, 14, and 17 undoubtedly share a common subpermafrost groundwater system, drilling in pingo 14 seems to have had no detrimental effect upon the growth of pingo 13. Even though pingo 17 has not been

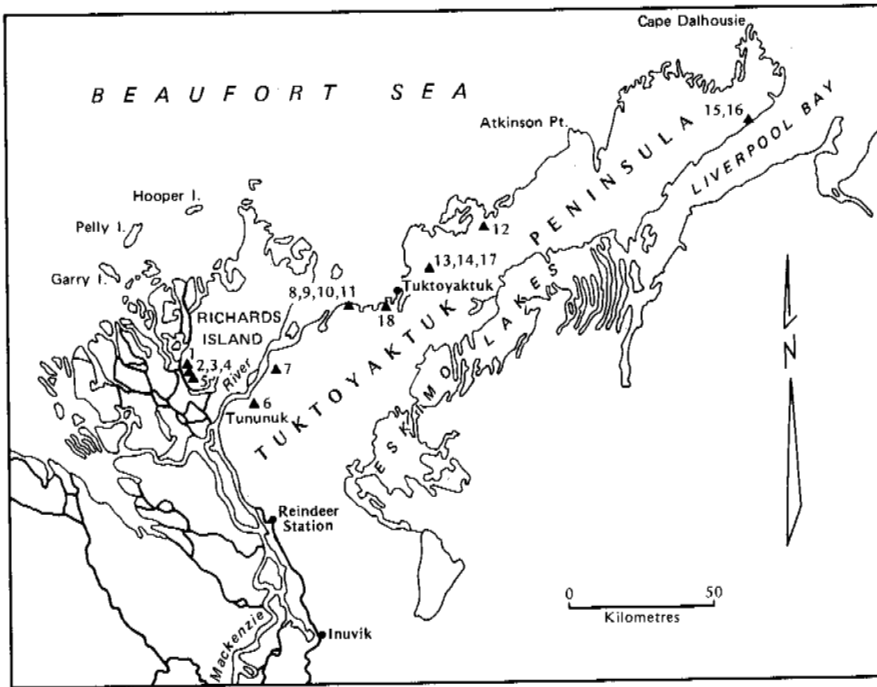

Figure 1. Location map. Pingos are assigned numbers, because most are unnamed.

Figure 2. Cross section of pingo 14 and the drained lake.

drilled, there is abundant evidence from periodic spring flow, peripheral pingo faulting with water loss, and subsidence of the top to show that pingo 17 is underlain by a large and deep water lens (Mackay 1977, 1979). Figure 6 shows a variable growth pattern for pingo 17 between 1974 and 1977 when there was frequent spring discharge and pingo rupture. From 1977-1979, following

extensive water loss from drilling in nearby pingo 14, the growth has been steady. No spring discharge has been observed for the 1977-1982 period.

Figure 3. Graph showing the height of a bench mark on the top of pingo 14 for the 1971-1982 survey period. Note the loss of height following each period of drilling.

PERMAFROST GROWTH AND PORE-WATER EXPULSION

When downward freezing occurs in saturated sand, such as is present beneath the drained lake of pingos 13, 14, and 17, pore water will be expelled in front of the freezing surface if drainage is permitted, but if drainage is blocked, the pore-water pressure will rise and may approach the overburden pressure (e.g. Arvidson and Morgenstern 1977; Khakimov 1957; McRoberts and Morgenstern 1975). It is permafrost growth accompanied by pore-water pressure which provides the mechanism for pingo growth. Furthermore, it is obvious that if a pingo has a subpingo water lens, the water pressure is high enough to uplift the superincumbent pingo with its ice core and overburden. In the case of pingo 14, the hydrostatic head of the subpingo water lens lies about 11 m above the top of the pingo and about 23 m above the lake flat.

There are numerous methods which can be used to estimate the rate of growth of permafrost in thawed sediments underlying a drained lake bottom, a widely used one being Stefan's solution:

$$z = \sqrt{\frac{-2Tkt}{Q_L}} = b\sqrt{t}, \quad (1)$$

where

z = depth of permafrost;
 k = thermal conductivity;

T = temperature, °C;

t = time;

Q_L = the volumetric latent heat of fusion of the soil;

b = a constant for Stefan's solution.

The rate of permafrost growth is

$$\frac{dz}{dt} = \frac{b}{2\sqrt{t}}. \quad (2)$$

From equations 1 and 2,

$$\frac{dz}{dt} = \frac{b^2}{2z} = \frac{z}{2t} = \frac{b}{2\sqrt{t}}. \quad (3)$$

If the porosity is η , the volume expansion of water to ice is 9%, all of the 9% excess volume is expelled as pore water, and the thickness of the layer of expelled pore water is H , then

$$\frac{dH}{dt} = .09\eta \frac{dz}{dt} = \frac{.09\eta b^2}{2z}. \quad (4)$$

The value of b for four recently drained lakes in the Tuktoyaktuk Peninsula area is about $3 \text{ m/yr}^{1/2}$ (Mackay 1979). If this value of b is used with a porosity (η) of 0.3 and a mean depth of permafrost (z) of 40 m (Figure 1), from equation 4 the expelled pore water would amount to about a 3 mm thick layer of water in a year. The cumulative addition of water to pingos 13, 14, and

Figure 4. Drill hole flow in 1977 from pingo 14. The water came from a depth of 22 m and jetted up 2.6 m high from a 7.5 cm diameter hole. The clear mineralized water had an orifice temperature of about -0.1°C .

Figure 5. Water pressure of pingo 14 as measured with a pressure transducer in the subpingo water lens (Figure 2). The drop in pressure in 1977 was associated with drilling and transducer installation.

17 is about $8,000 \text{ m}^3/\text{yr}$, the estimate being based upon the pingo areas and growth patterns. From the preceding, the area of permafrost pore water expulsion required to supply the $8,000 \text{ m}^3/\text{yr}$ of water at the rate of $3 \text{ mm}/\text{yr}$ is then about 2.7 km^2 , or about half the total area of the drained lake bottom. This seems to be of the right order of magnitude. The water which accumulates in a subpingo water lens, as sampled from spring and drill hole flow, has a much higher concentration of solutes than the original pore water because of the rejection of solutes during freezing (Mackay 1979). Consequently, the 0°C isotherm is typically many meters below the bottom of the ice-bonded permafrost. The "unfrozen" zone in Figure 1, as an example, is based upon the lack of ice-bonding, not upon a positive temperature.

GROWTH PATTERN

A pingo underlain by a subpingo water lens is in an unstable growth situation. At one extreme, the pingo will eventually rupture, if the yearly addition of water to the subpingo water lens exceeds that which is frozen; at the other extreme, the subpingo water lens will freeze through, if the yearly amount added is less than that which is frozen. Figure 7 illustrates three different growth types for pingos with subpingo water lenses. Type 1, constant rate of growth: Pingo 9, which had a 2.2 m thick water lens in 1978 (Mackay 1978), has a constant rise in elevation for the pingo top. If all of the 2.2 m deep water lens were to freeze solid in one winter, a thermal impossibility, without any addition or loss of water, the 9% volume expansion could only produce a summit growth of $20 \text{ cm}/\text{yr}$ in contrast to the actual growth of about $30 \text{ cm}/\text{yr}$. Consequently, there must be a net annual addition of water to the subpingo water lens. Type 2, decreasing rate of growth: The growth rate of pingo 8 is decreasing and presumably growth will soon cease. Pingo 8 was drilled in 1980, and although a "cavity" was penetrated beneath the summit, there was no artesian flow. The water lens appears to be freezing through without addition of more water. Type 3, erratic growth: Pingos 4 and 15 show episodic periods of growth from water accumulation, followed by subsidence from pingo rupture and water loss. The existence of a subpingo water lens is self-evident from the erratic growth pattern of Type 3, but the growth patterns of Types 1 and 2 could occur for pingos without subpingo water lenses.

CONCLUSION

Some pingos are underlain by a subpingo water lens whose freezing results in nearly pure "injection ice." The water pressure is derived from pore water expulsion which accompanies permafrost aggradation in saturated sandy

Figure 6. Graph showing the heights of bench marks on the tops of pingos 13 and 17 for the respective survey period.

Figure 7. Graph showing the changes in height of four pingos relative to a datum year. For pingos 4, 8, and 15, the datum year was 1969; for pingo 9, it was 1970.

sediments. The water pressure in a subpingo water lens is sufficient to uplift the superincumbent pingo. A pingo with a subpingo water lens is in an unstable situation and subject to rupture, water loss, and subsidence. Pingos with subpingo water lenses exhibit a variety of growth patterns.

FROST CELL DESIGN AND OPERATION

Daniel W. Mageau¹ and Mark B. Sherman²

¹R & M Consultants, Inc., Fairbanks, Alaska USA

²City Engineering Office, Fairbanks, Alaska USA

This paper presents the design and recommended operation of a frost heave cell for use in conducting laboratory frost heave experiments. Specific features of the design include split barrel construction for easy assembly, controlled top and bottom temperatures, well-insulated sides, simple thermistor installation for temperature measurement, and new heat exchanger details for top and bottom plates. Tests can be performed on undisturbed samples, remolded cohesive soil, or remolded cohesionless soil. Details of sample preparation are presented for each sample type. Test duration depends on soil type and amount of heave, and generally ranges from 1 to 3 days. Tests can be conducted at various overburden pressures. Test results are interpreted using the Konrad-Morgenstern segregation potential concept of frost heave.

INTRODUCTION

Many researchers over the past several decades have attempted to relate frost heave to soil index properties, the most common of which has been grain-size, (Penner 1968, Kaplar 1974, Rieke et al. 1983). Rieke et al. (1983) performed a series of laboratory frost heave tests in which the amount of silt and clay and the type of clay mineral were varied from test to test. They found that while relationships between frost heave and soil index properties do exist, the sensitivity of frost heave to even small changes in clay content (1-2%) resulted in significant changes in observed heave rate under the same testing conditions. It is concluded from these tests and from the lack of correlation between grain size and results from frost heave tests performed by others (e.g., Kaplar 1974, Leary et al. 1968) that soil index properties alone are insufficient to adequately assess the frost heave potential of a soil. Furthermore, it is our contention, and that of others (Konrad and Morgenstern 1982b), that laboratory frost heave tests are necessary to accurately determine the frost susceptibility of soil.

One drawback of laboratory frost heave testing in the past has been the lack of uniformity of test equipment, test procedures, and techniques to interpret results. In this paper, we present the design of a frost cell which, although similar in design to frost cells used by others, incorporates special features developed by the authors. Procedures for testing either fine-grained or coarse-grained soils are presented with special attention given to problems commonly encountered during frost heave testing. Finally, a method is presented to interpret frost heave test results based on a frost heave theory proposed by Konrad and Morgenstern (1980).

The purpose of this paper is not to present frost heave test results but rather to present a proven approach for performing consistent laboratory frost heave tests on a variety of soils along with details for obtaining the necessary parameters to analyze test results.

FROST HEAVE TEST EQUIPMENT

The cell described in this paper (Figure 1) uses a 150-mm high soil sample of either granular or fine-grained material. The test apparatus consists of 150-mm I.D. by 200-mm O.D. split nylon cylinder, instrumented along the sides with thermistors. The cylinder rests on a copper heat exchanger base plate. The soil sample (either remolded or undisturbed) is placed in the cylinder within a latex membrane, and a copper piston-like heat exchanger is situated on top of the soil. Lines in the top heat exchanger allow water from a reservoir (burette) to flow into the sample and eventually to the freezing front as it progresses through the sample. Freezing is initiated at the base of the sample, and as the sample heaves, the top piston moves upward. A vertical load is applied to this piston via a dead weight system to simulate field overburden conditions.

The cell is placed in a temperature controlled environment slightly above freezing. External coolant circulating baths supply a glycol-water mixture to the heat exchangers at adjustable preselected temperatures, allowing any desired gradient to be applied. Thermistors in the top and base plates permit the plate temperatures to be monitored during the test. Figure 2 is a schematic diagram of the frost cell experimental setup.

Design Considerations

The heat exchanger plates at the top and bottom of the sample must be capable of transferring a sufficient quantity of heat in or out of the sample in order to maintain the desired thermal gradient for the duration of the test. In turn, the cooling mechanism attached to the plates must be able to remove or supply this heat to maintain isothermal conditions in the plates within very close tolerances. Copper has been selected as the material for the heat exchanger plate, although aluminum has also been used successfully (Mageau and Morgenstern 1980, Rieke et al. 1983). The actual configuration of the top and base heat exchangers

is shown in Figures 3 through 6. Our design minimizes thermal gradients across the plate and between passages. Assuming a 50% water/50% ethylene glycol mixture at a minimum flow rate of 1.2 l/min, the total temperature drop in the fluid between the inlet and outlet should be on the order of 0.02°C, once a steady-state thermal gradient in the sample has been achieved.

The coolant baths should be capable of maintaining a temperature stability on the order of 0.02°C. Our experience has shown that overall temperature stability is improved if the coolant baths are located externally from the cell environment and coolant lines are well insulated. In order to minimize radial heat flow into the sample, the cells are insulated with 100 mm of polyurethane foam. The cell environment itself should be maintained as close to +1.0°C as possible. It has been found that a large cold room can be difficult to maintain at a constant temperature and that a small cold room is more desirable. Rieke et al. (1983) have successfully used a standard refrigerator modified to accept frost cell equipment.

The basic parameters measured during the frost heave test are temperature, water intake, and vertical heave. For temperature measurement, we recommend waterproof and pressure resistant thermistors, which are calibrated prior to each test using a carefully prepared ice bath. An accuracy of $\pm 0.01^\circ\text{C}$ is desirable in order to properly estimate thermal gradients and frost penetration. Water intake to the sample is measured with a burette accurate to ± 0.2 ml. Vertical heave is measured using an LVDT (or dial gage) accurate to ± 0.0025 mm. The accuracy of vertical heave measurement is especially critical for coarse-grained samples which may show little heave over the duration of the test. An automated data collection and storage system is recommended.

SAMPLE PREPARATION

Preparation of a soil sample for frost heave testing depends on the type of soil and on whether the sample is remolded or undisturbed. We recommend testing an undisturbed sample, as the soil structure and density would more closely resemble insitu conditions than would those associated with a remolded sample. However, for many engineering projects, it may not be feasible or, in the case of coarse-grained soils, it may not be possible to obtain undisturbed samples, and laboratory tests must be conducted on remolded samples.

Sample preparation for remolded cohesive soil differs from that for remolded cohesionless soil. The basic difference is that remolded cohesive soil is consolidated in a separate consolidometer, while remolded cohesionless soil is compacted in lifts inside the frost cell. Many natural soils are borderline between cohesive and cohesionless, and there is no absolute rule for determining to which category a soil should belong. If clay mineral is present, a soil with as little as 20% passing the #200 sieve may be considered cohesive. In general, external consolidation yields a more uniform and consistent sample and is used by the authors for any soil which has enough cohesion to remain intact after removal from the consolidometer.

This section for sample preparation is divided, therefore, into three categories based on the type of sample: undisturbed, remolded cohesive, and remolded cohesionless.

Undisturbed Soil

The required diameter of a sample to be tested in the frost cell is 150 mm (after extrusion from the sampler). A sample with a diameter smaller than 150 mm would allow water to migrate between the sample and the membrane and therefore is not used. A sample with diameter larger than 150 mm can be used after trimming, provided the trimming process does not result in voids along the sides of the sample. The sample length can range from 80 to 150 mm.

Remolded Cohesive Soil

Even in cohesive soil, material greater than 30 mm may be present and can lead to difficulties in sample preparation. Therefore, all material greater than 30 mm is removed from the sample and replaced with an equivalent weight of material larger than the #4 sieve and smaller than 30 mm. This procedure is expected to have little effect on frost heave test results since it is the silt and clay fraction (i.e., specific surface) which controls the heave process (Rieke et al. 1983).

A sufficient quantity of soil is then thoroughly mixed with enough distilled water to produce a slurry with a water content in excess of the liquid limit of the soil. The soil is allowed to soak for at least 12 hours. The slurry is then consolidated in a consolidometer (approximately 150 mm I.D.) at the pressure at which the frost heave test will be conducted. If this pressure is not sufficient to consolidate the sample so that it can be handled without deforming, the consolidation pressure is increased to a level which yields a sample that will not easily deform under zero confining pressure. This minimum consolidation pressure depends primarily upon the amount of fines (particularly the clay fraction) in the soil and typically ranges from 50 to 100 kPa.

If the sample is undisturbed or has been prepared using the consolidometer, the next step is to place the test specimen on the base plate and place the top cap (with a filter paper) on the sample. The latex membrane is installed around the sample and secured at the top and base plates using "O" rings. This membrane is allowed some slack to provide for stretching as the soil heaves vertically during the test. The membrane is coated with a silicone lubricant and the two barrel halves are placed around the sample and fastened. At this time the top cap is checked to ensure it is not binding.

Remolded Cohesionless Soil

As with cohesive soil, all material larger than 30 mm is removed and replaced with an equivalent weight of material larger than the #4 sieve and smaller than 30 mm. The soil is completely covered with distilled water and allowed to soak for at least 12 hours. The frost cell is partially assembled with the membrane attached to the base plate by means of an "O" ring and stretched over

the sides of the bottom portion of the nylon barrel. A low-viscosity silicone lubricant is applied to the inside walls of the barrel prior to attaching the membrane to reduce friction between the barrel and the membrane during the test.

The cohesionless soil is placed in the frost cell in 20-mm lifts and compacted to the desired density using a hand-held tamper 40-mm in diameter. Distilled water is added to each lift prior to tamping to ensure that the soil remains saturated. The top cap is placed on the sample (with a filter paper between the porous stone and the sample), and the membrane is attached to the top cap with two "O" rings. The top portion of the nylon split-barrel is placed around the top cap and secured.

FROST CELL PREPARATION

The remainder of the frost cell is assembled, including the insulation, load ram guide bar, and clamps, and the entire assembly is placed in the controlled-temperature cold room set at a temperature of approximately +1°C. The drainage lines are attached and de-aired, and the sample is consolidated to the desired pressure by placing appropriate weights on the hanger assembly. The sample is kept in the cold room overnight with the drainage lines open to allow equilization of both pore pressure and soil temperature. For most soils 12 hours should be adequate to dissipate excess pore pressures. For clay soils complete excess pore dissipation may take longer. A standard constant or falling head permeability test (without back pressure) can be performed on the sample at this time if desired. Otherwise, the sample is ready for testing.

TEST PROCEDURE

Coolant lines from the warm temperature bath ($T_w = +0.3^\circ\text{C}$) are attached to both top and bottom plates, and fluid is circulated for several hours in order to induce a uniform temperature in the sample.

In fine-grained soil, pore spaces are generally too small for initial nucleation of ice crystals to occur at the cold-side test temperature of -1°C . Therefore, initial nucleation must be induced by briefly supercooling the base of the sample. This procedure is usually not necessary for cohesionless soils. First, the coolant lines from the warm refrigeration bath are disconnected from the base plate (circulation through the top cap should be continued). Second, coolant lines from a separate refrigeration bath which has been set at -15° to -20°C are connected to the base plate. The change in height and base plate temperature readings are continually monitored after circulation is initiated. Nucleation, and subsequent change in height, should commence within 1 min. for most fine-grained soils. As soon as any change in height is observed, the coolant lines from the nucleation refrigeration bath are disconnected, and coolant lines from the bath set at -1°C are attached to the base plate. Fluid circulation is immediately initiated.

Readings for temperatures (top and bottom plates, sidewalls, and room), change in height and

water intake (or expulsion) are recorded at the following times: 0, 1 min, 5 min, 10 min, 20 min, 30 min, 1 hr, 2 hrs, 4 hrs, 8 hrs, 16 hrs (optional), and 24 hrs. Readings are recorded at least twice daily thereafter.

The test is continued for a minimum of 12 hours after the rate of frost penetration becomes approximately zero. The time for zero frost penetration to occur depends on the soil type and the amount of water intake. For cohesionless soils, which usually intake little water during the test, the total length of a frost heave test may range from 1 to 2 days. For silty material, the length of a test may range from 2 to 4 days. For soils with significant clay content, the length of a test may range from 3 to 5 days.

After completion of the test the sample is removed from the cell and examined. The location of the final ice lens (if visible) with respect to the bottom of the sample (cold-side) is measured. The sample is divided into frozen and unfrozen parts, and water content determinations are made on each. Frost heave (change in height), water intake, and frost penetration are then plotted as a function of time.

INTERPRETATION OF TEST RESULTS

Results from laboratory frost heave tests are interpreted using a mechanistic theory of frost heave developed by Konrad and Morgenstern (1980) which allows prediction of field frost heave behavior using parameters obtained from laboratory frost heave tests. The theory is derived from thermodynamic processes within the frozen fringe of soil between the frozen-unfrozen interface and the last ice lens. Simply stated, frost heave is controlled by the temperature gradient within the frozen fringe as expressed by:

$$v = SP(P_e) \text{ grad } T, \quad (1)$$

where v is the velocity of water intake (mm/s), $\text{grad } T$ is the temperature gradient across the frozen fringe ($^\circ\text{C}/\text{mm}$) and $SP(P_e)$ is the segregation potential ($\text{mm}^2/\text{s}^\circ\text{C}$) as a function of overburden pressure, P_e (kPa).

The amount of segregational heave (versus insitu heave) is thus given by:

$$hs = \sum 1.09 v \Delta t \quad (2)$$

where hs is the total segregational heave (mm) and Δt is the time interval (sec).

From equations (1) and (2) it can be seen that segregational heave is directly related to SP . However, SP is dependent on several variables. Because of the many unknowns associated with using laboratory test results for predicting field behavior, it is considered prudent to determine the highest segregation potential for a soil. Konrad and Morgenstern (1981) have observed that SP is at its maximum when the suction at the frozen-unfrozen interface (P_u) is zero. Moreover, they observed that P_u decreases as the warm-side temperature, T_w , decreases. By conducting the laboratory tests at T_w as close to 0°C as practical, the SP value obtained from test results can be maximized. SP is

also affected by the rate of cooling at the frost front. Konrad and Morgenstern (1982a) found that maximum SP value occurs when the rate of cooling is near zero (0.1°C/hr for Devon silt). This rate of cooling corresponds to the formation of the final (warmest) ice lens. Therefore, it is conservative to evaluate v and grad T from equation (1) at the time the final ice lens begins to develop, t_0 . Finally, SP is dependent on overburden pressure. As overburden pressure increases, the value of SP decreases. Therefore, a minimum of two frost heave tests is required to define a relationship between SP and pressure for a soil similar to that shown in Figure 7 for Devon silt.

To obtain values of v and grad T for use in equation (1), time t_0 must first be determined. If the final ice lens is visible, t_0 can be estimated by measuring the distance from the bottom of the final ice lens to the bottom of the sample at the end of the test and then scaling off this distance on the frost penetration versus time plot, as shown in Figure 8a. The velocity of water intake, v is then determined at time t_0 from the water intake versus time curve, as shown in Figure 8b. The value for grad T is determined from a plot of side-wall temperatures recorded at (or near) time t_0 , as shown in Figure 8c.

If no final ice lens is visible, such as with coarse-grained soils that exhibit little heave, time t_0 must be estimated by assuming that the rate of cooling at the frost front which corresponds to the maximum SP value occurs as the frost penetration rate approaches zero. Once this point on the frost penetration versus time curve has been established, values for v and grad T are determined in the same manner described above for samples when the final ice lens is visible.

It is acknowledged that there is a certain amount of error associated with determining SP values for a soil. It is the authors' opinion, however, that the test procedures and method of analysis described herein result in consistent and reproducible segregation potential values for a soil within an acceptable margin of error for most engineering projects.

The segregation potential concept is relatively new (1980), and its application to engineering projects has seen limited use. Nixon (1983), and Konrad and Morgenstern (1983) have reported good correlations between field behavior predicted from laboratory frost heave tests (similar to that described in this paper) and observed field behavior. It is hopeful that the use of a laboratory frost heave test such as that presented in this paper will eventually become standard practice for projects where prediction of frost heave is required.

CONCLUSIONS

The design of a frost cell and recommended procedures for testing undisturbed, remolded cohesive and remolded cohesionless soil samples have been presented. The cell is designed to minimize friction and radial heat flow and is relatively easy to assemble and disassemble. The test procedures involve applying constant warm and cold temperatures ($+0.3^{\circ}$ and -1.0°C) to the top and bottom

plates, respectively, and recording heave, temperature, and water intake until after the frost penetration rate becomes zero. The duration of the test can range from 1 to 5 days but typically ranges from 1 to 3 days. Test results are interpreted using the segregation potential concept of frost heave introduced by Konrad and Morgenstern (1980). This method appears to be the most reliable for assessing the frost susceptibility of a soil and should be used whenever prediction of field frost heave behavior is required.

Laboratory model studies were conducted to study the freezing process and the distribution of salt during advancement of a freezing front through a seawater saturated column of granular soil. The freezing front in a saline soil may be described as a zone of partially frozen soil. The strength of the frozen soil in the freezing zone is visually weaker than for soils above the freezing zone. The salt concentration and the unfrozen water content in the partially frozen zone decreases toward the colder temperature. It is shown that conventional analytical modeling of freezing front penetration will underpredict the rate of freezing when no account is made for the effects of salinity. The rate of advance to a given depth of freezing increased with increasing salinity.

The paper presents a discussion based on the results of 17 laboratory freezing column tests in which the effects of salinity on the freezing front advance and the redistribution of solutes was observed. Comparisons between observed behavior and computer simulations of three tests are given to demonstrate difficulties associated with analytical modeling freezing front penetration in a saline soil.

INTRODUCTION

The design of artificial islands for arctic waters requires a detailed thermal analysis to determine the extent of soil freezing that will occur during the design life of the structure. This analysis is important because the unfrozen/frozen interface at any time may represent the location of a potential failure plane through the island. For the long-term design of production islands, additional thermal analyses are required to determine the growth of a strengthening permafrost core within the island, thaw degradation around well conductors, thermal disturbance beneath production facilities, disturbance to subsea permafrost and thermal effects of pipelines and oil storage vessels.

There are many numerical computer models available to solve two-dimensional heat transport problems with the porewater phase change modeled at the frozen-unfrozen interface. Many of these models have been shown, through field and laboratory measurements, to accurately predict thermal regimes and the location of a freezing interface for soils with non-saline porewater. However, in the marine environment, where a significant concentration of sea salts are present in the porewater, the thermal regime during freezing is altered owing to the effects of freezing point depression, salt exclusion and solute transport.

In recognition of the need to predict the thermal regime in offshore artificial islands, computer simulations were performed of uniaxial freezing in saline and non-saline saturated gravels. The results from the computer simulations were compared to the results of laboratory freezing column tests performed on saline and non-saline saturated gravels. The computer comparisons demonstrate the difficulties associated with modeling uniaxial freezing of a saline saturated soil.

In addition, data is presented from the laboratory freezing column tests to demonstrate the redistribution of solutes during uniaxial freezing. The results are used to develop the relationship of solute concentration to the unfrozen water content profile. Finally, the effects of solute transport in a soil-water system as it relates to freezing of saline soils is discussed.

LABORATORY MODEL TESTS

A series of 17 large-scale tests were conducted in the laboratory to study the effects of salinity on uniaxial freezing of seawater saturated gravel. Detailed descriptions of the test apparatus and procedures are given by Mahar et al. (1982) along with typical results. Briefly, a 46 cm diameter soil column (see Figure 1) saturated with a seawater solution of a known salinity was frozen uniaxially from the top of the column downward. The initial porewater salinities ranged from 0 to 80 parts per thousand (ppt) and various freezing rates were applied. During freezing, the temperature profile at the center of the column was monitored at regular time intervals using a string of closely spaced thermistors. Porewater samples were extracted at various locations along the column during the test for salinity determinations. It was possible in certain tests, to extract porefluid in the partially frozen soil after the freeze front had passed.

The results from thirteen tests are summarized by Vinson et al. (1983) and demonstrate the general effect of salinity on the rate of freezing front penetration and the changes in unfrozen porewater salinity with time at discrete points in the soil column (for selected tests). It was

concluded, based on the laboratory tests, that the nature of the freezing interface was quite different for the distilled porewater and saline porewater cases. The freezing interface in the distilled porewater column was planar with clear ice filling the pore spaces. The location of the interface at any time was easily identified on the temperature profile by a distinct break at the zero degree (celsius) isotherm.

FIGURE 1 Schematic of freeze front penetration test system.

For the saline porewater cases, it was found that a distinct freezing interface did not exist. Instead, a zone of partially frozen soil with a high unfrozen water content beginning at the depressed freezing point isotherm (defined herein as the freeze front) was observed. The unfrozen water content was found to decrease with distance toward the colder temperatures from the freeze front. In addition, the location of the freeze front was not clearly identified by a break in the temperature profile.

Salinity measurements in the partially frozen zone, reported by Vinson et al. (1983) indicated very high values, reaching concentrations in excess of 100 ppt. The salinities were found to increase with decreasing temperature. The significance of these measurements, along with a presentation of additional tests, where more extensive salinity measurements were made, is presented later in this paper.

THERMAL ANALYSIS

In order to assess the potential of existing computer models to predict the thermal regime in soils with saline porewater, computer simulations of two of the freezing column tests were performed. The computer code selected for the simulation is based on a finite element model developed at the University of California at Irvine (Guymon et al. 1981). Computer code FROST 2B represents a two-dimensional model of

coupled heat and moisture transport in freezing/thawing soil with an isothermal soilwater phase change approximation. The numerical solution used to solve the governing flow equations is the nodal domain integration method with a linear trial shape function for triangular elements. Time domain solutions are obtained with the Crank-Nicolson method and fully implicit method for the heat transport and the moisture transport models, respectively. The computer code and model are similar to other thermal models presently used in design practice.

The two freezing column tests simulated with FROST 2B were identical with respect to test conditions with the exception that one was saturated with distilled water and the other with a seawater having a salinity of 28 ppt. In both cases, thermal properties for the soil were selected for input based on recommended values from the literature (Kersten 1949). No attempt was made to adjust the thermal properties to account for salinity except to use a depressed freezing point of -1.6°C for the saline porewater case.

The results of the two computer simulations are presented in Figures 2 and 3. The simulations for the distilled porewater case compare favorably with the laboratory measurements. Both the temperature profiles and the location of the freezing front were modeled accurately, indicating the adequacy of the computer method for non-saline soils.

FIGURE 2 Comparison of thermal model results to laboratory measurements- distilled porewater case.

In contrast, for the saline porewater case, (Figure 3) the simulations compared poorly with the laboratory measurements. The depth to the freeze front was significantly underpredicted based on the computer solution and the temperature profiles were inaccurate. The apparent effect of salinity on the thermal behavior of the soil-water system and, particularly, on the phase change

phenomena is strongly evident.

FIGURE 3 Comparison of thermal model results to laboratory measurements - saline porewater case (salinity = 28 ppt).

The primary source of error in the saline porewater case is found in the method of modeling the phase change. In the distilled porewater case, the phase change occurs at the freezing point isotherm (at the freeze front) where nearly all the porewater freezes, releasing its latent heat. This results in the sharp break in the temperature profile at the freeze front in both the computer simulation and laboratory test results.

In the saline porewater case, no clearly distinguishable freeze front exists. Freezing occurs over a range of temperatures and depths due to a changing solute concentration in the unfrozen porewater as a consequence of salt exclusion. During the phase change, latent heat is released gradually over the entire depth of the partially frozen region as temperatures are lowered. Since the computer model only allows latent heat release to occur instantaneously along a plane, significant error results.

Clearly, a better understanding of the effects of salinity on the freezing of soils is needed to develop accurate thermal modeling methods. The following sections of this paper addresses solute redistribution as it pertains to the soil freezing problem, based on a laboratory model of uniaxial freezing in saline gravel.

FREEZING OF SALINE SATURATED SOIL COLUMNS

In a saline saturated soil column subjected to freezing temperatures, ice crystal growth begins only as the freezing point depression is reached. The crystals grow in a pure (or nearly pure) water

ice form while excluding solute into the remaining unfrozen porewater (Sheeran and Yong 1975). As this occurs, the concentration of the unfrozen porewater increases, further depressing the freezing point. If the heat transfer is slow enough, the solute concentration in the unfrozen porewater will be maintained in equilibrium with the pore ice. Thus, the soil temperature at any point will be equal to the equilibrium solidification temperature for the enriched solute concentration of the unfrozen porewater. Further lowering of the temperature results in more ice growth and increasing the porewater salinity to maintain the equilibrium balance (Hallet 1978).

The effect of salt transport due to diffusion or natural convection downward through the column will cause this freezing process to occur more readily. A solute concentration gradient occurs above the freeze front in which higher solute concentrations and porewater densities occur at the colder temperatures (near the top of the soil column). This condition results in solute transport downward toward the lower concentrations due to convection associated with the density gradient and diffusion associated with the concentration gradient. As solute transport occurs, the salinity at a given point has a tendency to decrease. However, the decrease in salinity results in a reduction in the freezing point depression, thus stimulating further ice growth. The further ice growth, in turn, increases the salinity maintaining the concentration gradient in the unfrozen porewater. Given sufficient time and a sustained thermal gradient, it is believed that continued solute transport will occur until nearly all the solutes are leached out of the soil leaving the bulk porewater salinity near zero parts per thousand.

SOLUTE DISTRIBUTION

Three freezing column tests were conducted in which it was possible to extract porewater samples at discrete locations along the gravel column at any given time. The three test columns were prepared with initial porewater salinities of 16, 30, and 50 ppt. Typical salinity profiles at various times during the 50 ppt test are given in Figure 4. The salinity profiles verify the presence of high solute concentrations in the unfrozen porewater near the top of the column where the soil was at its coldest temperatures. The dashed line on Figure 4 represents the final salinity of the bulk porewater after thawing. The reduction in the bulk salinity from the initial value of 50 ppt may be attributed to solute transport due to the high concentration gradients in the partially frozen zone.

For each of the unfrozen porewater salinity measurements made during the three tests, the corresponding soil temperature was recorded. The salinity measurements for the 30 and 50 ppt tests are plotted against temperature in Figure 5. The results indicate that the porewater salinity for the 30 ppt case remained in equilibrium with the soil temperature as compared to the equilibrium

phase diagram for a pure NaCl solution (Jumikis 1966). However, for the 50 ppt porewater case, the measured salinities were in excess of the equilibrium concentration shown on Figure 5. The result suggest the freezing rate was rapid enough to prevent the solutes from diffusing away from the freezing zone, despite the high concentration gradients. If the heat transfer rate was reduced, it would be expected that the excess solute concentrations would decrease to concentrations given by the equilibrium phase diagram.

FIGURE 4 Salinity profiles at various times during a typical freezing column test.

UNFROZEN WATER CONTENT

In modeling heat transport with porewater freezing, the release of latent heat during the phase change dominates the solution. In the uniaxial freezing column case, latent heat becomes the primary source of heat conducted upward through the column. The amount of latent heat generated at any given point in the column is a direct function of the volume of water freezing out.

For a closed system in which a saline solution is permitted to freeze and, for simplicity, assuming that solute transport is negligible, the amount of water freezing out is a function of temperature and initial salinity and may be calculated from the results shown on Figure 5 (Sheeran and Yong 1975). The calculation is based on the principal that, for a given volume of

solution having a known initial salinity, the amount of water remaining unfrozen will be inversely proportional to its enriched solute concentration at the desired temperature. For example, when the solute concentration of the unfrozen porewater doubles, the amount of unfrozen porewater remaining is one-half of the original volume.

FIGURE 5 Measured salinity versus temperature relationship in unfrozen porewater for two freezing column tests.

Based on Figure 5, unfrozen water content versus temperature relationships for the three freezing column tests were derived as presented in Figure 6. Similar relationships were derived by Yong et al. (1973) based on phase equilibria for bulk saline solutions. From these relationships, the unfrozen water content profile for a soil column may be estimated at any time if the temperature profile and initial porewater salinity is known as shown in Figure 7 for the 30 ppt porewater case. Although there is some error associated with neglecting solute transport, the results presented demonstrate that throughout the soil column, above the freezing front, a significant unfrozen water content remains.

It has been shown that a significant percentage of the free water does not freeze in the freezing column tests. Thus, the lower measured temperature shown on Figure 3, compared to the computer simulation, may be explained by the fact that a smaller

amount of latent heat is released during the partial freezing of the porewater owing to solute exclusion. Further, the non-linear nature of the temperature profile above the freeze front is the result of the gradual release of latent heat as the temperatures are lowered at any given point. Therefore, in order to mathematically model the freezing of saline saturated soils, one must couple the heat flow equations with a constitutive relationship for the unfrozen water content as a function of temperature and initial salinity applied to all partially frozen zones.

FIGURE 6 Temperature versus unfrozen water content for three freezing column tests (derived from Figure 5).

CONCLUSIONS

The results from physical and numerical model studies of uniaxial freezing of a saline saturated gravel soil column have been presented. Emphasis was placed on identifying parameters affecting heat transport, soil porewater phase change and solute distribution. Based on the results of the model studies, the following may be concluded:

1. Existing numerical methods do not adequately model freezing of saline soils due to the effects of solute exclusion during the phase change.
2. The solute concentration in the unfrozen porewater of a freezing column of saline sat-

urated gravel increases toward the colder temperatures.

3. The unfrozen water content in the partially frozen soil above the freeze front decreases with decreasing temperature. Unfrozen water contents as high as 20 percent were observed at the top of the soil column in one test in which the soil temperature was measured at -8°C .
4. Salt transport occurs in a freezing soil column if a thermal gradient is maintained for an extended period of time.
5. To develop a computer model for the freezing of saline saturated soils, it is necessary to develop constitutive relationships between unfrozen water content, diffusivity and hydraulic conductivity as a function of temperature and initial salinity.

FIGURE 7 Temperature, salinity and unfrozen water content profiles for a freezing column test with initial salinity of 30 ppt.

A mechanistic approach to pavement design in continuous permafrost areas is examined. Typical material, environmental and loading conditions are evaluated for Barrow, Alaska. A presentation of typical pavement response parameters is made and used to evaluate several possible pavement structural sections.

INTRODUCTION

A mechanistic approach to pavement design involves (1) predicting stress, strains, and deflections in a pavement structure owing to a specified geometry and magnitude of wheel loading conditions and (2) adjusting the properties and thicknesses of the elements in the pavement structure to insure the predicted stresses, strains, and deflections are within allowable limits. The mechanistic approach provides flexibility in modeling a pavement structure owing to the fact that measured material properties associated with a range of thermal and drainage conditions in the field may be incorporated in the analysis.

To illustrate the mechanistic design approach, an analysis was performed for several conceptual pavement structures subjected to representative arctic environmental and loading conditions (specifically the Barrow, Alaska, area). Limiting pavement response parameters included (1) pavement surface deflection (associated with fatigue cracking and/or rutting), (2) horizontal tensile strain at the bottom of an asphalt concrete surface layer (associated with fatigue cracking), (3) vertical compressive stress at the top of rigid board insulation (associated with the design compressive strength of the material), and (4) vertical compressive strain at the top of the subgrade (associated with rutting). Pavement structural sections with various thicknesses of asphalt concrete, base, insulation, and subgrade were considered under three environmental conditions: (1) early winter, (2) late winter, and (3) spring thaw. The design loading condition selected was a fully loaded "DJB" dump truck and 100,000 repetitions in a 20-year design period. A performance evaluation rating system was established for limiting the pavement response parameters considered.

In general, pavements located throughout the state of Alaska or any cold region may be classified into three general surface types. These are (1) gravel surfaced, (2) flexible - bituminous surfaced, and (3) rigid - portland cement concrete (PCC) surfaced. The Alaska Department of Transportation and Public Facilities (Alaska DOTPF) maintains a total centerline network of about 8000 km (5000 mi) of which about 3520 km (2200 mi) are paved. Essentially all of the paved roads are

bituminous surfaced (asphalt concrete, bituminous surface treatment, seal coat, etc.).

Several types of pavement structures may be possible for continuous permafrost areas. Two basic types of pavement structures have been constructed in the Alaskan arctic over continuous permafrost areas. Most common are gravel surfaced roads. Other pavements include stabilized layers such as asphalt concrete or cement treated surfacing and are located primarily at Alaska DOTPF owned and operated airports.

For example, at Barrow, Alaska, asphalt concrete surfaced pavements constitute the runway, associated taxiways, and primary parking apron at the Wiley Post - Will Rogers Memorial Airport. The asphalt concrete is 229 mm (9 in) thick, overlying various unbound embankment materials (minimum total embankment thickness of about 1.4 m (4.5 ft)). Cement treated pavement is located in the general aviation apron (east end of aircraft parking area).

DESIGN CONSIDERATION AND METHODS

This section overviews some of the design considerations and methods associated with the development of the pavement concepts specifically for Barrow, Alaska. Included are the following subsections:

1. Site conditions;
2. Current pavement design practice;
3. Layered elastic theory;
4. Development of typical pavement cross sections.

Site Conditions

A brief review of the existing site conditions at a specific arctic location (Barrow) as they relate to a pavement structure follows. This includes a review of existing soil borings, aggregate sources, and other relevant materials.

The primary indications of various soil investigations include the following:

1. Permafrost underlies the Barrow area to a depth of about 400 m (1300 ft).
2. The Barrow area topography is flat to gently rolling and generally less than 8 m (25 ft) above mean sea level.

3. Seasonal variation of ground temperatures occurs in the upper 12 m (40 ft) of soil (the temperature changes decrease rapidly with increasing depth).
4. Ground ice can compose up to 100% of the volume (primarily silts, ice lenses, and wedges) in the upper 3.0 to 4.6 m (10 to 15 ft) of the soil profile.
5. Polygonal ground is common in the area (although with a variable density), thus indicating extensive ice.
6. Existing roads and streets are gravel surfaced. Gravel fill is generally 0.9 to 1.5 m (3 to 5 ft) thick, originally having been placed directly over the tundra. The thickness of the active layer beneath the existing roads in Barrow averages about 1.0 m (3 ft) (measured during August 1978). The maximum active layer depth measured in Barrow was 3.5 m (11.5 ft) (at a culvert). The depth of thaw in relatively undisturbed tundra extended 200 to 305 m (8 to 12 in) below the ground surface.
7. The fill materials composing the existing roads and streets can be broadly classified as gravels or sands. The dominant materials in these fills, according to the Unified Classification System, are sands (SM, SP-SM, SP and SW) followed by gravels (GM, GP and GP-GM).
8. The upper 200 to 305 mm (8 to 12 in) of some of the existing gravel surfaced roads has enough "binder" to reduce rutting in the surface layer.

Of major importance, as well, is the type and amount of available aggregates from borrow sources. Aggregate sources are limited and are of a gradation which precludes the production of significant amounts of crushed material.

Current Pavement Design Practice

Since World War II, the Corps of Engineers has developed pavement design procedures (street and airfield) that can be used to develop structural design requirements. The available design procedures for pavements subject to freezing and thawing in the underlying soils are based on either of two basic concepts:

1. Control of surface deformation resulting from frost action (or thaw).
2. Provision of adequate bearing capacity during the most critical climatic period.

Based on the above considerations, three separate design approaches can be used:

1. Complete protection method: Sufficient thicknesses of pavement and non-frost susceptible base course are provided to prevent frost penetration into the subgrade.
2. Limited subgrade frost penetration method: Sufficient thicknesses of pavement and non-frost susceptible base course are provided to limit subgrade frost

penetration to amounts that restrict surface deformation to within acceptable limits.

3. Reduced subgrade strength method: The amount of frost heave is neglected and the design is based primarily on the anticipated reduced subgrade strength during the thaw.

Hennion and Lobacz (1973) recommend that seasonal thawing and freezing should be restricted to the pavement (surfacing and non-frost susceptible base course) in continuous permafrost regions. The concept is comparable to the complete protection method wherein the critical factor is the depth of thaw rather than the depth of frost penetration.

The Alaska DOTPF (1982) has recently issued pavement design guidelines based on research begun in 1976. The primary objective was to study the various relationships that controlled the performance of flexible pavements. Approximately 120 pavement sections were selected on the existing state maintained road network for the research program. The results of that study (McHattie et al., 1980) have significantly influenced the new design procedure.

The Alaska DOTPF design guidelines focus on the fact that increased fines (No. 200 minus material in the unbound layers of a pavement structure) lead to increased thickness of asphalt concrete surfacing. In those portions of Alaska where asphalt concrete is readily available, increased fines in the underlying layers may be acceptable. However, in remote arctic regions the production of asphalt concrete is expensive and should be minimized. Thus, it is prudent to specify non-frost susceptible (NFS) materials in the underlying layers to the extent possible to minimize the following:

1. The requirements for asphalt concrete (if not eliminate its need, altogether);
2. The potential for frost heave;
3. The potential for other types of pavement distress such as alligator cracking and rutting.

Layered Elastic Design Approach

The use of layered elastic theory in evaluating on-grade pavement design concepts has several attractive features. First, estimated (or measured) material properties in the form of elastic moduli and Poisson's ratio for each layer are used. This provides flexibility in "modeling" the pavement structure thus reducing the need (or use) of design procedures not strictly suitable for cold regions. Second, the calculation process can be used to estimate the pavement response for any combination of material properties, layers and loading conditions.

The determination of the elastic material parameters for a mechanistic design approach (resilient or elastic modulus and Poisson's ratio) is difficult due to the complex and variable nature of the materials in each pavement layer and associated subgrade soils. To evaluate the initial pavement designs considered in this paper, all elastic parameters were estimated based on reasonable assumptions or published data. In practice, final pavement designs must be based on laboratory

derived elastic material parameters determined on the actual materials to be used in the pavement structural section and/or field correlations.

Modeling a pavement structure as a layered elastic system is a complex process if calculations of pavement response are made manually. In fact, layered systems with greater than three layers are difficult to solve without a computer program. Thus, various computer programs have been developed that can be used to accomplish the necessary calculations to generate the required stresses, strains, and deflections due to a given loading condition. A computer program was selected for use in this study that can treat multiple pavement layers and several individual wheel loads simultaneously.

The pavement responses for the cases studied can be compared with appropriate failure criteria to determine the potential performance of an in-service flexible pavement structure. Critical pavement response parameters include:

1. Pavement surface deflection;
2. Horizontal tensile strain at the bottom of the asphalt concrete layer;
3. Vertical compressive stress at the top of the rigid board insulation;
4. Vertical compressive strain at the top of subgrade (or permafrost).

The pavement surface deflection (if excessive) can be associated with fatigue cracking and/or rutting. The horizontal tensile strain at the bottom of the asphalt concrete layer can be used to estimate fatigue cracking. The vertical compressive strain at the top of the insulation is used to determine if the design compressive strength will be exceeded. Finally, the vertical compressive strains at the top of the subgrade can be used to estimate the potential for rutting. In the mechanistic approach to pavement design it is necessary to control or limit pavement responses to develop suitable pavement designs. Somewhat unique to cold regions, the importance of these pavement responses will vary greatly throughout the year. For example, the complete structural section will be in a totally frozen condition during the winter months. With all pavement layers frozen, pavement responses generally will be quite low resulting in little or no pavement distress. During the spring thaw, the pavement structure will experience its weakest condition resulting in the greatest amount (if not the majority) of pavement damage for the year.

Extensive work accomplished in various laboratories worldwide has resulted in tensile stress or strain relationships as a function of the number of loads to failure for asphalt concrete fatigue characterization. It is difficult to obtain a consensus among engineers as to how well laboratory derived relationships duplicate actual in-service fatigue for asphalt concrete pavements. In an attempt to avoid possible pitfalls associated with laboratory derived relationships, a fatigue relationship was chosen for this study that was developed from AASHTO Road Test data. This criterion was developed by Finn et al. (1977) and is as follows:

$$\log N_f = 15.947 - 3.291 \log \left(\frac{\epsilon}{10^{-6}} \right) - 0.854 \log \left(\frac{E}{10^3} \right)$$

where N = Number of loads of constant stress to failure;

ϵ = Tensile strain at the bottom of asphalt concrete layer;

E = Modulus (psi).

To estimate the potential for rutting, the criterion developed by Dorman and Metcalf (1964) was adopted. As for fatigue, this criterion was based on data derived from the AASHTO Road Test. The vertical compressive strain at the top of the subgrade is used to determine the number of loads to failure as follows:

Load Repetitions (Design Loads of DJB Truck)	Vertical Compressive Strain
100,000	1050 x 10 ⁻⁶
1,000,000	650 x 10 ⁻⁶
10,000,000	420 x 10 ⁻⁶
100,000,000	260 x 10 ⁻⁶

The allowable surface deflections for a pavement are based on criteria developed by Bushey et al. (1974) in California. The criteria are a function of the type of surface course (asphalt concrete or bituminous surface treatment), thickness and the anticipated number of traffic loadings. To convert the DJB design wheel load to a 22.2 kN (5,000 lb) wheel load (as used by the California DOT), a multiplier of 105 was used; i.e., a 71.2 kN (16,000 lb) wheel load for the DJB truck is 105 times more damaging than a 22.2 kN (5,000 lb) wheel load. The surface deflection criteria used are as follows:

1. Asphalt concrete (63.5 mm (2.5 in) thick):
 - (a) acceptable: <0.58 mm (0.023 in);
 - (b) marginal: ≈0.58 mm (0.023 in);
 - (c) unacceptable: >>0.58 mm (0.023 in).
2. Asphalt concrete (127 mm (5.0 in) thick):
 - (a) acceptable: <0.43 mm (0.017 in);
 - (b) marginal: ≈0.43 mm (0.017 in);
 - (c) unacceptable: >>0.43 mm (0.017 in).
3. Bituminous surface treatment:
 - (a) acceptable: <1.01 mm (0.040 in);
 - (b) marginal: >1.01 and <1.27 mm (>0.040 and <0.050 in);
 - (c) unacceptable: >1.27 mm (0.050 in).

The surface deflection criteria should be used only in a general way since the surface deflection is in part dependent on the assumed elastic modulus of the asphalt concrete layer.

The number of allowable load repetitions to failure (fatigue) were used to set the following criterion for asphalt concrete surfaced pavements:

1. Acceptable: >>100,000;
2. Marginal: ≈100,000;
3. Unacceptable: <<100,000.

In a similar manner, the allowable vertical compressive stress for the rigid insulation board was conservatively set at 80.7 kPa (11.7 psi). The following criterion resulted:

1. Acceptable: <80.7 kPa (11.7 psi);
2. Marginal: ≈80.7 kPa (11.7 psi);
3. Unacceptable >80.7 kPa (11.7 psi).

The final criterion selected was for rutting that is a function of the vertical compressive strain at the top of the subgrade (or permafrost):

1. Acceptable: $<500 \times 10^{-6}$;
2. Marginal: $\approx 500-800 \times 10^{-6}$;
3. Unacceptable: $>800 \times 10^{-6}$.

The failure criteria for fatigue, rutting, and surface deflection identified above were used to examine several possible pavement structural sections. It must be recognized that the failure criteria presented were originally developed for non-permafrost areas. Thus, the combination of the estimated elastic material properties in conjunction with the available failure criteria may result in less than desirable estimates of pavement life, although such estimates should be suitable for the development of pavement concepts.

Pavement Cross Sections

The design loading condition selected for analysis was a "DJB" dump truck that is commonly used in the Barrow area. This truck has a total of six wheels as shown in Figure 1. Fully loaded, each front wheel carries 72.6 kN (16,320 lbs) and each rear wheel 70.5 kN (15,840 lbs) (all at 345 kPa (50 psi) tire pressure). The design number of loaded DJB repetitions applied to a road was assumed at 20 per day. This results in approximately 100,000 repetitions in a 20-year design period. This estimate represents a "worst case" condition. There are few streets in the Barrow area that will experience this level of traffic; however, the estimate provides some latitude in accounting for other heavy traffic loadings (truck, heavy construction equipment, etc.).

Table 1 contains a brief description of the initial structural sections evaluated. The latter sections (cases 7 through 12) are analogous to gravel or a bituminous surface treatment surfaced road section. Figure 2 contains a sketch of the cross sections described above.

The elastic moduli used in the analysis were estimated. For the permafrost (subgrade), three moduli were used (6895, 689.5, and 6.9 MPa) (1,000,000, 100,000 and 1,000 psi). Permafrost with a modulus of 6895 MPa (1,000,000 psi) represents a condition well below freezing. A modulus of 689.5 MPa (100,000 psi) approximates "strong" permafrost but warming. Finally, a modulus of 6.9 MPa (1,000 psi) represents permafrost during thawing conditions. Actually, the effective modulus of thawed ice-rich ground approaches zero, although the modulus used represents a less than desirable condition.

The elastic moduli for the non-frost susceptible materials were estimated to be 140 MPa (20,000 psi) (assuming some lateral confinement). This may be somewhat unconservative for these materials in the unfrozen state but is conservative for the frozen condition. The pit-run material, if properly thawed and compacted, has the potential for a somewhat higher modulus (240 MPa (35,000 psi)) due to slightly increased fines (binder); however, lower moduli values also were used (140 and 70 MPa (20,000 and 10,000 psi)). Additionally, the insulation (Dow HI-35) was assumed to have the same modulus as the surrounding non-frost susceptible material.

Asphalt concrete is a viscoelastic material and its strength and deformation properties vary with temperature. The higher the temperature, the

lower the asphalt concrete elastic modulus. The necessity of using a "soft" asphalt at Barrow or any arctic site is apparent. Additionally, it is highly desirable to use crushed coarse aggregate in the mixture. Assuming the use of a "soft" asphalt, crushed coarse aggregate and a design surface temperature of 21°C (summer condition), a modulus of 1725 MPa (250,000 psi) was selected for the analysis. Only a complete mix design could allow the proper determination of the value.

The results of the pavement response to the design loads and structural section cases are summarized in Table 2. Also contained in this table is a summary of the failure criteria applied to the selected pavement response measures. Ratings for each case and criterion were made on the basis of the following:

1. A: criterion is within acceptable limits;
2. B: criterion is within marginal limits;
3. C: criterion is within unacceptable limits.

Additionally, the overall rating for each case is based on the lowest rating for any one of the four (or three) criteria.

On the basis of structural considerations alone, case nos. 1, 9, 10a, 11 and 12a are fully acceptable (refer to Table 2). Case 1 is surfaced with 63.5 mm (2.5 in) of asphalt concrete and cases 9, 10a, 11 and 12a are the same general cross sections except without the asphalt concrete (however, the layer moduli vary). Therefore, it may be an attractive alternative to construct a bituminous surface treatment over structural sections such as cases 9, 10a, 11, and 12a. The possible advantage of using asphalt concrete is a higher level of service but with the risk of increased maintenance and construction costs.

EVALUATION OF SELECTED DESIGN CONCEPTS

Initial construction costs are only one (but important) cost to consider. Additionally, the costs associated with the maintenance of a pavement structure need to be evaluated. Historically, on state maintained highway networks, asphalt concrete pavements may need to be overlaid with additional asphalt concrete every 10 years (although this period tends to vary significantly and is a function of the initial design and other site specific conditions). Generally, such overlays are about 40 to 75 mm (1.5 to 3.0 in) thick. For bituminous surfaced pavements, thermal cracks should be expected at a transverse spacing of about 12 m (40 ft) or less. These cracks should be sealed early each summer (minor maintenance). Tradeoffs between asphalt concrete and bituminous surface treatment flexible pavements are:

1. The asphalt concrete surface provides extra load capacity for the pavement structure; the bituminous surface treatment does not.
2. The asphalt concrete surface should provide a longer, reduced maintenance life; however, if thermal stability is not achieved, maintenance will be extensive and expensive.
3. The bituminous surface treatment is less expensive initially, provides for reduced

METHODS FOR DETERMINING THE LONG-TERM STRENGTH OF FROZEN SOILS

R. V. Maksimjak, S. S. Vyalov and A. A. Chapaev

Research Institute of Foundations and Underground Structures,
Moscow, USSR

Various methods are available for determining the strength characteristics of soils; and as numerous investigations have demonstrated, the values of the parameters being determined depend on the conditions and type of testing. The article discusses the problems of the impact of the test conditions and type of test on the value of the long-term strength characteristics of frozen soils. The tests were carried out to determine long-term strength and to compare the experimental data from uniaxial compression tests with constant loading, with those derived with a constant rate of deformation and a constant rate of loading and under conditions where the operating stress was relaxed. These investigations revealed the mechanisms whereby the soil strength decreased under various types of tests and demonstrated the possibility of determining long-term values for the strength of frozen soils from the various tests utilized.

Values of ultimate long-term strength (time-dependent failure) of frozen soils are the principal design characteristics in calculations of bearing capacities of foundations of structures.

At the present time the following methods for determining the strength characteristics of frozen soils are used as a standard practice in laboratory studies: (a) creep tests at a constant load ($\sigma = \text{const}$); (b) tests at constant rate of deformation ($V = \frac{d\epsilon}{dt} = \text{const}$) or at constant rate of loading ($V = \frac{d\sigma}{dt} = \text{const}$); or (c) the dynamometric test method [$\sigma = f(\epsilon)$, $\sigma = f(t)$]. Due to the large variety of methods used, the test results sometimes differ, causing different interpretation of the results. At the same time, the long-term strength is a physical characteristic of soil, therefore this should be an invariant independent of the test method.

To compare the test results and to determine the values of the long-term strength, the specimens of a given frozen soil, were tested using each of the above methods. Particular attention was paid to the dynamometric method, which in our opinion seems to be very promising.

The soil selected for investigation was frozen Chegan (neogenic) clay featuring a disturbed structure and a massive cryotexture. All the tests were performed under axial compression at a temperature $\theta = -5^\circ\text{C}$.

Creep tests under permanent loads are the most common types. According to this method, a conventional instantaneous value of the soil strength was determined first by applying a quick loading (20-30 s duration). Upon finding the instantaneous strength ($\sigma_{\text{inst}} = 3.75 \text{ MPa}$), identical specimens were tested under different constant stresses at a percentage of the conventional instantaneous strength (Vyalov et al. n.d.). The results of the tests in the form of creep curves are illustrated in Figure 1. The criterion for creep strength for a given time to failure of the sample was taken as the transition point on the creep curve where the

tertiary stage of creep (progressive flow) begins. Then, in compliance with the commonly accepted method, a long-term strength curve was plotted. The analytical expression takes the following form:

$$\sigma = a \cdot t^{-\lambda} \quad (1)$$

where a and t = the parameters of the strength of the frozen soil.

The correctness of the selected relationship is confirmed by the resulting straight-line plots of the long-term strength curve in logarithmic coordinates.

The ultimate long-term strength was taken as the soil strength corresponding to a 50-year service life (t_{calc}) of the structures. In this case equation 1 gives the value $\sigma_{\infty} = 0.52 \text{ MPa}$.

In the step-loading regime, the load was applied by steps equal to a certain percentage of the conventional instantaneous strength. The load at each step was held until the moment of conventional damping of deformations. The tests were carried out until, at some successive step of loading, the deformation tended to continue until failure occurred. The last step of loading, when a damping of deformations was observed, was taken as the ultimate long-term strength of the soil ($\sigma_{\infty} = 0.75 \text{ MPa}$).

The subsequent series of tests were performed at a constant rate of loading. The loading rates ranged from $\dot{\sigma} = 0.375 \text{ MPa}$ to 9.0 MPa . The test results (Figure 2) showed that the strength of the soil decreases with decreasing loading rate. For example, at $\dot{\sigma} = 7.5 \text{ MPa per hour}$ the value of $\sigma_{\text{fail}} = 2.4 \text{ MPa}$, while at $\dot{\sigma} = 0.75 \text{ MPa per hour}$ the parameter $\sigma_{\text{fail}} = 1.9 \text{ MPa}$.

The parameters of the long-term strength equation 1 were determined for constant rate of applied stress ($\dot{\sigma} = \text{const}$) according to the criterion of linear summation of defects. This criterion enabled the researchers to determine the analytical relationship between the time to failure and the

loading rate. On the basis of the obtained parameters the strength for a period of 50 years was calculated ($\sigma_{\infty} = 0.7$ MPa).

When testing the soils at a constant rate of deformation, the peak (σ_p) and residual (σ_r) strengths must be determined. The peak strength approaches the conventional instantaneous strength when the rate of deformation is high, while under it, it tends to approach σ_{∞} when the rate of deformation is low.

As the result of the tests, a family of stress-time curves (Figure 3) was obtained, which make it possible to characterize the change of the soil resistance to failure at a constant rate of deformation. The analysis of these curves indicates that the peak strength tends to decrease as the deformation rate decreases. For instance, the decrease of the deformation rate from $\dot{\epsilon} = 15 \text{ hr}^{-1}$ to 0.03 hr^{-1} reduces the value of the peak strength by 2.3 times ($\sigma_{\text{fail}_1} = 2.65$ MPa, $\sigma_{\text{fail}_2} = 1.17$ MPa).

The parameters of the long-term strength equation 1 were determined with due regard for the loading procedure ($\dot{\epsilon} = \text{const}$) according to the criterion of linear summation of defects together with the deformation equation expressed according to the theory of stress hardening. On the basis of the obtained parameters the 50-year strength of the soil was calculated to be $\sigma_{\infty} = 0.75$ MPa.

The dynamometric method of testing frozen soils for long-term strength consists of subjecting the soil specimens to a variable load that is gradually reduced in the deformation process. The method is described below.

The soil specimen is loaded through a dynamometer. Upon reaching the predetermined load, the dynamometer is retained in a fixed position. The stress imparted to the soil specimen through the dynamometer causes the development of creep deformations which in turn reduces the load applied by the dynamometer, thereby reducing the stress. In the test specimen* the process of decreasing the stress in the dynamometer lasts until the deformation of the specimen is stabilized and the load applied to the soil specimen and the internal forces of resistance of the soil reach equilibrium (Vyalov and Maksimyak 1970).

The tests showed that, in the range of the initial stresses ($\sigma_{\text{init}} = 0.1$ to $0.5 \sigma_{\text{inst}}$), there is a dependence between the final stress (σ_{final}) and the initial stress (σ_{init}). At initial stress $\sigma_{\text{init}} \geq 0.6 \sigma_{\text{inst}}$, the stress decreases practically to σ_{final} . The latter is taken as the value of the ultimate long-term strength of soil. In the experiments under consideration, it proved to be equal to $\sigma_{\infty} = 0.54$ MPa for the frozen soil tested.

In the present study, the dynamometric test method was improved by using a step-loading regime in combination with a dynamometer (Vyalov et al. 1980). In this method, the load was applied to the specimen in steps, as in the stepped tests under constant load. Each subsequent step of the load was applied only after the deformation of the preceding step had stabilized. Experiments with the specimens of the Chegan clay using step loading show that when the total stress imparted to the

specimen does not exceed $0.7 \sigma_{\text{inst}}$, the stress drops to the final value, which depends upon the initial load at each step. When the total load reaches or exceeds $0.7 \sigma_{\text{inst}}$ the stress drops to a final constant value, which appears to be independent of any further increase of the load. The results of such experiments are presented in Figure 4. The initial load in these experiments was $\sigma_{\text{init}} = 0.1 \sigma_{\text{inst}}$, while the value of each step was $\Delta\sigma = 0.1 \sigma_{\text{inst}}$. It can be seen from the illustration that the load at the first step has dropped to $\sigma_{\text{final}} = 0.4$ MPa, at the second step to $\sigma_{\text{final}} = 0.58$ MPa, at the third step to $\sigma_{\text{final}} = 0.64$ MPa, at the fourth step to $\sigma_{\text{final}} = 0.68$ MPa, at the fifth step to $\sigma_{\text{final}} = 0.7$ MPa, and, beginning with the sixth step, the final stress remains unchanged ($\sigma_{\text{final}} = 0.7$ MPa) in spite of the fact that the total load is still rising.

To develop an optimum test technique, a special study was undertaken on the effect of each step's load value on the final stress value (Vyalov et al. 1980). The tests were conducted at the following loading steps: 0.1, 0.16, 0.20, and 0.33 of σ_{inst} . The tests indicated (Figure 4) that with the step value of $\Delta\sigma = 0.16 \sigma_{\text{inst}}$, the stress at the first four steps drops to 0.2 MPa, 0.4 MPa, 0.5 MPa, and 0.7 MPa at the first, second, third, and fourth steps respectively. The initial load in this case increased from $\sigma_{\text{init}} = 0.56$ MPa to $\sigma_{\text{init}} = 2.5$ MPa, which corresponds to $0.7 \sigma_{\text{inst}}$. Further load increases reduces the stress to $\sigma_{\text{final}} = 0.7$ MPa, irrespective of the value of the initial load. However, with such a value of the step load, each test takes a long time, since each step is to be held until the deformations are stabilized, and several loading steps are necessary to reach the critical load ($\sigma = 0.7 \sigma_{\text{inst}}$).

With the increase of the step value, the number of steps for reaching the critical load diminishes. However, the increase of the value of the steps not only reduces the duration of the test but also impairs the accuracy of the results. Thus, for example, with a step value of $\Delta\sigma = 0.16 \sigma_{\text{inst}}$, the value of the critical load was $\sigma = 2.5$ MPa, but with a step equal to $\Delta\sigma = 0.2 \sigma_{\text{inst}}$ this load amounted to $\sigma = 2.66$ MPa. Moreover, with a value of $\Delta\sigma = 0.33 \sigma_{\text{inst}}$, the researchers failed to note the critical stress: before reaching a load of $\sigma = 0.66 \sigma_{\text{inst}}$ the final stress had not yet stabilized, and the application of the next step of the load caused the failure of the soil specimen. The experiments suggested that the most favorable value of the step is $\Delta\sigma = 0.1 \sigma_{\text{inst}}$.

To reduce test duration, a study was undertaken to determine the effect of the loaded time periods of the steps and of the initial load upon the value of the ultimate stress (Vyalov et al. 1980). With this object in mind, the relevant tests were performed under different initial loads, i.e., 0.1, 0.5, 0.6, 0.7, and 0.8 of the conventional instantaneous strength of the soil. The further loading operations were subjected to steps identical and equal to $\Delta\sigma = 0.1 \sigma_{\text{inst}}$. An optimum value of the step was selected to determine more accurately the value of the final stabilized stress. The experiments showed that regardless of the value of the initial stress, by gradually increasing the loading of the specimen in steps of $\Delta\sigma = 0.1 \sigma_{\text{inst}}$ starting from the initial load of $0.7 \sigma_{\text{inst}}$, the specimen-

*This test is often called a "relaxation" test.

dynamometer system tends to relax at a constant final stress $\sigma_{\text{final}} = 0.72$ MPa.

Thus, changing the value of the initial load has no effect on the value of the final stabilized stress, while decreasing the initial load increases the test duration. For instance, reduction of the tests by one step cuts the length of the test time by 72 hours.

The results of these experiments made it evident that the best variant is a test under an initial load lying within 0.5-0.6 of the conventional instantaneous strength of the soil under test.

These tests were conducted with every subsequent step being held until a predetermined stabilization of the deformations was attained. To reduce the duration of the tests, the effect of the time the applied load was held upon its final stabilized value was investigated. To this end, tests were performed in which the loading steps were held for 12 and 24 hours, as well as until the predetermined stabilization of the deformations was obtained. The investigations showed that, for 12- and 24-hour durations, the value of the final stress at each step is higher than at the previous step, up to the application of the last step of $\sigma_{\text{init}} = 0.9 \sigma_{\text{inst}}$, after which the soil specimen failed. Thus, the experimenters failed to succeed in obtaining the stabilized final stress.

Thus, the studies showed that the best variant is testing under an initial load of 0.5-0.6 σ_{inst} with a gradual step-by-step rise of the load in increments of $\Delta\sigma = 0.1 \sigma_{\text{inst}}$, with a predetermined stabilization of the deformation at each step of the loading.

Table 1 gives a comparison of the characteristics of long-term strength of frozen soil in various types of tests.

bonds, etc. (Vyalov et al. n.d., Vyalov et al. 1973).

Thus, when selecting the method for determining strength characteristics of frozen soils it is necessary to take into consideration the loading conditions and the state of the soil in situ.

However, it should be emphasized that to determine the long-term strength of the soil by testing at $\sigma = \text{const}$, as well as at constant stress and constant rates of loading and deformation, it is essential to obtain a family of creep curves. This requires the testing of a series of identical specimens. As a rule, this is accompanied by a large scatter of test results, and calls for an additional number of tests. The other shortcoming of these methods is the ambiguity in determining the time of failure of the soil specimens. Thus, despite the fact that these methods reflect correctly the state of the soil under constant and time-variable loads, they are time-consuming. The method of step loading at a constant stress allows the test to be performed with the use of one or two specimens. This method had the disadvantages characteristic of the previous methods in determining the moment of failure of the soil, and, on the other hand, requires too much time to accomplish the tests.

The most promising are the dynamometric test methods, i.e. the improved method of single loading and the revised method of stepped tests. They offer a number of advantages. First, they allow the value of the ultimate long-term strength σ_{∞} to be determined by testing only one or two specimens; second, they materially reduce the duration of the tests; and third, the values σ_{∞} are determined directly on the basis of the results of the experiments and require no preliminary mathematical

TABLE 1 Ultimate long-term strength of frozen soil σ_{∞} under various types of tests

σ_{∞} , MPa	Test conditions				Dynamometric method	
	$\sigma = \text{const}$		$\dot{\sigma} = \text{const}$	$\dot{\epsilon} = \text{const}$	Single loading	Stepped loading
	Single loading	Stepped loading				
	0.52	0.75	0.70	0.75	0.54	0.72

Analysis of these data demonstrates that all the obtained values could be divided into two groups: (a) a group comprising $\sigma_{\infty} = 0.5$ MPa for the case of $\sigma = \text{const}$ and $\sigma_{\infty} = 0.54$ MPa for the case of single dynamometric tests, and (b) a group including $\sigma_{\infty} = 0.75$ MPa in the case of stepped tests at $\sigma = \text{const}$, $\sigma_{\infty} = 0.7$ MPa whenever $\dot{\sigma} = \text{const}$, $\sigma_{\infty} = 0.75$ MPa for $\dot{\epsilon} = \text{const}$, and $\sigma_{\infty} = 0.7$ MPa in the case of stepped dynamometric tests.

Comparison of the foregoing data indicates that in all cases when the test specimens were loaded gradually the ultimate long-term strength turned out to be higher than the constant load. This is due to the fact that a gradual increase of the load strengthens the soil due to the rearrangement of the soil particles, development of new structural

processing. The particular dynamometric test method should be selected on the basis of the expected stress state of the soil in situ in the foundations of the structures to be built on permafrost.

OBSERVATIONS OF MARTIAN FRETTED TERRAIN

Michael C. Malin and Dean B. Eppler

Department of Geology, Arizona State University, Tempe, Arizona 85287

Fretted terrain is one of several lowland landscapes found on Mars that suggest intense geomorphic activity. Fretted terrain was formed initially during a period of heavy cratering and possibly fluvial activity early in martian history. Subsequent modification processes have been active in the "recent" past, and may still be active today. Evidence of the process(es) that formed the fretted terrain is generally lacking because of subsequent modification. The location of the terrain along the boundary between heavily cratered uplands and sparsely cratered lowlands that extends around the planet, and the orientation of portions of the terrain along structural trends associated with the boundary, suggest a tectonic origin in part. Subsidence through ground ice melting or sublimation may then have led to progressive deterioration of the relatively incompetent rock units. Modification of the surfaces has been widespread; most severely altered are valley floors and walls, and aprons surrounding mesas. Lineations on the surfaces of aprons resemble leveed channels, whereas those on valley floors, though superficially similar to medial moraines and other indicators of longitudinal flow, most likely reflect differential degradation by subsidence and eolian action. Measurements of the aprons show some similarities to certain terrestrial gravity-induced and gravity-driven mass flows.

INTRODUCTION

Fretted terrain is the name applied to a complex physiographic province marking a portion of the boundary between heavily cratered uplands and sparsely cratered lowlands on Mars. The terrain is characterized by steep, abrupt escarpments, and outliers of high-standing terrain surrounded by relatively smooth, flat-lying plains. The zone of most highly developed fretted terrain spans approximately 3500 km between 30°N, 28°W and 50°N, 350°W and is about 600 km wide. The importance to martian geology of fretted terrain lies in its spatial and temporal relationships to features suggesting profound changes in martian geological evolution: the terrain is developed only along the above mentioned boundary between "ancient" cratered terrains and "younger" sparsely cratered plains. This boundary probably reflects major tectonic events early in Mars' history (Mutch et al. 1976, Malin et al. 1978). Concurrent with or subsequent to these tectonic events, major erosional processes re-shaped portions of the martian surface (Malin 1976a, Mutch et al. 1976). Fretted terrains were formed, and have been modified, by these processes, and fretted landforms provide constraints on the nature and duration of the erosion.

Although early studies by Sharp (1973), Coradini and Arvidson (1976), and Malin (1976a) described fretted terrain morphology and age relationships from examination of Mariner 9 images, it was not until the receipt of Viking orbiter images, beginning in 1976, that more detailed study of the "fretting process(es)" could be conducted. Carr and Schaber (1977), Squyres (1978, 1979), Schultz and Glicken (1979), and Breed et al. (1980) suggested several alternative mechanisms for the

formation and modification of the fretted terrain, based on these Viking data. The papers by Carr and Schaber, and Squyres, addressed principally the modification of the fretted terrain. Features discussed by these investigators included lobate aprons beneath scarps and around mesas, and lineated valley floors. Carr and Schaber suggested that the features resembled those that are formed by frost creep or gelifluction, whereas their appearance suggested to Squyres that they formed by rockmass creep in a manner analogous to rock glaciers. Both Schultz and Glicken, and Breed and her co-workers, considered the initial formation of fretted terrain to require the action of liquid water, either as mudflows generated by subsidence over melted ground ice, as catastrophic floods, or as surface run-off.

MORPHOLOGY

No area of fretted terrain looks exactly like another. However, over a 3500 km distance two or three general assemblages of features occur. At the south and east end of the zone of principal occurrence, in Nilosyrtis, the assemblage of forms includes a ridge-and-valley topography strongly oriented parallel to the upland-lowland boundary, with flat or slightly concave valley floors that characteristically display longitudinal lineations (Figure 1). The valleys are typically a few kilometers across and several tens of kilometers in length. The ridges have subdued, rounded, undulating crests, some relatively narrow and others much broader (to 10-15 km). Valley floors occur at several discrete topographic levels; tributaries reach concordancy through gentle, ramp-like longitudinal slopes descending from higher to lower levels. Straight to arcuate or slightly

sinuous lineations (<100 m wide) within many of these valleys exhibit both positive and negative relief (probably less than a few tens of meters).

At the northwest end of the fretted zone (in Deuteronilus), the terrain is characterized by a progressive transition from undulating, heavily cratered surfaces indented by occasional channels to sparsely cratered lowland surfaces surrounding a few remnant outliers of high-standing terrain. These mesas typically have flat-tops and sharp brinks; their planimetric shapes vary widely, suggesting that there was little regional structural control of outline form. The lowland surface displays considerable variation in texture. However, most prominent of the characteristics of this area of fretted terrain are aprons surrounding each mesa and extending from the bases of other cliffs in the region (Figure 2). These aprons, reaching up to several tens of kilometers from the base of scarps, are faintly lineated in the direction generally perpendicular to the superjacent cliff. The lineations, usually less than a kilometer across, resemble shallow grooves (perhaps only a few tens of meters deep), and in some cases, leveed channels.

A third general pattern of fretted terrain occurs between the two areas discussed above (i.e., in Protonilus) and consists of a combination of their features (Figure 3). This pattern includes both mesas and ridges, separated by relatively narrow (<10 km), flat-floored valleys similar to those in Nilosyrtis; the pattern exhibits some regional tectonic alignment. Valley floors are coarsely lineated, but in places the lineations merge with pits and other irregular depressions, producing a chaotic and rough texture.

AGE RELATIONSHIPS

Estimates of relative age relationships between various elements of the fretted terrain, and between fretted and surrounding terrains, are derived from counts of impact craters (the number of superimposed craters is directly related to the amount of time a surface has been exposed to cratering) and from other examples of superposition.

Crater counts show that, in general, the highland surfaces are more heavily cratered and hence older than the lowland surfaces (Coradini and Arvidson 1976). The dearth of impact craters on the aprons and lineated valley floors, even in moderately high-resolution images, implies "extreme" relative youth. Crater counts by Carr and Schaber (1977) set an upper limit of about one crater larger than 1 km diameter per 2000 km², compared to surfaces on the superjacent highlands with values typically an order of magnitude higher. Assuming a relatively uniform flux of cratering objects, there are three possible explanations for this observation: (1) the aprons are young and unmodified, (2) the aprons are young and experiencing contemporary modification, or (3) the aprons are old but their surfaces have been "recently" modified. In all three cases the processes that crated the surfaces must have acted on Mars in the not-too-distant past. The mechanisms that crated the fretted terrain (as opposed to those that have modified the surface), however, appear to have operated substantially earlier (as indi-

cated by the number of large craters superimposed on the fretted terrain valleys and ridges), perhaps under conditions that no longer persist on Mars.

MEASUREMENTS OF FRETTED TERRAIN APRONS

Measurements of apron length perpendicular to superjacent scarp, scarp height above the apron (determined from measurements of shadow lengths), and scarp azimuthal orientation were made on aprons surrounding mesas in Deuteronilus. The results of these measurements are shown in Figures 4, 5, and 6. Figure 4 shows the relationship between scarp height and apron length for 50 aprons with similar morphology and occurrence. This type of plot is related to that used to compare landslides on the Earth, Moon, and Mars (e.g., Howard 1973, Lucchitta 1978), inasmuch as the scarp height is related to the potential energy available and the apron length is related to the efficiency of conversion of potential to kinetic energy. Our inability to measure volumes (owing to poor topographic control over most areas) prevents calculation of potential energies and flow efficiencies. No statistically significant trend is seen in the data, although there is a visual similarity to the landslide relationship that clearly derives its features from conversion of potential energy. It is not possible to demonstrate that aprons form on Mars as a result of gravity-induced movements, although their morphology suggest such an origin. Figure 5 shows the relationship of average apron length as a function of azimuth. A peak in this curve centered on N30E is apparent. Also plotted on Figure 5 are the azimuths of structural trends in the local area, measured on linear crater wall segments, scarps, and mesa cliffs. Figure 6 shows that scarp height is also a slight function of azimuth, but not in a manner consistent with that of apron length on azimuth.

The observation of an azimuthal dependence of apron length is a possible constraint on the nature of the fretted terrain modification process. Factors that might contribute to an azimuthal variation include structural and environmental variables (such as temperature, atmospheric pressure and H₂O content in solid or liquid form). As there is little correspondence between structural "grain" in the region and apron length (i.e., longest aprons are not at azimuths perpendicular to regional structure, nor are the most aprons perpendicular to the structural fabric), then the environmental factors may be responsible for the observed relationship.

ENVIRONMENTAL CONSIDERATIONS

Current conditions do not permit liquid water to occur in the near surface (<1 km deep) materials of the fretted terrain (Kieffer et al. 1977, Palluconi and Kieffer 1981). Diurnal variations of as much as 80°C occur, with maximum theoretical summer temperatures under current insolation conditions of -10°C. The average temperature is close to -73°C, and the winter low is about -120°C, at which point precipitation of the principal atmospheric gas (CO₂) acts as a buffer to prevent

appreciably colder surface temperatures. Highest rate of change of temperature occurs during morning illumination, when rates as much as 20°C/hour are observed. The eastern orientation of the longest aprons might indicate some influence of the rate of heating on the materials of the fretted terrain.

Variations in the obliquity (angle between the spin axis and solar equator) induced by gravitational perturbations of the other planets cause significant variations in martian surface temperatures and atmospheric pressure (Toon et al 1980). The temperature changes at many latitudes are quite large, but at 45°N the effects are small. The effects of obliquity variations on the magnitude and phase of the diurnal and seasonal temperature cycles at fretted terrain latitudes has not yet been computed. It is possible, and perhaps even probable, that such cycles will enhance the insolation received by eastern slopes, thus enhancing the effect seen in apron-length distribution.

The isotopic composition of nitrogen on Mars suggests that that planet once had significantly more nitrogen in its atmosphere. Studies of the isotopic composition of the rare gasses, oxygen, and hydrogen, and arguments made on the basis of cosmochemical abundances of these gases, seem to indicate that a denser atmosphere occurred early in martian history (e.g., Owen et al. 1977). Evidence of fluvial processes similarly date from that period (Malin 1976b, Pieri 1980). Such evidence is consistent with a warmer, "moister" environment conducive to many familiar processes of erosion. The exact nature of this environment (i.e., diurnal and seasonal temperatures, atmospheric pressure, and variations in it, insolation as a function of latitude, obliquity and eccentricity, and so on) is unknown, and thus consideration of it has not yet provided insight into surface evolution, although such studies are currently underway.

SPECULATIONS

Owing to the severe modification of valley wall slopes and floors, and the apparent retreat of scarps and the concurrent production of aprons, it is not possible to infer from available data on its present morphology the origin of fretted terrain. Its physical association with a boundary between old-and-high and low-and-young lands that extends around the planet, as well as the apparent control of some of its elements by structures related to this boundary, implies at least in part a tectonic genesis. Channels and evidence for collapse within the cratered uplands suggest some fluid activity, thought by some to involve ground ice melting and subsequent fluvial activity. Such evidence of erosion is lacking farther into the transition zone to lowland plains (as in Deuteronilus), and in areas where valleys are typically closed at one or both ends (as in portions of Nilosyrtris). Ground ice sapping (Sharp 1973), a process of ground deterioration occurring as ice sublimates without melting, releasing otherwise poorly consolidated materials, remains a viable and intriguing alternative.

Modification of fretted terrain appears to have occurred in the relatively recent past. Several different materials, and differences in their responses to different processes, are probably responsible for the variations in form seen in the fretted terrains. Aprons appear to form at the base of scarps in Deuteronilus; they are most likely formed of debris shed from these cliffs and transported as debris avalanches, debris flows, or debris creep masses. Each of these mechanisms is suggested by some observations, although none is consistent with all observations. The straited valley floors in Nilosyrtris and Protonilus show little evidence of flowage (despite the initial impression of longitudinal flowage evoked by the lineations) either off the valley walls or down the valley floors. Rather, the lineations appear to be formed by differential degradation of floor material by unknown processes (possibly ground ice deterioration and eolian action). Why such processes act to produce the organized pattern seen on the valley floors is similarly unknown, but the pattern may reflect structural control (for example, joints formed by cooling or differential compaction after emplacement) by the material being eroded. It is these unknown processes and material controls that present a great challenge to our understanding of Mars.

REVEGETATION OF FOSSIL PATTERNED GROUND EXPOSED BY
SEVERE FIRE ON THE NORTH YORK MOORS

E. Maltby and C.J. Legg

Department of Geography, University of Exeter
Amory Building, Rennes Drive, Exeter, Devon, England EX4 4RJ

Severe fire in 1976 ignited large areas of blanket peat on the North York Moors. Direct combustion, conversion to ash, and subsequent erosion have exposed a dense system of patterned ground at Rosedale. Disorientated mineral material and exhumed, sorted stone hummock-hollow terrain indicate periglacial activity dating to the Late Devensian or possibly immediate postglacial times. Geometric and chemical characteristics of the patterned ground are outlined. Revegetation by a succession of bryophyte species has been observed since 1976. Early colonization by *Ceratodon purpureus* and lichens (*Lecidea* spp.) has given way to a clear pattern adjusted to moisture conditions involving *Polytrichum piliferum* (dry hummock microsites) and *Polytrichum commune* (moist hollow microsites). Factors influencing colonization on the fossil hummocks are examined and compared with patterns of mature vegetation in contemporary periglacial environments.

INTRODUCTION

Thaw-freeze processes mold both the landscape detail and small-scale vegetation patterns in high latitudes, high altitudes, and at the margins of ice masses. There has been considerable interest in the relationships between active periglacial conditions, frequently producing distinctive patterned ground, and vegetation responses (e.g., Billings and Mooney 1959, Bryant and Scheinburg 1970, Hopkins and Sigafos 1950, Warren Wilson 1952). Much of the early work has not considered the process and rates of plant colonization of distinctive periglacial features. The investigations of Heilbronn and Walton (in press) fill this gap for sorted features in the Subantarctic.

Although sorting processes are still active in Britain in some high mountain areas (e.g., Tinto Hill, Lanarkshire (Miller et al. 1954)) the present temperate climate and modern vegetation cover are generally inimical to patterned ground formation. Abundant evidence exists, however, for fossil periglacial features, including patterned ground elements (Fitzpatrick 1956). In some cases, distinctive vegetation responses have been related to complex fossil subsoil structures which cause large variations in textural, hydrological, and parent material (nutrient) conditions over small distances (Williams 1964). Often, however, there is no obvious vegetation response, and no information exists on how fossil patterned ground exposed by removal of later soils or deposits might influence vegetation development.

STUDY AREA

The North York Moors are an isolated, compact Jurassic upland of some 550 mi² (1,425 km²) in northeast England (Figure 1). The area is dominated by an extensive plateau surface comprising mainly Middle Jurassic grits, sandstones, and shales which attains a maximum altitude of 454 m.

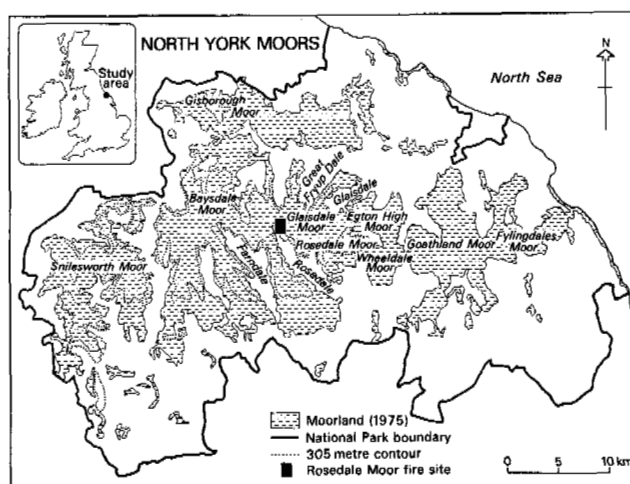

FIGURE 1 Location map.

Ice overran the area in all but the last (Devensian) glaciation and removed most pre-Pleistocene soils. Some evidence for the survival of earlier palaeosols has been described (Bullock et al. 1973), but such relict features are rare and do not occur on the central plateau moorland watershed. The upland block has been subjected to strong periglacial modifications. This has resulted in marked congelifraction, disorientation, and downslope mixing of bedrock strata. The evidence for frost riving is apparent when removal of the postglacial peat cover exposes a litter of angular blocks, many of which have been tipped into a vertical position by downslope movement or by ground ice activity or by reorientation in the mollisol (Plate 1). The exhumed landscape is often strongly reminiscent of fell-field.

PLATE 1 Irregular and disorientated sandstone fragments resembling fell-field, typical of the exhumed periglacial surface exposed by peat and soil removal from plateaus on the North York Moors.

The evidence for patterned ground development elsewhere on the North York Moors has been largely inferential based on air photographs and vegetation contrasts. Polygonal networks of cotton grass (*Eriophorum* spp.) occupying debris-filled cracks in bedrock in the otherwise heather (*Calluna vulgaris*) dominated vegetation of the upland have been described by Dimbleby (1952). Infill of the 3 m deep gaps is thought to have occurred when wedges of ground ice melted with amelioration of the periglacial climate. It is by no means certain, however, in which cold period the features formed. Much of the plateau is dominated by blanket peat, which in places exceeds 3.5 m depth. The peat generally comprises *Eriophorum* and *Sphagnum* remains, and the succession to *Calluna* almost certainly indicates some recent drying out of the surface (Tansley 1968). Type soil and peat profiles are described in Bendelow and Carroll (1976). Postglacial vegetational history, and possible cause of change, peat development, and soil alteration have been thoroughly investigated (e.g., Dimbleby 1962, Simmons 1969, Cundill 1971, Simmons and Cundill 1974, Atherden 1976).

Rainfall totals for the moorland plateau are relatively low compared with other upland areas in Britain. Annual amounts exceeding 1,140 mm (45 ins) are exceptional. Winters are cold by oceanic temperature standards, with a January mean of 1.7°C. Snow may lie for 45–80 days depending on altitude, and on average there are 75 days with frost.

Rosedale Moor Site

Severe 'accidental' fire persisting for 4 weeks affected 32 ha of moorland at the head of Rosedale in August 1976. The site occupies mainly gently sloping land, generally 1°–3° on the southern moorland flank of the central plateau within an altitudinal range of 380–403 m. Vegetation cover over the entire area was eliminated, but underlying peat and organic horizons were altered to a varying extent depending on depth, moisture, and presence of

structural features allowing localized entry of oxygen (Maltby 1980). In the northwest part of the burnt area on the most gentle gradients and at the highest elevation, the thin blanket peat/peaty horizons originally averaged 300 mm depth and were associated with both stagnohumic gley and iron pan stagnopodzol profiles. The fire burnt most intensively in this area and ignited most of the organic materials to a fine powdery red-yellow ash. Only a small proportion of the original peat was incompletely combusted, and such residual material was charred into hard fragments. Deflation and erosion of the ash by surface wash rapidly exposed a series of stone hummocks and intervening hollows comprising a distinctive patterned ground complex (Plate 2).

PLATE 2 Hummock with residual charred peat surrounded by ash 1 year after the fire. (Scale is 1 m.)

This hummock-hollow complex occupies a SSW facing upper slope facet and seems to be restricted to this part of the site. The features may extend in elongated form downslope, but the intact moorland surface makes the geometry of stony areas difficult to establish with certainty. The progress of erosion, differential recolonization patterns elsewhere in the fire-site, and a general account of biological, chemical, and physical alteration of substrate conditions are given in Maltby (1980).

Methods

The position of over 50 distinctive stony hummocks has been recorded. For each feature, measurements were made of diameter (including for random examples long axis (D_1) and short axis (D_2) measurements where these could be clearly defined), height, and stone length for five individuals from each hummock.

Permanent markers were established shortly after the fire, and changes in surface morphology and vegetation colonization have been monitored through repeated analysis of point quadrat frames and at 0.5 m intervals along a line transect. Photographic records have been maintained throughout the postburn period, and detailed maps of the mosaic of colonizing bryophyte species made for selected sites. Soil samples have been taken from the surface 65 mm

in representative areas of each surface type for routine chemical analysis. Cations were extracted with 1 M ammonium acetate, organic carbon determined by a wet oxidation procedure (Walkley and Black 1934), nitrogen using a Carlo Erba nitrogen analyzer (model 1400), and pH measured at sticky point.

Detailed examination of a representative zone of the patterned ground was made in 1981, 5 years after the fire. A transect was established extending between two ash filled hollows and over the long axis of a stony hummock with a small area of disturbed ash caused by damage to the bryophyte turf. Vegetation, soil, and topographic characteristics were recorded in 0.25 x 0.25 m quadrats. Frequency of exposed stones is much increased on the hummocks; hence the percent cover of species is expressed as percent stone free area of the quadrat.

RESULTS

Patterned Ground Complex

The striking regular spacing of the hummocks is illustrated in Plate 3.

PLATE 3 The patterned ground complex at Rosedale with colonization of the ash filled hollows by *Ceratodon purpureus* (light grey) and residual charred peat remaining on the hummocks (dark grey) 3 years after the fire.

For further analysis the features have been stratified into three groups according to slope position and angle. Amplitude of the hummock-hollow microtopography is greatest on the lowest slope angle (<1°) nearest the plateau summit. Height decreases, and the hummocks become more elongated with increasing distance downslope and the associated increase in gradient (Table 1). There is no statistically significant change in size, but variability increases downslope. The hummocks downslope have become fully revegetated by a dense moss carpet; eventually, they are impossible to measure accurately. It appears that they are more subdued because

of original genesis rather than because of differential exhumation of the stone hummocks upslope by greater contemporary erosion.

TABLE 1 Geometric Characteristics of Exposed Hummocks.

Slope Position Angle (Sample n)	Hummock Statistics			
	Diameter (m)	D_1/D_2 ¹	Height (mm)	Stone long axis ²
Upper (28) <1.0	2.31 ₃ ±0.08	1.47	156.3 ±07.3	152.0 ±09.4
Middle (15) 1-2°	2.05 ±0.11	1.58	136.0 ±08.3	113.5 ±06.9
Lower (10) >2°	1.99 ±0.22	1.88	107.0 ±05.6	95.8 ±04.2
All (53)	2.20 ±0.07	-	141.2 ±05.3	128.2 ±06.9

¹Hummock long (D_1)/short (D_2) axis.

²Mean of samples, each comprising five individuals.

³Standard error.

The hummocks comprise a convex surface of angular sandstone blocks above a circle of distinctly imbricated stones which dip toward the centre of the features. Blocks and fragments are generally moderately weathered and possess a characteristically bleached outer skin where acids from the peat have removed iron. In the intervening hollows, the pedogenic eluvial (E(g)) horizon of the ignited and eroded soil contains abundant small stones, but the larger blocks which make up the hummocks are absent.

Higher combustion temperatures are inferred in the hollows compared with the hummocks because most of the original peaty cover of the hollows was reduced completely to ash, whereas on the hummocks a much larger proportion of material remained as charred peat (Plate 2). This may have been related to the differential thickness of the peat, which prior to the fire gave no surface expressions of the buried pattern.

Microenvironment for Plant Colonization

In contrast to controlled fires associated with moorland management, the severe burn resulted in (1) radical alteration of physical and chemical substrate properties (Figure 2) and (2) destruction or dramatic reduction of the viable seed bank and root stocks in burnt surface horizons, delaying establishment of vascular plants (Table 2).

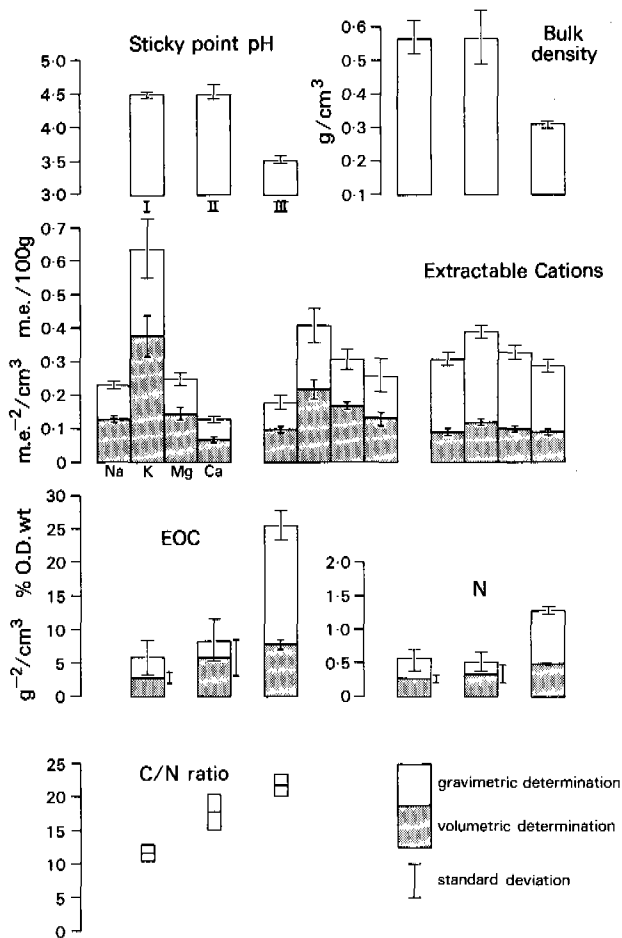

FIGURE 2 Analytical characteristics of surface 65 mm of ash-dominated surfaces above subdued micro-relief (I), exhumed patterned ground with distinctive microrelief (II), and intact peat surfaces (III). EOC is easily oxidizable organic carbon (Walkley and Black 1934).

The mosaic of residual charred peat and ashed material found at the patterned ground site provides a juxtaposition of contrasting habitats with soil pH ranging from less than 4 to more than 6.5 and parallel changes in nutrient status (Table 3). In the absence of vegetation and original organic cover, surface runoff increases and water retention declines, resulting in a change from wet and often waterlogged conditions to a frequently xeric environment. Exposure of the surface to frost action, wind, and surface water leads to sustained surface instability and erosion. Colonization is therefore not by the usually dominant heath and moorland species but by a succession of algal, lichen, and bryophyte species, whose distributions are related primarily to the substrate and microclimatic variations caused by the exhumed microtopography.

The Pattern of Colonization

Primary colonization of the site during the

first year following the fire was by algae. These were predominantly filamentous forms over the ash surface, though gelatinous and coccoid types were present on the surface of charred peat. The latter were accompanied by the ubiquitous presence of *Lecidea uliginosa* on crusted peat surfaces and numerous conspicuous patches of *Lecidea granulosa*. The surface film produced by these species has been shown to inhibit the germination of seeds of *Calluna vulgaris* and may be a significant factor affecting further colonization.

TABLE 2 Number of Points Represented by Each Surface or Vegetation Type Recorded in 1979 and 1982 for the Whole Area of Patterned Ground

	Number of Point Observations	
	1979	1982
Granular peat	31	0
Charred peat	6	6

TABLE 3 Surface Characteristics of the Hummock-Hollow Complex and Adjacent Peat

	Analysis of Surface 0-20 mm					
	Extractable nutrients				pH	Moisture content
	Na	Mg	K	P		
Charred peat (hummock) 1977	70	64	73	25	3.6	60-135%
Ash 1976	156	349	945	60	5.8-7.2	50-140%
1977 (hollow)	72	119	240	73	5.0-6.8	
Intact peat 1977	109	142	56	44	3.2-3.4	400-450%

The ashed material in the hollows was particularly susceptible to frost disturbance during the first and second winters, and piprake formation was observed on numerous occasions. However, during the second summer following the fire *Ceratodon purpureus* rapidly covered and stabilized ashed surfaces. *Ceratodon purpureus* is an acrocarpous moss having low (10-20 mm) "short turf" morphology (Gimingham and Birse 1957). This species then also spread to the charred peat of the stony hummocks, establishing particularly in the cracks created by

shrinkage of the charred peat. The occurrence of *Ceratodon purpureus* seems to be related to the chemical quality of the ash deposits and thin residual peat, as it is totally absent from neighboring sites with a relatively intact peat surface or deeper residual peats, where *Dicranella heteromalla* and *Pohlia nutans* are abundant.

During the third season following the fire, *Polytrichum piliferum* became widely established. The somewhat taller (20–30 m) "tall turf" morphology of this species with a spreading underground rhizome-like system enabled it to gain immediate dominance over the *Ceratodon purpureus*. Though covering the ground more rapidly in the hollows, this xeromorphic species quickly established on the hummocks in sheltered microsites provided by desiccation cracks in the residual peat and in the shelter of stones.

Polytrichum commune, which is morphologically dominant over the other two species, has also established in the area, growing through and over the *Polytrichum piliferum* turf such that by 1982 it represented almost 40% of all plant cover. It is, however, less xeromorphic than *Polytrichum piliferum* and is largely restricted to the hollows on deeper ash, and areas downslope where soil moisture is higher. The situation six seasons after the fire is therefore a mosaic of *Polytrichum commune*, and *Polytrichum piliferum* reflecting soil moisture. *Ceratodon purpureus* is abundant but at this stage is rarely more than a degenerate or dead turf beneath the *Polytrichum piliferum* (Figure 3).

FIGURE 3 Distribution of different species along a scale transect across typical hummock and hollow features. (Stones are indicated schematically only.)

Where the protective surface of mosses has been broken the secondary recolonization process is slow, and open patches of unstable, frost-heaved ash remain for some time, with an open mixed community of the three bryophyte species developing over a 2 year period.

On the patterned ground, vascular plants are restricted to a limited growth of the small annual grass, *Aira praecox*, at the margins of frost-disturbed sites, and the occasional plants of

Agrostis tenuis, *Poa annua*, and *Festuca ovina*, predominantly in the hollows, originating probably from sheep droppings.

DISCUSSION

The microrelief described here is a somewhat unusual example of periglacial patterned ground since it combines hummocks and rings of imbricated stones more characteristic of stone circles. The stone hummocks contrast markedly with the fossil polygons described elsewhere on the North York Moors (Dimbleby 1952) and perhaps bear greatest morphological similarity to earth hummocks (Washburn 1973). These are widespread south of the tree line, and typical examples 1–3 m in diameter and 0.40–0.50 m high have been described in the northern Mackenzie Valley and North Yukon (Zoltai and Pettapiece 1974). In contrast, these modern microrelief counterparts are generally not described as stony. However, excavation of similar surviving features on Dartmoor has revealed that a stone core may have segregated at some depth due to ground ice (D.J. Miller personal communication). The occurrence of earth hummock features elsewhere in Britain has been reviewed by Pemberton (1980), who discounts a periglacial origin in favor of much more recent development either during the "Little Ice Age" or in some cases even within the last 150 years. He has reasoned that the microrelief of original periglacial hummocks would not have survived postglacial events. This would not necessarily contradict a true periglacial origin for the Rosedale features, however, since they have been protected by a peaty cover for a significant part of the postglacial.

The dominant features of the vegetation colonizing the burnt area are the abundance of bryophyte species but absence of vascular plants. Although similar successions of moss species may be observed following fire in other heath vegetation (e.g., Clement et al. 1980), the scarcity of vascular plants is generally unusual for sites in the north temperate zone. Similar patterns, however, are described for fire on patterned ground at Kokolik River, Alaska, where a tundra fire over "high centred polygons" results in 70% cover of *Marchantia polymorpha* and *Ceratodon purpureus* but only 5% cover of vascular plants (Hall et al 1980). Following controlled burning for moorland management, the establishment of vascular plants from seed or buried rootstocks occurs during the first season after fire, and subsequent spread is by vegetative growth. Where initial colonization is delayed by severe fire which destroys the seed bank and potential regeneration centers, establishment is further inhibited by changes in the substrate quality, ecesis resistance of the bryophyte communities, and grazing pressure. Establishment of vascular plants is therefore extremely slow and depends upon the availability of suitable microsites. These may occur either on dung or where the moss turf has been broken to expose the subsurface ash.

Frost lift is undoubtedly important in reducing the rate of colonisation during the first two winters and subsequently in patches where the moss turf is broken. These areas, however, are not obviously related to the pattern of fossil hummocks and therefore frost and exposure are not the prime

factors in determining the vegetational pattern associated with the hummocks. This contrasts with the observations of Heilbronn and Walton (in press) in which the establishment of vascular plants on patterned ground is directly related to particle size and frost movement. The distribution of plants in mature vegetation on patterned ground, and a complex of interactions between exposure, frost action, and the insulating and stabilizing properties of vegetation have been described elsewhere (e.g. Webb 1972, Warren Wilson 1952). The early colonisation patterns developed on the Rosedale site, however, appear to reflect the controls of substrate quality and microclimate.

CONCLUSION

Examination of active features in modern periglacial environments can assist greatly in the interpretation of fossil landforms. However, the reverse may be true also under special conditions. The vegetation succession on the patterned ground microrelief exposed by a major peat fire on the North York Moors parallels examples of postfire development on sorted ground features in the Arctic. Continued monitoring will establish the full extent to which the exhumed periglacial microrelief influences progressive vegetation development in a climate less severe than that normally associated with active hummock formation or contemporary stone sorted features.

ULTIMATE LONG-TERM STRENGTH OF FROZEN SOIL
AS THE PHASE BOUNDARY OF A VISCOELASTIC SOLID-FLUID TRANSITION

Chi-Sing Man

Department of Civil Engineering, University of Manitoba, Winnipeg, Manitoba, Canada R3T 2N2

Herein we explore the possibility of using wave propagation methods to determine the ultimate long-term strengths of frozen soils. Our discussion is based on the assumptions that the creep behavior of frozen soils (under conditions of non-failure) could be modeled as nonlinear viscoelastic, that the ultimate long-term strengths of a frozen soil in fact constitute the phase boundary of a viscoelastic solid-fluid transition, as well as the lack of smoothness of such a transition. The general discussion is illustrated by a detailed analysis of one particularly simple example, namely, why we could likely locate by experiments of wave propagation the phase boundary of a saturated sand-ice material under low-stress conditions. Finally we discuss the possibility that for frozen soils the transition from solid to fluid behaviour be strain-controlled rather than stress-controlled, and explain briefly how wave propagation experiments could still be used to determine the transition strain which demarcates between, for each given temperature, the solid and fluid behavior of frozen soils.

INTRODUCTION

Materials which creep under a sustained load are susceptible to loss of strength in time. Soils, frozen and unfrozen alike, are no exception. The importance of this fact has long been recognized in geotechnical engineering (see, for example, Casagrande and Wilson 1951). To characterize the reduction of strength in time, the concept of "long-term strength" is introduced. Under uniaxial compressive stress conditions the long-term strength or "creep failure stress" $\sigma_f(t_f, \theta)$ of a soil for the "elapsed time to failure" t_f and temperature θ is defined as the stress level under the sustained isothermal loading of which will lead to failure of the soil after a load period of length t_f ; σ_f is a function of t_f and θ . (For simplicity the discussion in this paper will be restricted mainly to uniaxial compressive stress conditions, and we shall adopt the sign convention that compressive stress and compressive strain are positive.) The limit of the function $\sigma_f = \sigma_f(t_f, \theta)$ for a constant θ as t_f approaches infinity is called the "ultimate long-term strength" at the temperature θ . Methods for the determination of ultimate long-term strength are discussed in the literature (see, for example, Vyalov 1979, chap. 9). Although we have used the temperature as the parameter in the definitions above, in general it could be replaced by other physical variables. For example, the volume fraction of sand could be used as the scalar parameter for saturated sand-ice mixture in random packing when other factors which affect long-term strength are held constant.

Everyone who has had the experience of running constant-stress creep tests on frozen soil must be familiar with the following difficulty: Given a creep curve which attenuates over a relatively

short interval of time to a very low rate of strain, it is practically impossible to determine without prejudice whether the curve should be extrapolated to the long-term as exhibiting attenuating creep or as approaching stationary creep at a low strain rate. The implication of this difficulty is that no conventional method for the determination of ultimate long-term strength could deliver that quantity for sure, because all such methods rely on extrapolation into a regime in which we literally do not know how we should extrapolate.

Here it may be argued that in practice what we are really interested in is the loss of strength during the life time of a structure, not the "ultimate" strength. But, to determine strength reduction in the long run (say, in time units of decades), the conventional experiments themselves may take a rather long time to complete, if we do not accept ready-made formulae like Vyalov's "law of strength reduction" as applicable *a priori*.

The unsatisfactory situation described above raises the question whether we can have other experiments that could be completed in a relatively short time and will deliver the ultimate long-term strength of frozen soils without ambiguity. Once such new experimental methods become available, studies on the improvement of frozen soils to enhance their ultimate long-term strength would become feasible.

In the classical theory of linear viscoelasticity, a material is characterized by its creep compliance J or its relaxation modulus G . A linear viscoelastic material is called a solid (e.g., "the standard linear solid") if the time derivative of its creep compliance $\dot{J}(t)$ approaches zero as the time t approaches infinity, and is called a fluid (e.g., "the Maxwell fluid") if $\dot{J}(t)$ approaches a positive constant. Under constant stress a linear viscoelastic solid will exhibit only attenuating creep, and a fluid will

ultimately undergo stationary creep. Linear viscoelastic solids and fluids, indeed, have very different mechanical behavior under many circumstances (Pipkin 1972, chap. 3). Thus far in this section we have restricted our discussion to one given temperature. Should we consider a range of temperatures, then a material could be a linear viscoelastic fluid, say, for temperatures θ above some fixed temperature θ_0 and be a solid for θ below θ_0 . If we use a straight line segment to represent the range of temperatures under consideration, each temperature will correspond to one phase of the material---either solid or fluid. Thus we have a "phase diagram", and θ_0 is the "phase boundary"

which divides those temperatures at which the material is solid from those temperatures at which the material is fluid.

The foregoing discussion can be generalized for nonlinear viscoelastic materials which manifest solid-fluid transitions. For nonlinear materials whose transitions are temperature and stress controlled, the phase diagram will be defined on a domain D in the θ - σ or temperature-stress plane. Each point (θ, σ) in D corresponds to a phase of the material---either solid or fluid, and we call each (θ, σ) a phase point. If the material is solid at the phase point (θ, σ) , then the creep curve defined by the temperature θ and the stress level σ exhibits attenuating creep; otherwise the creep curve will ultimately manifest stationary creep. The phase boundary which separates the solid and the fluid phase points is now a curve in the domain D . Consider the straight line defined by a fixed temperature θ . Suppose this straight line meets the phase boundary curve at the point $(\theta, \sigma_\infty(\theta))$. Suppose, without loss of generality, that for all $\sigma > \sigma_\infty(\theta) > 0$, the (θ, σ) 's are fluid phase points, and that for $0 < \sigma < \sigma_\infty(\theta)$, the (θ, σ) 's are solid phase points. Suppose further that for the material in question the nonlinear viscoelastic model is valid under conditions of non-failure, and that stationary creep will invariably lead to ultimate failure. If a series of constant-stress creep tests were performed on samples of such a material at the same

temperature θ but at various stress levels, and if we could determine ultimate long-term strength from such experiments, we should conclude that $\sigma_\infty(\theta)$ be the ultimate long-term strength of that material. (See Figure 1.)

One basic premise of this paper is that the foregoing discussion can be applied to frozen soils. It has been said that under non-failure conditions the behavior of a frozen soil is similar to that of a "non-linear Maxwell body" (Ladanyi 1981). As far as creep under constant stress is concerned, the preceding statement will be correct only if the stress applied is above the ultimate long-term strength. For stress levels lower than the ultimate long-term strength, it would be more appropriate to say that a frozen soil behaves like a nonlinear viscoelastic solid. Indeed, for a fixed temperature, if the ultimate long-term strength at that temperature demarcates between solid and fluid behavior, it is the phase boundary of the viscoelastic solid-fluid transition.

The main object of this paper is to study the possibility of locating that solid-fluid phase boundary by wave propagation methods. Since the solid-fluid transition of frozen soil might be strain-controlled rather than stress-controlled, we shall round off our discussion by explaining briefly how wave propagation studies could be used to clarify the important question whether ultimate long-term strength is really a constitutive quantity for frozen soils.

NOTATION AND PRELIMINARIES

Hereafter we shall assume that all samples of the frozen soil under consideration are homogeneous and they undergo homogeneous deformations in creep tests. In particular, we assume that each sample is prepared under the same standardized procedure at some fixed temperature, brought to the test temperature and cured for a fixed length of time before test at that temperature. Let L_0 and $L(t)$ be the original length of a sample and its length at time t after loading, respectively. Then $F(t) \equiv L(t)/L_0$ is the deformation gradient at time t and $\epsilon \equiv 1 - F$ is the compressive strain. In what follows we shall explicitly distinguish a function and the values it assumes. For example, while $f(\cdot)$ denotes a function with the dot standing for the running variable, $f(x)$ will be the value of the function $f(\cdot)$ when the variable in question takes the specific value x .

Let D be a domain in the θ - σ plane which defines the range of temperature and stress level within our interest. Each constant-stress creep test is defined by a point (θ, σ) in D ; here θ is the temperature of the test and σ the stress applied. To each (θ, σ) is associated a creep curve. We shall denote by $\epsilon(\cdot; \theta, \sigma)$ the creep curve parametrized by the control variables (θ, σ) ; here the dot \cdot , as usual, stands for the running variable, which for the present instance is time. And we shall denote by $\epsilon(t; \theta, \sigma)$ the strain assumed at the time t by the creep curve $\epsilon(\cdot; \theta, \sigma)$. If a creep curve has a point of inflection, there is tertiary creep and the creep

FIGURE 1 Phase diagram of a typical nonlinear viscoelastic material. The curve $\sigma = \sigma_\infty(\theta)$ defines the phase boundary of the solid-fluid transition.

curve will be defined only for some finite interval of time. On the assumptions that frozen soils are nonlinear viscoelastic materials under conditions of non-failure, and that it is prolonged stationary creep that leads to failure, we replace the tertiary portion of each creep curve with a straight line segment which extends to $t = \infty$ and has its slope equal to the minimum strain rate. After this surgery and reconstruction, every (θ, σ) in D will correspond to a creep curve which as a function of t is continuously differentiable and is defined on the interval $[0, \infty)$. Henceforth when we use the symbol $\varepsilon(\cdot; \theta, \sigma)$ or refer to a creep curve, unless otherwise stated we shall mean the one after reconstruction. Let

$$\dot{\varepsilon}(\infty; \theta, \sigma) \equiv \lim_{t \rightarrow \infty} \frac{\partial \varepsilon}{\partial t}(t; \theta, \sigma). \quad (1)$$

A point (θ, σ) in D with $\sigma > 0$ is called a solid phase point if $\dot{\varepsilon}(\infty; \theta, \sigma) = 0$; it is called a fluid phase point if $\dot{\varepsilon}(\infty; \theta, \sigma) > 0$. The intersection of the frontier of the set of solid phase points and that of the fluid phase points is called the phase boundary. Hereafter we shall denote the phase boundary and a generic point on it by $\sigma_\infty(\cdot)$ and $(\theta, \sigma_\infty(\theta))$, respectively. (Here we assume that for each θ , there is only one $\sigma_\infty(\theta)$.) It is our basic assumption that $\sigma_\infty(\theta)$ is indeed the ultimate long-term strength at the temperature θ . When another physical variable replaces the temperature as the parameter, the foregoing discussion and definitions would still apply after obvious modifications.

When the temperature θ is the parameter, what follows is a familiar empirical fact: When the points (θ_1, σ_1) and (θ_2, σ_2) are sufficiently close to each other, the corresponding reconstructed creep curves $\varepsilon(\cdot; \theta_1, \sigma_1)$ and $\varepsilon(\cdot; \theta_2, \sigma_2)$ become virtually indistinguishable. (This empirical fact can be stated in a precise way after we endow the set of creep curves with a suitable topology---then it simply says that the mapping $(\theta, \sigma) \mapsto \varepsilon(\cdot; \theta, \sigma)$ is continuous. A topology to that effect was presented by Man (1982). In what follows we shall assume that a suitable topology has been chosen, but will leave the chosen topology implicit. Suffice it to say here that the set of creep curves is embedded in the space E of continuously differentiable functions $f(\cdot)$ defined on $[0, \infty)$ with $\dot{f}(\infty) < \infty$; a suitable topology is defined on E and the set of creep curves is given the induced subspace topology.) Now suppose (θ, σ_1) is a solid phase point, (θ, σ_2) is a fluid phase point, and $|\sigma_2 - \sigma_1|$ is small. Then the creep curves $\varepsilon(\cdot; \theta, \sigma_1)$ and $\varepsilon(\cdot; \theta, \sigma_2)$ are practically indistinguishable. As a result, unless we wait so long that the creep test at temperature θ and stress level σ_2 brings the sample in question to failure, there is no way to tell whether σ_2 exceeds the ultimate long-term strength $\sigma_\infty(\theta)$. Moreover, by means of creep tests alone we can

never say for sure that σ_1 does not exceed $\sigma_\infty(\theta)$. This explains why it is difficult to determine ultimate long-term strength by creep tests.

In what follows we explore the possibility of locating the phase boundary $\sigma_\infty(\cdot)$ by means of wave propagation methods.

A SIMPLE EXAMPLE

The best way to illustrate why we could likely locate the phase boundary $\sigma_\infty(\cdot)$ by wave propagation experiments is perhaps by way of a simple example.

Consider saturated mixtures of ice and a fine sand (in random packing). The discussion below will be restricted to one given temperature and such other experimental conditions that the single parameter which affects the ultimate long-term strength of the sand-ice material could be taken as the volume fraction of sand v . As ice has zero ultimate long-term strength, sand-ice mixtures with low values of sand concentration presumably would behave like a viscoelastic fluid. If mixtures with sufficiently high sand concentration have non-zero ultimate strengths, the phase boundary $\sigma_\infty(\cdot)$, which is now a curve in the v - σ plane, will meet the $\sigma = 0$ axis at some point $(v_0, 0)$. (See Figure 2.) In other words, under the above assumptions, those mixtures with $v < v_0$ always behave like viscoelastic fluids in creep tests at the given temperature; those with $v > v_0$ will behave like solids when the compressive stress σ does not exceed $\sigma_\infty(v)$, and like fluids when $\sigma > \sigma_\infty(v)$.

According to Stevens (1975), for the propagation of infinitesimal sinusoidal progressive waves (peak dynamic stress 0.1-0.5 psi, frequency 500-10,000 Hz), "the theory of linear viscoelasticity appears to be adequate for frozen soils". This suggests that if the stress has always been maintained at a sufficiently low level and the strain has always been small, the sand-ice material can be adequately described by the constitutive relation

$$\varepsilon(t) = J(0; v)\sigma(t) + \int_0^t \dot{J}(\tau; v)\sigma(t - \tau)d\tau, \quad (2)$$

FIGURE 2 Phase diagram of a saturated sand-ice mixture (in random packing).

for a range of v that contains v_0 ; here $J(\cdot; v)$ is the creep compliance when the volume fraction of sand takes the value v , $J(0; v)$ the initial value of $J(\cdot; v)$, $\dot{J}(\cdot; v)$ the time derivative of $J(\cdot; v)$, and τ is a dummy variable which runs from $\tau = 0$ to $\tau = t$. Since the point $(v_0, 0)$ is on the $\sigma = 0$ axis, to locate it we can restrict ourselves to experimental situations under which Equation (2) is valid. Henceforth we shall base our further discussion in this section on Equation (2).

In Equation (2), the creep compliance $J(\cdot; v)$ is that of a fluid for $v < v_0$, and is that of a solid for $v > v_0$. Since $J(\cdot; v)$ has drastically different characteristics for $v < v_0$ and for $v > v_0$, it is convenient to express $J(\cdot; v)$ in terms of two functions. Let $J^f(\cdot; v)$ and $J^s(\cdot; v)$ be defined for $v < v_0$ and $v > v_0$, respectively, such that $J^f(\cdot; v) \equiv J(\cdot; v)$ for $v < v_0$, and

$J^s(\cdot; v) \equiv J(\cdot; v)$ for $v > v_0$. For each v ,

$J^f(\cdot; v)$ and $J^s(\cdot; v)$ are in fact creep curves for unit step stress. Let $\dot{J}^f(\cdot; v)$ and $\dot{J}^s(\cdot; v)$ be the corresponding functions of time that define the creep rate per unit stress. We assume that $J^f(\cdot; v)$, $\dot{J}^f(\cdot; v)$, $J^s(\cdot; v)$, and $\dot{J}^s(\cdot; v)$, as functions of v , are continuously differentiable. This assumption of smoothness seems to be consistent with the experimental findings of Goughnour and Andersland (1968) and Hooke et al. (1972).

Under this assumption, for instance, the secondary creep rate $\dot{J}^f(\infty; v)$ is a continuously differentiable function of v . Let $J_v^f(\cdot; v)$ and $J_v^s(\cdot; v)$ denote the derivatives of $J^f(\cdot; v)$ and $J^s(\cdot; v)$ with respect to v , respectively. By the assumption of smoothness they are continuous as functions of v . (The words "continuous" and "continuously differentiable" above can be given a precise meaning when the topology on the space E is made explicit.)

Now let us consider what happens to $J^f(\cdot; v)$ and $J^s(\cdot; v)$ when $v \rightarrow v_0^-$ and $v \rightarrow v_0^+$, respectively. From what I can gather from the reported experimental findings, the best guess is $J^f(\cdot; v_0^-) = J^s(\cdot; v_0^+)$. Should it be true, then the creep curve $\epsilon(\cdot; v_1, \sigma) = J^f(\cdot; v_1)\sigma$ for $v_1 < v_0$ will be practically indistinguishable from the creep curve $\epsilon(\cdot; v_2, \sigma) = J^s(\cdot; v_2)\sigma$ for $v_2 > v_0$, when $|v_2 - v_1|$ is sufficiently small, and thence creep tests are not suitable for the determination of v_0 .

Even if $J^f(\cdot; v_0^-) = J^s(\cdot; v_0^+)$, however, $J_v^f(\cdot; v_0^-)$ need not be equal to $J_v^s(\cdot; v_0^+)$. In other words, even if two functions take the same value at a given point, their derivatives need not

take the same value there. Indeed the best uninformed guess is that the derivatives take different values, i.e., $J_v^f(\cdot; v_0^-) \neq J_v^s(\cdot; v_0^+)$. (An argument by "genericity" can be given here. Such an argument was presented by Man (1982) when he discussed a similar problem.) In what follows we shall assume that $J^f(\cdot; v_0^-) = J^s(\cdot; v_0^+)$,

$J_v^f(\cdot; v_0^-) \neq J_v^s(\cdot; v_0^+)$, and in particular $J_v^f(0; v_0^-) \neq J_v^s(0; v_0^+)$, unless stated otherwise.

For a material which has its constitutive relation defined by Equation (2) for a given v and has density $\rho(v)$, it is well known (Coleman et al. 1965, Coleman and Gurtin 1965) that the value of $(\rho(v)J(0; v))^{-1/2}$ is equal to (i) the intrinsic velocity of acceleration waves, (ii) the intrinsic velocity of shock waves, and (iii) the "ultrasonic speed" of infinitesimal sinusoidal progressive waves propagating in a homogeneous sample of the material. Let $U \equiv (\rho(v)J(0; v))^{-1/2}$. For our sand-ice mixtures,

$$U = \begin{cases} (\rho(v)J^f(0; v))^{-1/2}, & \text{if } v < v_0, \\ (\rho(v)J^s(0; v))^{-1/2}, & \text{if } v > v_0. \end{cases} \quad (3)$$

Since ρ is a smooth function of v , U is a continuously differentiable function of v both for $v < v_0$ and for $v > v_0$ by the assumption of smoothness on J^f and J^s . Moreover, $U(v_0^-) = U(v_0^+)$ because $J^f(0; v_0^-) = J^s(0; v_0^+)$. But

$$\frac{dU}{dv}(v_0^-) \neq \frac{dU}{dv}(v_0^+), \quad (4)$$

because $J_v^f(0; v_0^-) \neq J_v^s(0; v_0^+)$ and $dJ^f(0; v)/dv = J_v^f(0; v)$, $dJ^s(0; v)/dv = J_v^s(0; v)$. (Proof that the two preceding equalities necessarily hold can be given when the topology on the space E is stated explicitly.)

If we determine $U(v)$ by appropriate wave propagation experiments for the sand-ice material at various sand concentrations, the graph we obtain by plotting $U(v)$ against v should be smooth for $v \neq v_0$ but has a discontinuous change in slope at $v = v_0$. Thus the critical volume fraction of sand v_0 in princip could be determined by wave propagation experiments, provided that $J_v^f(0; v_0^-) \neq J_v^s(0; v_0^+)$, which is very likely to be true. Theorems on the attenuation of waves (Coleman and Gurtin 1965) provide other possible ways of determining v_0 by wave propagation methods.

It should be clear that the discussion above is based in part on the assumed lack of smoothness of the solid-fluid transition.

DETERMINATION OF ULTIMATE LONG-TERM STRENGTH

Although the preceding example concerns only linearly viscoelastic materials, small strains and low stresses, wave propagation methods are by no means so restricted; indeed the foregoing argument can be generalized so that it also pertains to nonlinear materials under finite deformations and arbitrary levels of stress.

Henceforth we shall restrict our discussion to one given temperature θ and for simplicity shall suppress the symbol θ from all expressions. For instance, the ultimate long-term strength $\sigma_\infty(\theta)$ at the temperature θ will be denoted by σ_∞ .

We assume that under conditions of non-failure the frozen soil in question is described by the constitutive relation

$$\sigma(t) = G(F_r^{(t)}; F(t)), \quad (5)$$

i.e., the stress σ at a body point at time t is determined jointly by the past history $F_r^{(t)}$ of the deformation gradient up to time t and the present deformation gradient $F(t)$ at that body point; here the past history $F_r^{(t)}$ is a function defined on the interval $(0, \infty)$, and $F_r^{(t)}(s) = F(t-s)$ for $0 < s < \infty$, where the positive quantity s is defined through the present time t and the past time t' by $s \equiv t - t'$. The pair $(F_r^{(t)}, F(t))$ together defines the history of the deformation gradient up to time t . It should be emphasized that in Equation (5) the functional G is generally nonlinear, and its domain of definition would include histories for which the corresponding strain $\epsilon \equiv 1 - F$ need not be small, either for the present time t or for any time t' in the past.

Consider a constant-stress creep test in which a compressive stress σ is applied to a sample of the frozen soil at $t = 0$. Since the sample has always been in the "original" configuration before the load is applied, $F_r^{(0)}(s) = 1$ for all s in $(0, \infty)$, and we write $F_r^{(0)} = 1_r^{(0)}$. If $F_0 \equiv F(0)$ describes the instantaneous response to the loading, then

$$\sigma = G(1_r^{(0)}; F_0) = \sigma(F_0). \quad (6)$$

If Equation (6) could be inverted, we obtain $F_0 = F_0(\sigma)$. Since $\epsilon \equiv 1 - F$, we have $\epsilon(0; \sigma) = 1 - F_0(\sigma)$.

Suppose for the frozen soil in question the transition from solid to fluid behavior is determined by the level of stress σ in the sample. Suppose also, without loss of generality, that the compressive stress σ corresponds to a fluid phase point if $\sigma > \sigma_\infty$ and to a solid phase point if $\sigma < \sigma_\infty$. It is convenient to introduce two new

functions ϵ^s and ϵ^f defined through the expressions $\epsilon^s(\cdot; \sigma) \equiv \epsilon(\cdot; \sigma)$ for $\sigma < \sigma_\infty$, and $\epsilon^f(\cdot; \sigma) \equiv \epsilon(\cdot; \sigma)$ for $\sigma > \sigma_\infty$. We assume that ϵ^s and ϵ^f are continuously differentiable as functions of σ . Furthermore, empirically we have $\epsilon^s(0; \sigma_\infty^-) = \epsilon^f(0; \sigma_\infty^+)$. But, the preceding equality notwithstanding, by the same argument as in the last section, in general it is most likely that

$$\frac{d\epsilon^s}{d\sigma}(0; \sigma_\infty^-) \neq \frac{d\epsilon^f}{d\sigma}(0; \sigma_\infty^+). \quad (7)$$

As defined by Coleman et al. (1965), the "instantaneous tangent modulus" E corresponding to the history of deformation $(F_r^{(t)}, F(t))$ determines the instantaneous response to a small strain impulse superimposed at the present time t on the given history of (possibly finite) deformation. Corresponding to history of the form $(1_r^{(0)}, F_0(\sigma))$, E is a function of σ only and is given by

$$\begin{aligned} E(\sigma) &\equiv E(1_r^{(0)}, F_0(\sigma)) \\ &= - \lim_{\Lambda \rightarrow 0} [G(1_r^{(0)}; F_0 + \Lambda) - G(1_r^{(0)}; F_0)] / \Lambda \\ &= -(d\sigma/dF_0) = [d\epsilon(0; \sigma)/d\sigma]^{-1}; \end{aligned} \quad (8)$$

here Λ stands for the strain impulse superimposed at time $t = 0$ on the history $(1_r^{(0)}, F_0)$, for which the strain ϵ_0 corresponding to the deformation gradient F_0 need not be small. If we can determine $E(\sigma)$ for various values of σ , the graph we obtain by plotting $E(\sigma)$ against σ is continuous for $\sigma < \sigma_\infty$ and $\sigma > \sigma_\infty$. By Equation (7), however, the same graph will suffer a discontinuous jump at $\sigma = \sigma_\infty$. Thus the ultimate long-term strength σ_∞ could be determined from the plot of $E(\sigma)$ versus σ .

For the class of materials described by Equation (5), it is well known that those with fading memory behave as perfectly elastic materials in sufficiently fast processes. While frozen soils in general do not behave as materials with fading memory, experience with seismic studies does seem to corroborate the contention that they also behave as elastic materials in sufficiently fast processes. Granted this, if our sample, which has been in the original configuration until $t = 0$, is subjected to a stress σ that produces a homogeneous strain $\epsilon_0 = 1 - F_0(\sigma)$ at time $t = 0$, and we let an acceleration wave of arbitrary amplitude propagate through the sample immediately after it has developed the homogeneous strain (which need not be small), the average velocity of propagation of the wave through the sample should give a good approximation to the value $(E(\sigma)/\rho_0)^{1/2}$, from which $E(\sigma)$ could be calculated after we substitute in the density of the original configuration ρ_0 . We use the word "approximation" in the preceding assertion because

the wave takes, however short, a finite time to propagate through the sample, which is creeping during this time under the stress σ . Nevertheless we expect this approximation to be good enough for the evaluation of $E(\sigma)$. Instead of acceleration waves, we can also let infinitesimal sinusoidal progressive waves of higher and higher frequency propagate through copies of our sample after they have developed the initial homogeneous strain under the constant stress σ . Infinitesimal progressive waves of frequency ω has a propagating speed $v(\omega)$, and the "ultrasonic speed" (i.e., the limit of $v(\omega)$ as $\omega \rightarrow \infty$) is equal to $(E(\sigma)/\rho_0)^{1/2}$. This gives an alternate way to determine $E(\sigma)$ as a function of σ , but this second method, unlike the first, requires extrapolation.

CLOSING REMARKS

In the preceding section an attempt is made to convince the reader that we should try using wave propagation methods to determine ultimate long-term strength of frozen soil. The reader may not be convinced by the argument above, especially if he believes that for frozen soils the transition from solid to fluid behavior occurs only after a certain amount of strain has developed, i.e., if he believes that the solid-fluid transition of frozen soil is strain-controlled rather than stress-controlled. Indeed, such a belief can easily find indirect support from the literature. (For example, the role of strain is underlined by Ting (1983) when he attributes the correlation of minimum creep rate and the time to reach that rate to "the existence of an approximately constant strain at the minimum strain rate".) But this belief, if true, implies that ultimate long-term strength is not a constitutive quantity for frozen soils and it has no significance independent of the specific process in question. On the other hand the strain which demarcates between solid and fluid behavior would be a constitutive quantity and it would merit our attention and study.

In this regard the argument presented above remains valid if we consider phase diagram in the ϵ - θ plane instead of the σ - θ plane and modify our argument accordingly. To determine the transition strain at temperature θ , we subject similar samples at the given temperature to various constant homogeneous strains, let acceleration waves and infinitesimal sinusoidal progressive waves propagate through the samples, plot the intrinsic velocity of the acceleration waves or the ultrasonic speed of the infinitesimal progressive waves against the strain and look for discontinuity in the graph of the plot. By performing wave propagation experiments at various times d after the constant homogeneous strain in question has been imposed, we can also investigate whether the duration d has any appreciable effect on the transition strain. If the phase transition is determined purely by the amount of strain developed, the duration d should have no effect on the transition strain. It should also be pointed out that even if the solid-fluid transition for each given temperature is purely strain-controlled, we shall still obtain a transition stress when we perform

the experiments suggested in the preceding section; the transition stress thus obtained, however, is not related to the ultimate long-term strength.

No physical conjecture could win the respect of the sceptical empiricist before it is corroborated experimentally. Being a theorist, I lack the means to test what I believe. Here I do not claim that ultimate long-term strength could indeed be determined by wave propagation methods, for that concept itself may not even be a constitutive quantity and thence lacks physical significance. But I do strongly believe that wave propagation methods are useful in general in the study of the solid-fluid transition of frozen soils, and in particular for ascertaining whether ultimate long-term strength is really a constitutive quantity. The present paper would have served its purpose if it could draw the attention of some experimentists to the possible fruitfulness of using wave propagation methods in the study of ultimate long-term strength.

PILE DRIVING AND LOAD TESTS IN PERMAFROST
FOR THE KUPARUK PIPELINE SYSTEM

Victor Manikian

ARCO Alaska, Inc., Anchorage, Alaska 99510 USA

Drilled and slurried piles have been used at the North Slope of Alaska. These tests were conducted for the determination of a faster pile placement method in permafrost. Ultimately this refined, thermally-modified pile driving method was selected by ARCO Alaska, Inc., in 1980 in its construction of the aboveground Kuparuk Pipeline.

INTRODUCTION

Placement of structural foundation support piles on Alaska's North Slope generally has been performed using drilled holes and slurry backfill techniques. The process of drilling, placing, aligning and slurrying piles is time consuming and requires considerable manpower and equipment. A method of accomplishing the same results more quickly, using fewer men and less equipment, and the early success of specially-modified driven H-pile structural shapes in permafrost (Crory 1973, Crory 1975, Nottingham 1981), prompted ARCO Alaska, Inc., to initiate a series of driving and load tests starting in February 1980.

These field tests were designed to verify the practicality of driving piles in cold permafrost on a production basis using thermally modified predrilled pilot holes. This technique employs a small drilled pilot hole, generally 15.2 to 21.6 cm (6 to 8.5 in.) in diameter depending on pile diameter, filled with water, heated to a minimum of 66°C (150°F). The pilot hole is filled with the hot water 30 min before driving in frozen granular soils and 60 min before driving in frozen fine-grained soils, in order to raise the surrounding soil temperature and facilitate the pile placement. Thermal modification and pile driving procedures were refined to suit the arctic pile driving. Ultimate adfreeze strengths of these piles were determined by load tests after isolating and eliminating the effects of end bearing and the active layer. In Prudhoe Bay, heaving forces from silty soils in the active layer have controlled the design of lightly-loaded piles (Crory 1965).

Driving tests were conducted in three phases, with a total of 45 piles being driven. In Phase 1, 27 pipe piles were driven to a depth of 4.6 m (15 ft) in frozen silty sand using a Delmag D15 diesel hammer and predrilled, thermally-modified pilot holes. In Phase 2, eight reinforced H-piles were driven to depths ranging from 6.7 to 7.6 m (22 to 25 ft) in frozen silts and sands, using thermally-modified pilot hole procedures similar to those used in Phase 1. Phase 2 also included the installation of two drilled and slurry pipe piles. In Phase 3, ten pipe piles with cast

steel tips were driven into frozen river gravelly sands, using the Phase 1 procedures.

Short-term pile load tests were performed on seven piles and long-term (creep) tests were performed on five piles. For comparative purposes the two slurried piles were subjected to short- and long-term (creep) load tests under conditions similar to those used for driven piles. All piles were loaded until an apparent failure occurred. In the long-term load tests, the piles were loaded until the load-deformation plots indicated that irreversible progressive failure, greater than 0.5-in. (1.3 cm) downward movement, had occurred.

The following paragraphs describe each of the three testing phases and results obtained from them.

PHASE 1 - PILE DRIVING AND LOAD TESTS FOR
PIPE PILES IN FROZEN ICE-RICH
SILTY SAND SOILS

Test Equipment and Installation

The test site near the ARCO airstrip represented typical Prudhoe Bay soil conditions with ice-rich frozen silts overlying frozen sands and gravels. The selected site was the center of a 30 m (100 ft) diameter polygon surrounded by ice wedges.

The test piles were set on a 1.5 m (5 ft) centers grid to allow use of a 3 m (10 ft) long test beam at any location. Vertical load testing equipment was sized to develop a minimum of 3.52 kg/cm² (50 psi) adfreeze working stress and 7.0 kg/cm² (100 psi) adfreeze ultimate stress for a 45.7 cm (18 in.) diameter pile over the embedded test length. For the vertical tests, 273,000 kg (600 kips) capacity jacks were used.

Previous experience with driving in cold weather showed that, if kept warm, single-acting diesel hammers would operate satisfactorily. A decision was made to use a D15 Delmag, single-acting diesel hammer, with a maximum rated energy of 3,750 kg-m (27,100 ft-lb), which turned out to be too large for the smaller 27.3 cm (10.75 in.)

diameter piles. The Delmag D15 hammer was mounted on a Marion 36,000 kg (40-ton) crane with semi-fixed leads. In addition, the test driving experiment required a Nodwell track-mounted Mobile B-61 drill.

Pile Driving - General Approach

The general approach was to establish a method using hot-water-filled, drilled pilot holes that would provide the quickest pile driving without affecting pile integrity. Various pile wall thicknesses and tip reinforcing were used, along with variable thaw times for water in the pilot holes. Pile placement proceeded in the following general manner:

1. Drill pilot hole.
2. Fill pilot hole with hot water.
3. Align driving equipment and pile.
4. Allow for sufficient time for ground around pilot hole to thaw or warm.
5. Drive pile.

Pilot holes were drilled using a Mobile B-61 drill. The pilot holes were 15.2 cm (6 in.) diameter for the 27.3 cm (10.75 in.) and 32.4 cm (12.75 in.) diameter piles, however, 21.6 cm (8.5 in.) diameter holes were used for the 45.7 cm (18 in.) diameter piles. Each pilot hole was visually logged by a field geologist, and site soil samples were recovered for laboratory analysis. Following pilot hole drilling, and for varying periods before driving, the holes were filled with hot water of different temperatures in order to modify soil thermal conditions and determine their effect upon the subsequent driving effort.

Driving Operations and Results

Driving proved extremely easy, when using the hot-water-filled pilot holes, if the water remained in place for sufficient time. In this project, rated hammer energy was rarely developed, except occasionally during the final stages of pile driving. With continuous, uninterrupted driving and proper pilot hole thermal modification, an average driving time of about 5 min was required for the 4.6 m (15 ft) penetration. The diesel impact hammer provided a very important gauge in the pile driving experiment, between success and failure, of thermally-modified piles against piles driven in a drilled pilot hole without hot water. Thermally-modified pile No. 4 recorded 22 blows per 30.5 cm (22 blows/ft) near its tip penetration while pile No. 5 with its dry-bored hole recorded 263 blows per 30.5 cm (263 blows/ft) near its tip penetration.

After the pipe test piles were driven, their interior was reamed and the soil inside and below the test pile tips was removed for inspection purposes. Removal of inside soil 15-30 cm (6-12 in.) below the pile tip allowed pile load testing to measure adfreeze frictional strengths directly without end-bearing effects. Reaming also provided a convenient way to install thermistors to measure pile wall temperatures. The reaming operation was specified for load test

research only and is not to be construed as part of normal construction operations.

After the pile tests were completed, two piles, Nos. 7 and 16, were pulled for further examination of their tip failures. Their progressive tip failures were caused by uneven lateral tip pressures. This type of failure usually occurs during light driving and would not be produced by the axial buckling condition commonly caused by overdriving.

From a structural point of view, pipe piles can be successfully driven into permafrost if certain precautions are taken. Driven into water-filled pilot holes they try to follow the path of least resistance, and if not properly centered in the thermally-modified zone or if they encounter a discontinuity, they will experience variable tip pressures. These in turn are resisted primarily by pile bending and lateral soil pressure. If the tip is not strong enough and thus owing to ring bending cannot resist uneven lateral pressures, a type of progressive tip failure will result. During these tests, four pipe piles (with thinner walls) were driven with tips, however, they were not the hard cast steel types nor were they as thick. Piles with these tips, fabricated from mild steel plates, did prove more successful when tested against similar piles with open ends. The design of the pile tips were flush on the outside to ensure continuous contact to the pile surface and avoid air gaps.

Of the 27 piles driven in Phase 1, using the parameters indicated above, 10 piles were driven without deformation. From the results of various methods tried, Table 1 has been prepared to show the relationship of parameters affecting driving piles in permafrost. Based on these test results, installation of driven pipe piles in frozen silty sands, require pilot holes and, prior to driving, a thermal modification time between 40 and 60 min to prevent tip damage.

In general, for these tests, planned position tolerances of less than 5 cm (2 in.) and plumbness of less than 2% from the vertical were achieved without difficulty. Minor leveling adjustment of piles was accomplished during the pile driving operation by gently pushing the pile into alignment with heavy equipment. Generally, with preparation and care, driving tolerances can be made as accurate as may be required for design.

Short-Term Vertical Load Tests

Purpose and Procedures: Since little adfreeze data exist on piles driven in permafrost and there are virtually no data on piles driven in Prudhoe Bay permafrost conditions, short-term tests were planned to establish starting points for better definition of long-term load and creep rate tests.

Two short-term tests, Pile Nos. 2 and 17 were conducted. Because of the length of time required for pile load distribution, short-term load tests do not produce usable data other than for short-term loading. Additional tests, called "reheat tests", were run on the two test piles

after their initial significant deformation (failure), to determine pile load resistance when allowed a short recovery time of approximately 1 day.

After the driving operations, piles were reamed out below the tip to relieve pile tip support capacity in order to determine adfreeze frictional values after the isolation and elimination of the end bearing effects. Test procedures for Phase 1 included a downward vertical pile load application. Excavation of the top meter (3 ft) of soil adjacent to each test pile assured an effective test length of 3.7 m (12 ft) below the frost heave zone.

Initial readings were taken and loads were applied in increments of 17,850 kg (39,270 lbs). A minimum time interval of 15 min was provided between load applications to allow for pile settlement stability. Periodic deformation readings were taken, and ground temperatures were recorded.

Results: In general, each pile began to show signs of rapid failure after about + 0.38 cm (0.15 in.) of settlement. Tests were carried out to settlement of 0.64 cm (0.25 in.) or more to ensure that maximum resistance conditions had been encountered. Results of the short-term load tests are summarized in Table 2.

Pile No. 17 was driven primarily into massive ice and sustained a short-term adfreeze stress of 5.1 kg/cm² (72 psi) before failure. This was considerably lower than the 7.0+ kg/cm² (100+ psi) values of test pile Nos. 2, 19 and 23 in Table 2, though still significant. Normally, allowable design adfreeze stress considers creep effects for sustained loading conditions and this effect becomes critical when ice is used as structural support.

Reheal tests were run on Pile Nos. 2 and 17 after their deformation (failure) and the short recovery period of 1 day. As indicated in Table 2, the fast recovery of the adfreeze stress of these piles provides interesting data that could be used for short-term pile design use under emergency conditions.

Long-Term Vertical Load Tests

Purpose and Procedure: The purpose of these long-term tests was to add information to the developing data base on design criteria. As experience is gained from long-term sustained pile loading in permafrost, it becomes apparent that, in certain designs, creep-related settlements control rather than adfreeze strength (Nixon, 1976). The design of pipeline supports, with large short-term live loads, has adfreeze strength criteria which will limit the creep to a design limit.

After completion of the short-term tests, the two test beams and equipment were moved to Pile Nos. 19 and 23. Tests were performed by applying sustained loads of 17,850 kg (39,270 lbs) in 2-week load increments. Jack pressure readings,

dial gauge readings, survey levels, and temperature readings were taken every day at night, and before and after load changes.

Results: Figure 1 presents the results of the load test on pile No. 19 during the long-term test. Of particular interest in this diagram is the adfreeze and deformation curve slope, which are indicated for curves within usable design ranges only. It should be noted that, over these usable creep ranges, the average ground temperature remained fairly stable, with only minor deviations during the testing period.

At the conclusion of long-term testing, which concluded after 103 days with a load of 125,000 kg (275 kips) and adfreeze stress of 3.4 kg/cm² (48 psi), pile No. 19 was failed in a manner similar to the previous short-term tests (i.e., every 15 min, jack pressure was increased by loads of 17,850 kg until pile failure). Results of long-term load tests on pile Nos. 19 and 23 are summarized in Table 3.

The short-term tests which were conducted at the conclusion of the long-term testing of pile Nos. 19 and 23 indicated very high short-term adfreeze strengths in permafrost. These values were 8.2 kg/cm² (116 psi) for pile No. 19 and 9.1 kg/cm² (129 psi) for pile No. 23.

PHASE 2 - PILE DRIVING AND LOAD TESTS FOR SLURRY PIPE AND DRIVEN H-PILES IN FROZEN ICE-RICH SILTY SAND SOILS.

Test Plan

Subsequent to the Phase 1 tests in early 1980, Phase 2 tests were initiated to accomplish the following:

1. Establish feasibility and requirements for driving H-piles through a gravel workpad into underlying frozen fine-grained soils.
2. Determine comparative adfreeze strengths, both short- and long-term, for slurry pipe piles and driven H-piles.
3. Determine the feasibility of driving longer pile embedment lengths. Phase 2 piles were driven at least 6.7 m (22 ft) below grade compared to 4.6 m (15 ft) for Phase 1 piles.

Little literature is available regarding the strength of driven piles or the comparative strength of driven versus slurry piles in cold permafrost. For this reason, in Phase 2 it was planned to drive two test H-piles 6.7 m (22 ft) below grade, and place two slurry test pipe piles 6.7 (22 ft) below grade. Six H-piles were also driven 7.6 m (25 ft) below grade for anchor piles. H-piles were structurally designed to resist variable tip loading and localized buckling under driving conditions.

Test Equipment and Implementation

Contrary to the previous pile testing in which the piles were loaded vertically downward, tests

in this series were planned to pull the piles upward, in tension. In this manner, a realistic test of adfreeze strength without pile end-bearing effects could be realized for driven H-piles and slurry pipe piles. For every 1,000 kg of load on the jack, 500 kg of load was transmitted to the test pile.

Pile load jacks, load beams, and equipment were sized for ultimate loads of 7.0 kg/cm² (100 psi) adfreeze, applied to a 45.7 cm (18 in.) pipe pile frozen 4.9 m (16 ft) into the ground. All test piles were cased with a 61 cm (24 in.) diameter pipe down 1.8 m (6 ft), with the annulus filled with an oil-sand mixture and the pile wrapped with plastic in this upper zone to prevent adfreeze bond stresses in the active layer.

The driven piles were placed in accordance with the following procedures:

1. Drill a 15.2 cm (6 in.) pilot hole to the tip elevation.
2. Position pile leads initially with Delmag D15 pile hammer.
3. Fill pilot hole with water heated to a minimum of 66°C (150°F).
4. After waiting 40-60 min for thermal modification of hole in silty sands, drive pile.
5. Keep installation records of blow counts, drive time, water temperature, etc. (See for example, the summary shown in Table 1.)

The slurry test piles were placed in 61 cm (24 in.) diameter holes using a premixed sand slurry with a consistency similar to 15.2 cm (6 in.) slump concrete. Slurry piles were accurately positioned and firmly held in place until freeze-back was assured.

Placement and driving proceeded as expected, except at certain locations where pilot holes were drilled out of plumb. Since driven piles follow the pilot hole closely, this resulted in piles being driven out of plumb. Immediately after driving, piles that were driven out of plumb in excess of test requirements were adjusted into close tolerances by pushing with a Caterpillar 966 loader. This method did not seem to bend or otherwise damage piles treated in this manner, if performed before freezeback occurred.

In summary, the eight H-piles were driven using production driving techniques in an interrupted manner. Actual setup and driving time for individual piles ranges from 15 to 30 min. All piles (except where pilot holes were drilled out of plumb) were driven without difficulty.

Short-Term Vertical Load Tests

Test pile No. 2 was a driven HP 10 x 57 with angle reinforcement. This pile was rapidly loaded in increments of 35,700 kg (78,540 lbs) every 15 minutes. The results are summarized in Table 2.

Test pile No. 9 was a slurry 45.7 cm (18 in.)

diameter pipe pile. Testing proceeded with this pile in a manner similar to that used for pile No. 2 up to the adfreeze value of 6.3 kg/cm² (89.3 psi). At this stress level the pile began to show signs of significant creep, a 15.2 cm (6 in.) diameter pin, which was part of the load beam connecting system, broke at a load of 441,000 kg (970 kips) and the test was terminated. The projected load to failure was estimated at about 455,000 kg (1,000 kips) or near the ultimate equipment capacity. The results are summarized in Table 2.

Long-Term Vertical Load Tests

Test pile No. 4 was a driven HP 10 x 57 with angle reinforcement. The pile failed at 2.1 kg/cm² (30.5 psi) during long-term adfreeze tests, conducted in accordance with the previously outlined procedures. The short-term loading completed at the end of long-term tests indicated maximum adfreeze values of 7.9 kg/cm² (111.8 psi) using the encompassed perimeter and 5.0 kg/cm² (70.7 psi) for the contact perimeter area. The results are summarized in Table 3.

Test pile No. 7 was a 45.7 cm (18 in.) diameter slurry pipe pile. The pile failed at an adfreeze bond stress value of 2.5 kg/cm² (36.2 psi) during long-term tests. Short-term loading completed at the end of long-term tests indicated a maximum adfreeze value of 6.6 kg/cm² (94.1 psi). The results are summarized in Table 3.

PHASE 3 - PILE DRIVING AND LOAD TESTS FOR PIPE PILES IN FROZEN GRAVEL

Test Plan

Ten 27.3 cm (10.75 in.) diameter by 1.27 cm (0.5 in.) wall pipe piles were driven using APF 0-14001 tips in frozen gravel and 15.2 cm (6 in.) diameter pilot holes, drilled 0.61 m (2 ft) deeper than the nominal tip embedment.

Concerns had been expressed regarding driving piles in frozen gravelly soils. As a result, these tests were planned primarily to drive pipe piles with cast steel tips to depths of 4.6 m (15 ft) in frozen gravelly materials. The test site was adjacent to the Sagavanirktok River, where typical riverbed soils included frozen sandy gravels. Following driving, load tests were performed to establish data concerning adfreeze strengths in these soils. Tests were initially conducted during the summer, when ground temperatures are generally warmest and adfreeze values are lowest.

Adjustments were made to the hot water thaw time after initial driven tests indicated high blow counts. It was determined that a 20-min minimum waiting period produced best results before driving in the gravelly soils. Pilot holes drilled in thawed active layer gravels had top-caving problems that interfered with pilot hole thawing. For this reason, pilot holes drilled 0.61 m (2 ft) deeper than the pile tip

embedment helped contain the surface caved-in gravels. A summary of driven piles for Phase 3 is shown in Table 1. The vertical load tests were performed by extracting the piles upward in tension, similar to the Phase 2 load tests.

Short-Term Vertical Load Tests

Short-term testing on pile No. 4 was begun in August 1980 but upon applying 36,000 kg (78.5 kips) tension on the pile, the pile suddenly failed and the test was terminated. Results of ground temperature monitoring indicated that this pile was only embedded in 2.1 m (7 ft) of frozen soil. The calculated adfreeze stress over this region of frozen contact indicates a value of 1.9 kg/cm² (27.7 psi). The calculated adfreeze stress over the 4.6 m (15 ft) of thawed and frozen soil contact equals 0.9 kg/cm² (12.9 psi), as shown in Table 2.

Testing of pile No. 7 began in November 1980 after the previously thawed active layer had refrozen. Results indicated an increase in adfreeze strength over test pile No. 4. The maximum adfreeze bond stress yielded approximately 3.6 kg/cm² (51.7 psi), see Table 2.

Long-Term Vertical Load Tests

Long-term load test procedures were conducted in accordance with the Phase 2 test program. Pile No. 2 failed at approximately 3.4 kg/cm² (48.5 psi) over the embedded pile test length. Pile No. 9 failed at an adfreeze bond stress value of approximately 2.3 kg/cm² (32.3 psi). The results on pile Nos. 2 and 9 are summarized in Table 3.

For piles driven into frozen gravelly sand, the adfreeze values achieved were not as high as those achieved for the piles in frozen fine-grained soils. One contributing condition may have been warmer ground temperatures at this test pile location, which were due to the effect of the river floodplain and time of year.

CONCLUSIONS AND RECOMMENDATIONS

The results of these field tests to verify the practicality of diesel pile driving in cold permafrost, on a production basis using thermally modified, predrilled pilot holes, are encouraging. Subsequent to these tests the use of vibratory hammer for driving production piles has also proven successful. The technique of employing a small drilled pilot hole filled with water heated to a minimum of 66°C (150°F) prior to placement is effective. Thaw time before driving was approximately 30 min for frozen granular soils and 60 min for frozen fine-grained soils in order to raise the surrounding soil temperature and improve the pile driving. A summary of the pile driving tests is given in Table 1.

The results of the pile load tests conducted during this program provided useful information for development of pile design criteria. The pile load testing equipment, especially designed for arctic conditions, worked well. The development

of design criteria should recognize permafrost peculiarities such as loading conditions and creep. For purposes of comparison, Tables 2 and 3 are provided as a summary of short-term and long-term (as compared to short-term) load test data for all load tests.

Generally, differences between soil types were more important than installation techniques in the determination of adfreeze strengths. Driven pile placement methods produced comparable strengths to typical slurried piles in ice-rich silty sandy soils. However, driven piles in frozen gravelly soils indicate lower adfreeze values than ice-rich silty sands due to their location near the rivers and the warmer ground temperature effects.

Some significant factors affecting pile performance are soil temperature, pile diameter, and creep. For design, two conditions should be considered, short-term loading and long-term creep.

Based on results of these tests, it was determined that pipe and H-piles could be driven in permafrost with acceptable accuracy, providing ARCO Alaska, Inc. with a technically sound alternate pile placement method. The thermally-modified pile driving method was ultimately selected in 1980 for the aboveground Kuparuk Pipeline systems design.

ACKNOWLEDGEMENTS

The permission of the owners of the Kuparuk Pipeline System to publish this paper is gratefully acknowledged.

The consultant selected to conduct the test program, under guidelines determined by ARCO engineering, was Mr. D. Nottingham of Peratrovich and Nottingham, Inc. The field construction for the installation of these testing facilities and the surveying services was conducted by VECCO, Inc. Recognition is given to the above for their efforts.

¹ Short-term loading at completion of long-term test.

² Encompassed perimeter area is considered rather than actual contact area, since creep will tend to occur on that basis.

³ Initial test plus reheal test duration.

* Load test attempt failed 2 min after load application. Pile was partially frozen (2.1 m, or 7 ft, from tip) and ground temperatures may have been higher than initially measured due to thermal modification.

Phase 1 load tests were conducted as downward tests.

Phase 2 & 3 load tests were conducted as uplift tests.

TABLE 3 Summary of Long-Term Vertical Load Test Results: Phases 1, 2, and 3.

Test Phase	Pile No.	Size		Soil Type	Placement Method	Monitored Soil Temp. at Failure		Maximum Adfreeze Strength		Test Duration (days)
		Dia. (cm)	Wall (in.)			(°C)	(°F)	(kg/cm ²)	(psi)

¹ Encompassed perimeter area is considered rather than actual contact area, since creep will tend to occur on that basis.

² Failed during short-term testing subsequent to long-term tests (see Table 2).

* Failed during long-term testing. Results are documented graphically in Figure 1.

GEOMORPHOLOGICAL MAPPING AND ENVIRONMENTAL PLANNING
IN PERMAFROST REGIONS

R. Mäusbacher

Department of Geographie, University of Heidelberg
Heidelberg, Germany

With the help of the geomorphological map of Oobloyah Bay, Ellesmere Island, N.W.T., Canada, the applicability of the legend, developed in a priority project of the German Research Foundation, in permafrost regions is demonstrated. In addition, possibilities for the practical applicability of geomorphological information like this are presented. For the user who is informed about the terminology used in geomorphological maps, different levels of information (e.g., slope angles, subsurface material, etc.) can be printed separately. For those not informed about the terminology, the geomorphological information can be prepared with ecological evaluation on the basis of a suitability test, which allows direct use for nongeomorphological problems.

INTRODUCTION

With the financial aid of the German Research Foundation (DFG), there was a research project established in the Federal Republic of Germany in 1976, creating geomorphological maps at scales of 1:25,000 (GMK 25) and 1:100,000 (GMK 100) (Barsch and Liedtke 1980). Focusing on these two different scales, guidelines for the field work activities and the legends of maps were to be developed, applicable to all regions (lowland, mountains, and high mountains) of the FRG. The field work guidelines for mapping the exemplary sheets are based on the legends developed by Leser and Stäblein (1975) for the GMK 25 and Fränzle et al. (1979) for the GMK 100, employing up-to-date international experience in this field (Leser 1981).

The geomorphological map 1:25,000 Oobloyah Bay, Ellesmere Island, N.W.T., Canada, prepared during the Heidelberg/Ellesmere Island Expedition is also based on the legend developed for the GMK 25. The aim of this mapping program was to test the applicability of the legend in a permafrost region.

Considering the ever increasing human activity in permafrost regions, environmental planning in these areas is becoming more and more necessary (Robitaille 1960, St-Onge 1965, Kreig and Reger 1976, Everett et al. 1978). Therefore, the problem of practical applicability of geomorphological information on environmental planning in these regions will be discussed also.

EXPEDITION AREA AND BASE MAP

The expedition area is located in the north-western part of Ellesmere Island, near Oobloyah Bay at 81.5°N and 83.5°W (Figure 1). Geologically, it is a synclinal valley of about 15 km fringed by two anticlines: in the north the so-called Krieger Mountains reaching heights of more than 1,000 m, and in the south the Neil Peninsula, climbing up to 600 m above sea level. This association with the geological structure, however, is only reflected in

FIGURE 1 Location of study site.

major landforms. The landforms mapped at 1:25,000 scale are the product of glacial, fluvioglacial, cryogenetic, and marine processes (Mäusbacher 1981).

For the field survey and the cartographical presentation the author used orthophotomaps at 1:25,000 with 25 and 50 m isolines. These were produced from aerial photographs of the National Air Photo Library, Ottawa, Canada (Hell 1981).

THE LEGEND

Unlike many other legends, this one does not contain a catalog of individual landforms. It is developed on a system of basic elements combined so that the cartographical presentation of the relief

is given by a combination of different layers of information. These levels are differentiated in the following manner:

- . slope angles (divided into three groups: low-land, mountains, and high mountains)
- . axes of curved slope and crest segments and curvatures of hillocks and depressions (basic line >100 m)
- . steps and breaks of slope, valleys, minor landforms, and roughness (basic line <100 m)
- . subsurface material (bedrock and unconsolidated deposits); classification of unconsolidated deposits is given by the German Industrial Standard (DIN) 18196
- . hydrography
- . morphogenetic process areas (only those processes are mapped that are responsible for the latest significant shaping of an area)
- . individual actual processes and traces of processes
- . topography and supplementary information (e.g., drilling site)

The cartographical means of expressions are symbols, colors, and screens.

The advantages and disadvantages of this legend for the preparation of the sheet on Oobloyah Bay is shown in the following remarks:

. The mapping of slope angles is only possible if large scale aerial photos or maps with contour lines are available. As for all detailed investigations, one of these mapping bases are necessary, the mapping of slope angles does not represent any problem.

. Due to thin vegetation cover, morphographical elements such as axes of curvatures, breaks of slope, etc., could be derived from the aerial photographs. Therefore only the morphometrical differentiation (radius of curvatures, heights of steps, etc.) had to be studied in the field. This is a great advantage if the time for field mapping is limited.

. Most of the probings and trenchings had to be carried out at the end of the summer because then the depth of the active layer was thickest. With the aid of information (morphography, hydrography, etc.) previously mapped, it was possible to select more representative probing sites. In addition, these probings made it possible to determine the approximate maximum thickness of the active layer in different soils.

. For the display of the hydrographical situation, the legend had to be extended. This indicates that the legend for hydrography depends more on climatic conditions than does the other information.

. The hierarchical system of decisions for the registration and delimitation of the geomorphogenetic process areas developed for the GMK 25 (Barsch and Liedtke 1980) could not be used. Due to these guidelines, all areas with active processes had to be presented in the same color (orange). Using this system it would not have been possible to differentiate glacial, fluvioglacial, and the other processes. Therefore, active process areas could not be shown. All actual processes are presented with symbols of "individual active processes."

These statements concerning the different items of the legend indicate that the legend developed first of all for geomorphological mapping in Central Europe is also adoptable to permafrost regions.

APPLICABILITY TO ENVIRONMENTAL PLANNING

Geomorphological maps such as geological and soil maps are, first of all, information systems prepared by scientists for scientists. According to the aim of geomorphology is to explain landforms and the processes which create them, geomorphological maps contain a global view of the relief forms, as well as evidence of present and past morphogenetic processes that have contributed to the evolution of the landscape. That means that these maps are very complex with a high data concentration, which makes their reading by a nongeomorphologist quite difficult. Due to the importance of the relief parameters on environmental problems including planning, the content of geomorphological maps must be presented in a form, which is easily understood by nongeomorphologists. With the legend, used in the Oobloyah Bay region, it is possible to derive special maps.

Derivative Maps

Due to the conception of the legend, all layers of information can be printed separately and all combinations are possible (Figure 2). Thereby the

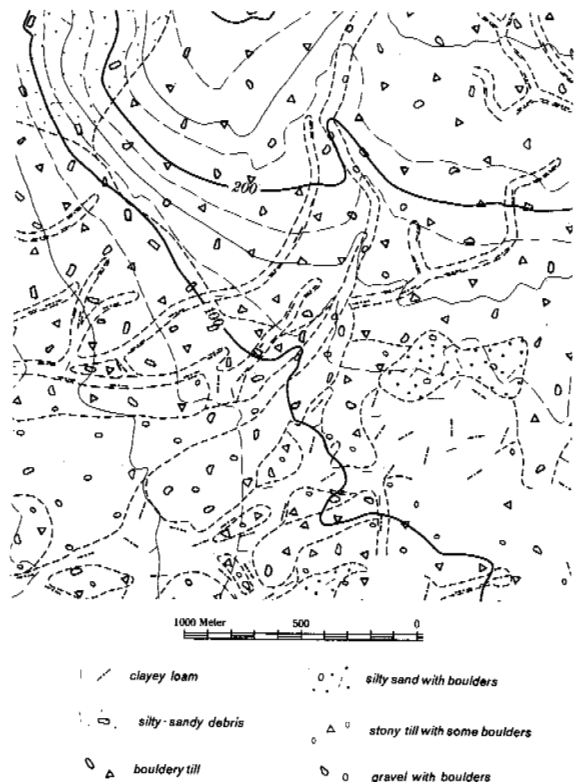

FIGURE 2 Derivative map with only one level of information; substrate near the surface.

density of information can be diminished without loss of information. This is important, as for nongeomorphological problems often only parts of the whole array of information are necessary. Prerequisite to the use of this "derivative map" (Barsch and Mäusbacher 1980) is that the user is well informed about the terminology of geomorphological maps (classification of bedrock and unconsolidated material, definitions for the geomorphological processes, etc.). Therefore, these products will be used first of all by scientists in the neighboring sciences of geomorphology (geology, applied geology, and soil sciences). Several possible applications of the different levels of information are shown in the following examples.

The actual processes, the substrate near the surface, and the slope angle are of great importance for planning infrastructure. Using this information, the estimation of actual and potential danger is possible.

Additionally, by employing the slope angle and the subsurface material, the traffic limitations (load capacity of the active layer, maximum angle of climb for vehicles, and traversing of drainage ways) can be estimated.

In the framework of planning transport arteries (oil pipelines) the encroachment on the environment by defective pipes has to be taken into account. Since the degree of the encroachment is first of all dependent on the distribution (transport by water or gravity) of the damaging material, morphology and hydrography are of considerable influence.

All parameters of the geomorphological map, and additionally the potential radiation derived from slope angle and exposure, are important for soil science and botany because soilgenesis and the distribution of plants in areas without human impact are dependent on the form and genesis of relief (Everett et al. 1978).

For all these examples the necessary transfer of the GMK information for different problems had to be made by the user.

Interpretative Maps

For the potential user who is not versed in geomorphological map terminology, the geomorphologist has to prepare his information in a way which will allow its direct use for nongeomorphic problems. For this preparation, ecological evaluation on the basis of a suitability test, developed for environmental planning purposes, would be a good solution. With this procedure of a land systems classification, different ecological parameters are evaluated with regard to human use and impact (Leser 1974, Seibert 1975). According to the information given by geomorphological map, the land systems classification is realized with a "multiple factor analysis" dominated by relief parameters. That means that the delimitation of the units is carried out with several parameters (morphography, subsurface material, hydrography, etc.), the majority of which are relief parameters. An extract of the land systems map of Oobloyah Bay is shown by Figure 3. These maps can also be used as base maps for soil and vegetation mapping (Everett et al. 1978).

In the second step the parameter used for the delimitation of the land systems will be classi-

fied. But this step is only possible if these para-

meters are already quantified and if threshold values are defined. The latter procedure, at the present time is difficult for many factors because measurements which show the relations between the different parameters (e.g., dependence of slope stability on slope angle and subsurface material) are not available. This problem is also shown by the two following examples.

A very important factor is potential solar radiation because it influences snowmelt, depth of thaw, and distribution and growth of vegetation. These values are not shown directly in the geomorphological map; however, they can be calculated with trigonometrical and astronomical equations using the values of slope angle and exposure (Gessler 1925, Heyne 1969). The values calculated with $\varphi = 80^\circ$ (latitude of the expedition area) and with the slope angles of the GMK 25 Oobloyah Bay are shown in Figure 4.

expo- slope angle	sure	S	SW/SE	E/W	NW/NE	N

15°		302	294	294	241	193
35°		219	209	205	187	150

FIGURE 4 Daily means (only for the days from 22.2 to 19.10) of potential solar radiation in W/m^2 for $80^\circ N$ (expedition area) and the slope angles of the GMK 25 Oobloyah Bay.

According to other authors (Knoch 1963), a scale of five parts is used for the classification of these values, and the threshold values are adapted to the local values. That means that the classes are formed starting with the maximum and minimum values. This is reasonable as long as absolute threshold values are not available, because for most problems the local differentiation is more important. The corresponding classification is shown in Figure 5.

The second example contains the potential danger by actual geomorphological processes, particularly

class	potential solar radiation	valuation
I	300 - 350	very high
II	250 - 300	high
III	200 - 250	moderate
IV	150 - 200	low
V	100 - 150	very low

FIGURE 5 Key for the classification of values of solar radiation.

by landslides and mud flows. For this example the mapped actual processes, the slope angle, and the subsurface material are used as basic values. Threshold values are derived from values of slope angles and the subsurface materials of these areas showing actual geomorphological processes. Due to limited data for this classification, a scale in three parts was selected (Figure 6).

class	slope angle and subsurface material		potential danger
	mud flow	land slides

	stony till	debris over sandstone $0-7^\circ$	

FIGURE 6 Key for the classification of actual geomorphological processes of the sheet on Oobloyah Bay.

In the third step the classified parameters are evaluated by associating suitability values to the different classes. Prerequisite for this type of allocation, however, is knowledge of the degree of influence (positive or negative) which each of these factors display concerning the different problems. Therefore, the evaluation of each problem has to be done separately.

For example, solar radiation controls the process of snowmelt and the depth of active layer. Therefore, the evaluation of these two processes is a precondition for evaluating solar radiation. An example is shown in Figure 7.

The second example monitors the evaluation of the geomorphological processes concerning man-made buildings (houses, roads, pipelines, etc.). In this connection it is postulated that an area with high risk is unsuitable for buildings (Figure 8).

In the last step the factors evaluated for the same problem are combined (e.g., for thickness of the active layer, solar radiation is combined with soil moisture as a function of grain size distribution, and with hydrographical information). This total value is the result of calculating the arithmetical means of the values of suitability for each factor. These values, besides others, form the content of the interpretation map. The cartographical presentation of an interpretation map like this is discussed in Mäusbacher (1983).

class	evaluation	suitability	suitability values
I	very high	very good	1
II	high	good	2
III	moderate	moderate	3

CONCLUSIONS

The legend developed for geomorphological mapping in Central Europe is also applicable in permafrost regions as shown by the Oobloyah-Bay map (Mausbacher 1981). In addition, interpretation of the geomorphological information for non-geomorphological problems is possible. The array of interpretations at this time depends on the threshold values, which are available for the different factors.

ACKNOWLEDGEMENTS

THE INFLUENCE OF SURCHARGE LOADS ON FROST SUSCEPTIBILITY

E.Y. McCabe and R.J. Kettle

Department of Civil Engineering, University of Aston in Birmingham, U.K.

When a frost susceptible soil is frozen and the heave is restrained, either partially or completely, heaving pressures will also be generated. The work reported in this paper describes a laboratory study of the interactions between heave, heaving pressure, and surcharge pressure. The tests were performed on a highly frost susceptible mixture of sand and ground chalk to which various amounts of coarse aggregate were also added to produce a range of granular mixtures. The frost heave and heaving pressures were determined for these materials. To quantify the effects of surcharge, several levels of loading were applied to the freezing specimens, with either dead loads or an air-diaphragm system, to produce surcharges between 3 and 120 kN/m². Freezing behaviour was clearly modified by the application of surcharge loads, and for each material a hyperbolic relationship was established between frost heave and surcharge. Although the complete elimination of frost heave was not achieved, the application of low surcharges produced large reductions in heave. The surcharge required to render each material non-frost susceptible was dependent on heaving pressure rather than frost heave, as demonstrated by the ratio between surcharge pressure and heaving pressure. Typically, a 5% ratio was sufficient to achieve a 50% reduction in heave.

INTRODUCTION

Reductions in heave, following increases in the overburden pressure, have been widely reported in literature, and this approach has been suggested as one of the possible ways of controlling frost action in frost susceptible soils. It is unlikely that heave could be completely eliminated in many engineering locations, such as highways or airfield construction, because of the high surcharges that could be required. However, with structures such as pipelines and LNG tanks, the weight and stiffness of the structure could provide significant restraint to the heave forces developed in the soil. The associated pressures will act on the structure and must be allowed for during design so that the inter-relation between heave, heaving pressure and overburden pressure is of considerable interest.

The influence of surcharges, or overburden pressures, were reported some fifty years ago (Taber 1930, Beskow 1935) and since then others have demonstrated that surcharges can reduce the heave exhibited both in the laboratory and the field (Aitken 1974). It has been suggested (Hill and Morgenstern 1977, McRoberts and Nixon 1975) that there is a critical "shut-off pressure" at which moisture transfer to the freezing front ceases so that subsequent heave may be controlled. More recently, however, it has been demonstrated (Penner and Ueda 1977) that no "shut-off pressure" exists for soils, providing that freezing is continued for a sufficiently long period, although marked reductions in heave rate are produced when an external load is applied. Under such conditions, frost heave will coexist with the developed heaving pressures.

Takashi et al (1971) derived an empirical

equation connecting heave and surcharge load and again underlined that the complete elimination of heave would be difficult. The majority of the investigations have been concerned with the relationship between heave and surcharge stress. However, this investigation has been concerned with the inter-relationships between heave, heaving pressure, and surcharge stress. Of particular interest has been the level of surcharge required to render the soils non-frost susceptible, as defined by the U.K. criterion (Crony and Jacobs 1967).

MATERIALS

These have been considered (McCabe 1982) as mixed granular materials produced by artificial blending. The basic matrix consisted of a highly frost susceptible mixture of sand and ground chalk (ratio 4:1). Three types of coarse particles were selected -- blastfurnace slag, basalt, and limestone -- each presieved to the 3.35-20mm group. Each aggregate was blended with the matrix to produce various mixtures containing up to 50% coarse particles.

Outline of the Investigation

Initially a series of frost heave and heaving pressure tests were performed on mixtures containing up to 50% coarse particles. The frost heave was measured in the cold room following the procedure of the TRRL frost heave test (Crony and Jacobs 1967, TRRL 1977). The heaving pressures were determined when the heave was restricted by a stiff reaction frame. The specimen was supported in a multi-ring cell and frozen from the top by using a thermoelectric device (TED) or a cryostat

system. Detailed results are reported elsewhere (Kettle and McCabe 1981, McCabe and Kettle 1982, McCabe 1982). From these results a limited number of mixtures were selected for the study of the influence of the surcharge. These were made on the basis of the following conditions:

1. Materials with similar heaves, but different heaving pressures (30% slag, 30% basalt).
2. Materials with similar heaves and similar heaving pressures (30% basalt, 20% limestone).
3. Materials with different heaves, but similar heaving pressures (30% basalt, 10% limestone).

The data for these materials are collected in Table 1.

TABLE 1. Heave and Heaving Pressure Results.

Materials	Total Heave (mm)	Heaving pressure (kN/m^2)
matrix	25.0	300
30% slag	16.0	192
30% basalt	16.4	250
20% limestone	16.4	246
10% limestone	18.4	254

SURCHARGE TEST PROGRAMME

Low Level Surcharge

It was considered (McCabe 1982) that low-level surcharges could be produced by placing steel weights on top of the frost heave specimens, with the self refrigerated unit (SRU) being the most suitable facility for such tests. The specimens were prepared following the standard procedure for the TRRL frost heave test (Cronney and Jacobs 1967, TRRL 1977). The specimens are wrapped in waterproof paper in the standard test, but this was not sufficiently strong to provide adequate lateral support to the surcharged specimens. Oversize Tufnol rings were, therefore, slid over the paper-wrapped specimens, and this system was shown (McCabe 1982) to produce similar results to those of the standard specimens. The conditioning and freezing procedure followed that of the standard TRRL frost heave test, apart from the application of the surcharge. The steel weights were applied to the top of the specimen when it had just started to freeze with a heave of 0.1 mm. This occurred approximately 10 hours after the start of the test. Application of the surcharge before frost action had commenced could produce consolidation in the material and so modify the effects of frost action. It was considered that if the steel weights were placed directly on the Tufnol cap they could modify the boundary conditions since they would rapidly cool to -17°C . It was, therefore, decided to place the weights in a slightly elevated position, on a wooden support table, so that air could circulate above the specimen as in the standard test.

High Level Surcharge

It was not possible to apply surcharges greater than 16 kN/m^2 with the dead weights, and so a Bellofram air diaphragm was employed. This was

used in conjunction with a controlled heave unit (CHU) (McCabe 1982). The specimens were produced as for the Low Level Series and positioned in the CHU as shown in the arrangement detailed in Figure 1. The specimen was conditioned for 24 hours at $+4^{\circ}\text{C}$ and frozen from the top by using a circulating cryostat. The air diaphragm was not connected to the air supply until freezing had commenced, so as to, again, prevent pre-test consolidation. The frost heave was continuously monitored on a trace recorder. The test was normally stopped when the rate of increase in heave was less than 0.01 mm/hour (McCabe 1982), and at least two tests were performed on each material.

FIGURE 1. Modified CHU for frost heave test with surcharge.

DISCUSSION OF THE RESULTS

Low Level Surcharge

The results for the sand-snowcal matrix are given in Table 2, and those for the selected aggregate-matrix mixtures are given in Table 3. It can be seen from Table 3 that, although the 30% slag and basalt mixtures have similar frost heaves without surcharge, the basalt mixture requires a much higher surcharge to reduce the heave to the non-frost susceptible value of 9.75 mm. It is interesting to note that the basalt mixture developed a higher maximum heaving pressure than the slag mixture. The sand/snowcal matrix, with even higher values of frost heave and heaving pressure, also required significantly higher surcharges to reduce the heave to values below the 13 mm criterion for frost susceptibility as is apparent from the results in Table 2.

TABLE 2. Frost Heave Values for Sand/Snowcal Matrix Under Different Levels of Surcharge.

Surcharge (kN/m ²)	Heave (mm)	Surcharge Heaving Pressure (%)
0	25.01	0
3.25	20.79	1.1
7.86	18.23	2.6
12.48	13.91	4.2
15.25	12.25	5.1

The 30% basalt and 20% limestone mixtures, as indicated in Table 3, required similar surcharges to reduce the frost heave to approximately the same value. However, the 10% limestone mixture which initially had a higher frost heave but a similar heaving pressure to 30% basalt and 20% limestone mixtures, required a similar level of surcharge to achieve similar heaves to those developed by other mixtures. It appears, therefore, from the above results that the heaving pressure dictates the behaviour of a particular material under surcharge. Those materials that had developed higher heaving pressures required greater surcharge to reduce the frost heave and, hence, the frost susceptibility.

In order to examine this influence, the surcharges were expressed as proportions of the appropriate maximum heaving pressure. It is clear from Tables 2 and 3 that all the materials exhibited a reduction in frost heave as the surcharge ratio was increased. Of particular interest, it is apparent that with all the materials the frost susceptibility classification was reduced from highly frost susceptible to non-frost susceptible (below 13 mm) with comparatively low surcharges -- equivalent to 4-5% of the maximum heaving pressure.

To investigate this relationship, the percentage reduction in heave was calculated and is plotted in Figure 2 against the level of surcharge, expressed as a percentage of the maximum heaving pressure. A regression analysis revealed a linear relationship between the two parameters ($r = 0.96$) and this regression line can be expressed as:

$$Y = 8.81X$$

where Y is the reduction of heave (%) and X is the surcharge/heaving pressure ratio (%).

Thus, for all the materials tested only a relatively low surcharge was required to reduce frost susceptibility, and this may be calculated if the frost heave and heaving pressure are known.

FIGURE 2. Relationship between reduction of heave and surcharge ratio.

High Level Surcharge

The results are summarized in Table 4 and are presented in Figure 3 together with the data from the previous section for the low-level surcharge. The relationship between frost heave and surcharge is hyperbolic, which agrees with other experimental work (Nakazaka and Ueda 1976) and theoretical considerations (Kaplur 1970). It can clearly be seen that in order to reduce the frost heave to below 10 mm, only relatively low surcharges are necessary, although limited movement is still apparent at high surcharges. Indeed, movements of the order of 0.1 mm, corresponding to the stiffness of the load cell (McCabe 1982), accompanied the maximum pressures recorded in the heaving pressure tests. It would, therefore, appear that for the materials tested shut-off pressures were not achieved. Thus, while it was not possible to eliminate heave completely, it is reduced through an increase in the surcharge.

FIGURE 3. Frost heave against surcharge.

The surcharge is not uniquely related to frost heave. It can be seen from Figure 3 that different surcharges are necessary for different materials to produce a given value of heave. Those materials with higher frost heaves and, especially, heaving pressures required higher surcharge for a given reduction in frost heave and hence frost susceptibility.

FIGURE 4. Reduction of heave against surcharge ratio.

In Figure 4 the reduction in heave is plotted against the ratio of surcharge to heaving pressure, including data from Figure 2. It appears that there are two separate relationships between the reduction in heave and the surcharge ratio. At low levels of surcharge, up to 5% of the heaving pressure, there is a very clear relationship such

that quite small changes in the surcharge produced marked differences in the reduction of heave. A surcharge ratio of approximately 5% is sufficient to reduce the heave by 50%. However, significantly higher levels of surcharge are required to achieve larger reductions in heave, so that for the complete elimination, if possible, of heave would require extremely high surcharges.

From these experimental results it seems that the magnitude of heaving pressure dictates the behaviour of a soil when frozen under surcharge loads. Typically, for two materials with similar frost heaves but different heaving pressures, the material that developed the higher heaving pressure required a higher surcharge to achieve the same reduction in heave. Thus, the magnitude of any reduction in heave depends on the heaving pressure rather than the initial heave value.

This investigation is currently being extended to study the heat flow through the surcharged specimens when subjected to controlled freezing. These measurements are being coupled with the water intake rate so that linkage may be developed between the thermal parameters and the soil properties to predict frost heave and heaving pressures.

CONCLUSION

1. Relatively low surcharges produced reductions in frost heave and hence frost susceptibility.
2. The frost heave was related to surcharge by a hyperbolic curve that depended on the type of material.
3. For all the materials, the surcharge required to render a material non-frost susceptible was dependent on the heaving pressure rather than the frost heave.
4. The ratio of surcharge pressure to heaving pressure can be used to predict the reduction in heave. A ratio of approximately 5% was sufficient to achieve 50% reduction in heave and so considerably modified the frost susceptibility.
5. The complete elimination of the frost heave was not achieved, even at high levels of surcharge, although frost heave was considerably reduced.

ACKNOWLEDGMENTS

The authors wish to thank the University of Aston for making available facilities and for providing the opportunity to undertake the research reported in this paper. An acknowledgement is also extended to the Science and Engineering Research Council for assistance in funding the continued investigation.

AN INVESTIGATION OF TRANSIENT PROCESSES
IN AN ADVANCING ZONE OF FREEZING

R. W. McGaw, R. L. Berg, and J. W. Ingersoll

U.S. Army Cold Regions Research and Engineering Laboratory
Hanover, New Hampshire 03755 USA

Studies have indicated a relation between subfreezing temperature in a fine-grained soil and pressure (moisture tension) in the film water adjacent to an ice lens. During the experiments reported here, concurrent measurements were obtained of temperature and pressure in the liquid water phase of a freezing silt soil. Freezing was from the top down utilizing an open system, with the water table held at the base of a specimen 30 cm long. The freezing front advanced into the specimen at a generally decreasing rate from 20 mm/day to 5 mm/day. The tests utilized a special tensiometer developed at CRREL that continues to measure moisture tension below a temperature of 0°C as long as continuity with the unfrozen water is maintained. Moisture tensions were registered continuously up to 75 kPa (0.75 atm), after which the tension remained constant or decreased slightly. Temperature corresponding to the maximum tension was -2.0°C; the tensiometers were unfrozen at this temperature. Atmospheric pressure was indicated in the soil water until the local temperature was colder than about -0.45°C. Combining the pressure-temperature data with data on unfrozen water vs. temperature resulted in an apparent moisture characteristic for the unfrozen water phase that is dependent on temperature.

Taber (1918) first showed that the major cause of volume increase when a moist soil freezes is the formation of segregated ice, i.e., ice composed of water in excess of that which was already present in the unfrozen soil. Subsequent investigators are still seeking a rational explanation for the drawing-up of excess water from lower depths in response to freezing.

Beskow (1935) and others have demonstrated that a gradient of negative pressure (i.e., suction) develops within the moisture phase of a fine-grained soil during freezing. It is known that liquid water can withstand tensions equal to several hundred atmospheres owing to its intrinsic molecular cohesion. However, the presence of dissolved air typically reduces the measurable tension to the order of one atmosphere, inasmuch as the nucleation and expansion of bubbles locally interrupts the continuity of the water phase in the soil.

Although moisture tensions are known to exist below an advancing freezing front, and are suspected to exist within the freezing zone itself, the seat of these tensions has not yet been adequately explained. Recent attempts by Derjagin and Churaev (1978), Loch (1978), Miller (1978), O'Neill and Miller (1980), and others to develop comprehensive theories of frost heaving that could rationalize this and other occurrences during freezing have not been fully successful. Such theories have required critical assumptions in their development that pertain to the levels of temperature and pressure existing within the freezing zone itself. These assumptions are at present supported by little or no substantive experimental information.

In an effort to begin to remedy this situation, the tests reported here were designed to provide concurrent measurements of temperature and pressure in the moisture phase of a freezing silt soil.

MATERIALS AND METHODS

Two silty soils were each frozen unidirectionally by applying increasingly colder temperatures to the upper surface with the lateral surfaces insulated. The two soils used were Graves sandy silt from western Massachusetts and Northwest silt from the vicinity of Fairbanks, Alaska. These soils were frozen in a saturated condition at densities of 1.60 and $1.39 \times 10^3 \text{ kg/m}^3$, respectively. Selected physical properties are listed in Tables 1 and 2.

Experimental results for the Graves sandy silt are presented in this paper. Analysis of the results for the Northwest silt is presently in progress and will be reported in a subsequent paper, together with a comparison of the behavior of the two soils.

A special apparatus was designed and fabricated to contain the 30-cm long soil specimen during freezing and to support the devices for measuring temperature and moisture tension. Top and bottom temperatures were maintained to a tolerance of 0.01°C by separate fluid baths; the upper temperature was adjusted daily to cause the advance of a freezing front into the specimen at a generally decreasing rate between 20 mm/d and 5 mm/d over a 24-day period. The specimen was subsequently allowed to thaw over an 8-day period.

De-aired water was supplied continuously to the bottom of the soil through a porous stone connected to an external water supply, which was maintained at a temperature of 4°C. The external water table was held level with the bottom of the specimen.

Temperatures along the length of the soil column were measured using closely spaced thermistors mounted within the wall of the containing vessel. It had been determined that this arrangement registers actual soil temperatures within 0.05°C.

TABLE 1 General properties.

*Similar to U.S. modified AASHO procedure.

Moisture tensions were measured in the unfrozen and the frozen portions of the soil column by means of special tensiometers designed at CRREL to respond to moisture tensions both above and below 0°C. These tensiometers have been described in detail in McKim et al. (1976). Briefly, they differ from conventional tensiometers in two respects: a) the sensing element is a strain gauge mounted on an internal metal diaphragm that is vented to atmospheric pressure on the side away from the soil; soil moisture tension is applied to the forward side of the diaphragm in the conventional way through a porous ceramic tip; and b) the porous tip in contact with the moist soil is filled with a 10% solution of ethylene glycol and water, which remains unfrozen to a temperature of approximately -4°C (25°F).

During the development of these devices at CRREL it had been determined that a) the antifreeze does not diffuse into the soil water (because the ethylene glycol molecule is both large and hygroscopic); b) in 10% aqueous solution, the density of the antifreeze is 1% greater than that of water, but its viscosity is twice that of water; c) within experimental error the calibration with soil moisture tension is found to be the same for a 10% solution as for water (surface tension of the aqueous solution being only 5% greater than that of water). The physical properties referred to here are from data given by Dow Chemical Co. (1956).

Experimentally, the use of a strain gauge transducer (rather than a manometer) provided a very fast response to rapidly changing moisture tensions in the transient freezing situation. This effect was the result of the extremely small volume changes required to deflect the diaphragm and thereby to register the amplitude of the moisture tension.

RESULTS AND DISCUSSION

During the freezing tests, temperatures to the

nearest 0.01°C and moisture tensions to the nearest 0.1 kPa (0.001 atm or approximately 1 cm water) were recorded once daily along the full length of the soil specimen. Immediately following each reading the temperature at the surface was reduced by 0.5°C to maintain a continuously advancing frost front during the subsequent 24-hr period. By this procedure each set of readings represented the response of the freezing specimen 24 hours after a change in applied surface temperature, essentially ensuring that the measured tensions were in phase with the measured temperatures.

Figure 1 is an example of the data obtained daily for temperature and moisture tension in the Graves sandy silt, plotted as a function of depth. Figure 2 is a graph of moisture tension vs. temperature in the freezing zone for the entire test period; data are shown for depths of 5, 10, and 15 cm below the original surface.

Several occurrences are notable in the record of moisture tension at temperatures below 0°C. Not only was tension registered continuously by the tensiometers, but the pressure differed significantly from atmospheric only when the local temperature of the soil was colder than about -0.5°C. The level of moisture tension then increased rapidly as temperatures became lower, finally reaching an apparent maximum tension between 70 and 80 kPa (0.7 to 0.8 atm). Thereafter, the tension remained constant or decreased slightly. The temperature associated with the apparent maximum moisture tension was approximately -2.0°C for the Graves sandy silt.

In these tests, no attempt was made to monitor the location or amount of ice formation behind the freezing front. Ice was clearly present because heaving was measured at the surface of the specimen. Nevertheless, the continuous recording of moisture tension by the tensiometers indicates that an unfrozen (liquid) water phase remained that was continuous with the liquid in the tensiometer.

APPARENT MOISTURE CHARACTERISTIC FOR UNFROZEN WATER IN A FREEZING ZONE

Figure 3 is a graph of the unfrozen water content for this soil as a function of the below-freezing temperature; this plot is a transcription of unfrozen-water data measured by a nuclear magnetic resonance (NMR) procedure described in Tice et al. (1982). At the time of this writing, the data

shown were unpublished (Tice, personal communication).

Combining the data of Figures 2 and 3 provides an important new step in the assessment of frost heaving, and results in an apparent moisture-tension characteristic for the water remaining unfrozen behind the freezing front (Fig. 4). The combining of pressure and temperature information in this way rests on the assumption that the pressure measured by the tensiometers is that of the unfrozen water itself, i.e., that the state of water in the active freezing zone is the same as it is in Tice's steady-state tests.

An observed correspondence in the two types of test supports this assumption: the temperature of initial nucleation found by Tice on cooling when he seeded with ice (-0.45°C) is very nearly the same temperature at which moisture tension first exceeds the hydrostatic level in the advancing freezing front. Moreover, a steep gradient of moisture tension develops at temperatures colder than -0.45°C , giving rise to the probability that it is the pressure of the unfrozen water that is being measured.

It is important to note that the moisture characteristic presented in Figure 4 represents the pressure of liquid water measured relative to the atmosphere external to the specimen. This is because the reference gas in the tensiometer (i.e., on the non-wetted face of the diaphragm) is the atmosphere of the room; a tube in the tensiometer assembly provides a positive vent to the ambient air. Thus, the tensiometer reading is the actual pressure in the liquid water behind the freezing front. This test does not determine what interfaces exist within the soil in conjunction with the water.

Unlike a moisture characteristic for an unfrozen soil, the freezing-zone moisture characteristic is not independent of temperature. Each

FIGURE 3 Unfrozen water content vs. temperature for Graves sandy silt (data by Tice).

intersection of moisture tension and unfrozen water content on a plot such as Figure 4 corresponds to a narrow range of temperatures below 0°C. The observed range of temperature is most likely the result of local variations in gradation, density, or water content in the vicinity of the tensiometer. In addition, a normal moisture characteristic corresponds to an air/water interfacial system within the soil; the freezing-zone moisture characteristic probably conforms both to a water/ice interfacial system with a lower intensity of surface energy, and an air/water interfacial system within the soil somehow coupled to the former.

SUMMARY AND CONCLUSIONS

In the tests reported here, a silty soil was frozen unidirectionally using specially designed apparatus that allowed the measurement of moisture tensions and temperatures in the freezing zone. The highest (warmest) temperature at which significant moisture tension developed was approximately -0.45°C, which corresponded to the warmest nucleation temperature for ice measured independently in steady-state tests for unfrozen water on the same soil.

FIGURE 4 Freezing-zone moisture characteristic between unfrozen water and external atmosphere for Graves sandy silt.

The measured variation of moisture tension took place in a zone approximately 7.5 cm (3 in.) in vertical dimension bounded by the temperatures of -0.45°C and -2.0°C. The level of moisture tension observed ranged from nearly zero (hydrostatic) to 75 kPa (0.75 atm).

Water flowed through the unfrozen soil below the freezing zone under a moisture tension gradient that was barely detectable, consistent with the measured water intake and the estimated hydraulic conductivity of the soil tested. Moisture tension gradients in the freezing zone reached a maximum of approximately 7.0 kPa/cm (1 atm/15 cm).

Utilizing measured values of temperature, moisture tension, and unfrozen water, a freezing-zone moisture characteristic was derived for the soil tested. For moisture tensions from 0 to 75 kPa the unfrozen water content in the freezing zone was in the range 2% to 3% by dry weight.

The capability of deriving the freezing-zone moisture characteristic for a frost-susceptible soil represents an important development in the prediction of the amount of segregated ice in a freezing soil. The resulting correspondence among the factors of temperature, moisture tension, and unfrozen water content will provide a better calibration of existing simulation models of the frost

heaving process and may lead to computer algorithms for the freezing zone that are more nearly physically based than those presently in use.

BENEFITS OF A PEAT UNDERLAY USED IN ROAD CONSTRUCTION ON PERMAFROST

Robert L. McHattie, Senior Research Engineer and
David C. Esch, Chief of Highway Research

STATE OF ALASKA DEPARTMENT OF TRANSPORTATION AND PUBLIC FACILITIES
DIVISION OF PLANNING AND PROGRAMMING-RESEARCH SECTION
2301 Peger Road, Fairbanks, Alaska 99701

In 1973, two adjacent experimental road sections incorporating peat underlays were constructed on a permafrost foundation site near Fairbanks, Alaska. The project's objective was to determine if the theoretical advantage of such a design technique would in fact prevent thawing of the thermally unstable foundation. Because the thermal conductivity of peat is much lower in a thawed condition than when frozen, it should act as a summertime thermal barrier while allowing considerable winter refreeze to occur. Field studies have continued through 1982 in order to estimate the long term consequences of this construction method.

Results indicate that a 0.75 m thick layer of consolidated peat can provide significant protection against permafrost degradation under at least the central portion of a road embankment in a warm (-1°C) permafrost area. However, side slope and ditch area thawing and settlement problems, which result primarily from the insulating effects of snow cover, were not prevented by the installation of the peat underlay.

INTRODUCTION

Thaw consolidation due to the melting of ground ice is a costly problem associated with road construction on permafrost. Embankment thicknesses necessary to prevent thaw and differential settlement are often economically impractical. This is especially true in discontinuous permafrost areas where permafrost temperatures approach 0°C. Under such conditions, highway construction methods are usually employed which avoid disturbance of the natural ground cover and in particular, cut sections. This report summarizes a 9 year field study of experimental roadway cut sections which utilized peat as an underlay material in an attempt to reduce or prevent differential settlements. These sections were placed within a new roadway alignment traversing warm permafrost and located approximately 97 km southeast of Fairbanks, Alaska.

Because of its high moisture content and, therefore, high thermal mass, peat has been used in Norway since 1903 as a soil replacement layer to control frost heaving under railways and roads (Skaven-Haug 1959) (Solbraa 1971). However, with a frozen conductivity nearly twice its thawed value, peat should be better suited to preserving a frozen state than a thawed one. This behavior suggested placement of peat into road embankments where a warm permafrost foundation must be maintained.

PHYSICAL SETTING

The study site is located on the Richardson Highway, about 106 km southeast of Fairbanks. The field site is about 1.6 km north of and 76 m above the Tanana River in an area of rolling hills. A cut of up to 9 m in frozen silt was required as a

part of a realignment constructed in 1972 and 1973.

The roadway cut intersects a contact between a weathered and frozen schist bedrock and frozen aeolian silt. The natural ground surface is composed of a 0.3 m layer of miscellaneous organics topped by 0.2 to 0.3 m of sphagnum moss. The insulating quality of the surficial organic mat has resulted in a local active layer thickness of 0.5 to 0.8 m. Indigenous black spruce trees have minimized summer's solar heating and the winter's insulative snow layer.

Local silts were characterized by organic contents between 3 and 7% by weight, with 90% minus 0.074 mm, 10% minus 0.01 mm particle size fractions. Excluding the active layer, silt moisture contents decreased with depth and ranged between 30 and 87%, averaging 47%. All samples were above their liquid limit values of 23 to 30%.

Moisture contents within the schist bedrock ranged between 16 and 22%, indicating some potential for thaw-settlement within this material.

Climate conditions at the site are average for interior Alaska with cold dry winters and warm dry summers. The mean site air temperature averaged approximately -3.9°C with short duration extremes of about -51°C and +35°C. Fairbanks weather records compiled since 1931 indicated annual freezing and thawing indices near -3,080 and +1,830°C-days respectively.

DESCRIPTION OF THE RESEARCH SITE

A location was selected for the peat study between Stations 3246+30 and 3252+17 on a Richardson Highway reconstruction project. Figure 1 shows a plan view of the research site. Note that stationing locations described in this report are in English units (feet).

FIGURE 1 Plan view of research site

GENERAL DESIGN

Calculations of seasonal thaw depths used for design of the study sections were based on the Modified Berggren method (U.S. Army 1966). Assumptions made for the in-place peat materials included an equilibrium moisture content, after thawing, of 125% and an unfrozen moisture content of 40% in frozen peat. Frozen peat was used because thawed material was not readily available for construction purposes. Calculations indicated that maximum seasonal thawing would advance 0.6 to 1.0 m into the consolidated peat, covered by a 1.5 m gravel layer and an asphalt pavement. For peat placed in an initially frozen state, it was apparent that consolidation would occur in any portion subsequently thawed. Thaw consolidation tests indicated that the peat would compress to about 60% of its original thickness under 1.5 m of fill.

Only a thin granular overlay was initially placed above the peat to carry construction traffic and to promote maximum thaw and consolidation of the peat during construction. A one year waiting period was specified prior to fill completion and pavement placement, to ensure consolidation of the peat layers. Initial (frozen) peat layer thicknesses of 1.2 to 1.5 m were selected, to give consolidated thicknesses of approximately 0.7 and 0.9 m.

For purposes of comparison, a 30 m long control section, similar to the 1.2 m peat embankment design but containing no peat, was also placed within the construction cut. It was to be built using only granular fill and calculations indicated that a maximum yearly thaw of about 4.6 m could be expected. The control, 1.2 m and 1.5 m experimental sections will be referred to as sections A, B

and C respectively.

INSTRUMENTATION

One cross-section located in each of the three test areas was selected for temperature monitoring instrumentation. A system of 204 transducers was installed for monitoring thaw depths and temperature changes with time. An undisturbed forest location 27 m left of the road centerline was also instrumented for purposes of general comparison.

Settlement plates were installed at the top, middle and base of the peat layers in sections B and C so that consolidations within and beneath the peat could be measured. Air temperatures were recorded continuously, as were pavement and side slope temperatures at a depth of 2.5 cm. Temperatures along all the transducer strings were recorded monthly.

CONSTRUCTION

Hand clearing of the test area began July 9, 1972. No cut excavation or removal of the insulative moss layer was allowed until daily average temperatures approached freezing. All excavation and placement of frozen peat materials was accomplished between October 16 and 27, 1972, under subfreezing air temperatures. Minor thawing occurred only on the south facing cut slope prior to winter. A total of 4,770 cubic meters of frozen peat was placed in a 1.2 m thickness (sta. 3248+10 to 3249+80) and 1.5 m thickness (sta. 3250+00 to 3251+65).

Construction of the test sections was done in two stages. The 1972 construction included peat placement followed by a 0.9 to 1.2 m covering of decomposed granite. This stage ended November 1, 1972 and normal traffic was allowed over the section during the 1972-1973 winter. Work resumed on the study sections on June 24, 1973. The embankment was raised to final subgrade profile with alluvial gravel, followed by placement of 15 cm of subbase, 11.4 cm of base course and a 3.8 cm thick asphalt concrete surface. The test section was completed July 24, 1973, about a year ahead of schedule. Early completion was problematical, because a year of peat thaw and consolidation was part of the initial research design strategy to prevent excessive postconstruction settlements.

MATERIALS

Properties of embankment materials used in this study are indicated in Table 1. Thermal properties were estimated based on moisture and density data.

Frozen peat used as embankment fill ranged in structure from coarse to fine fibrous. Moisture and organic contents varied from 124 to 300% and 39 to 54% respectively. Compacted wet density was approximately 945 Kg/m³. Thaw consolidation tests indicated that under 1.5 to 1.8 m of fill, the peat would compress to about 60% of its initial thickness. Moisture contents after thaw consolidation testing averaged 95%.

TEMPERATURE AND SETTLEMENT OBSERVATIONS

General Temperature Observations

Annual temperature and snowfall data are summarized in Table 2. Site air temperatures averaged -3.2 degrees C during the period of study. Air freezing and thawing indices averaged -2,900 and 1,940°C-days, respectively.

Surface temperatures and their relationships to air temperatures are presented in Table 3. The N factors calculated for these freezing and thawing

* Instrumentation used for measuring surface temperature variations was removed during the summer of 1977.

TABLE 2 Climatological data table

seasons refer to the ratio of ground to air freezing and thawing indices. Average air and surface temperatures, calculated over the same 2½ year period, indicate average air, pavement and side slope surface temperatures to be -4.6, -1.1 and 2.9°C, respectively.

The subsurface thermal regime was greatly affected by surface temperature differences between centerline and side slope/ditch areas. Annual refreeze at the centerline of both peat sections extended through the seasonal thaw zone during all years of the study. In contrast, a perennially thawed zone or "talik" developed

** Snowfall data is from Eielson A.F.B., located 48 km northwest of site.

TABLE 3 N Factors

under the control section centerline after the unusually warm winter of 1976-1977. Maximum seasonal thaw depths have continued to increase under sections A and B. Only section C provided enough thermal barrier to actually stabilize and in fact contain annual thaw penetration.

Ditch and side slope areas experienced very little wintertime cooling due to heavy wintertime accumulations of snow. Progressively deeper thawing under shoulders and side slopes of all test sections, due to the lack of seasonal cooling, produced taliks that continued to grow through the duration of the study.

Temperature versus depth

Seasonal lag is the response time necessary for seasonal surface temperature extremes to be reflected at a given depth. An assessment of the data indicates that seasonal temperature lag was virtually unaffected by the presence of the peat. Temperature extremes within the permafrost layer shifted by approximately 16-20 days per meter of depth.

Temperatures at depths below 9 m are indicated by the deep thermistor data plotted on Figure 2.

FIGURE 2 Temperature history of deep thermistors

Prior to 1977, the peat insulated sections were characterized by temperatures which were yearly variable but generally decreasing. No such seasonal variations occurred in the non peat control section, which has continually warmed since 1974.

Bottom thermistor temperatures of all sections have risen since 1977. This trend has been strongest in the peat sections (B and C), which have become warmer at depth than the control section. A slight, local warming trend is further evidenced by the natural ground thermistor, which has indicated slight warming since about 1979.

Heat Flow Analysis

The test sections can be compared on the basis of vertical heat flows into and out of the underlying permafrost. Cumulative heat flows were estimated based on vertically spaced thermocouple pairs located within the permafrost, just below the depth of maximum thaw. Since the soil between thermocouples remained frozen, a constant conductivity of 2.1 W/mK, estimated from known soil

moisture and density conditions (Kersten 1949), was assumed for the analysis.

Cumulative heat flows in terms of kJ/m^2 are plotted on Figure 3. Positive values indicate a net accumulation of heat going into the ground (net warming), while negative values indicate a net heat loss or net cooling. All heat flow data are cumulative from the beginning of the project.

FIGURE 3 Cumulative heat flow into ground

Figure 3 provides a fairly clear demonstration that a thermal advantage in terms of vertical heat flow is gained beneath the cleared roadway as a result of the peat layering, while the snow-covered ditch continued to warm by vertical heat flow throughout the study. It also indicates, however, that a slight but continual heat gain commenced in 1979, even at the centerline of the peat sections. This plus some lateral heating from the ditch/shoulder talik areas would account for the temperature increases at all centerline, deep thermistor locations.

Recent trends in ground heat flow and temperature rise appear to have followed the obvious rise in recent air temperature averages indicated in Table 2. Air warming was reflected more quickly by the non peat control section, where a steadily positive heat accumulation began in 1977.

Seasonal Thaw Depths

Maximum seasonal thawing was found to occur under the test sections in late September or October. The changes in maximum thaw depth from 1973 to 1982 (Figures 4, 5 and 6) illustrate that thawing has progressively increased to the present time. Only the centerline area of section C has shown an apparent stabilization, with a maximum seasonal thaw depth to date extending only slightly below the original cut surface. Ditch areas of section C were subjected to the deepest

FIGURE 4 Section A--Maximum thaw depths

FIGURE 7 Section A--Residual thaw zones

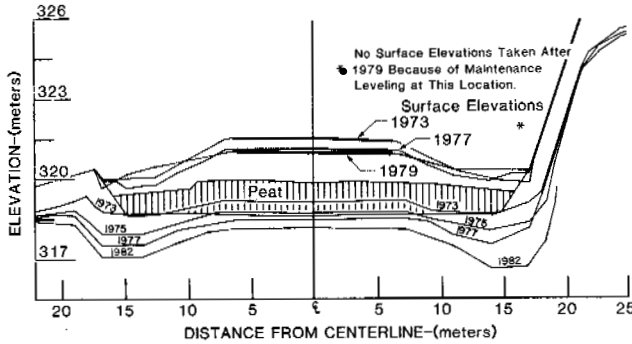

FIGURE 5 Section B--Maximum thaw depths

FIGURE 8 Section B--Residual thaw zones

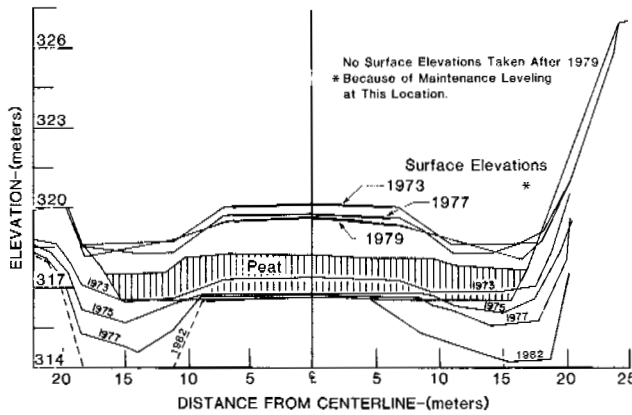

FIGURE 6 Section C--Maximum thaw depths

FIGURE 9 Section C--Residual thaw zones

measured seasonal thaw.

Residual Thaw Zones

As indicated by Table 3, the roadway side slope and ditch areas had an average annual surface temperature considerable above the average air temperature. This extreme warming has resulted because the unvegetated gravel surfaces are exposed to the intense warming effects of the summer sun while protected by an insulating snow cover during winter. These areas have thawed more deeply each summer than the maximum depth of re-freezing. Talik growth created by this thermal condition is illustrated in Figures 7, 8 and 9. Taliks warm quickly after summer thawing of the

overlying seasonal frost layer and progressively deeper annual thawing of the underlying permafrost therefore readily occurs. This results in continuing settlements in the ditch and side slope areas even though an equilibrium thaw depth may have been reached in a more central portion of the paved roadway. Side slope settlements can eventually lead to differential settlements, and cracking of the roadway shoulder. Such settlements are evidenced in Figures 8 and 9 by the irregularly shaped side slopes and ditches.

Settlement Observations

Consolidation histories for the peat layers in both test sections are shown in Figure 10. Essentially no elevation change was measured for any of

FIGURE 10 Settlement plate elevation changes

the bottom settlement plates.

Centerline thermocouples indicate that maximum seasonal thawing within section B progressed from the mid point to the bottom of the peat layer between September 1973 and 1977. By 1977 the original 1.2 m thickness had decreased to 0.61 m, and to 0.55 m by October 1982. Similarly, maximum thaw depths reached the mid depth point of the peat layer of section C during September of 1977 and have since appeared to stabilize at the base of the peat. The original 1.5 m thickness had decreased to 0.91 m by 1977, and to 0.73 m by October 1982.

Conclusions

The thermal advantage of peat layering was demonstrated very clearly in the 1973-1977 ground temperature data. A rise in average air temperature since 1977 has caused a generally correlative ground temperature increase and has somewhat obscured the long term effects of peat placement. In general, however, peat improved thermal conditions under the road surface but demonstrated no positive effect in the side slope and ditch areas.

Stabilization of the maximum annual thaw depth has occurred only under the central roadway portion of section C, which exhibits a 1982 consolidated peat thickness of 0.73 m. All other disturbed areas within the research site have shown an unattenuated thaw depth increase since 1973.

Ditch taliks formed in each experimental section apparently without regard to the presence or absence of peat and caused side slope and shoulder cracking. It was obvious that the peat layers did not completely alleviate differential settlement related problems at the research site. The exaggeration of subsurface temperature variations due to a combination of peat layering and warm ditches may, in fact, actually tend to accentuate differential settlements in the case of a uniform permafrost foundation. Conversely, where massive ice exists in the foundation, peat

should protect the central portion of the roadway from localized thermokarst effects and reduce necessary maintenance. Combined use of peat construction and wintertime removal of snow from roadside areas should result in a relatively low maintenance road structure for the warm permafrost environment.

USE OF SEASONAL WINDOWS FOR RADAR AND OTHER IMAGE ACQUISITION
AND ARCTIC LAKE REGION MANAGEMENT

Jack C. Mellor

U.S. Department of the Interior, Bureau of Land Management
P.O. Box 1150
Fairbanks, Alaska 99707 USA

This paper introduces regional remote-sensing data and methods that can provide arctic lake basin characterizations for economical site-specific management decisions. It also illustrates conditions and time periods, hereafter referred to as "windows," that can reduce natural-resource/human-activity conflicts and enhance remote-sensor acquisition of aquatic resource inventory data. Most oil exploration activity can be completed in a cost-effective manner with the least environmental disturbance during the winter surface use window. Lakes, rivers, and wetlands can be managed much like a terrestrial environment during the long arctic winter. Lakes, ponds, and hygroscopic soils cover most of the Arctic Coastal Plain and support an active flora and fauna that are susceptible to disturbance during the short summer. Some seasonal land management factors to be considered are overland and ice-road travel, avoidance of critical habitats during periods of high wildlife use, and water withdrawal from lakes. Data useful for regional inventory, classification, and management of arctic lake resources are April radar images, ice thicknesses, and summer aerial photographs and satellite images. April radar images of arctic lakes may be used to interpret isobaths separating three ranges of water depth (approximately 0-2 m, 2-4 m, and >4 m).

INTRODUCTION

Most of the Alaska Arctic is being studied, explored, and/or leased for energy resource development. Permafrost, ice thicknesses, and surface water present physical conditions that affect oil and gas field operations and wildlife. Seasonal windows can favor the gathering of data for resource inventories and industrial field operations during specific, limited time periods on the Alaskan Arctic Coastal Plain (Figure 1). Knowledge of specific lake depths and regional ice thicknesses aids land managers, who assess resource conflicts, and land users, who need supplies of winter water and heavy overland transport.

From June to September, the Alaskan Arctic Coastal Plain is a wetland continuum covered with tens of thousands of lakes and ponds. Regional inventory or comprehensive lake surveys do not exist. No lake-specific data are available for the vast majority of Arctic Coastal Plain lakes. The only regional data available are thematic maps, such as land cover from computer-classified LANDSAT digital data (Morrissey and Ennis 1981, Walker et al. 1982), which provide only generalized information. Most surface land management decisions are based on exiguous field data and past experience. Site-specific assessments are accomplished when necessary but are kept to a minimum in light of expensive field logistic costs.

Water is a predominate surface feature, which supports a very active flora and fauna, during the summer on the Arctic Coastal Plain. Winter brings changed and reduced faunal distributions and a frozen surface substrate from which lakes, rivers,

and wetlands are difficult to discern. Surface water can be evaluated using summer photographs and satellite images.

The bathymetry and potential uses of lakes can be evaluated with winter radar images. Past investigators (Sellmann et al. 1975, Elachi et al. 1976, Arcone et al. 1979, Weeks et al. 1977, 1978, 1981, Mellor 1982a) have identified the potential use of radar images to separate lake areas into two categories, those areas that freeze to the lake bottom versus those that do not. The radar image studies reported here were aimed at applying these findings by quantifying and regionally mapping this radar interpreted 1-2 m isobath. During the course of this research a second mappable isobath (≈ 4.0 m) was discovered, and the mechanism proposed by the above authors, for radar signal returns through ice containing columnar gas bubbles, was strengthened (Mellor 1982a).

METHODS

Data were acquired to test the hypothesis that significant aquatic resource inventory and assessment could be accomplished economically by applying knowledge of arctic lake ecosystems to regional remote sensing image interpretations. Figure 1 identifies study areas A, B, and C, where lakes were sampled and the stippled transect from Barrow to the Brooks Range where repetitive Side-Looking Airborne Radar (SLAR) images were acquired at a frequency of 9.1 to 9.4 GHz (≈ 3 cm wavelength) to

study the use of radar images for determining lake depths. This paper highlights potential use of airborne radar, photographic, satellite multispectral scanner, and lake ecosystem data that can aid in the management of Arctic Coastal Plain resources. The detailed verification of regional remote-sensing data acquisition and the interpretation methods is provided in Mellor (1982a) and is summarized in Mellor (1982b).

The use of such terms as "operating windows" and "design solution" has only recently crept into arctic resource management (U.S. Department of the Interior, 1983), but the concepts and practices to which they apply have been evolving over the past decade. Biologists and Arctic engineers have identified time periods and conditions when wildlife and the tundra surface can be significantly disturbed. Stipulations developed for field operating windows by identifying those time periods outside the critical periods of impact (i.e., summer thaw, caribou calving, and peregrine falcon and waterfowl nesting) to address that season when activities could be conducted without adverse effect. Design solution and window concepts are provided to the petroleum industry in lease stipulations before exploration field planning begins. This encourages their cooperation and effort in pre-design planning of environmentally sound operating procedures.

RESULTS AND DISCUSSION

Ice Thicknesses and Lake Depths

Human activity in the Arctic and the physical presence and activity of fish and wildlife are intimately tied to the freeze/thaw cycle. Most of

the surface water volume on the Arctic Coastal Plain is frozen by late April as the ice approaches 2 m in thickness. Lake basins typically have a small percentage area where depths exceed 2-3 m.

Figure 2 illustrates ice accretion on arctic lakes based upon 1978-1979 data taken from nine lakes located within lake study areas A, B, and C within the transect in Figure 1 (Mellor 1982a). Ice accretion continued into May 1979 in northern-"A" and mid-coastal "B" plain lakes, while some surface and perimeter melt occurred in foothill "C" lakes. Ice grew most rapidly during October, immediately after freezing over, and was thicker on northern than on foothill lakes throughout the winter.

As ice thickens the winter biota must either move to deeper water or become inactive where frozen to the bottom. The deeper areas are often of small volume with extreme temperature and dissolved oxygen and solute conditions. The amount of water remaining under winter ice cover is critical to aquatic life and is also the only freshwater source for human/industrial activity in this permafrost region lacking in ground water.

Regional ice thickness data in combination with SLAR images have been used to interpret lake isobaths. Regional ice thickness and the 3 April SLAR image in Figure 3 were used to classify the larger lake areas labeled with three ranges of water depth: (a) 0 to 1.5 m, (b) 1.5 m to 4.0 m, and (c) greater than 4.0 m. This image shows an area of deep mid-coastal plain lakes ("B" area in Figure 1) approximately 100 km south of Barrow, Alaska. By 3 April 1979, ice thickness was approximately 1.5 m. The black perimeters of lake images marked "a" depict where they are frozen to the bottom from the shoreline out to the 1.5 m

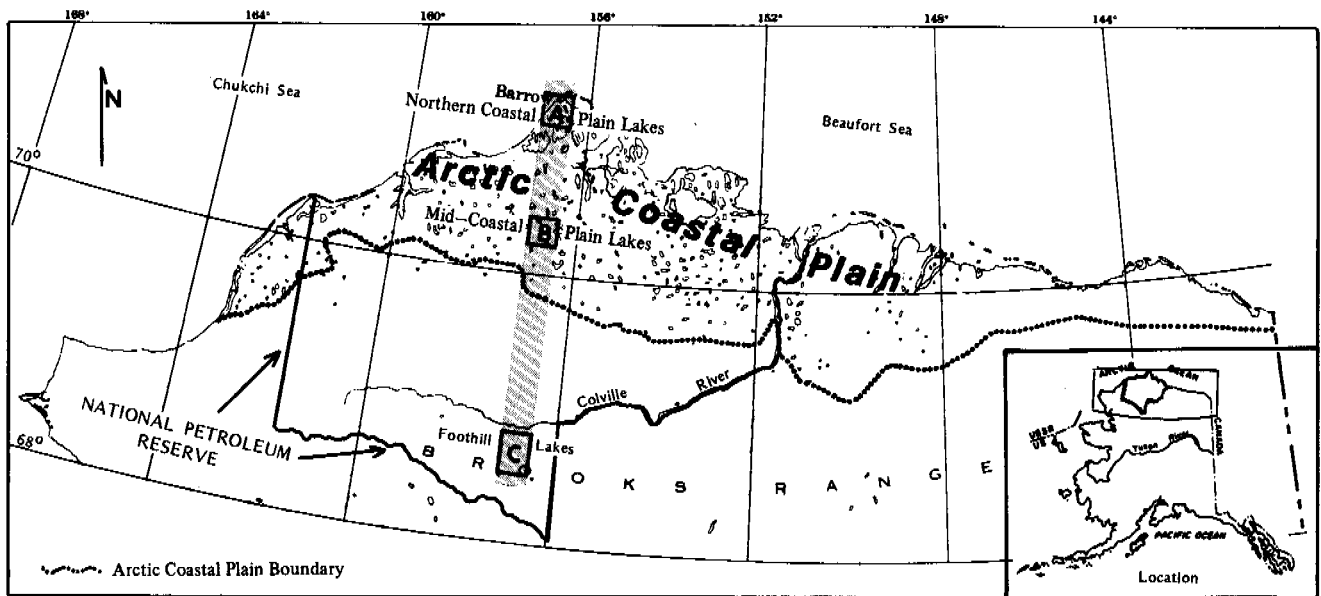

FIGURE 1 Location of the Arctic Coastal Plain, National Petroleum Reserve in Alaska, and study areas within the Alaskan Arctic.

FIGURE 2 Average ice thickness at 1-month intervals as a function of latitude along the study transect.

isobath. One lake in the southwest corner of the image is frozen to the bottom across the entire 2 km long basin. The white areas marked "b" are shallow areas where liquid water exists below the ice from 1.5 m to approximately 4 m. The gray areas over the central portions of four imaged lake basins marked with a "c" have been interpreted to be greater than 4 m deep.

Although devoid of overwintering fish, lake basins shallower than 1.5 m thaw early in the summer, thus attracting early waterfowl arrivals. Lakes with maximum depths in the second category (1.5-4.0 m) may have only marginal amounts of water for winter fish survival. Lakes with water depths greater than 4 m ("c" category) have the greatest potential for a well-established fishery. The areal extent of each depth category compared with the proposed water withdrawal from a lake identifies potential industry/fishery use conflicts. SLAR images acquired in April 1980 over 8 million ha of the National Petroleum Reserve in Alaska (NPR-A) are being used to inventory the three depth ranges for thousands of basins on the 12 USGS, 1:250,000 scale quadrangles covering NPR-A. The mapped depths are used to assess potential conflicts between industry and fish and wildlife uses and to determine the best lakes that may be used as winter water sources and ice runways.

Remote-Sensing Inventory Windows

Remote-sensing of lakes using the visible portion of the electromagnetic spectrum (i.e., aerial photographs and LANDSAT images) is plagued by a variety of difficulties. During the winter, skies are often clear, but the sun is low, on or below the horizon, and the lakes are frozen over and snow covered. The Arctic Coastal Plain, to the uninitiated aerial observer, might appear like a flat, ethereal white sand desert lacking anything to relieve the homogeneity. During the 3 months of ice-free summer (i.e., July-September), while the sun is high and the lakes discernible, incessant ground fog plagues efforts to image the surface synoptically. Completely cloud- and fog-free synoptic, summer coverage of the Arctic Coastal Plain

does not exist from either the National Aeronautics and Space Administration (NASA) high-altitude aerial photographic program or the past 10 years of LANDSAT Multispectral Scanner (MSS) images, but these data are sufficient and helpful for updating the 1955 photographic data used for surface water identification on U.S. Geological Survey maps.

Computer-aided characterization of the many Arctic Coastal Plain basins could aid lake inventory and lake data management. For example, a computer software system has been developed (Mellor 1982a) that manipulates summer LANDSAT digital data features (i.e., area, perimeter, crenulation, and centroid). The latitude and longitude of each lake centroid identifies each lake in the data files, providing for retrieval by user-specified geographic area. Lack of LANDSAT images with ice-free basins and cloud-free skies have, among other things, impeded testing and application of this automated system. Lake surface areas are frequently measured manually from aerial photographs for site-specific assessments, but this method is expensive to apply regionally.

Winter ice cover provides a fortuitous medium for radar image interpretation for the ranges of lake depths discussed earlier. April is the best

FIGURE 3 SLAR image acquired over mid-coastal plain "B" lakes, 3 April 1979 with depth interpretations annotated (i.e., (a) 0-1.5 m, (b) 1.5-4.0 m, and (c) >4.0 m).

month to record frozen lakes in the Alaskan Arctic because the ice has reached its greatest thickness in the southern foothill lakes before any surface melting occurs. Moisture at the surface or within the ice matrix absorbs the radar signal preventing a strong return upon warming that occurs during May in the Arctic.

The depth interpretation window results from Arctic lake conditions that are different from lower-latitude lakes that lack the strong radar signal returns. The unique aspect of Arctic lake SLAR images is the strong return (Figure 3 with white image "b" areas) over the intermediate 1.5-4.0 m depth range. This depth is a dominant characteristic of Arctic thaw lakes.

The mechanism hypothesized for the strong SLAR signal return is the existence of multitudes of columnar gas bubbles (1-15 cm high) observed in ice cover over lake areas from 0-4 m depth (Mellor 1982a). The gas bubbles are incorporated into the ice matrix after the dissolved gases reach saturation within the limited volume of water beneath the ice. Apparently the columnar bubbles scatter the incident signal radially and forward (downward) without changing the vertical angle of incidence. After reflecting off the ice/water interface the radar signal is forward (upward) and radially scattered and emerges from the ice and snow cover in the shape of an inverted cone. Since the surface of the cone maintains the angle of the incident radar signal, the return signal is strong and produces the bright image over the lake areas less than 4 m deep but deep enough to have water beneath the ice cover. Fewer bubbles provide less radial scattering in ice over lake areas with >4 m depth and produce subtle gray tones ("c" areas) signifying less signal return. Areas frozen to the lake bottom, that lack a finite ice/water interface to reflect the signal, produce a black image ("a" areas). Subtle changes in SLAR image gray tones over lakes can be caused by factors other than >4 m lake depth (i.e., lakes almost frozen to the bottom and ≈ 2 o/oo dissolved salts). More field verification of these hypotheses and criteria (i.e., depth ≈ 4 m with reduced bubble content in ice cover and increased SLAR image gray scale) are warranted.

The conditions favoring the occurrence of bright SLAR images acquired over Arctic Coastal Plain lakes versus ice-covered, lower-latitude lakes that lack the bright images are as follows. Persistent winds mix the Arctic Coastal Plain lakes so that they are nearly saturated. Most area of even the large deep basins is within the 0-4 m depth range, in which the bright image returns can occur. The long freezing season both concentrates the gases below the ever-thickening ice and incorporates the columnar bubbles within it. Lack of terrain relief allows for image acquisition with little or no shadows. Finally, throughout the arctic winter and spring, lack of solar energy and persistent freezing temperatures cause dry ice and snow conditions conducive to radar signal penetration. Radar signal reflection observations relative to different natural Arctic snow conditions show little correlation with snow roughness characteristics observed.

Additional information can be obtained from sequential radar images acquired throughout the freezing season. For example, images from November, January, and March may be used to determine

0.5, 1.0, and 1.5 meter isobaths, respectively (Mellor 1982a, 1982b). Future satellites may acquire repetitive regional radar images that will provide an economic means for further water depth inventory.

Activity Management Windows

With the warmth of April and May, arctic wildlife activity increases significantly. Raptors, such as the endangered peregrine falcon, arrive in April to begin nesting. During May, caribou begin calving in large, concentrated numbers, and migratory waterfowl arrive in search of ice-free lakes and ponds in which to feed, molt, and nest. The thawing of the active layer above permafrost begins coincident with snow-melt during May. Cross-country transport of heavy equipment that would disturb the tundra surface and could also disturb calving and nesting wildlife must be curtailed.

Figure 4 illustrates these windows of critical wildlife use and some human activities during the calendar year. Since most human and wildlife activities are intimately associated with the presence, absence, or thickness of ice cover, a curve for mid-coastal plain lake average ice thickness measured during 1978-1979 (Mellor 1982a) is included. The active layer and water surfaces begin to re-freeze in September, initiating the following progression of thickening ice and increased use by heavy equipment until breakup begins in May and June. Cross-country tractor trains begin tundra travel about the first of November when the active layer has frozen down to approximately 30 cm and there is an average of 15 cm of snow cover. By then, lake ice of about the same thickness (30-50 cm) is safe for light aircraft and surface vehicle use. SLAR images can be used to locate shallow basin areas that freeze to the bottom early in the winter, providing early yet safe trails and landing sites for heavy transport. Snow and water have been used successfully to construct winter ice roads, pads, and airports on the tundra to avoid permanent construction with gravel. January lake surfaces are thick enough to support heavy tractor train transport. February ice thickness on lakes can attain 1.2 m, providing natural landing strips for heavy aircraft, such as the Hercules C-130. Freshwater sources dwindle in both number and volume as the ice thickens. By March water basins greater than 2 m deep must be found to provide a reliable source of water, and care must be taken to avoid dewatering critical fish habitat. April SLAR image depth determinations can help locate sources and assess potential use conflicts with fish such as dewatering and polluting. For example, lake areas with depths from 0.5 to 1.5 m have unfrozen water from late June to February (Figure 4). Cross-country use of the tundra surface is terminated during May snow-melt. Breakup progresses rapidly in June, precluding travel except by boat or improved roads and airstrips. In June and July breakup coincides with the single most critical period of wildlife use. Critical raptor and waterfowl uses continue through most of August. Caribou calving occurs from mid-May to mid-July, and some important summer migration continues through mid-September. Although some potential summer wildlife disturbance

FIGURE 4 Calendar of wildlife/human activity windows relative to mid-coastal plain 1978-1979 ice thicknesses.

exists from aircraft use and improved all-season facilities, breakup and an unfrozen active layer limit vehicle surface travel and construction during these critical wildlife use windows. Infrequent floatplane use occurs while the lakes are ice-free.

The natural separation between human and wildlife use shown in Figure 4 may change with Arctic oil and gas development. Human activity in summer will increase in direct proportion to the construction and maintenance of permanent all-season facilities and must be analyzed carefully to minimize conflicts in use between industry and fish/wildlife. During oil and gas exploration, use conflicts can be reduced by recognizing the natural separation of use windows; encouraging the use of temporary winter ice roads, ice pads, and ice strips; and by discouraging construction of all-season roads and airstrips. This will conserve migratory concentrations of fish and wildlife and

populations with low productivity that are sensitive to disturbance by human activity.

SUMMARY

Arctic conditions permit only a narrow summer window for acquisition of visible spectral, remote-sensing data of lake surface characteristics. Active radar systems can provide a reliable means for acquiring both Arctic lake surface and depth characteristics, because they are not dependent upon solar energy or clear skies absent during much of the year. Other physical and climatic conditions provide fortuitous radar interpretation windows for Arctic lake basin characterizations. April radar images and ice thicknesses are being used to interpret three ranges of Arctic lake depth.

Arctic conditions cause natural use windows

that separate critical summer wildlife use periods from most present human activity including winter oil and gas exploration in NPR-A. Permanent all-season facility development needs careful planning to minimize fish and wildlife use conflicts. Lake depth determinations from April SLAR images can be useful in evaluating winter water supplies and also avoiding conflicts with fisheries.

PERMAFROST DYNAMICS IN THE AREA OF THE VILUY RIVER
HYDROELECTRIC SCHEME

P. I. Melnikov and B. A. Olovin

Permafrost Institute, Siberian Branch
Academy of Sciences, Yakutsk, USSR

During 14 years of operation of the hydroelectric installation the permafrost in the flooded zone has thawed to a depth of 15-17 m and to a depth of 20-50 m in the base of the dam. During the construction phase and during the first few years of operation freezing of the taliks below the river bed to a depth of 10-20 m was observed as a result of the drainage of the construction site, the systematic disturbance of the snow cover and to intense air convection in the rock fill. The permafrost layer which had formed had thawed almost completely by 1982. The temperature field of the dam is characterized by extremely low mean annual temperatures; however, the spatial characteristics of the zone of negative temperatures differ significantly from those forecasted using a stationary model. The formation of temperature anomalies within the body of the dam is due to use of highly gas-permeable materials ($k=1 \cdot 10^{-7} \text{ m}^2$) in its construction.

In water development projects fundamental changes occur in the conditions of the external heat exchange of permafrost formation owing to (1) artificial regulation of the river run-off and construction of water storage reservoirs, (2) removal during the construction of considerable volumes of earth material, (3) driving mining workings, and (4) construction of dikes and dams. The variation of the hydrological regime of rivers is characterized by an increase in winter run-off, intensification of filtration processes at the base and shore contiguities of dams, and a rise in the mean annual temperatures of the rock surface in the flowage zone.

For hydroelectric projects, the study of the temperature dynamics of the strata in the zone of thermal effect is necessary to predict filtration losses from water reservoirs and to evaluate the stability of structural elements of engineering projects. The prediction of the nonstationary temperature field, taking into account water filtration, may currently be highly approximate due to the low reliability for determination of the filtration properties (permittivity and piezoconductivity) of thawing permafrost, carried out most frequently by indirect methods. Water development projects in the extreme North are marked by the extreme complexity of permafrost-hydrogeological conditions, by a large number of factors that influence the temperature field at the base of the project during construction and operation, and by the nonpredictability of the many physical properties of the strata near the project. This paper presents some results of long-term temperature observations around one of the largest hydroelectric stations in the USSR, constructed in an area of continuous permafrost. The structure, construction methods, and primary changes in the development of the temperature field inside and at the base of the Viluykaya Hydro structures have been reported in a series of papers (Biyarov 1975, Kamensky 1973, Olovin and Medvedev 1980).

ENGINEERING-GEOLOGICAL AND GEOCRYOLOGICAL
CONDITIONS OF THE REGION

The Viluy Hydro dam, 75 m high and 600 m long, was erected in West Yakutiya on a stratum intrusion of weak-jointed dolerites (diabase), existing to a depth of more than 100 m. The dolerite permeability in the region of the river bed is, according to field test measurements, about 1 m per day. Before construction, the permafrost permeability of the dam base after thawing was not specifically investigated. On the basis of visual estimations in developmental work, the rough value of the permeability of the thawing ground was assumed to be 10 m per day. Deep pressure grouting was planned for areas with higher permeability.

The frozen rock temperature on watersheds varies from -1° to -3°C and averages -2.5°C in areas with undisturbed soil-plant cover. The frozen rock temperature at the bottom of the annual temperature variation zone varies from -1 to -9°C , depending on the distance from the river bank, exposure, mean slope angle, surface altitude, and lithology. Statistical treatment of geothermal observations on slopes has shown that outside the thermal influence zone of the Viluy River ($L \geq 100-200 \text{ m}$) the frozen rock temperature varies in accordance with:

$$t = -6.6^\circ + \Delta t(z) + 0.037\beta - 1.4 \cos(63 \pm \alpha) + \Delta t(\alpha_m),$$

- where t = the temperature at a depth of 20 m;
 $\Delta t(z)$ = the empirical correction for the difference in surface altitudes;
 β = the angle between the drop line and north ($\beta = 0-180^\circ$);
 α = the incidence angle of the slope (positive value α is taken for slopes of north and near-north exposure, the negative value for south);
 $\Delta t(\alpha_m)$ = the temperature correction, taking into

account the presence on the slope of a suffusion-destruction subfacing of a rock stream slope.

The influence of the various factors on permafrost temperature decreases in the following order:

- Slope exposure, $\Delta t(\beta) \leq 5.6^\circ\text{C}$;
- Absolute elevation, $\Delta t(z) \leq 2.9^\circ\text{C}$;
- Presence of abrupt slopes, $\alpha > 40^\circ\text{C}$, with an extension of steep areas $l > 10\text{-}15\text{ m}$, $\Delta t(\alpha_m) = 2.1\text{-}2.5^\circ$;
- Incidence angle of the slope at $\alpha < 25^\circ$, $\Delta t(\alpha) \leq 1.0^\circ$.

The thickness of the permafrost bench on the watershed areas near the hydro project is 600-800 m. Ice in porous spaces is found only in the upper levels: in a layer 80-90 m thick in the river bed and 300-320 m on watersheds. Below this, water shows increased mineralization. The temperature field in the river valley has been traced down to 100 m. In the interval of the depths studied the rocks are in a frozen state. Taliks (unfrozen ground within permafrost) occur everywhere beneath the river bed, but since all the temperature curves for bore holes driven in the river bed are characterized by negative gradients, one may surmise that the river bed talik in areas of bed narrowing is not an open one.

The permafrost water content outside the weathering zone, due to the presence of crack-vein ice, does not exceed several percent and increases toward the ground surface and toward the valley edges by the most disturbed process of frost weathering.

PERMAFROST THAWING IN THE FLOW ZONE

Permafrost thawing dynamics within the reservoir bed have been studied for 15 years in an experimental area about 1 km from the dam. The rocks in this area are represented by jointed dolerites, weathered from the surface down to 1 m to form grus and crushed rock. The area had been entirely stripped of trees, and the soil-plant layer was completely removed from a considerable portion. The extent of the study area extended for 600 m perpendicular to the valley. The surface slope is 7.9° . The depth of seasonal thawing, which under natural conditions did not exceed 1.5-2.0 m, increased to 3.4-4.0 m after the soil-plant layer had been removed. The thermal diffusivity K of the frozen dolerite as measured by in situ methods at depths of 20-50 m is $28 \cdot 10^{-4}\text{ m}^2/\text{hr}$ at a variation coefficient of less than 5%; from 10-20 m, K increases up to 34 or $35 \cdot 10^{-4}\text{ m}^2/\text{hr}$; heat conductivity coefficient λ is 2.27 W/m·K at 20-50 m and at 2.76-2.84 W/m·K at shallower depths. The permafrost temperature in the area is -4 to -4.5°C . The mean annual water temperature in the reservoir is close to 4°C .

Statistical treatment of observations from three bore holes in the flow zone over a 12-year period has yielded empirical relationships between the thawing depth ξ (m) and time τ (years) of the form

$$\xi = C_1 + C_2 \sqrt{\tau},$$

notably for bore hole 25:

$$\xi = -1.21 + 4.83 \sqrt{\tau}, \text{ m} \quad (1)$$

bore hole 26:

$$\xi = -1.57 + 5.03 \sqrt{\tau}, \text{ m} \quad (2)$$

bore hole 27:

$$\xi = 2.51 + 3.83 \sqrt{\tau}, \text{ m} \quad (3)$$

The relationship between ξ and τ is characterized by the following correlation coefficients: dependence (1) 0.976;

(2) 0.955;

(3) 0.973.

During the last 5 years the dolerite's mean rate of thawing has been 0.6-0.7 m per year. The obtained data characterize the mean rates of thawing of dolerite, due solely to conductive heat transfer.

The permafrost thaw rate at the base of the dam is influenced largely by convective heat transfer, due to water filtration through the jointed rocks of the base. The mean rate of permafrost thawing at the base of the grouting gallery (Figures 1 and 2) varies from 0.8 to 1.2 m per year on the right-hand bank (bore holes 2-4), up to 7-8 m per year (bore holes 9 and 10) on the left-hand bank. The extremely large thaw rates observed in 1973 and subsequent years in the vicinity of bore hole 1 are due to an additional influence of horizontal heat flow on the side of the right-bank water supply channel. The high thaw rates in the upper 10-m layer observed at the time the reservoir was filled (1968-1969) in the vicinity of bore holes 3 and 4 (Figure 3) are due to the high permeability of the upper levels of the cryogenic structure. As the reservoir was filled, the permafrost thawed very rapidly around the tunnel conduits that supplied water from the canal to the hydroelectric units of the right-bank station. The permafrost thaw rate was about 5 m per year radially from the water duct walls.

Permafrost thawing at the base of the left-bank structures occurred with a significant time lag despite the higher permeability of the rocks. In 1975 the talik was only 2 m thick, about 10 m wide, and it was located at the base of the left-bank supply canal beneath the upper cofferdam 24 m high (the maximum water pressure on the side of the upper reach was 0.17 mPa), indicating a very insignificant discharge of filtration flow in the left-bank contiguity and an extremely insignificant thawing of the base of the river diversion canal.

The talik below the river bed began to freeze while the dam was under construction, after a short time blocking of the bed in 1964 and full blocking in 1965. During that period the soil-plant layer was almost completely removed and the conditions of snow cover formation, as compared to natural ones, were substantially violated. In the river bed this resulted in the formation of a permafrost layer up to 8-9 m thick in the extended area of the bed and 10-12 m thick in the narrowed area due to the decrease of mean annual temperature from $3\text{-}4^\circ$ to -3° to -4°C . In the winter of 1964-65, a 40-m-high retaining wall of rock fill was constructed, causing the mean annual temperatures of the base surface near the geometric axis of the dam to decrease to -10° and -15°C . Toward the downstream wall the low mean annual temperatures were from -20° to -30°C .

An estimate of the freezing rate of the base can be made by the known formula $\xi = (2\lambda \cdot \Delta t \cdot \tau / q_0 W)^{0.5}$, in the form

$$\xi = (f \cdot \Delta t \cdot \tau)^{0.5} \quad (4)$$

convenient for using the data on the thermal physical properties of dolerites, influencing the value of the empirical coefficients in formulas 1 through 3). Taking into account that permafrost thawing in the flow zone occurred as a result of an increase in the surface mean annual temperature by $\Delta t = 8^\circ\text{C}$, the mean value of ξ for dolerites of the study area can be determined by formulas 1 through 3, assuming $C_1 = 0$, thence

$$\xi = 2.65 \frac{M^2}{\sigma C / \text{yr}}.$$

Thus, for rough calculations of freezing rate in the absence of water filtration in base rocks one may use a semi-empirical formula

$$\xi = (2.65 \cdot \Delta t \cdot \tau)^{0.5} \text{ m}, \quad (5)$$

where τ is measured in years; Δt in $^\circ\text{C}$.

Formula 5 can be used to determine the freezing depth of the dam base in the river bed which at a single temperature jump for the surface $\Delta t = 20^\circ\text{C}$ should have been 16 m within 5 years of the start of construction (1970) and 23 m 10 years later, in 1975.

As the dam filled, rock freezing occurred, most intensively in regions distant from direct contact with the water reservoir. The main reasons for deep freezing were earth material fill at negative air temperatures and intense inter-pore air convection in large fragmented rocks of the retaining wall. In the construction stage the dam-retaining wall and the loam shield core were almost completely frozen up to 20 m in height. Due to the high air permeability of the rock fill, on the order of $1 \cdot 10^{-7} \text{ m}^2$ (10^5 darcy) and a substantial difference in the air densities of the atmosphere and the inter-pore space throughout the year, there is air motion through the surface of a dry slope with periods of 24 hours and 1 year. There is a close correlation between air flow Q , through the dam surface, and ground layer temperature t_B :

$$r(Q, t_B) = 0.3 - 0.6.$$

There are 3 circulation patterns—winter, summer, and mixed. In winter the air motion is predominantly ascending and in summer, it is descending. Mixed circulation may be observed at any time of the year. It is a circulation pattern in which atmospheric air enters the middle part of the retaining structure and divides into two flows, ascending and descending. The total air flow, as measured with flowmeters with a receiving surface area of 22.5 m^2 (1.5 m wide and 15 m long along the slope drop), varies throughout the year in the direction with an amplitude of 50 m^3 per hour. Fluctuations of instantaneous flow values during the day are several times smaller.

As a result of air convection in the retaining structure, there are anomalously large annual temperature variations, reaching several $^\circ\text{C}$ even 50-60 m away from the surface of a dry slope. The

mean annual temperatures of the rock fill are lower by $10-20^\circ\text{C}$ than those characteristic of West Yakutiya. The depth of seasonal freezing-thawing near the dam crest reaches 20 m (Figure 3). In the 14 years since the beginning of construction the mean annual temperature of rocks within the dam body increased by $5-10^\circ\text{C}$, the amplitude of annual variations decreased substantially, and frozen loams in the shield thawed completely. In the river bed, rapid thawing of rocks occurred where the dam base comes into contact with the retaining wall. The increase in the rock temperatures might be due to a lowering of their permeability caused by collapse of earth material that was weakly pressurized during construction and to the formation of intraground ice due to infiltrating atmospheric precipitates and condensation of water vapor from the air moving through the pores of the rock filling.

Despite the continual decrease of the area with negative rock temperatures, the spatial distribution of mean annual temperatures is far from being a relevant stationary state as predicted in terms of an analog model (Kudryavtsev et al. 1963) that took into account the possibility of heat transfer only by the mechanism for molecular heat conduction. Evidently, it will take several decades to establish a stationary state for the dam at Viluy Hydro, in the course of which the porous space in the negative temperature zone can be completely filled with ice.

The main source of water for the formation of intraground ice is seepage. The mean flow of water through the dam's surface is about 100 kg/m^2 per year.

The lowest temperatures in the rock fill were observed under the road on the berm at the 16 m mark (Figure 3a). The berm is constructed where the river bed is narrowest, not exceeding 100-200 m at normal water level; therefore at the berm base there are favorable conditions for deep freezing of the dam and formation of a continuous ice-ground curtain. The temperature variations in bore holes 14, 17, 18, and 19 (Figure 4b), as measured in 1972-1975, confirm the deep freezing of the talik below the river bed at the base of the dam. Observations of the intensity of air filtration through the dry slope of the dam in the range of 0-16 m and a study of pit walls driven in rock filling from 16 m showed that the amount of intraground ice in the pore space does not exceed 50% of its volume, therefore despite the low temperatures of the rock fill this was not an essential obstacle to the water flow, filtered through the shield and base and moving toward the tail race on the same surface as the dam base. The flow of filtered water during 1967-1974 seems to have been in the region of point A (Figure 4b). The short-term permafrost formed earlier has now practically entirely thawed, while the permafrost boundary approaches what it was before construction (Figure 4c).

CONCLUSION

Several years of investigations and observations at Viluy Hydro, constructed under the climatic conditions of the extreme North and the massive

propagation of rock permafrost, yielded unique data characterizing the heat and mass exchanges within the body of a rock-filled dam, at its base, and in the river bed, as well as an understanding of the influence of the water reservoir in thawing the underlying permafrost. The construction of the hydro project has greatly influenced the thermodynamic characteristics of the permafrost. This influence is propagated tens of meters away from the boundaries of the structures erected. With a general trend toward permafrost degradation occurring at a rate of from 0.6 to 7-8 m per year, in individual areas there is rapid freezing of taliks. This must be taken into account in the design of drainage systems.

During the past 14 years of project operation, the heat and mass exchange within the body of the dam, at its base, and in the river bed has not stabilized. The formation of a temperature field continues on and its dynamics do not yet permit an accurate prediction of the thermodynamic cryogenic process that is occurring. The investigation and observation at the Viluy hydro project must be continued and extended.

ISOTOPE VARIATIONS IN PERMAFROST WATERS ALONG THE
DEMPSTER HIGHWAY PIPELINE CORRIDOR

F. A. Michel

Department of Geology, Carleton University, Ottawa, Ontario, Canada K1S 5B6

Oxygen-18 contents of permafrost waters have been determined for representative core samples from the proposed Dempster Highway pipeline route. Many samples contain water with an isotopic content ($\delta^{18}\text{O} = -20$ to -23‰) similar to modern precipitation which suggests significant groundwater migration near surface. Samples from the unglaciated northern Yukon have ^{18}O contents ranging from -14 to -27‰ which are suggestive of climatic changes since the late-Wisconsinan. Superimposed on these variations are $2 - 2.5\text{‰}$ fluctuations formed by isotope fractionation during freezing.

INTRODUCTION

Information about the history of permafrost, and the water or ice contained within the permafrost zone at any site, can be obtained through the study of environmental isotopes. Mackay (1972) demonstrated through the use of oxygen isotopes that relic land-based permafrost exists within the Beaufort Sea, while Stuiver et al. (1976) were able to distinguish zones of marine and glacial water within permafrost in Antarctica. Detailed isotope investigations within the Mackenzie Valley and the Mackenzie Delta (Michel 1982, Michel and Fritz 1978, 1982a) have been successful in documenting the existence of age variations for water (ice) in the permafrost, and correlating these isotope variations to paleoclimatic conditions. In this paper, variations in the isotopic composition of permafrost waters collected along the proposed Dempster Highway pipeline route are described. The term 'permafrost waters' is used, herein, to refer collectively to H_2O in all 3 states of existence within the permafrost, most of which will usually be as ice.

STUDY SITES

The proposed route for the Dempster Highway pipeline closely follows the Dempster and Klondike Highways from Inuvik to Whitehorse. The major physiographic regions traversed by the route include the Mackenzie Delta, Mackenzie Valley, Peel Plain, Richardson Mountains, Eagle Plain, Ogilvie Mountains, Tintina Trench, and Pelly Mountains. Permafrost has been encountered along the entire route with the largest ice-rich sections located in the unglaciated Eagle Plain of the northern Yukon (Foothills 1978). A large number of core samples, from boreholes located along the entire route, were provided by Foothills Pipe Lines (Yukon) Ltd. from their 1978 drilling program.

On the basis of the borehole logs provided to the author by Foothills Pipe Lines (Yukon) Ltd. and a preliminary examination of samples from a number of boreholes, a detailed investigation was

undertaken on core material from the Eagle Plain - northern Ogilvie Mountains region. All available core samples from boreholes 78-141, 78-142, 78-148, and 78-165, were processed for isotopic analysis. The location of each borehole is shown in Figure 1.

ANALYTICAL PROCEDURE

All samples were shipped frozen from the field to Calgary where they were stored in freezers for geotechnical testing. Samples which were not tested were sent frozen to the author at the University of Waterloo in 1981. Upon arrival, the samples were stored in a walk-in freezer at -10°C .

Each sample processed was unwrapped in the freezer where the outer layer of soil and ice were removed and discarded. The innermost core of each undisturbed sample was described and then sealed in a thick-walled plastic bag. The sample was first allowed to thaw completely and equilibrate at room temperature. Each sample was then placed within a steel jacket and subjected to a controlled hydraulic pressure in order to squeeze water from the soil. The procedures for water extraction are described by Patterson et al. (1978).

To determine the ^{18}O content of a sample, 8 ml of water were equilibrated for at least 4 hours with a standard CO_2 gas. The oxygen isotope ratio of the equilibrated gas was measured relative to a laboratory working standard. To measure the ^2H content of selected samples, 20 μl of water were circulated over hot uranium metal ($800^\circ - 850^\circ\text{C}$) and converted to hydrogen gas for analysis. Both the oxygen and hydrogen isotopes were measured using a Micromass 602D mass spectrometer at the Isotope Laboratory, Department of Earth Sciences, University of Waterloo. The results are expressed as parts per thousand (permil, ‰) difference between the sample and the reference: Standard Mean Ocean Water (SMOW). These differences are referred to as δ values and a negative value describes a concentration less than that of the reference standard. The analytical error in δ for ^{18}O is less than 0.2‰ , while the error for ^2H is less than 2.0‰ .

DISCUSSION OF RESULTS

Shallow Groundwater

Throughout the area of study, shallow groundwaters have been sampled for isotope analyses. ^{18}O contents are consistently within the range of -20 to -23‰ (Michel and Fritz 1982b). During the preliminary examination of core material by Michel and Fritz (1982b), the water within the uppermost permafrost was generally found to have $\delta^{18}\text{O}$ values in the range of -19 to -22‰ . The uniformity of $\delta^{18}\text{O}$ values within a relatively narrow range for groundwaters and upper permafrost waters is indicative of the average annual composition of modern precipitation and this provides a reference with which to compare the isotopic composition of other permafrost waters.

Eagle Plain - Northern Ogilvie Mountains Region

Previous studies by Michel (1982) and Michel and Fritz (1978) were undertaken in areas which were glaciated during the late-Wisconsinan. As a result, it is impossible to determine whether the $\delta^{18}\text{O}$ values of -29 to -31‰ reported in these studies represent waters which infiltrated from melting glaciers, or directly as precipitation. Glacier ice could have formed from snow which fell tens or hundreds of kilometres away from the point of melting and, therefore, would not be representative of the local climate at the time of melting and recharge.

The Eagle Plain, lying between the Richardson Mountains to the northeast and the Ogilvie Mountains to the south, is an area which was not glaciated during the Wisconsinan. The northern edge of the Ogilvie Mountains was subjected to localized alpine glaciation, but the cores examined during the study were from beyond the limit of glaciation. Therefore, it is possible within this region to examine isotope profiles with groundwater recharge which was not derived from glacier ice. However, when examining cores from low-lying areas, such as valley floors, it is necessary to recognize the possible existence of meltwaters from alpine glaciers. Four cores from the region have been examined during the present study.

Borehole 78-165 is located adjacent to the Dempster Highway just south of where the highway crosses the Eagle River. The borehole was drilled approximately 10 m from the edge of the bank along the Eagle River valley. This bank rises several tens of metres above the valley which served as a major glacial spillway during the late-Wisconsinan period. Work by Hughes et al. (1981) indicates that deglaciation of the Peel River - Bonnet Plume Basin area to the south was underway by 16,000 years ago.

The ^{18}O profile shown in Figure 2 reveals the presence of two distinct water masses. Within the silt and clay units below 10 m, the ^{18}O contents are slightly less negative than modern groundwater values ($\delta^{18}\text{O} = -21.5\text{‰}$) for the area. The waters are considered, therefore, to be representative of a slightly warmer time

period. The ^{18}O contents of water within the organic silts vary between -26 and -27.5‰ and are approximately 6‰ more negative than modern waters in the area. A temperature estimate based on these data would indicate that these waters were recharged during a period when the annual air temperature was at least 9°C lower than today. If such an estimate is correct, then the waters would have to be late-Wisconsinan in age. The deeper permafrost waters are considered to be part of a groundwater flow system active during the Holocene. Crampton (1979) has reported the existence of a thick interpermafrost talik within the Eagle River valley near this site and water encountered in the talik was under pressure.

Further to the southwest, borehole 78-148 was drilled on gently sloping ground approximately 3 km east of the Ogilvie River. The stratigraphy at this site consists of peat and organic silt to a depth of 2 m underlain by 4.5 m of silt which overlies at least 3.3 m of gravel. Core samples available for study do not include the gravel unit at depth.

As can be seen in Figure 3, the ^{18}O profile displays a shift from modern values near surface (-20 to -22‰) to more negative values (-26 to -27‰) at depth. The $\delta^{18}\text{O}$ values in the range of -26 to -27‰ are similar to those in the organic silts of borehole 78-165. These values would yield a similar temperature estimate as previously described for borehole 78-165 and these waters are assigned, therefore, to a late-Wisconsinan age.

It is unlikely that the shift to less negative values toward the surface is the result of mixing between modern groundwaters and late-Wisconsinan groundwaters, since such an effect would tend to produce a smoothed profile. Variations formed as a result of freezing could have a magnitude of up to 2.8‰ for ^{18}O , if the isotopic fractionation occurred under equilibrium conditions (Michel 1982). In the profile of Figure 3, variations at a depth of 4 m exceed the 2.8‰ value and cannot be explained solely by fractionation during freezing. Therefore, this gradual shift is probably representative of changing climatic conditions since the late-Wisconsinan.

The lowermost sample analysed in this borehole has a much higher ^{18}O content than the sample immediately above and is several permil less negative than modern water in the area. Examination of the ^2H vs. ^{18}O plot in Figure 4 reveals that this sample has not been altered by secondary processes. The thick gravel unit only 0.5 m below this sample could represent a former interpermafrost talik through which isotopically heavier Hypsithermal waters have migrated. Exchange with such waters could result in the present isotopic composition. Unfortunately, without a sample from the gravel it is impossible at present to determine if this was the case.

Boreholes 78-141 and 78-142 are located further upstream along the Ogilvie River (see Figure 1). Core material recovered from borehole 78-141 consists primarily of organic silt with some segregated massive ice zones. The borehole is located near the river on gently sloping

ground; a mountain is located immediately to the north. The isotope profile for this core (Figure 5) is devoid of any major shifts throughout the 6 m section. The minor fluctuations which do exist are characteristic of fractionations resulting from freezing as described by Michel (1982). The lack of major variations in this core could be due either to the formation of permafrost in this section during a period of constant climatic conditions, or it could reflect the destruction of previously existing isotopic variations by groundwater migration.

Borehole 78-142 is located on a hillside sloping 3° westward toward the Ogilvie River. During drilling, a total of 16.45 m of massive segregated ice was encountered between a depth of 1.25 and 19.0 m. Peat and organic silt overlie most of the massive ice (Figure 6). Between the two main ice sections, a 0.9 m zone of silty sand was encountered. Drilling was terminated after 0.5 m of silt was cored beneath the largest ice section. Unfortunately, no samples of the ice were retained during the drilling program. Therefore, all isotopic determinations reported are for waters from the sediment-rich horizons.

In Figure 6, the organic-rich sediments above the massive ice can be seen to have a relatively constant oxygen-18 composition similar to modern water. The silty sand layer at a depth of 5.2 - 6.1 m contains ice with much lower ^{18}O concentrations (approximately -29‰). The lowermost silt at a depth of 19.0-19.5 m has a $\delta^{18}\text{O}$ value of -14.7‰ which is much less negative than present-day values.

Without isotope data for the ice sections, it is very difficult to interpret these fluctuations. The lowermost silt sample is characteristic of a warmer climatic period than currently exists and is isotopically more positive than would be expected for water from the Hypsithermal. Examination of the $^2\text{H}-^{18}\text{O}$ relationship for this core in Figure 4 reveals that the deep sample lies to the right of the meteoric water line. If this is a result of evaporation during storage, the corrected $\delta^{18}\text{O}$ value would be approximately -18‰ , which would then make a Hypsithermal age reasonable. However, since there was no evidence of evaporation when the core sample was examined during processing, it is doubtful whether such an adjustment can be made legitimately to the isotopic value. It is also possible that the offset from the normal trend could be due to a minor fractionation during freezing causing a decrease in the slope of the $^2\text{H}-^{18}\text{O}$ line. Regardless of how the $\delta^{18}\text{O}$ value is manipulated, the water still must be from a climatically warmer time period than currently exists in the area.

The low concentration of ^{18}O in the silty sand samples could be explained in two ways. First, the water may be representative of conditions during the glacial maximum of the late-Wisconsinan. It should be noted that the ^{18}O contents of these samples are roughly 2‰ less than the samples from boreholes 78-148 and 78-165. This could be explained either by local variations in the average annual isotopic composition of the precipitation or by time

differences between the water masses.

Secondly, the contact between the lower massive ice and the silty sand unit may represent a former permafrost table. The organic-rich sediments accumulating above the silty sand would have been seasonally frozen and water saturated. During freezing from the surface downward, the silty sand layer could have acted as a confined aquifer through which groundwaters migrated. In this situation, a closed system environment of freezing, similar to that for the formation of frost blisters as described by van Everdingen (1978), could develop once part of the aquifer was completely frozen. This would explain both the 3.3 m of massive ice above the silty sand layer and the very low concentration of ^{18}O in the ice of the silty sand. To confirm such a hypothesis would require analysis of the massive ice above the silty sand.

CONCLUSIONS

Four cores collected from the un-glaciated Eagle River-Ogilvie Mountains region of the northern Yukon have been examined for their ^{18}O contents. Two of the cores contain large fluctuations in isotopic composition which are suggestive of paleoclimatic variations during the past 20,000 years. Permafrost waters interpreted as being late-Wisconsinan in age have $\delta^{18}\text{O}$ values of -26 to -28‰ and suggest that temperatures were on average 9°C lower than today. These $\delta^{18}\text{O}$ values are slightly less negative than waters in the Mackenzie Delta region which have also been interpreted as late-Wisconsinan in age. This discrepancy may be the result of localized variations in the isotopic contents of precipitation or it might reflect the presence of some glacial meltwater in the Mackenzie Delta samples.

One core contained permafrost waters with $\delta^{18}\text{O}$ values similar to modern precipitation and shallow permafrost waters ($\delta^{18}\text{O} = 21.5\text{‰}$). This has been interpreted as indicating either formation of the permafrost during a period of constant climatic conditions or destruction of ^{18}O evidence for past climatic variations due to groundwater migration.

The fourth core encountered large quantities of massive ice, but only samples from the sediment-rich sections were available for study. At depth, the permafrost waters have an isotopic composition which is interpreted as indicating a warmer climatic interval. Above the main massive ice zone $\delta^{18}\text{O}$ values of -29 to -30‰ were encountered. To determine whether these values are related to the late-Wisconsinan period or to a closed system fractionation effect would require analysis of the massive ice zones.

ACKNOWLEDGEMENTS

My thanks are extended to Dr. P. Fritz of the University of Waterloo for his helpful discussions during this study and for the analytical work conducted at his laboratory. I

would also like to thank Dr. A. Judge of the Department of Energy, Mines and Resources for his continued support of this research. Finally, I would like to express my appreciation to Foothills Pipe Lines (Yukon) Ltd. for kindly providing the core material and borehole logs, and to Mr. D. Fisher of Foothills for his support of the program.

BEHAVIOR OF CONCRETE STRIP FOUNDATIONS ON THAWED LAYER OF CLAYEY PERMAFROST

Alexey Mindich

Design and Construction Department, Portland Cement Association,
Skokie, Illinois 60077 USA

This paper reports on laboratory and field investigations into the behavior of thawed layers of clayey permafrost under strip plate loads. The aim was to study the load-settlement relationships of unfrozen as well as thawed soil layers. Such relationships were found to be nonlinear and were expressed in terms of a maximum load and a parameter dependent on the soil layer thickness, the foundation shape, and soil properties.

INTRODUCTION

Two-layer soil systems with a weak thawed upper layer underlain by a stiff frozen base are often encountered in permafrost regions. Thawing of the upper layer of clayey permafrost is accompanied by a decrease in its bearing capacity and by its transformation into a semi-liquid state. Whether a structure can be founded on such soil depends on the deformability as well as the bearing capacity of the soil. The latter is important because even a small load can cause the thawed clayey soil to be squeezed out from beneath the foundation, causing the collapse of the supported structure.

An extensive study into the behavior of two-layer soil systems consisting of a weak soil layer underlain by a rigid base was carried out in the laboratory as well as at an outdoor site. The aim was to determine the settlement of the weak soil layer considering its nonlinear stress-strain characteristics, to estimate the maximum load, and to ascertain the influence of soil layer thickness on both the settlement and the maximum load.

TEST SETUP

Laboratory Experiment

The laboratory research was carried out on soil contained in a mold 1940 mm long, 820 mm wide and 600 mm deep. Load was applied through strip test plates 150, 225, and 300 mm wide. The length of each plate equaled the width of the mold. Each segment was loaded independently. The load on the soil was kept concentric. The load on and the settlement of only the middle segment of the test plates were considered as test results, to avoid the influence of the mold walls (Figure 1). The load on the test plate was increased in steps of 15 kPa until an average pressure (strip plate load divided by plate area) of 120-180 kPa was attained. The value of load attained at the end of a load step was kept substantially constant (within ± 0.25 kPa) during measurements following that step. Settlement of the test plate as well as vertical and horizontal displacements of the six surface

FIGURE 1 Laboratory test setup. 1, strip plate; 2, plate settlement dial gages; 3, surface markers; 4, cold air duct.

markers (three on each side of the strip plate) were measured with an accuracy of 0.01 mm 5 minutes after a load increment, 10 minutes thereafter, and every 20 minutes after that, until stabilization of test plate settlement was accomplished. Strip plate settlement was assumed to have stabilized when it increased by no more than 0.02 mm in 20 minutes and by no more than 0.05 mm in 1 hour of observation. Only the final value of plate settlement corresponding to each load increment was considered in analyzing the test results. Consideration of creep beyond the stabilization of plate settlement was excluded from this study. Such consideration would have interfered with the purpose of this investigation, which was to gather primary data on the behavior of clayey soil layers from large-scale tests (Mindich and Vyalov, 1973).

The thickness of the weak soil layer was 75, 150, 300, and 450 mm in tests with unfrozen soil layers underlain by a rigid base. Tests with artificially thawed soil overlying frozen soil were carried out in the same mold. A 500 mm thick soil mass was frozen by means of cold air driven through a cold air duct under the bottom plate of the mold. Then the upper part of that frozen soil was artificially thawed. The thickness of the thawed layer was 35-40, 60-70, 130-180, 260-280, and 430-440 mm. Thus, the ratio (λ) of the thickness of the weak soil layer (h) to the width of the loading plate (b) was varied from 0.25 to 3.

Field Experiment

In addition to the laboratory tests described above, on-site experiments were carried out on an artificially thawed 0.5 m thick layer of loam permafrost. The 1000 x 2400 mm test plate consisted of three 800 x 1000 mm sections. The horizontal and vertical displacements at six points, three on each side of the test plate, were measured (Figure 2). Horizontal displacements inside the thawed soil layer were recorded by means of colored sand poured into vertical cuts that extended through the layer from each measuring point on the surface. Preparatory work consisted of removal of vegetation, leveling of the test site, and installation of devices and equipment. Two rods with electrothermometers mounted at a close regular interval of 50 mm were embedded into soil on two sides of the test plate location. The depth to the boundary between frozen and unfrozen soil (i.e. the depth to the thermometer reading 0°C) was thus known at all times. This depth was verified by poking pointed

FIGURE 2 Field test. 1, positions of horizontal surface and of vertical strips before test; 2, the same after test.

steel rods into the soil at random locations. At the time when the test plate was ready to be installed in position, the thickness of the thawed soil layer was 0.3 - 0.35 m. Special heating plates were used to increase the thickness of the thawed layer. After a few hours of intensive pre-heating of a 3.5 x 5.0 m area, the thickness of the thawed layer equaled 0.42 - 0.45 m, and at the beginning of test, that value was $h_{ave} = 0.45 \pm 0.01$ m. 200 hours after the test began, the average thickness of the thawed layer was 0.48 m, and at the end of the test, 0.60 m. Considering that the final test plate settlement was about 0.10 m, it can reasonably be assumed that the thickness of the thawed layer equaled a constant average value of 0.5 m. The settlement of the middle section of the test plate as well as the surface marker displacements were measured with an accuracy 0.01 mm.

Plate settlement was considered to have stabilized when it did not increase by more than 0.05 mm in 2 hours of observation. The test plate settlement and the displacements of the surface markers were registered every 15 minutes during the first hour after each load increment of approximately 50 kPa, every 30 minutes during the second hour, and every hour thereafter up to the stabilization of plate settlement. Plate settlement during the test is illustrated in Figure 3.

FIGURE 3 Graph of strip plate settlement with time.

SOIL PROPERTIES

The soil chosen for laboratory research was similar to the weak thawing clayey soil of the Vorkuta region of the USSR. Such strain and stress properties are commonly possessed also by "young" and "light" clays such as muds of littoral zones of seas, on flood plains of rivers, and so forth. The properties of the laboratory research soil (kaolin) and of the field test soil are listed in Table 1.

The stress-strain relationships of the test soil were investigated using Bishop's triaxial test apparatus and also on compression and shear devices. The relationships were found to be nonlinear and describable by a hyperbolic function (Vyalov and Mindich, 1974).

Table 1 Soil Properties

Characteristic	Laboratory Test Soil	Field Test Soil
Liquid limit, percent	46.5	32.3
Plastic limit, percent	28.6	17.5
Water content, percent	36.0	21-23
Unit weight, kg/m ³	1850	1990
Specific gravity	2.62	2.68
Porosity, percent	48.0	39.2
Angle of internal friction, deg.	18.0	18.5
Cohesion, kPa	7.0	40.0
Initial stress-strain modulus, kPa	850	2340
Poisson's ratio	0.40	0.35

Settlement and Maximum Load

The results of laboratory strip plate tests for different values of b and h are shown in Figures 4a-d. The results of the field tests are shown in Figure 5a (curve 1).

The load-settlement curves in Figures 4 and 5 can be approximated by the following expression (Popov, 1950):

$$s = (Ap) \cdot \frac{1}{1 - p/p_{max}} \quad (1)$$

where $A(\text{mm/kPa})$ is a coefficient that depends on the soil properties, the shape and size of the plate, and thickness of the compressed soil layer. Equation (1) can be written in a linear form:

$$\frac{p}{s} = \frac{1}{A} - \frac{1}{A p_{max}} p \quad (1a)$$

Parameters A and p_{max} were determined by fitting linearized graphs of equation (1a) to the test data in coordinates p/s versus p . An example of such curve fitting for data from the field test is shown in Figure 5. Dots plotted in Figure 5a in

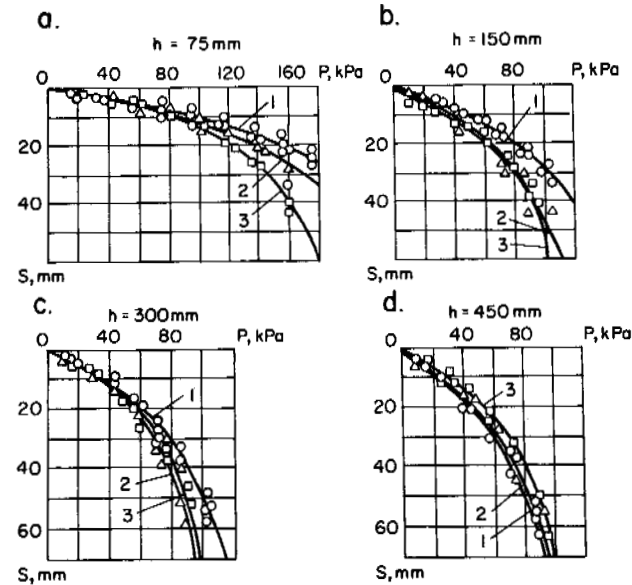

FIGURE 4 Results of strip plate tests for different plate widths and layer thicknesses: (1) $b = 150$, (2) $b = 225$, and (3) $b = 300$ mm.

coordinates p versus s correspond to the values of stabilized settlement for each load increment shown in Figure 3. Then the same dots were plotted in coordinates p/s versus p . Linearization of this series of dots by the least square method yielded the equation

$$p/s = 6.9 - 0.0075p \quad (1b)$$

FIGURE 5 (a) Test data and load-settlement relationships; (b) auxiliary graph for determination of parameters of empirical load-settlement relationship (curve 1).

From equations (1a) and (1b), $A = 1/6.9 = 0.145$ mm/kPa and $p_{max} = 6.9/0.0075 = 920$ kPa. Parameters $1/A$ and p_{max} can be determined directly as shown in Figure 5b. Curve 1 in Figure 5(a) is a plot of equation 1, with values of A and p_{max} as determined above. Linear regression analysis in this particular case gave values of residual standard deviation and correlation coefficient of 0.296 and 0.932, respectively.

The values of A and p_{max} for the laboratory tests were determined in the manner indicated above, and are listed in Table 2.

Parameter A

Referring to Equation (1), $s = A_0 p$ represents a straight line tangent to the initial portion of the s - p curve, and $\frac{1}{1 - p/p_{max}}$ determines the deviation of the s - p curve from that straight line.

Assuming that the theory of elasticity is applicable to the initial straight portion

$$A = b \frac{1 - \nu^2}{E_0} C \quad (2)$$

where E_0 and ν are the initial stress-strain modulus and the Poisson's ratio of the soil, respectively, and C is a nondimensional coefficient, dependent on the shape of the loading plate or foundation and on $\lambda = h/b$. Gorbunov-Posadov (1946) computed and tabulated values of C for different values of λ ranging from 0 to 25, based on the linear

elastic theory. For strip foundations, these theoretical values can be approximated by

$$C = \frac{1.07 \lambda}{1 + 0.4\lambda} \quad (3)$$

Use of the empirical equation (3) not only gives

TABLE 2 Parameters Involved in Load-Settlement Relationship, Equation (1)

Layer Thickness mm	Plate Width mm	Relative Layer Thickness $\lambda = h/b$	Parameters of Equation (1)		
			P_{max} kPa	A mm/kPa	
				Test Data	by Eq. (2)
75	300	0.25	420	0.074	0.072
75	225	0.33	302	0.072	0.069
75	150	0.50	226	0.071	0.066
150	300	0.50	206	0.139	0.132
150	225	0.67	177	0.200	0.126
150	150	1.00	155	0.169	0.113
300	300	1.00	172	0.200	0.226
300	225	1.33	135	0.200	0.206
300	150	2.00	134	0.182	0.176
450	300	1.50	163	0.298	0.297
450	225	2.00	145	0.256	0.264
450	150	3.00	140	0.212	0.216
500	1000	0.50	920	0.145	0.167

good correlation with theoretical results (in most cases within 2-3%) but also allows determination of the value of coefficient C when $\lambda \rightarrow \infty$ (indicating transition from a finite layer to a semi-infinite half-space). According to equation (3) that value $C_{\infty} = 2.68$, whereas the theoretical solution yields $C_{\infty} \rightarrow \infty$ and $C = 2.66$ for the maximum value of λ ($= 25$).

Ultimate State of Soil Behavior

The ultimate state of a soil layer supported on a rigid base was considered by Vyalov (1966) and Mandel and Salencon (1969). According to Vyalov, a drastic reduction in the bearing capacity of a weak soil layer takes place following the formation of a plastic zone under the loading plate (Figure 6a). This plastic zone acts as a wedge which consolidates and slides the surrounding soil apart. Mandel and Salencon assumed that a weak soil layer loses bearing capacity following the formation of differently shaped plastic zones which are exposed to the surface and correspond to the overflow of soil beyond the plate edges (Figure 6b). It is stated in both papers that the value of maximum load depends on the value of $\lambda = h/b$.

To determine the actual soil behavior, a ditch was dug on the test ground, following the conclusion of the field test. One edge of the ditch was along the centerline of the loading strip and connected the measuring points (Figure 2). The measurement of distances between the vertical strips of colored sand showed that the maximum horizontal

displacements had taken place at the interface between the thawed and frozen soils, rather than on the free surface, confirming the sliding apart of the soil. The primary mechanism of the failure of

Figure 6 Limit state of a weak soil layer underlain by a rigid base (a) according to Vyalov, (b) according to Mandel and Salencon.

a weak soil layer supported on a rigid foundation bed is the dislocation of soil in different directions caused by the penetration of an elasto-plastic soil wedge that forms under the loading plate. A secondary mechanism is the simultaneous partial overflow of the soil (more exactly, the lifting of the free soil surface) beyond the plate edge.

Maximum Load

Maximum load by definition is supposed to be the load that corresponds to infinite deformation or settlement. Working with a weak soil layer of finite thickness, it is not possible to directly determine that value experimentally, because a decrease in soil layer thickness due to plate settlement leads to an increase in the maximum load which is a function of soil layer thickness. In the laboratory experiments presented, the value of plate settlement was restricted not to exceed 40-60 mm or 20-30 percent of the strip plate width. The experimental data were sufficient to establish the nonlinear character of the load-settlement relationship and to enable graphical or analytical determination of the maximum load value for each test, using the method described earlier.

Values for p_{max} based on the laboratory tests are plotted as a p_{max} function of λ in Figure 7a, where points 1, 2, 3, etc., correspond to the different h and b combinations listed in Table 2. It is evident that p_{max} decreases with an increase in λ and approaches a minimum value equal to the limit load of a semi-infinite half-space. The test data can be approximately represented by

$$p_{max} = \alpha \frac{\lambda}{\lambda - \beta} \quad (4)$$

where, for the test soil, $\alpha = 131$ kPa and $\beta = 0.180$. The theoretical solution of Mandel and Salencon (1969) shows dependence between p_{max} and λ in the same form as equation (4). However, as shown by curve II on Figure 7a, for any λ , the theoretical solution yields a lower p_{max} than is given by equation (4), with α and β values as given above.

Figure 7 Relationship of P_{max} with λ , and generalized load-settlement curve.

Load-Settlement Relationship

Combining equations (1) - (3), the final $s-p$ relationship becomes

$$s = A \frac{p}{1 - p/p_{max}} = b \frac{1 - \nu_0^2}{E_0} \cdot \frac{1.07\lambda}{1 + 0.4\lambda} \cdot \frac{p}{1 - p/p_{max}} \quad (5a)$$

Equation (5a) applies to strip foundations only. For foundations of other shapes, equation (5a) can be generalized, using equation (4), to:

$$s = A \frac{p}{1 - p/p_{max}} = (b \frac{Y\lambda}{1 + Z\lambda}) \cdot \frac{p}{1 - p(\lambda - \beta)/\alpha\lambda}, \quad (5b)$$

where Y and Z are parameters to be determined from a test. They depend on soil properties and on the shape of the loading plate or foundation. Referring to equation (5a), when the test data are plotted in the coordinate system $s/(Ap_{max})$ versus (p_{max}/p) , the resulting curve is valid for any value of λ . Figure 7b shows such a generalized curve, with the values of E_0 and ν_0 from triaxial tests. The test data, including those from laboratory tests with artificially thawed clayey soil layers, were correlated with the generalized curve through the use of a computer. The coefficient of correlation was a low 0.93, demonstrating the reliability of equation (5a).

It was earlier found experimentally (Mindich and Mirenburg, 1973) that equation (1) can be used for evaluation of settlement and carrying capacity of driven piles, particularly those driven into plastic frozen soils (with temperatures around -1.5°C).

CONCLUSION

The necessity of considering the nonlinear

properties of thawed clayey soil layers underlain by permafrost is illustrated by Figure 5a, where curve 1 illustrates the experimental load-settlement relationship corresponding to equation (1), straight line 2 represents the relationship $s = Ap$ predicted by the linear theory with the value of A as given by equation (2), and curve 3 shows the results of analytical calculation of settlement by equation (5a). All three curves are based on a value of $\lambda = 0.5$ which corresponds to the field test. Curve 1, because of the way the parameters A and p_{max} of equation (1) were derived, is in the closest agreement with the load-settlement data from the field test. The analytical prediction, curve 3, overestimates strip plate settlement by 10-15 percent. Use of the linear theory for calculation of the possible settlement of a strip foundation on a thawed clayey soil layer can result in significant underestimation of the predicted settlement and in uncertainty as to the relationship between the design load and the bearing capacity of the soil layer.

The settlement of a strip foundation supported on a thawed clayey soil layer and the maximum load allowable on such soil (both quantities are needed for design purposes) can be determined in two ways.

"Field" Method

This method consists in carrying out no less than two strip plate load tests directly at the construction site, with different ratios of the thawed soil layer thickness to the width of the strip plate. The number of load increments should be no less than 7 or 8. Sufficient time for stabilization of settlement should be allowed between successive load increments. Test results (load p and the corresponding settlement s) should be plotted in coordinates p/s versus p . The best fit of equation (1a) to the plotted points would yield the parameters A_i and $p_{max i}$ for each test. Having two pairs of values, $p_{max i}$ and λ_i , the numerical values of α and β of equation (5b) can be found from equation (4). Data A_i , b_i , and λ_i from two tests can be used to find an average value of parameter Y from equation (5b); parameter $Z = 0.4$ for strip foundations. This method results in the load-settlement relationship for a strip foundation on a specific construction site.

Analytical (General) Method

Such soil parameters as initial stress-strain modulus E_0 , Poisson's ratio ν_0 , cohesion c , and angle of internal friction ϕ_0 can be determined from laboratory tests usually accompanying the prospecting of a construction site. With these values, the maximum bearing capacity of a thawed soil layer can be theoretically computed (Mandel and Salencon, 1969). The calculated p_{max} and the experimentally determined values of E_0^{max} and ν_0 can be substituted in equation (5a) for the prediction of the load-settlement relationship of a strip foundation supported on clayey thawed soil underlain by permafrost.

ACKNOWLEDGMENT

The author would like to express his deep appreciation to Professor S. S. Vyalov whose ideas and scientific advice were of immense value.

WELL CASING STRAINS DUE TO PERMAFROST THAW SUBSIDENCE
IN THE CANADIAN BEAUFORT SEA.

D.E. Mitchell¹, D.D. Curtis², S.W. Laut¹, N.K. Pui¹, A.S. Burgess²

¹ Dome Petroleum Limited, Calgary, Alberta, Canada

² Acres Consulting Services Limited, Calgary, Alberta, Canada

Permafrost sediments will experience local melting and thaw subsidence with the prolonged extraction of 60° to 85° C hydrocarbons through production wellbores. Design concerns include the settlement of topside production systems and the potential detrimental effects of the displacement-controlled loading of production casings. A total stress analysis, assuming undrained loading, was employed in parametric, single-well studies to assess the influence of the composite thaw subsidence loading mechanisms -- thaw strain and stiffness reduction. The thaw strain results from the potential 9% pore-ice to pore-water volume reduction in ice-bonded permafrost. The stiffness reduction strain is due to the increase in the soil's undrained compressibility with the melting of the pore ice. The validity of the undrained approach to thaw subsidence analysis has been supported by a major field investigation and monitoring program performed during the drilling of the Tarsiut N-44 exploratory well in 1981-82.

INTRODUCTION

In the early 1970s, Exxon, Arco, and BP pioneered research into geotechnical problems related to the extraction of hydrocarbons in the Arctic environment of Prudhoe Bay, Alaska. Specifically, they were concerned with the thermal degradation of permafrost penetrated by "hot" production casings and the resulting soil-displacement-controlled loadings of those casings. The term "thaw subsidence" was coined to describe this phenomenon.

The Prudhoe Bay work was laudable because of its completeness. It encompassed field coring, laboratory testing, definition of constitutive mechanisms, finite element modelling and a full-scale, 5-spot field thaw test. The 5-spot test provided data for the verification of the proposed mathematic model; but, the calibration process was not as satisfying as it might have been. According to Mitchell (1977):

"The initial model runs matched the field test qualitatively and predicted casing strains that were within +/- 0.02% strain of the field test results. The mechanical properties were then adjusted to match the results at the base of the permafrost and the greatest casing strains in the region of alternating strains. The model tracked the measured strains of these specific joints within the accuracy of the field test measurements without any further adjustments."

In 1978, Dome Petroleum Limited initiated a similar research program preparatory to feasibility level design of offshore production structures for their Canadian Beaufort acreage. Exploratory drilling activities in this region had documented the presence of unbonded (no pore ice)

and bonded (pore ice) permafrost sediments up to 600 m in thickness. The basic objective of the program was to extend the Prudhoe Bay work to define a more general, non site-specific and non material-specific approach to the thaw subsidence problem. The "Prudhoe" approach was not felt to be directly applicable to the Beaufort regime because of the difficulty in reliably defining pre and post-thaw pore pressures and the difference in soil types between the two areas. The Prudhoe Bay materials are primarily coarse-grained, while those in the Beaufort are fine-grained.

To this end, both single well and multi-well production configurations were analyzed. A summary of the single well study and the complementary field and laboratory testing programs is presented herein.

THAW SUBSIDENCE MECHANISMS

Two schools of thaw subsidence analysis were reviewed prior to initiation of the single well analytical studies: that of the Prudhoe Bay researchers, Mitchell and Goodman, and that of Morgenstern and Weerdenburg from the University of Alberta. Both teams identified two soil straining mechanisms integral to the thaw subsidence problem. The first relates to phase change and the 9% pore-ice to pore-water volume reduction in ice-bonded permafrost on thaw. This has been addressed under the heading of Thaw Strain by the University of Alberta and Pore Water Pressure Reduction by Mitchell and Goodman. The second soil straining mechanism pertains to the decrease in load-carrying capacity of the soil as the pore material changes from ice to water. This mechanism has been commonly termed Stiffness Reduction.

Phase Change Strain

The phase change of pore ice to water will result in a potential soil volume decrease equivalent to 9% of the pore ice volume. For initially saturated conditions in soils, this can be accommodated by:

- (a) a volumetric contraction of the soil skeleton (thaw strain) under free boundary conditions;
- (b) a reduction in pore water pressure potentially to desaturation within the pore space, if full volumetric contraction is not permitted;
- (c) imbibition of water.

Processes (a) and (b) take place without any flow of water into or out of a representative element of the soil and, therefore, represent "undrained" conditions. In contrast, process (c) would be regarded as "drained" because it involves movement of water from high to low potential.

The thawing of normally consolidated, fine-grained materials under unconstrained conditions will generally induce a volumetric strain because the material is compressible (process (a)). In contrast, dense or coarse-grained materials under the same conditions may not experience the full strain because of the restraining stiffness of the soil skeleton. The result is a decrease in pore pressure that can be permanent (process (b)) or transient (process (c)) if the material possesses a high enough permeability to allow water inflow and satisfaction of the reduced pore water pressure.

Stiffness Reduction

The stiffness reduction loading mechanism can be conceptualized by a two parameter, elastic spring model (Figure 1). The model comprises a series of horizontal beams and vertical springs to represent the permafrost and thawed soil annulus surrounding the well casing.

Prior to thaw, the soil/springs are stiff because of the pore ice and the system is in equilibrium. On thawing, the stiffness of the

FIGURE 1: CONCEPTUAL STIFFNESS REDUCTION MODEL

soil/springs is reduced as the ice changes to water and the beams deflect downward due to their self-weight. The full downward deflection is prevented by the end restraint at the casing and the permafrost, resulting in stress transfer (arching) to these boundaries. This causes a reduction in vertical load at the base of the permafrost and the "springs" in the basal, unfrozen material expand. This results in a compressive straining of the casing within the frozen zone and its tensile straining in the underlying unfrozen material (Figure 3a).

PARAMETRIC SINGLE WELL STUDIES

Basic Approach

The undrained total stress methodology was selected for use in the majority of the Dome analyses on the basis of the predominantly fine-grained nature of the Beaufort materials and concern over the general validity of the pore pressure reduction approach to phase change loading. The pore pressure reduction concept was questioned on the basis that the establishment of pore pressures in the ice and subsequently in the thawed ground on an a priori basis was highly contentious.

Finite Element Modelling

The finite element program NONSAP was chosen for analysis of the thaw subsidence phenomenon because of its linear and non-linear capabilities. The structured model was axisymmetric with a fixed base and roller side. A permafrost thickness of 600 m was selected in light of recorded Beaufort conditions, and the external lateral boundary was set at a radial distance of 500 m to meet the zero displacement criterion (Figure 2). The modelled casing was 500 mm in diameter, and any structural contribution of a grouted annulus was conservatively neglected. A no-slip condition at the casing/soil interface was assumed during preliminary analysis.

The thaw strain and stiffness reduction loading mechanisms were treated separately and then superimposed for the linear elastic analyses. The elasto-plastic analyses required that both loading mechanisms be combined and incrementally applied during modelling.

FIGURE 2a: FINITE ELEMENT MODEL CONFIGURATION

FIGURE 2b: SINGLE WELL PARAMETRIC GEOMETRY

The desired thaw strains were input as initial strains into the finite element model. The volumetric thaw strain was distributed equally in three orthogonal directions, i.e., $\epsilon_r = \epsilon_z = \epsilon_\theta = \epsilon_v/3$. A brief discussion and derivation of initial strain loads is presented in Appendix A.

The casing stresses and strains resulting from the stiffness reduction mechanism were assessed by comparing the pre-thaw and post-thaw regimes (i.e. E_{FROZEN} vs E_{THAWED}). Derivation of the constitutive laws for the stiffness reduction mechanism is presented in Appendix B.

Parametric Runs

Two basic deposit geometries were investigated in the single well parametric study package:

- (a) a homogeneous soil stratigraphy with variable thaw radius, and
- (b) a layered stratigraphic sequence with a fixed 12 m thaw radius.

With a homogeneous soil stratigraphy, the peak casing strains occurred at the base of the permafrost. Maximum compressive casing strains occurred adjacent to the thawed soil, while peak tensile casing strains were found directly below and adjacent to the unfrozen soil (Figure 3a). A summary of the homogeneous geometry results is presented in Figure 4, along with the basic design parameters.

FIGURE 4: AXIAL CASING STRAINS AS A FUNCTION OF THAW RADIUS (HOMOGENEOUS STRATIGRAPHY)

Deep coring of Beaufort sediments revealed a layered stratigraphy made up of materials with sharply varying mechanical properties; therefore, layering effects were investigated using a repeating stiff and soft material couplet. The "layered" casing strains followed similar mean trends to their homogeneous counterparts, but the interbedding induced minor strain variations that locally amplified the general trends (Figure 3b). The worst-case layer configuration was a thin, soft-soil layer located below a thick-stiff layer. A summary of the layered sequence results is presented in Figure 5.

FIGURE 5: AXIAL CASING STRAINS AS A FUNCTION OF SOIL LAYERING (12 m THAW RADIUS)

The general conclusion of the parametric work was that a layered sequence represented the critical design scenario, ceteris paribus, and that changes in compressibility within interbedded sequences most significantly affected the casing strains. Cursory elasto-plastic analysis marginally reduced the strains predicted from the elastic model, but did not alter this basic conclusion.

TARSIUT N-44 CASE HISTORY

General

A major field investigation and thaw subsidence monitoring program was performed during the drilling of the Tarsiut N-44 well in 1981-82 to latterly aid in model verification. A preliminary calibration run had been made using Prudhoe Bay results, but this, in spite of good agreement between field and model results (Figure 6), did not represent an objective verification of the approach because of the lack of original laboratory data in the literature. The Tarsiut program included field drilling, sampling, logging, and testing; field casing instrumentation and monitoring; laboratory testing; and back-analysis of the measured casing strains through finite element modelling.

DOMESTIC WELL CASING STUDY - PRUDHOE BAY

12 MONTH THAW PROFILE, GEOLOGICAL HISTORY

FIGURE 6

Field Investigations

The geotechnical field investigation at Tarsiut "piggy-backed" the well drilling operation to the 650 m depth level. The first phase of the program was carried out between 20 m and 170 m below the island/seabed contact, and was effectively a standard geotechnical investigation with pseudo-continuous sampling of the formation at 1 metre intervals and local in-situ testing. The retrieved samples were subjected to simple index testing in the field (i.e., density, temperature, strength, total and frozen moisture contents, etc.) and then preserved for shipment south in thermostatically controlled freezers.

Operational and schedule constraints precluded geotechnical coring in the lower portion of the permafrost zone. As a result, the second phase of the investigation, which related to the 170 m to 650 m depth range, involved the inference of lithology from drill bit cuttings, drilling performance, geophysical logs, and sidewall cores.

The investigations revealed that the Tarsiut N-44 foundation stratigraphy was characterized by interbedded silts and clays with isolated sand stringers. Bonded permafrost soils existed between 60 m and 410 m below the island/seabed contact and contained little or no visible ice. Temperatures measured downhole and in core samples indicated that minimum ground temperatures approached -3.5°C . The consistencies of cohesive units ranged between firm and very stiff when thawed, and test results indicated that these soils were moderately compressible and normally consolidated.

Casing Instrumentation

In-situ temperatures, pore pressures, and casing strain data were considered to be crucial to the successful verification of a thaw subsidence model, and a downhole instrumentation system was designed to effect the retrieval of such data during the drilling and testing period at Tarsiut N-44. Integral to the system was a monitoring casing joint that housed two temperature transducers, three pore pressure transducers, and nine strain gauges (3 hoop and 6 axial). These instruments were sensed by downhole data acquisition units and, subsequently, a topside wellhead

data concentrator and processing unit (Figure 7).

Six, 30-inch diameter and eight, 20-inch diameter monitoring joints were installed within the permafrost zone at Tarsiut. Specific locations were selected to obtain casing strain data representative of material type (i.e. located in the middle of massive deposits) and facies changes (i.e., located at layer boundaries).

FIGURE 7

Laboratory Testing Program

Previous research showed that the primary design variable in the thaw subsidence analysis was the modulus of deformation (E_{μ}) and that small design changes in elastic properties were more important than increased sophistication in modelling technique. As a result, Dome Petroleum Limited commissioned EBA Engineering of Edmonton to evaluate the frozen and thawed deformation moduli (E_{μ}), Poisson's ratios (ν), and thaw strains (ϵ_{ν}) of the retrieved Tarsiut cores. A complete description of the temperature and stress path-controlled testing program is documented in the referenced report.

While detailing of the testing program results is not possible herein due to their proprietary nature, the following qualitative statements can be made concerning the program findings:

- (a) the measured thaw strains were compatible with the mineralogy, pore water salinity, and in situ temperatures of the samples;
- (b) the measured thaw deformation properties agreed well with those of normally consolidated "southern" materials;
- (c) the measured frozen deformation properties were generally lower than those reported in the literature because of their "warm" nature, but were compatible with the mineralogy, pore water salinity, and in situ temperatures of the materials.

- (d) the thaw strain treatment of phase change loading appears to be justified.

Tarsiut Back-Analysis

Casing strain data for the Tarsiut back-analysis was selected from the January to April 1982 time period. All mechanical drilling- and testing-related strains, such as casing hanging and tensioning, were subtracted from the pup joint gauge data on the basis of drilling records. The remaining strains were felt to be attributable to the thaw-induced, soil displacement-controlled loading of the casing and, therefore, represented the datum for model verification.

The amount of thaw generated by the N-44 exploratory well was obtained through the use of a finite element thermal program. Input parameters included pre-drilling measured formation temperatures, external wellbore temperature variation with time measured by the in situ temperature sensors, and the thermal conductivities, volumetric latent heats, and volumetric specific heats of composite soil layers. The thaw radius for the Tarsiut scenario was thereby predicted to be 1.75 m.

Due to the low measured casing strains and small thaw radius, the thaw-induced strains were modelled using the linear elastic portion of the finite element program. Input moduli and thaw strains were obtained from representative material stress/strain curves as determined by EBA Engineering. The thaw strain and stiffness reduction loading mechanisms were analyzed separately and then superimposed in accordance with the methods outlined previously.

As shown in Figure 8, the predicted casing strains agree well with those measured, in both magnitude and trend. The displayed results pertain to the initial thaw subsidence model run using objectively selected material properties. A subsequent parametric study showed high sensitivity to material properties, thereby lending credence to the laboratory testing procedure and the method of analysis.

FIGURE 8

FUTURE WORK

On the basis of the Tarsiut N-44 validation study, the undrained thaw subsidence approach is being used to analyze the more realistic multi-well/cluster development scenario. The work will be performed as a joint industry sponsored research project (APOA 209) and will include examination of the influence of production structure-induced consolidation (i.e. negative skin friction) and the stability of deviated well clusters. It is anticipated that this study will be completed by January 1984.

ACKNOWLEDGEMENTS

The writers wish to acknowledge the contributions of personnel from Dome Petroleum Limited (R. Saint, M. Bradshaw), Acres Consulting Services (Dr. A. S. Burgess), EBA Engineering Ltd. (Dr. W. D. Roggensack, Dr. D. Taplin, P. Ruffell, P. Romeril), and the University of Alberta (Dr. N. R. Morgenstern, P. Weerdenburg) to this study. We also thank Shelly Lewchuk for her assistance in preparing this paper and the Tarsiut partners (Gulf, Dome, Norcen, and Canterra) for permission to publish it.

APPENDIX A

Finite Element Treatment of Initial Strains

1 - Finite Element Analysis (Axisymmetric) with Initial Strain Loads

Start with the result of the minimization of potential energy.

$$\{P\} = [K] \{\Delta\} \quad (1)$$

This equation applies to the whole continuum

Where $\{P\}$ = global force vector (loads)

$[K]$ = global structure stiffness matrix

$\{\Delta\}$ = unknown nodal displacement.

For an individual element

$$[K] = [B]^T [D] [B] dV \quad (2)$$

Where $[K]$ = element stiffness matrix

$[B]$ = relates displacements to strains.

Also

$$\{\epsilon\} = [B] \{\Delta\} \quad (3)$$

$$\{\sigma\} = [D] (\{\epsilon\} - \{\epsilon_0\}) \quad (4)$$

Where

$[D]$ = constitutive matrix for an axisymmetric solid

$\{\epsilon\}$ = strain from applied loads

$\{\epsilon_0\}$ = initial strain.

With the element stiffness matrices formed, the structure stiffness matrix can be assembled for the entire continuum.

The applied loads generated by the initial strains are

$$\{F\}^e = [B]^T [D] \{\epsilon_0\} dV \quad (5)$$

The element force vector $\{F\}^e$ is assembled into $\{P\}$. Knowing $\{P\}$ and $[K]$, one can solve for the overall displacements

$$\{\Delta\} = [K]^{-1} \{P\} \quad (6)$$

The results of (6) are substituted into (3) then (4) to obtain stresses.

APPENDIX B

2 - Stiffness Reduction Loading - Undrained

(a) Initial Stress State

$$\sigma_z = \gamma h; \sigma_r = K_o \sigma_z; \sigma_\theta = K_o \sigma_z$$

Where γ = total soil density

h = height of soil above element centroid

(b) Initial Strain - Frozen State

$$\epsilon_{zF} = \frac{\sigma_z}{Eu_F} - \frac{\nu u_F}{Eu_F} (\sigma_r + \sigma_\theta)$$

$$\epsilon_{rF} = \frac{\sigma_r}{Eu_F} - \frac{\nu u_F}{Eu_F} (\sigma_z + \sigma_\theta)$$

$$\epsilon_{\theta F} = \frac{\sigma_\theta}{Eu_F} - \frac{\nu u_F}{Eu_F} (\sigma_r + \sigma_z)$$

Where Eu_F = undrained Young's Modulus (frozen)

νu_F = undrained Poisson's Ratio (frozen)

(c) Initial Strain - Thawed State

$$\epsilon_{zT} = \frac{\sigma_z}{Eu_T} - \frac{\nu u_T}{Eu_T} (\sigma_r + \sigma_\theta)$$

$$\epsilon_{rT} = \frac{\sigma_r}{Eu_T} - \frac{\nu u_T}{Eu_T} (\sigma_z + \sigma_\theta)$$

$$\epsilon_{\theta T} = \frac{\sigma_\theta}{Eu_T} - \frac{\nu u_T}{Eu_T} (\sigma_r + \sigma_z)$$

Where Eu_T = undrained Young's Modulus (thawed)

νu_T = undrained Poisson's Ratio (thawed)

(d) To compute the change in initial strain due to stiffness reduction, the frozen initial strains are subtracted from thawed initial strains.

FROST FEATURES IN THE KARST REGIONS OF THE WEST CARPATHIAN MOUNTAINS

Pavol Mitter

Museum of Slovak Karst and Protection of Nature
Liptovský Mikuláš, Czechoslovakia

The action of freezing and thawing on limestone near cave entrances in the high mountains of Czechoslovakia produces modification of rock walls, rock shelters, debris ramparts, and sorted polygons and stripes in the frost-weathered debris of the cave floor. Debris ramparts, about 1 m high and wide, form near cave entrances. They are the result of intense frost action caused by the outside freezing air entering the cave and contacting the moisture-soaked, jointed limestone walls. Frost-weathering debris on the cave floors near the entrances is sorted into small polygons and stripes by frost action.

INTRODUCTION

The occurrence of permafrost is rare in Czechoslovakia. A special type of permafrost exists in the high mountains, in colluvium and mainly in ice caves among which Dobsinská Ladová jaskyna (968 m), Silická Ladnica (503 m), Demänovská Ladová jaskyna (837 m) and Ladová jaskyna na Muráni (860 m) are the best known localities. The areal extent of permafrost in ice caves is only several 1000 m². The occurrence of frost stirred soil forms can be expected on the border of the glacier where the surface part of sediments partly melts in summer and where favorable conditions for typical solifluction arise. During research of the karst in the Západné Karpaty (West Carpathian) Mountains in the territory of Slovakia, we often met forms of relief which are influenced by or depend on frost activity. Some of them are due to periglacial processes without the existence of permafrost (Washburn 1973). In winter, when the air temperature often alternates below and above 0°C, mostly in sunny localities, the weathered mantle of loose sediments alternately freezes and thaws, and gives rise to favorable conditions for frost shattering and sorting of soils. In our country, Sekyra (1960) has evaluated the effect of the frost on the soil and Demek (1972) has suggested the classification and the terminology of cryogenic forms. Some manifestations of frost activity are considered to be due to periglacial processes, but others are due to local ice growth and exfoliation.

We have directed our attention partly to the effect of temperature changes on the rock walls of limestones and dolomites, on the rock walls of shelters, and on the unvegetated entrance areas of caves.

FORMATION OF ROCK WALLS, ROCK SHELTERS, AND CAVE ENTRANCES

The formation of debris ramparts in front of cave entrances is a manifestation of frost action. The debris ramparts are about 1 m high and 1 m wide. They are vertical to the axis of the cave entrances and may extend in front of the entire entrance if

it is beneath a great rock wall.

Debris ramparts have been found from a lower elevation of about 600 m to the highest ones at elevations of 800-1000 m; they are the most widespread. They form and are preserved in front of entrances oriented to various cardinal points if cryogenic processes cannot remove the debris rampart, e.g. Malá jaskyna za Kanel'om (997 m) in the Nízke Tatry (Figure 1) and Lôm (862 m) and Biela jaskyna (840 m) in the Vel'ká Fatra.

Weathered material falls from the rock walls mostly in spring, suggesting a direct relationship to frost action. This area is in contact with the outside atmosphere as well as with the air in the cave. In addition, surface water seeping downward through minor joints in the rocks and condensation moisture are very important in frost weathering. Most of the rock shelters in the intensely tectonically shattered limestones may be considered to be chiefly a product of frost action.

The difference between the formation activity of frost action and formation that occurs without frost action is evident in Malá jaskyna za Kanel'om, a horizontal cave about 43 m long. The entrance is partially filled by debris that had been isolated from the inner part of the cave. The walls of the entrance are modified by frost weathering. The weathered material and powder sinter on the floor of this part of the cave are sorted by frost action. The walls of the inner part of the cave, however, have been separated for a long period of time from the outside atmosphere and they are smooth, with the original form of erosion and karst formation, without traces of frost weathering. Even debris on the floor in the inner part of the cave is not frost-sorted (Figure 2).

PATTERNED GROUND

Patterned ground is a common phenomenon on rock shelter floors and in cave entrances. It forms where debris and powder sinter have accumulated. We use the term "powder sinter" to indicate a modification of secondary CaCO₃, which occurs on the walls of rock shelters and in cave entrances in

FIGURE 1 Entrance to the cave Malá jaskyňa za Kancl'om with debris rampart.
(Photo by P. Mitter)

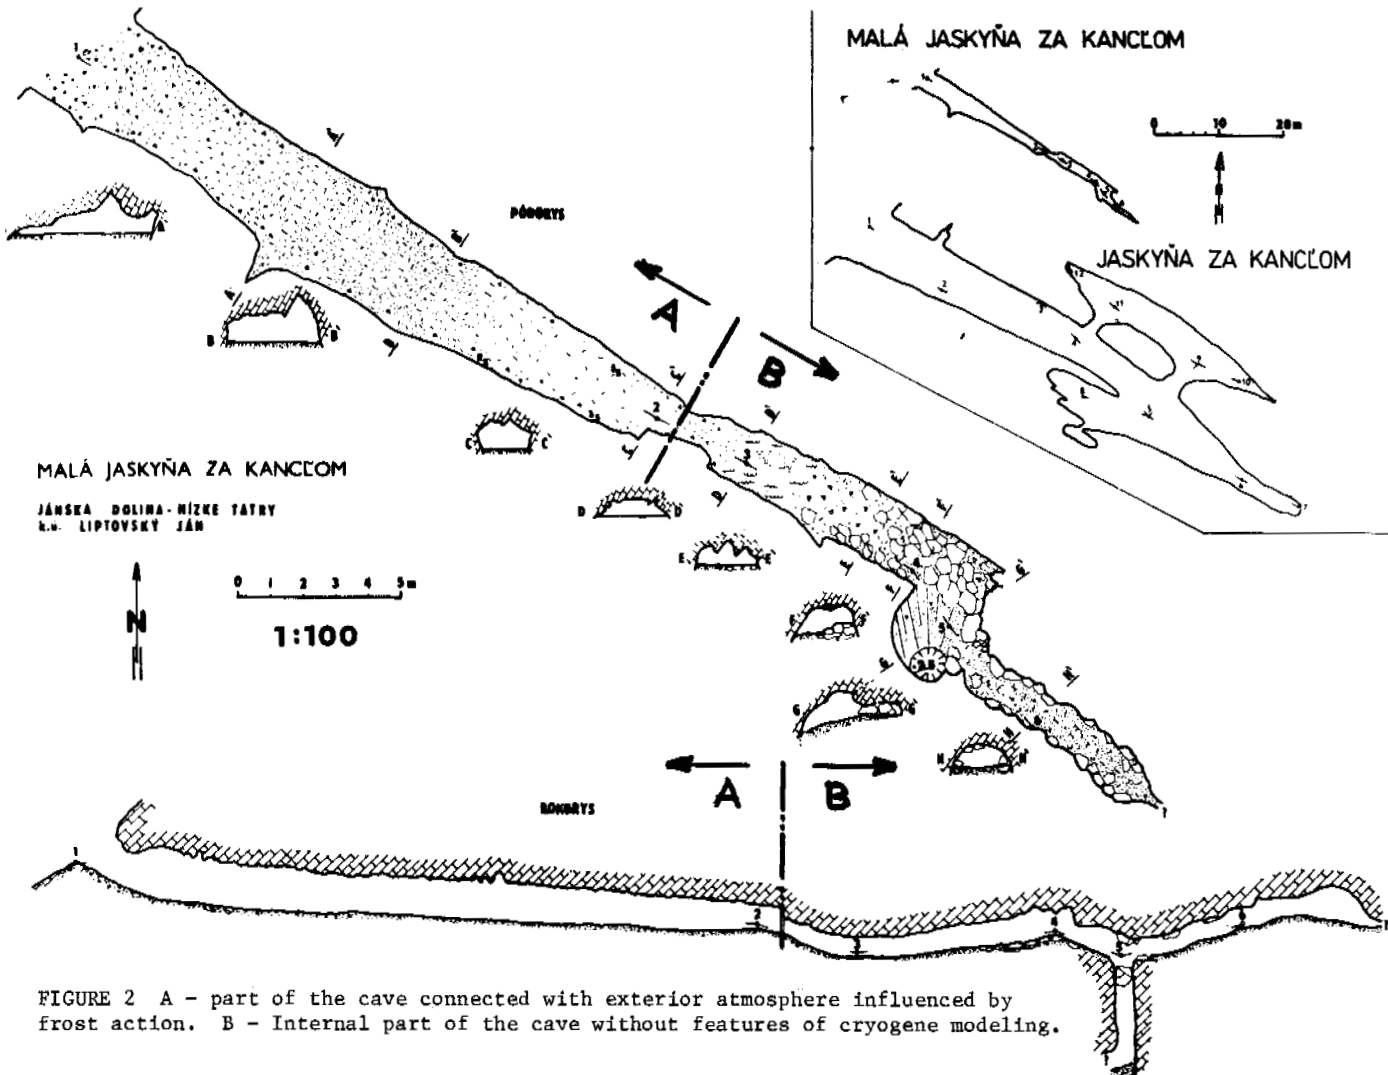

FIGURE 2 A - part of the cave connected with exterior atmosphere influenced by frost action. B - Internal part of the cave without features of cryogenic modeling.

FIGURE 3 Patterned ground in the cave Jelenia/Vel'ká Fatra Mountains.
(Photo by P. Mitter)

cold climates [Ložek (1964) used the term "pěnitec], forming separate crystals on the walls that float very slowly by percolated water to the floor of the shelter or cave. The unconsolidated material on the floor consists of debris, powder sinter, and the insoluble residue of limestone, which holds water well and creates a very favorable environment for frost action. There is often water there, and during more humid periods this sediment turns almost marsh-like. This type of wet sediment is favorable for the formation of patterned ground (Figure 3). The absence of vegetation and humus substance and the absence of the immediate effects of rainfall exclude the possibility that this phenomenon is a product of processes other than frost action, as Panos (1973) reported from the Belanské Tatry Mountains. We also found small non-sorted polygons in places with no debris. Our findings lower the altitudinal limit of the occurrence of patterned ground considerably from those of Jahn (1970).

SORTED STRIPES

Sorted stripes commonly occur on inclines in the floors of rock shelters and in the entrance areas of caves. The environment and the mechanism by which they are formed are very similar to those in which sorted polygonal forms occur; however, the inclines provide very favorable conditions for sediment movement. We wish to emphasize the importance of these processes in the creation of rock shelters, small caves, and cave entrances.

In the Západné Karpaty Mountains, where the mean annual air temperature ranges from $+5^{\circ}\text{C}$ to -3.7°C from the lower slopes to the top (the highest point in Czechoslovakia with a meteorological station), and the annual precipitation is 900-2000 mm, weathered material and free sinter material are transported out of caves by alternate freezing and thawing, mainly at the beginning and the end of the winter period. The transported material accumulates in front of the caves. In the Jelenia Jaskyňa cave (844 m), which has a spacious entrance and permits easy contact with the outside atmosphere, features of cryogenic transport occur as far as 35 m back in the cave from the entrance. Transported material in front of the Piesková cave in the Vel'ká Fatra Mountains can be seen in Figure 4. In many small caves, we have noted small sorted polygons, unsorted polygons, and sorted stripes.

After 10 years of research on karst in the Vel'ká Fatra and the Nizke Tatry Mountains, examining several tens of small caves and rock shelters, we believe that frost weathering and the transport activity of frost (Figure 5) play the main role forming in these caves and shelters. A specific type of cave or shelter is formed where the solution features are greatly subdued and frost-weathering phenomena are well developed. We term such caves "slope caves." The main features of these caves are: (1) linear form, (2) cave walls that are modelled by mechanical weathering, (3) cave floors that incline to the exit of the cave, and (4) debris on the floor of the cave that exhibits sorted polygons and stripes. These caves can be up to some tens of meters long.

FIGURE 4 Entrance to the cave Piesková with debris transported from the cave by frost action. (Photo by P. Mitter)

FIGURE 5 Development of slope caves with cryogenic transport material from the cave.

CONCLUSIONS

On the exposed parts of the middle and high elevations of the Západné Karpaty Mountains, under the existing central European climate, frost action is one of the most important geomorphic factors of the karst regions. In front of caves, remarkable ramparts of debris form as a result of frost action on the exposed rock walls. In cave entrances, where there is easy, direct contact with the outside atmosphere, and in small caves as well, small sorted polygons and stripes form in the weathered debris on the cave floors. Cryogenic processes transport the loose sediments on the inclined cave floor towards the exit, and special types of caves, e.g. "slope caves," are created.

GEOPHYSICAL MEASUREMENTS OF SUBBOTTOM PERMAFROST
IN THE CANADIAN BEAUFORT SEA

J. L. Morack¹, H. A. MacAulay and J. A. Hunter

Geological Survey of Canada, 601 Booth Street, Ottawa, Ontario, Canada

¹Currently on sabbatical leave from the University of Alaska,
Fairbanks

Early marine seismic refraction interpretations on the Canadian Beaufort Sea shelf have indicated the widespread occurrence of ice-bearing sub-seabottom sediments. A large area of the shelf is underlain by coarse grained high velocity (> 3000 m/s, typical of ice-bonded sand and gravel) Cenozoic sediments. Recent data have reaffirmed the subdivision of this area into two major seismic layers, a deep thick continuous layer with the upper surface generally greater than 100 m below the seabottom, and a thin discontinuous layer at depths of 5-50 m below the seabottom. High resolution multichannel refraction seismic surveying has provided detailed structure of these layers.

INTRODUCTION

The existence of subsea permafrost in the Beaufort Sea shelf was predicted by Mackay (1972). Subsequent studies (Hunter and Hobson 1974, Hunter et al. 1976, 1978, MacAulay and Hunter 1982, Morack and Rogers 1982, 1983, Neave and Sellmann 1982, Osterkamp and Harrison 1982, Rogers and Morack 1980, Sellmann and Chamberlain 1979) in the Alaskan and Canadian Beaufort Seas have shown that ice-bonded sediments exist under large areas of the continental shelf.

Hunter et al. (1978) employed seismic refraction techniques on first arrival events from oil industry records to determine depths and velocities of thick ice-bonded permafrost. These measurements were limited by the large spacing of the hydrophone groups and the preferential attenuation of refraction events. Recently, the oil industry has been collecting high resolution reflection data in some areas of the Beaufort Sea shelf. The shorter hydrophone lines, the closer spacing of the hydrophone groups, and the higher source frequencies used for these data are much better suited to the refraction interpretation of ice-bonded subsea permafrost. This paper presents the analysis of two such lines.

The location of these lines is shown in Figure 1. Line A transects the outer Beaufort Sea shelf and Line B the inner shelf to the east of Mackenzie Bay. Also shown in this figure are areas underlain by shallow and deep high velocity refractors as determined from previous work (Hunter et al. 1978).

SEISMIC VELOCITIES OF ICE-BONDED
PERMAFROST

Seismic velocities of water-saturated materials increase with decreasing temperatures below 0°C responding to the increase in interstitial ice content. Ice content varies directly with grain size (i.e., sand generally contains higher ice content than clay) and inversely with pore water

salinity (saline interstitial water lowers the freezing point).

Numerous laboratory measurements of seismic velocities of ice-bonded permafrost have been made (Aptikaev 1964, Nakano et al. 1971, 1972, King et al. 1982). Velocity ranges for samples taken in the Canadian Beaufort Sea are discussed in detail in the paper by King et al. Their data show that the increase in ice content, and hence seismic velocity, with decreasing temperature below 0°C is less dramatic for fine grained than for coarse grained materials. Velocities for ice-bonded sand in the Beaufort Sea range from 4,000 m/s down to approximately 2,500 m/s, and may be as low as 1,800 m/s if the materials are only partially ice-bonded. Velocities for ice-bonded silt range from 3,300 to 2,200 m/s, while those for ice-bonded clay range from 2,300 to 2,000 m/s. These velocity ranges may be a few hundred m/s lower if the materials are only partially ice-bonded. These general velocity ranges are used later in this paper for the interpretations given to the refraction sections.

DISCUSSION OF HIGH RESOLUTION DATA

Detailed seismic refraction data have been analyzed along two marine survey lines (A and B in Figure 1) recorded during the summers of 1979 and 1981 for Dome and Gulf Petroleum. An air gun array was used as the source in both cases. Line A data were taken using the near 24 equally spaced hydrophone groups of a longer streamer giving an effective length of 767 m with a 240 m offset from source to near group. The shot points were spaced every 33.3 m for reflection analysis; however, only every tenth shot point was analyzed for refractors. Line B data were collected using 96 equally spaced hydrophone groups along a 600 m long streamer having a 14 m offset. Every eighth shot point was analyzed giving a spacing of 100 m. The first 0.80 s of the Line A data and 0.50 s of the Line B

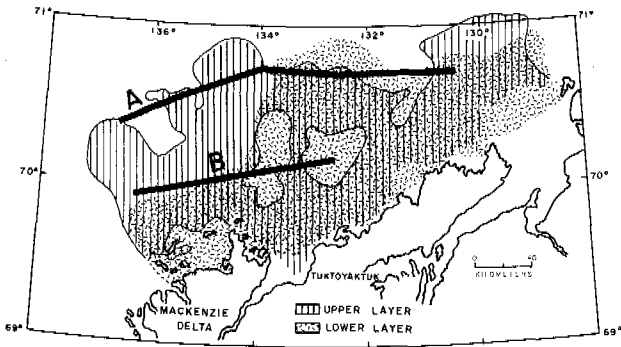

FIGURE 1 Map of the study area showing locations of seismic lines. Shaded areas indicate locations of upper (< 60 m) and lower (> 100 m) ice-bonded sediments as determined from previous studies.

data were made available for refraction analysis. A typical "wiggly trace" record for the Line B data is shown in Figure 2. The first arrival events were manually picked using microcomputer assisted digitizing techniques. The data were analyzed for depth and velocity information using standard refraction techniques (Telford et al. 1976). The different refraction events were easily determined by displaying the data as a reduced travel time plot where arrival times were shifted by the amount x/v , where v is near the refractor velocity.

ISO-OFFSET TIME SECTIONS

The first arrival times for all records were displayed in a format that we call an "Iso-Offset Time Section." This is a plot of shot point locations along the horizontal axis and first arrival time in the downward direction. Arrival times at a given hydrophone group for each of its shot point locations are then connected by straight line segments. The position of each hydrophone group was shifted by one-half its distance from the shot point to more accurately locate the midpoint of the ray path. An Iso-Offset plot for Line A is shown in Figure 3. The vertical spacing of the connected lines decreases as the seismic velocity increases due to the shorter interval time. Thus, a sharp velocity contrast is indicated by a change in the density of the connected lines; areas underlain by high velocity material appear as areas of closely spaced lines on the plot. Figure 3 shows at a glance the locations along the line where high velocity materials exist. Additionally, the vertical displacement of the high density segments gives a qualitative indication of the depth of the velocity discontinuities; those segments appearing later in time occur at greater depth.

For the purposes of discussion here, the shelf area has been divided into several geotechnical divisions suggested by M. J. O'Conner (personal communication, 1983). From the west, these divisions are the Kringalik Plateau, the Ikit Trough, the Akpak Plateau, the Kugmallit Channel, the Tingmiark Plain, the Niglik Channels, and the Kaglulik Plain. Line A traverses the outer shelf

FIGURE 2 Typical "Wiggly trace" record showing high velocity refractors.

area and crosses all of these divisions. The west end of the line beneath the Kringalik Plateau shows a few shallow high velocity events. The section beneath the Ikit Trough shows a depression in the high velocity zones. The area beneath the Akpak Plateau is characterized by nearly continuous shallow high velocity materials. The Kugmallit Channel area shows a shallow layer, having a seismic velocity in the range of 1,800-2,100 m/s, underlain by a deeper high velocity (> 2,500 m/s) layer which is visible for most of the rest of section as a gradually upward sloping layer. East of the Kugmallit Channel this deep layer is overlain by a shallow high velocity layer which shows two definite depressions at the Niglik Channels. All of these high velocity segments have been interpreted as ice-bonded or ice-bearing materials. In general there is a good correlation with the suggested geotechnical divisions.

Figure 4 shows an Iso-Offset plot for Line B which traverses the inner shelf. Because of the large number of shot points examined, this line is shown in three segments. The velocity contrasts are much more apparent than those in Line A because of the increased number of traces per record and because the vertical time scale is only one-half that of Line A. Beginning at the west end of the line, sections B-1 and B-2 up to approximately 135° W longitude show only an occasional high velocity segment. Beneath the Akpak Plateau an almost continuous shallow high velocity layer is present. Underneath this shallow layer, a deeper high velocity layer is apparent along much of the section. Across the Kugmallit Channel the shallow high velocity refractor is only sporadically present, whereas the deeper high velocity layer is essentially continuous. Along segment B-3 the deep high velocity layer continues and short segments of a shallow layer occur. The refraction analysis indicates that the depth from the sea surface to

FIGURE 3 Iso-Offset section of seismic Line A.

FIGURE 4 Iso-Offset section of seismic Line B shown in three adjoining segments.

the top of the shallow high velocity layer ranges from 20 to 60 m, while the depth to the top of the deep high velocity layer is between 120 and 160 m. The seismic velocities of the high velocity layers in segments B-2 and B-3 are greater than 2,500 m/s indicating ice-bonded materials, while those in segment B-1 are greater than 1,800 m/s indicating ice-bearing materials. In general the Iso-Offset section does not correlate as well with the suggested geotechnical divisions as the previously discussed section farther offshore.

RESULTS OF REFRACTION ANALYSIS

A detailed refraction analysis and interpretation has been carried out on selected portions of both Lines A and B. Figure 5 shows an Iso-Offset section from Line A which crosses the Kugmallit Channel. Beneath this is a plot of the refraction analysis including calculated velocities and depths to refractors. The error bars shown on the velocity data points are the standard deviations of the least squares fits made to the time-distance

FIGURE 5 Iso-Offset section and velocity-depth section for a portion of Line A. The numbers shown beneath the depths are ranges for the corresponding refractor velocities in m/s.

plots. The errors shown for the depth calculations are the propagated errors of the velocities and time intercepts used in the calculation. A water velocity of 1,420 m/s was used for the depth calculations when a water arrival was not observed on the records. This occurs when the first arrivals are generated by a shallow high velocity layer.

West of the Kugmallit Channel the section shows a number of discontinuous high velocity zones within 50 m of the seabed. These can be divided into three segments exhibiting different velocity characteristics. At the west end is a dipping layer with velocities ranging from 2,000 to 2,500 m/s. This material is interpreted to vary from partially ice-bonded to ice-bonded fine grained materials. To the east of this is a section showing a shallow layer where the velocities are from 2,600 to 3,800 m/s. This layer is interpreted to be ice-bonded sands. Immediately to the west of the Kugmallit Channel is a shallow layer having velocities ranging from 2,200 to 2,500 m/s which are interpreted to be ice-bonded fine grained materials.

The section beneath the Kugmallit Channel indicates a refractor approximately 25 m beneath the seabed with velocities ranging from 1,800 to 2,100 m/s, and a deeper refractor approximately 160 m below seabottom with velocities of 2,200 to 3,500 m/s. The upper layer is interpreted to be partially ice-bonded or ice-bonded fine grained sediments and the deeper layer to be partially ice-bonded or ice-bonded sands.

East of the channel the section shows a high velocity layer lying essentially at the seabed. The layer exhibits velocities in the range of 2,500 - 3,700 m/s indicating ice-bonded fine sands. Due to the high velocity of this refractor, a hidden layer probably exists above it. Its absence in the refraction analysis would make the calculated depth of the high velocity layer too shallow. Beneath this layer the continuation of the deeper layer is evident on the Iso-Offset plot but has not been included in the refraction analysis due to a lack of information of the intervening material velocities. The amplitude attenuation of the seismic signals indicates that the thickness of the shallow ice-bonded layer is probably no greater than 50 m; however, additional data including drill hole data is needed to confirm this. Thus a low velocity zone is probably present beneath the shallow ice-bonded layer in this region. This section illustrates how useful it is to have a high resolution reflection profile in conjunction with the refraction analysis. The reflection profile shows the layering, while the refraction analysis supplies the velocities needed to calculate depths.

A detailed analysis of a section of Line B-2 just west of the Kugmallit Channel is shown in Figure 6. An Iso-Offset section and the refraction analysis are shown. This section is characterized by discontinuous shallow high velocity refractors which lie from 20 to 60 m beneath the seabed and a deep high velocity refractor which is nearly continuous at a depth of approximately 125 m below

FIGURE 6 Iso-Offset section and velocity-depth section for a portion of Line B. The numbers shown beneath the depths are the corresponding approximate refractor velocities in m/s.

the seabed. The velocity of these refractors is approximately 3,500 m/s and indicates that they are ice-bonded sands. In areas where the shallow high velocity layer is absent, the deep layer is overlain by materials having velocities of approximately 1,600 m/s whose upper surface is essentially the seabed.

A thin hidden layer is undoubtedly present in the case of the shallow high velocity layers, and consequently the calculated depths are slightly shallow. Again from the amplitude behaviour of the seismic signals, the thickness of these shallow ice-bonded layers is estimated to be less than 50 m. A short segment of the deep layer is also apparent on the Iso-Offset section beneath the shallow layer near the west end. It is only slightly "pulled up" above the deep layer lying just to the east, again indicating that the upper layer is thin. An apparent gap in the deep layer is present near the east end of the section. The anomalous velocity values that occur at each end of the gap are explained by recalling that the hydrophone line extends across several shot points. These incorrect velocity values are responsible for the nature of the depths shown.

COMPARISON OF REFLECTION AND ISO-OFFSET SECTIONS

The previous sections have shown that the Iso-Offset display allows a quick determination of the location of high velocity materials and gives a qualitative indication of their depths. Another use of this display is for the identification of shallow high velocity materials on high resolution reflection sections. Figure 7 shows a Common-depth-point stacked reflection section of Line B-2 and the corresponding Iso-Offset section. The high velocity layers have been marked on the reflection section and the correlation between the two sections is generally excellent. The shallow high velocity event on the reflection section usually occurs as a bright spot. Where it is not obvious, the Iso-Offset section confirms its occurrence.

ACKNOWLEDGMENTS

The authors wish to thank Dome Petroleum Ltd. and Gulf Canada Resources Inc. for permission to publish data and for their cooperation and encouragement in this research by freely supplying seismic data tape for reprocessing.

THE UTILITY OF REMOTELY SENSED DATA FOR PERMAFROST STUDIES

Leslie A. Morrissey

Technicolor Government Services, Inc., NASA/Ames Research Center,
Moffett Field, California 94035 USA

The presence of permafrost determines to a large degree, the capability or suitability of land for development. Many environmental factors which influence permafrost can be studied through the analysis of remotely sensed data. This paper discusses the utilization of remotely sensed data in the development of derivative maps and data layers based on associations among vegetation and terrain factors and permafrost conditions. An approach will be presented for deriving data layers from an existing data base to illustrate their potential contribution to predictive permafrost modeling.

INTRODUCTION

Land cover maps derived from satellite data have been utilized extensively by natural resource managers. However, land cover information alone provides only one piece of the puzzle. The utility of such information can be greatly extended when remotely sensed data is integrated with other data to provide resource managers with derivative maps specifically tailored to complex environmental issues. For example, in Alaska the presence of permafrost may determine the capability and suitability of land for development. Many environmental factors which influence or reflect permafrost conditions can be studied through the analysis of remotely sensed data. It is the purpose of this paper to demonstrate the utility of remotely sensed data in the development of derivative maps for integration into predictive permafrost models through illustration with a select number of examples.

Scientists at NASA/Ames Research Center and the Alaska Department of Natural Resources (ADNR) have conducted a cooperative effort to test the feasibility of using LANDSAT digital data in conjunction with topographic data to map forest cover types in a study area northwest of Fairbanks (Morrissey and Ambrosia 1982). The primary objective of this demonstration project was to test and evaluate a technique combining multi-date LANDSAT data with digital terrain data to provide forest resource information -- specifically stand size, crown cover density, and species composition -- in a cost effective and timely manner. A multivariate clustering approach, using multispectral waveband combinations from both August and September (1979) dates, provided the basis for an initial land

cover classification. This preliminary product was refined using elevation, slope, and aspect information.

Digital elevation data were acquired and registered to the LANDSAT satellite data. Slope and aspect data were calculated from the elevation data (Figure 1). In addition, statistical tests were utilized to determine significant relationships between forest cover types derived from LANDSAT and terrain. The results of these tests provided the basis for grouping and reassigning spectral classes within specific topographic gradients during the final classification process and resulted in a detailed timber type map encompassing the Fairbanks, Livengood, and Minto Flats regions.

The use of an existing data base, such as the Tanana data base, will be used to illustrate the development of derivative maps based on select vegetation and terrain factors that are associated with permafrost distribution. The potential utility of this existing data base for permafrost mapping will be demonstrated by a number of examples.

Existing maps of permafrost distribution are general, primarily because of a lack of more extensive and detailed information (Pew 1966). The delineation of permafrost boundaries from conventional aerial photography is difficult and requires extensive and costly work for confirmation. Moreover, photo-interpretation does not lend itself to convenient or accurate mapping of extensive areas. However, an alternative approach that acknowledges the close interaction of landscape factors within a region is based on the development of predictive environmental models. Such

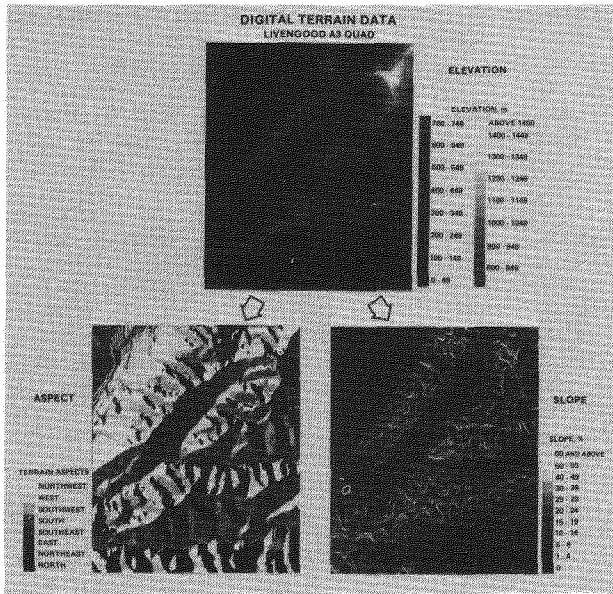

Figure 1 Aspect and slope derivative data layers generated from digital terrain data.

models, based on known relationships among permafrost and biotic and terrain factors, have great potential for providing increased understanding of the character and distribution of permafrost over large regions.

Mapping permafrost is a much more difficult task than mapping vegetation because underlying permafrost interacts with the landscape in a myriad of ways. Understanding the interrelationships among the various factors that affect the distribution and character of permafrost is the key to developing predictive permafrost models. Brown (1969) provides a thorough review of factors which influence discontinuous permafrost. Figure 2 illustrates the development of environmental models designed to predict the occurrence of permafrost based on the integration of derivative maps. Initially, this model would require a systematic collection of ground data relating to a wide range of vegetation and terrain factors, together with their spatial correlation. The correlations would permit the determination of environmental associations that constitute the basis for the predictive model. A data base could be devised which integrates those environmental factors (or surrogate factors) that are highly correlated with the occurrence of permafrost. Three environmental factors,

vegetative cover, topographic data and snow cover, and their corresponding derivative maps are shown in Figure 2. This data base could be compiled from available maps, photo-interpretation of low and high altitude and satellite imagery and digital classification of satellite imagery. The resulting predictive model could then be used to generate regional maps for testing and refinement as appropriate. The next section will discuss the environmental factors in Figure 2 in more detail and illustrate their contribution to a permafrost model.

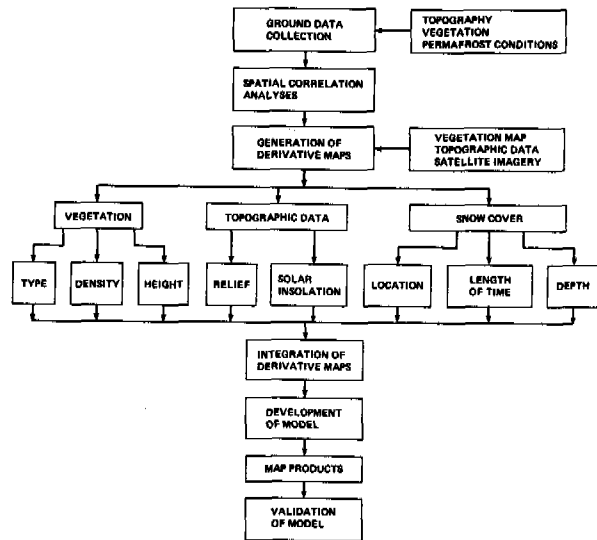

Figure 2 The development of a permafrost model based on the integration of derivative maps.

ENVIRONMENTAL FACTORS

Creation of a permafrost model involves the development of derivative maps to be utilized as surrogates for other factors indicative of the presence or absence of permafrost. For instance, vegetation alone does not indicate the existence of permafrost. However, it is well known that permafrost indirectly affects vegetation by controlling drainage, by maintaining low temperatures in the root zone, and by providing an impervious substrate that restricts the extent of root growth (Price 1972). Consequently, it is possible to develop correlations between vegetation types and the probability of permafrost occurrence. In this way, knowledge of the reciprocal

relationship between vegetation types and permafrost can be utilized in the development of a predictive model. Similarly, other vegetative and terrain factors can be integrated and modeled to predict permafrost conditions. A close correspondence between vegetation types and the presence or absence of near surface permafrost in the uplands of the discontinuous-permafrost zone of central Alaska has been noted by numerous investigators (Stoekeler 1949, Rieger et al. 1963, Péwé 1966, Dingman and Koutz 1974). In general, black spruce scrub forests and shrub bogs are indicative of underlying permafrost close to the surface, while white spruce, birch and aspen forests occur on slopes which are free of near surface but which may have permafrost below the surface. On the basis of these relationships, classes within the detailed timber type map (referred to above) can be reclassified to reflect the probability of permafrost occurrence based on vegetation type.

Forest stand structure indirectly affects permafrost by influencing near surface conditions. Trees shade the ground from solar radiation and intercept some of the snowfall in winter. Furthermore, the density and height of trees influence the micro-climatic effects of ground surface wind velocities (Brown and Péwé 1973), wind speeds being lower in areas of dense growth than in areas where trees are sparse or absent. Tree height and density, as well as other timber factors, have been derived from satellite imagery using multistage sampling techniques (Morrissey and Ambrosia 1982) and could be utilized as individual data layers to further refine permafrost models.

Various terrain conditions have important effects on permafrost growth and thickness (Brown and Péwé 1973). Surface relief directly influences permafrost formation by controlling the amount of solar radiation received by the ground. In the discontinuous zone, permafrost may occur only on north-facing slopes, which receive less solar radiation; in the continuous zone, permafrost on north-facing slopes may be thicker with a thinner active layer than south-facing slopes. Relief also influences snowfall accumulation and vegetative cover, which in turn affect permafrost thickness. Digital topographic data (slope, aspect, and elevation) can provide the basis for modeling permafrost based on terrain conditions -- for instance, in the discontinuous zone, north-facing slopes have the highest probability of permafrost occurrence, south-facing slopes have the lowest probability, with other slopes having intermediate probability values.

In addition, solar illumination information can be derived from slope and aspect data to measure incoming solar radiation through time for an additional refinement of the model. Dingman and Koutz (1974) found that the distribution of vegetation and permafrost is closely related to the influx of solar radiation.

Snow cover influences permafrost distribution and thickness by controlling heat transfer to the ground through insulation from the atmosphere (Gold and Lachenbruch 1973, Grandberg 1973, Thomas et al. 1978). Snowfall conditions and the length of time that snow is on the ground are important factors. While early, heavy snowfall in winter effectively insulates the ground from the severe cold, preventing permafrost aggradation, thick snow cover that lasts late into spring delays thaw and has the opposite effect. Even in the discontinuous zone, snow cover can be a critical factor in the formation and existence of permafrost (Brown and Pewe 1973). The thickest and most extensive permafrost and thinnest active layer exist in areas of minimal snow cover. A comparison of satellite images throughout spring and fall can provide locational information concerning the accumulation of snow, length of time on the ground, and depth (Figure 3). Measurements in the microwave region not only provide an all weather capability but have been shown to have potential for determining snowpack properties, such as snow depth and snow water equivalent, which cannot be determined in other portions of the spectrum (Barnes 1981).

NORTHWEST OF FAIRBANKS, ALASKA

Figure 3 Snow cover monitoring from sequential LANDSAT satellite imagery (note: the May scene is cloudfree while partially snow covered, while the June scene is free of snow but partially cloud covered).

Permafrost maps based on vegetative cover, terrain conditions, and snow cover can be integrated with other information such as soils, climatic, hydrologic, and geologic data to further refine the model. However, the effect of additional data layers to the models predictive accuracy is not clear. The addition of increasing layers of information in the modeling process may increase the likelihood of error in the model itself. The inaccuracies of each data layer may be compounded when combined with other layers. Conversely, the errors in one data layer may counterbalance those in other layers, increasing the models overall performance. In general, each model must be examined on a case specific basis and subjected to empirical verification.

SUMMARY

The immense size, lack of ground transportation and harsh climatic conditions in arctic and subarctic regions make remote sensing techniques and satellite derived information well suited for reconnaissance mapping of permafrost. The availability of satellite data at various spatial resolutions and in various portions of the electromagnetic spectrum provides both a baseline and a periodic updating mechanism for use in environmental studies. Future satellite sensors, with increased spectral and spatial resolution, will enhance the utility of remotely sensed data for both regional and site specific studies. However, before this data can be fully exploited, two fundamental areas of research must be addressed. Initially, the spatial interrelationships between the various vegetation and environmental factors and the occurrence of permafrost require further study. This type of research has been continuing for a number of years and the complexity of the task requires additional study. Second, systematic research is required to evaluate the utility of present and future remote sensor data for information extraction relevant to arctic and subarctic regions. In addition, there is a need for fundamental research to identify spectral, spatial, and temporal resolution requirements for specific features. For example, the spatial resolution that is required to identify polygonal ground patterns on the Arctic Coastal Plain.

A tremendous potential exists for the utilization of remotely sensed data to provide meaningful resource information for permafrost studies. The integration of this remotely derived data with other ancillary data in a geographic information system context is the next logical step in

the process of mapping permafrost in harsh and inaccessible arctic and subarctic regions.

THE ROLE OF PRE-EXISTING, CORRUGATED TOPOGRAPHY
IN THE DEVELOPMENT OF STONE STRIPES

Mark P. Muir

Quaternary Research Center, Mail Stop AK-60
University of Washington, Seattle, Washington 98195 USA

An experiment was conducted to explore the role of small-scale topography in the development of stone stripes. The surface of a silt loam with a homogeneous admixture of gravel was shaped into sinusoidal corrugations with wavelengths ranging from 0.05 to 0.8 m. The soil was then subjected to both diurnal and storm-length freeze-thaw cycles. Surface heave and subsurface temperature were monitored electronically. Sorting was measured by displacement of marker stones and changes in gravel concentration in soil samples. The volume concentration of gravel increased in the soil underlying troughs. Marker stones tended to move toward the nearest trough. Stones close to the surface in more steeply inclined regions traveled the greatest lateral distance with several stones moving as far as 40 mm. Sorting related to topography was apparent only under the larger corrugations. Heave records indicate that significant heave occurred in troughs during the thaw portion of the temperature cycle. Residual differences in heave between the crests and troughs of sinusoids on the order of 1 mm per storm-length freeze-thaw cycle tended to accentuate relief through time.

INTRODUCTION

The development of sorted patterned ground requires both lateral and vertical components of sorting of coarse particles in the soil. As a soil freezes, coarse particles tend to move in the direction of local heat flow relative to the soil matrix (Corté 1966). The combination of lateral and vertical components of sorting can only occur then, when a freezing front is nonplanar as it penetrates a soil. This may result from lateral variations in soil-moisture content, sorting, vegetation, or relief (Schmertmann and Taylor 1965, Nicholson 1976). A laboratory experiment was designed to study the sorting involved in the formation of stone stripes in a soil with an initially corrugated topography comparable to rills on a hillslope. Such topography has been implicated in the development of stone stripes (Brockie 1968).

EXPERIMENTAL DESIGN

Silt loam was mixed with about 15% by volume of gravel (volume of gravel/total volume of saturated soil plus gravel). The gravel consists of clasts ranging from 10 to 30 mm in diameter obtained from a quarry in glacial outwash deposits. The soil was then placed in a container with length of 3.6 m and width of 2.5 m to an average depth of about 0.2 m (Figure 1). Underlying the soil and separated from it by a sheet of muslin was a 20 mm thick layer of sand. Perforated pipes running through this layer were connected by pipes (water headers) rising through the soil to an external water supply system. Water could be added to the soil through these pipes at any time. The container is located in a cold room capable of achieving temperatures as low as -50°C and has controls

for automatic cycling of temperature.

FIGURE 1 Plan view of the experiment showing the locations of thermocouple piles (TP), individual thermocouples (T), and water headers (WH). Also shown are the three marker stone trenches A, B, and C.

Parallel corrugations were formed on the surface of the soil to produce five sets of sinusoids with wavelengths of 0.05, 0.1, 0.2, 0.4, and 0.8 m (Figure 2). The amplitude of each sinusoid was one-tenth the wavelength. Three flat-floored trenches were cut to different depths perpendicular to the trend of the sinusoids (Figure 2). Glitter was spread in a thin layer over the floor of each trench to function as a marker horizon. One hundred twenty-eight painted marker stones were emplaced in the side walls of the trenches. Their

positions were surveyed and the trenches were back filled.

FIGURE 2 (Top) Cross-sectional view of the experiment showing water headers (heavy line), thermocouple piles (light lines extending to the base of the soil), and the wooden structural supports for individual thermocouples (light lines terminating at the soil surface). Note the sinusoidal topography. (Bottom) Cross-sectional view of one set of sinusoids showing the depth to marker horizons A, B, and C relative to the amplitude A of topography. SS marks the 20-mm thick sand substrate.

Soil samples taken prior to shaping the topography had a volumetric moisture content of 0.40. The gravel concentration was $14.0 \pm 3.6\%$ by volume (volume of gravel/bulk volume of sample) and showed no significant variation with depth. Additional samples were taken after the topography was created, but only to an average depth of 78 mm. The mean concentration of gravel in these samples was 8.5% by volume. Therefore, the processes by which the original topography was formed caused substantial downward movement of gravel, leaving the near-surface region relatively depleted in gravel at the start of the experiment. The same processes were used to re-create the topography over marker stone trenches after they were back filled and it is inferred that the marker stones were similarly displaced. Independent experiments show that negligible (< 1 mm) lateral movement accompanied this vertical displacement. Thus, at the start of the experiment, the gravel and marker stones had random horizontal distributions, but were concentrated at depth.

The soil was then subjected to a series of freeze-thaw cycles, including 100 diurnal and 12 storm-length (2 to 10 days of freeze) cycles. During the thaw portion of a cycle, the ambient temperature in the cold room was raised from -5°C to between 12° and 20°C in 8 hours. The maximum temperature depended on whether and how long infrared heaters were used to accelerate thawing. The temperature was then lowered in 4 hours back to -5°C , where it remained until the next thaw.

Heave was monitored continuously with linear displacement heave transducers. Soil temperature was recorded by a network of isolated thermo-

couples and two verticle groupings of thermocouples (thermocouple piles).

RESULTS

Sorting

Following the conclusions of the experiment, the soil was dried to prevent gravel movement during excavation. Twenty-eight sites were excavated with 2 to 3 samples taken every 40 to 50 mm vertically throughout the soil column at each site. Each sample was analyzed for bulk density, porosity, and concentration of gravel.

The mean concentration of gravel by volume for these samples was $23.3 \pm 3.3\%$ (volume of gravel/volume of solid constituents of soil). As the minimum sample width was 100 mm, the sampling discriminated between gravel concentrations under crests and troughs only in the three largest sets of sinusoids. The mean concentration of gravel was $22.1 \pm 3.8\%$ for crest sampling sites (12 samples) and $24.8 \pm 2.6\%$ for trough sites (8 samples). A t test comparing data from crest and trough samples shows that they represent statistically distinct populations with a significance level greater than 97.5%. Thus, lateral sorting occurred in the larger sinusoids, with clasts converging on troughs.

During periods of thaw, solifluction transferred material from the crests to the troughs, particularly in the larger corrugations. As fine material was preferentially transported, the degree of sorting implied by the data understates the actual lateral movement toward troughs.

The lateral displacements of marker stones are shown in Figure 3. Almost all stones showing lateral displacement moved toward the nearest trough. Stones located near the surface in regions of steep slope experienced the greatest lateral displacement, with several stones moving as far as 40 mm.

Throughout the experiment, there was a distinct soil-moisture gradient parallel to the corrugations with soil moisture increasing in the positive x direction. In the larger sinusoids, this resulted in a marked change in small-scale mass-wasting processes along the length of corrugations. Solifluction on the drier end of a corrugation was characterized by debris flows, whereas the relatively wet end commonly experienced thin mud flows. Although differences in soil moisture may have affected the pattern and magnitude of heave along a corrugation, the degree of sorting was unaffected (Table 1). The absence of a distinct change in sorting along this gradient during a period in which significant sorting occurred suggests that topography controlled sorting more effectively than did soil-moisture gradients parallel to the corrugations.

Marker stones in the B and C trenches under corrugations with wavelengths of 0.2 m or less were not systematically displaced toward troughs. These stones all moved in the same lateral direction, perhaps in response to a soil-moisture gradient oriented perpendicular to the corrugations, with increasing moisture in the direction of the larger sinusoids.

FIGURE 3 The lateral displacements of marker stones relative to topography. The upper graph shows topography without vertical exaggeration. The lower graph has a vertical exaggeration of 3.95. The arrows are displacement vectors for marker stones. Arrow tails mark the original position of marker stones within the soil. Arrows point in the direction of displacement. The scale for displacement is shown on the map. Dots represent stones with lateral displacement less than 3 mm.

TABLE 1 Two Comparisons of Groups of Marker Stones From Different Trenches.

Trench	Range of Y Co-ordinates of Position (m)	Depth (m)	Number of Stones in Group	Mean Δy (mm)	Mean $((\Delta y)^2)^{1/2}$ (mm)
A	0.880-1.420	0.099-0.116	9	3.9 ± 16.3	13.8 ± 10.8
B	0.800-1.500	0.108-0.127	8	3.8 ± 14.9	12.5 ± 9.0
A	0.940-1.365	0.061-0.081	9	-2.8 ± 21.0	16.1 ± 13.7
B	0.850-1.350	0.064-0.092	6	0.8 ± 23.5	19.2 ± 13.0

The groups of stones in each comparison come from equivalent positions with respect to the sinusoidal topography, but from marker stone trenches on opposite sides of the experiment.

These results may be considered using data from this experiment in conjunction with a simplified model of the temperature field in the soil. Consider a homogeneous half-space with a topography described by

$$h = h_0 \cos(2\pi y/\lambda) \quad (1)$$

where h_0 is the amplitude of the topography, y is a point on the surface, and λ is the wavelength of the topography. The temperature T at a depth z under the point y is a function of the average surface temperature T_0 , heat flow q at a distance below the surface, and thermal conductivity k (Turcotte and Schubert 1982) such that

$$T = T_0 + qz/k - qh_0/k \cos(2\pi y/\lambda) \exp(-2\pi z/\lambda) \quad (2)$$

This may be rearranged to

$$T - T_0 - qz/k = qh_0/k \cos(2\pi y/\lambda) \exp(-2\pi z/\lambda) \quad (3)$$

to isolate the factor dependent on topography. Therefore, subsurface isotherms have the same wavelength as, and are in phase with, topography, but their amplitudes attenuate exponentially with depth.

It is important to note that this model neglects the considerable effects of latent heat and water transport in the freezing of wet soils. Thus, any results derived from it must be considered as purely conceptual. Also, this model is strictly valid only for small slopes. As the amplitude of each sinusoid is one-tenth its wave-

length, the experiment is in reasonable compliance with this restriction.

The depth at which the ratio of attenuation R (amplitude of isotherm/amplitude of topography) reaches a particular value is

$$z = (1/\ln R/2\pi)\lambda \quad (4)$$

Lateral displacement should occur then, at greater depths under larger corrugations than under smaller ones. Depths associated with values of R for the range of wavelengths in this experiment are shown in Figure 4.

FIGURE 4 Values of the attenuation ratio R with the associated depths for the range of wavelengths in the experiment.

The relative size of clasts to corrugations may also be an important factor in reducing the importance of topography in sorting under small corrugations. In this experiment, the size of the average clast was within one order of magnitude of the wavelengths of the 0.1 and 0.05 m sinusoids. Clasts under these sinusoids were subjected to a range of heaving directions that, to some extent, were competing with each other. This probably inhibited lateral displacement related to topography.

Surface Heave

Heaving of the trough during thaw was common (sites T1 and T2 in Figure 5). The largest measured heave was 1.1 mm at site T1. The relative timing, rate, and magnitude of trough heave varied greatly, both geographically and temporally.

Mackay (1983) has measured heave during seasonal thaw at a number of sites in the Canadian Arctic. One site (Garry Island, N.W.T.) heaved 14.4 mm in one summer. He argues that heave during thaw occurs when water flows into a zone of permafrost at sub-zero temperatures and refreezes. Local soil structure seems to be important in increasing the permeability of permafrost.

The rapidity with which heaving began after the onset of thaw (T1 in Figure 5) implies that water flowed into frozen ground utilizing soil

structure, probably cracks, to penetrate beyond the thaw front. The variability of trough heave during thaw may reflect strong control of local crack systems.

FIGURE 5 (Top) Ambient temperature versus time for October 28-29, 1981. INF denotes the time in which the infrared heaters were turned on. (Bottom) Surface heave versus time for October 28-29, 1981, at four sites. The position coordinates of the measurement sites are as follows: T1 ($x = 0.6$, $y = 1.65$), C1 ($x = 0.6$, $y = 1.25$), T2 ($x = 1.9$, $y = 1.65$), and C2 ($x = 1.9$, $y = 1.25$). Data is in meters.

Crests generally heaved only when ambient temperatures were sub-zero (C2 in Figure 5). At the end of storm-length freeze-thaw cycles, there was a residual change on the order of 1 mm in relief between the crests and troughs in the 0.8 m sinusoids. This differential heave tended to accentuate relief through time. Washburn (1980) has summarized the research describing differential heave in patterned ground. This process tends to elevate regions of fine material relative to regions of coarser material.

In this experiment, differential heave seems to have arisen from the flow of water into regions at depth below crests during thaw and its subsequent freezing. The increase in basal temperature beneath a crest to a magnitude approximating that at the surface (between 1900 and 2300 hours at a depth greater than 0.2 m under the crest in Figure 6) probably reflects an influx of melt water from

FIGURE 6 The upper graph represents ambient temperature versus time for June 26-27, 1981. INF denotes the time interval in which the infrared heaters were turned on. The lower pair of graphs represents subsurface temperatures through time measured with the two thermocouple piles. The heading (e.g., 1400-1700) above each pair of graphs is the time interval in which the measurements were made. Temperatures were recorded at one-hour intervals. For each group of four temperature profiles, the solid line corresponds to the temperature with depth at the start of the time interval. Succeeding measurements are indicated by successively more broken lines. The dashed line shows the second temperature measurement in the time interval, alternating dots and dashes represent the third measurement, and the dotted line is the fourth.

the surface. The thermal signal of a forming ice lens is likely to be an anomalous local increase in temperature due to the release of latent heat in regions with temperatures of 0°C or lower. The increase in temperature under the crest at depths of 0.1 to 0.17 m between 2300 and 2400 in Figure 6 may be due to this process, though the change in temperature (0.1°C) is at the limit of resolution for the thermocouples employed in this experiment.

Changes in the surface elevation of the soil may have been due not only to frost heave and thaw consolidation, but to other factors as well, such as changes in soil moisture or thermal expansion of the soil. The component of change due to

thermal expansion as the soil thawed may be estimated in the following way. The average increase in temperature in the soil over the depth of the soil under the crest was about 2°C (Figure 6 between 1400 and 2000 hours). The soil thickness under the crest is about 0.3 m. Horiguchi (1978) reported a value of $4.8 \times 10^{-5} \text{ }^{\circ}\text{C}^{-1}$ for the linear coefficient of thermal expansion of ice. This value is much larger than that for most silicate rocks (Lachenbruch 1966). Using this value to ensure that the magnitude of change of length due to thermal expansion is not underestimated yields a value for the maximum increase in surface elevation because of thermal expansion as

soil thawed of 2.9×10^{-5} m, which is negligible. The comparable value for sites in troughs would be as little as one third this number because of the lesser thickness of soil there.

Thermal expansion of the steel heave transducers may be computed as follows. The change in ambient temperature during a temperature cycle was approximately 20°C (-5°C to $+15^\circ\text{C}$). At maximum extension, which occurred when transducers were located in the trough of the 0.8 m sinusoid, the length of the transducers didn't exceed 0.3 m. The linear coefficient of thermal expansion for steel in this temperature range is $1.1 \times 10^{-5} \text{ }^\circ\text{C}^{-1}$ (Resnick and Halliday 1966). The maximum expansion of a heave transducer during a temperature cycle then, is 6.6×10^{-5} m. This amount is also negligible. Values at other sites range up to 50% less, since the transducers weren't fully extended. The sense of movement, as recorded by the heave transducers, is equivalent to a heave of the soil surface.

A simple experiment was performed to determine whether the hydration of clay minerals by melt water during periods of thaw would produce surface heave. Water was poured on a thawed, dried sample of the soil used in the experiment and the change in surface elevation was measured. Instead of heaving, the surface was lowered about one mm. Apparently, changes occurred in the soil structure, such as the elimination of void spaces, which tended to decrease the soil volume. Thus, measurements of heave during thaw probably underestimate the actual amount of ice lens growth taking place.

Marker Horizons

Some of the horizons were deformed such that they appeared to conform to the topography (Figure 7). This may be a result of structure imposed on the soil by the formation of ice lenses. Any volumetric expansion of the soil will be perpendicular to the local orientation of the freezing front as ice lenses form. After thawing, a remnant porosity may exist as an expression of this, which records the deformation of the soil. This deformation should have the same wavelength as and be in phase with topography. In other words, it "mimics" the topography. Local variations are large enough, though, that most horizons show deformation that has no discernible relationship to topography.

CONCLUSIONS

Freeze-thaw cycles in soils with corrugated topography can induce sorting analogous to that found in stone stripes, if the corrugations are large enough. Small stone stripes probably do not form in this way, because temperature variations induced by the presence of topography die out so quickly beneath corrugations of small wavelength.

Frost heaving under sinusoids is characterized by instances of trough heave during thaw and residual differences in heave that accentuated topography through time.

FIGURE 7 This photo shows the crest of a 0.4 m sinusoid in cross-section with the B marker horizon indicated by pin heads. The upper scale of the ruler is in centimeters.

BIOGEOGRAPHIC SIGNIFICANCE OF STEPPE VEGETATION IN SUBARCTIC ALASKA

Fossils in late-glacial deposits of Beringia suggest that a dry grassland or steppe was a fundamental part of the periglacial vegetation mosaic. This is consistent with the expected effect of the Bering Land Bridge on climate during glacial maxima: colder and drier overall, possibly with shorter and warmer summers when deeper seasonal thaw created conditions suitable for steppe plants but inimical to the dominant taxa found here today. Remnants of that vegetation may persist today in Siberia and the continental interior of Alaska and adjacent Yukon on steep, dry south-facing bluffs and terraces. We reconnoitered the steppe flora and its communities on bluffs and terraces along the Yukon, Tanana, Copper, and Porcupine rivers, examining both glaciated and unglaciated areas and surfaces of Tertiary, Quaternary, and Holocene ages. These steppes are comparable to those of the upper to middle Yana and Indigirka drainages and the upper Kolyma River in western Beringia. Steppe vegetation of Alaska and Yukon is to a significant degree composed of vascular plants that are either the same species or close relatives (vicariants) of Siberian species. Others are American taxa either endemic to eastern Beringia or the same as or vicariants of taxa found in continental western North America. The mosses and lichens are mostly members of a widely distributed, although often disjunct and rare, flora of arid and semi-arid regions. The Asian taxa presumably arrived in eastern Beringia via the Bering Land Bridge, some perhaps as early as late Tertiary. The American contribution to the modern steppes might be both ancient and recent, since the present mix of species could also reflect contributions from a post-glacial warm interval. These taxa became restricted to their present sites during the Holocene by the expansion of taiga and mires.

INTRODUCTION

Numerous fossils of a grazing megafauna dominated by mammoth, bison, and horse (but also including saiga) and pollen indicating a relative abundance of sage (*Artemisia* spp.), grasses, and willows (and an absence of spruce, birch, and alder) have been recovered from late-glacial deposits in eastern Beringia (Alaska and Yukon). Reconstructing a grassland or steppe from this evidence has been considered consistent with and necessary for the support of this fauna. The apparent shift to a vegetation rich in birch, spruce, and alder during the Pleistocene-Holocene transition provides one explanation for the rapid extinction of the grazers (Guthrie 1968). Since the pollen record for roughly the same time period from places widely separated from each other is similar, the concept of a widespread, full-glacial Beringian steppe emerged. Since studies of modern pollen have failed to identify a modern analog for this steppe, some have assumed that both the plant and animal communities were reduced by extinctions in the Holocene (Matthews 1976, cf. Hopkins et al. 1982).

Young (1976a,b) and Yurtsev (1963, 1972, 1981), on the other hand, have suggested that late-glacial steppe remnants persist in areas of northeastern Asia and northwestern America--on steep, dry south-facing bluffs and terraces. Stimulated by the data from studies by Hanson

(1951), Gjaerevoll (1958-1967), Shacklette (1966), Young (1976a,b), and Batten et al. (1979), we have begun a multiyear, international project to study the steppe flora in these local, azonal habitats of Alaska and Yukon where the zonal vegetation is taiga. Our objectives are to describe the flora and vegetation and to compare and contrast our results with those for similar landscapes in Chukotka and eastern Siberia. Through a study of floristics and the systematics of the taxa we can obtain indirect evidence with which to assess the validity of relict status for the modern plant community.

VASCULAR PLANTS

The relict nature of the modern steppe is inferred from (1) the general floristic similarity of the present vascular vegetation to the late-glacial, herb-rich pollen assemblage and (2) the specific floristic similarity of the vegetation in two distant areas of the Beringian refugium that today share an extremely continental climate and are isolated by environments inimical to exchange or dispersion. Explanation for the disjunction is the Holocene separation and reduction of a once continuous distribution for these plant communities that developed when Beringia was hypercontinental in climate and the Bering Land Bridge enabled the migration of Asian taxa to America.

Steppes were examined over a wide geographic area, and on surfaces of late Tertiary (Yukon and Tanana rivers), late Pleistocene (Porcupine River), and early Holocene (Copper River) ages. In these river valleys, a fairly predictable set of xerophilous herbs, sage (predominately *Artemisia frigida*), lichens, and mosses occupies the south-facing slopes and terraces over sections of tens of meters up to several kilometers and over a vertical extent of 200-300 m. These steppes are comparable to the montane steppes of the upper to middle Yana and Indigirka drainages of northeastern Yakutia and the upper Kolyma River. Major differences are the absence in Alaska and Yukon of true tufted grass species of *Festuca* and *Helictotrichon* and the lower floristic diversity of the vascular taxa, suggesting that portions of the Asian steppe failed to expand eastward. Nevertheless, to Yurtsev who has experience in both countries the impression of overall similarity was remarkable.

Preliminary analysis shows that the flora is a composite of several elements. Some of the prominent taxa such as *Calamagrostis purpurascens*, *Poa glauca*, and *Potentilla hookeriana* are common subarctic steppe plants of both eastern and western Beringia and also occur in dry habitats in arctic and alpine areas. Other taxa such as *Rosa acicularis*, *Solidago decumbens*, *Galium boreale*, and *Zygadenus elegans* are derived from open woodlands nearby. Some such as *Amelanchier alnifolia* and *Apocynum androsaemifolium* are species of temperate woodlands and grasslands that are restricted at their northern limits to these generally warmer sites. But there are, however, several taxa generally restricted to bluffs, terraces, cutbanks, and outcrops. Some of these can be found also growing on active floodplain gravels, and others can inhabit scree and similar alpine habitats where limestones predominate. Notable are endemics to the continental interior of Alaska and Yukon (*Draba murrayi*, *Penstemon gormanii*, and *Podistera yukonensis*), disjuncts and vicariants from similar continental areas of northeastern Asia (e.g., *Alyssum americanum*, *Plantago canescens*, *Silene repens*, *Artemisia alaskana*), and disjuncts and endemic vicariants from the high plains and continental intermontane valleys of western North America (*Cryptantha shackletteana*, *Erysimum angustatum*, *Eriogonum flavum* var. *aquilinum*, *Townsendia hookeri*).

Table 1 shows the vascular taxa more or less restricted in the subarctic to steppe bluffs. The arctic-alpine cryophyte element is omitted. Data are from Hansen (1951) and Gjaerevoll (1958-1967) for the Copper River, from Shacklette (1966), Young (1976a,b), and Batten et al. (1979) for the upper Yukon River region, and our own observations on the Copper, Tanana, and Yukon rivers (D.F.M., B.A.Y.) and on the Porcupine River (R.H.). Comparative data from steppes in central and southwestern Yukon (YT) are from Porsild (1951, 1966), Johnson and Raup (1964), Hoefs et al. (1975), Nimis (1981a), Hulthen (1968), and D. Murray (unpublished).

*New to Alaska

The upper Yukon River has the most extensive system of steppe bluffs and also the largest array of endemic and disjunct taxa. The steep slopes in this region were never glaciated or reworked by riverine processes in the Quaternary. The physical isolation of vascular endemics from their closest morphological relatives and the disjunct bryophytes discovered here suggest an ancient origin for these taxa. Clearly some of the disjuncts arrived at their present positions in the Holocene (e.g., *Carex filifolia* at Chitina), and although associated with arid grasslands, they cannot be interpreted as late-glacial relicts. *Eriogonum flavum* var. *aquilinum*, *Erysimum angustatum*, and *Cryptantha shackletteana* are endemics only weakly differentiated from species more widespread in arid regions of western North America; therefore it is tempting to imagine the migration of these stocks northward during early to mid Holocene warm intervals via the northern prairies and intermountain dry grasslands into southwestern and central Yukon and adjacent interior Alaska. Isolation was soon effected by development of boreal forest and mires and the concomitant rise in the permafrost table, reducing steppe environments to habitats where strong topographic and geomorphic controls maintain steppe-like conditions. That relatively complex steppe communities can form within postglacial time is evident from the vegetation at Chitina on the Copper River and the extensive well-developed steppes in the region of Kluane Lake in southwestern Yukon.

MOSSES AND LICHENS

The moss and lichen flora studied (by B.M.M.) consists of a large group of xerocontinental species that fully support the notion of present-day steppe. They are part of a widely distributed, though often highly disjunct, arid lands flora of families and genera showing great specialization, presumably to enhance survival in extremely hot and/or dry conditions. In this regard, the composition of the steppe moss flora is particularly striking. Although analysis is preliminary, 30 species in 13 families have thus far been identified (Table 2). Of these, 21, or 2/3 of the total, are members of just two families, Pottiaceae and Grimmiaceae, both of which show many xeric adaptations.

The lichen flora is composed of about 15 families in which the genera and species are more evenly distributed, but many of the genera are characteristic of steppe and other arid landscapes. Especially important on xeric, fine soils are the genera *Dermatocarpon*, *Diploschistes*, *Endocarpon*, *Fulgensia*, *Psora*, *Toninia*, and *Squamarina* and on coarser soils *Xanthoparmelia*. Among other important genera of subarctic Alaskan steppes are *Acarospora*, *Aspicilia*, *Caloplaca*, *Candelariella*, and *Collema* (Table 3).

Of the twenty-one taxa in the two moss families that are important on the steppes, Pottiaceae and Grimmiaceae, five are new to Alaska, including one that is new to North

America, and six represent significant range extensions (Table 2). Five of the forty lichens reported here are also new to Alaska (Table 3) (B. M. Murray unpublished). Thus the cryptogamic steppe flora is of great phytogeographic interest.

The azonal steppe floras of northeast Asia (see Yurtsev 1981) and Alaska are only recently becoming known, but when these floras are compared with each other and with those of zonal steppes of Middle and Central Asia and even deserts of North America, great affinities are apparent.

Several species have a cosmopolitan distribution. Indeed most of the important taxa found on Alaskan steppes are widely distributed, occurring in Europe, Central and Northeast Asia, and other parts of North America; some also occur in North Africa and South America. Some are widespread in these areas; others are very disjunct or occur only in a portion of this general range. For example, the moss, *Indusiella thianschanica*, found at one unglaciated site on the Yukon River where several endemic vascular plants occur, is known otherwise only from mountain steppes in the Caucasus, Middle and Central Asia, and adjacent Siberia and one locality in North Africa (B. M. Murray unpublished). The lichen, *Fulgensia desertorum*, found in the Copper River valley, is known otherwise from Eurasia and Colorado (Poelt 1971).

Mosses and lichens both have generally wider distributions than vascular plants and often demonstrate less endemism. Whereas long distance dispersal may account for such patterns, the large, dramatic disjunctions and the presence of a repeated suite of species in steppe sites argue for persistence over a long period of time, and lack of endemism argues for great genetic stability. There is no question of the capability of mosses and lichens to persist. They very well fit Hoffmann's (1981) principles for survival (of mammals) in refugia: (1) be adapted to the right habitat, that is, one that can survive periods of change; (2) be small; (3) live in a large refugium; and (4) avoid competitors. The habitat of most steppe mosses and lichens is the fine soil between the above-ground parts of vascular plants.

It is likely that many of the xerocontinental bryophytes and mosses will be shown to have wider and more continuous ranges as azonal steppes and other arid habitats become better known and comparisons are made with Asian and North American material. Until recently, *Caloplaca tominii* was known only from Eurasia, but it is now known also from Yukon Territory (Nimis 1981b), and, based on re-identified material, from Northwest Territories and Saskatchewan, Canada; Montana, Utah, S. Dakota, Utah, Washington, and Wyoming, USA; and Peru (Thomson 1982)—and now Alaska.

In addition to the historical (age) differences between sites, edaphic differences determined by lithology affect the distribution of taxa. Coarse soils and rubble slopes tend to have a greater proportion of vascular plants and cryptogams from the arctic-alpine floristic element; thus the bluffs of the Copper River,

where the bedrock is deeply mantled by calcareous loess, are differentiated from the upper Yukon and Tanana river regions where carbonate-rich soils can overlie both acid and basic parent material. At Chitina soil lichens characteristic of calcareous crust soils typical of steppes are common: Caloplaca tominii, Fulgensia desertorum, Psora decipiens, Squamaria lentigera, and Toninia caeruleonigrans. These steppes show a great affinity to those in southwestern Yukon (Nimis 1981a) and to the Canadian prairies (Looman 1964), and several are found on loess on end moraines of present day glaciers in Yukon and Alaska (B. M. Murray unpublished). Since bedrock is abundantly exposed at the Yukon and Tanana sites, saxicolous taxa such as Lecanora spp., Rhizoplaca spp., Psorula rufonigra, and Spilonema revertens are found there. The less basic soil and the coarser texture accounts for the presence also of the genus Xanthoparmelia. Consequently, more information on soil chemistry will be gathered as field work progresses.

FLORISTICS AND PALEOECOLOGY

What relationship is there between the flora, vegetation, and physical environment of the steppe bluffs today and those of Beringia during late-glacial time? If the steppe communities were in fact widespread and dominant, well-drained soils had to be far more common than they are today. It would follow that the permafrost table was below present levels, yet not to the extent of precluding the growth of ice wedges or the preservation in frozen ground of faunal remains.

If we take the view of Cwynar and Ritchie (1980) that pollen influx was very low for all taxa and that the influx of Artemisia did not change during the Pleistocene-Holocene transition, then the protracted drought of an intensely continental climate coupled with broad, more extensive braided floodplains and sand seas might have provided sufficient trophic support for a modest grazing megafauna and allowed for the vegetation mosaic that seems appropriate (Schweger and Habgood 1976).

If we adopt another proposal by Cwynar and Ritchie (1980) that the sage responsible for the pollen in the late-glacial record was A. arctica, and not A. frigida as has been assumed, then an image of herb-rich communities more similar to fellfields emerges. The permafrost table need not be lower, and as Péwé (1975) has suggested, it might have even been higher. Their points are persuasive, but the abundance of arctic-alpine cryophytes in their pollen spectra is not fatal to the idea of a steppe-like vegetation, for we would expect with the lowering of tree line during cooler times that the mountain and steppe species would mingle. Indeed, cryophytes are found on steppe bluffs today. While it is true that their lists of taxa include genera that are well distributed in the Arctic and do occur on fellfields, certain species of those genera are definitely restricted to temperate dry grasslands and reach their northern limits at steppe sites in Alaska.

Our data show that occurrence of a complex of xerophilous temperate woodland and steppe species and cryophilous arctic-alpine species is determined by topography and soils. Such large gaps in distribution exist between these communities and others in Asia and western America that normal methods of dispersal cannot create them today. Long distance dispersal of such a complex flora is less likely than the formation of these communities by reduction of formerly more widespread ranges. These plants could only have been more widespread under conditions different from today, conditions that better match the cold, dry full-glacial intervals when the Bering Land Bridge was in place. These plants did not arrive simultaneously as a single community, but at intervals since the Tertiary when appropriate conditions prevailed.

The flora of these steppes is ancient, but the communities they form are not necessarily relicts of any one specific period. More likely these steppes have received migrants from Asia beginning in late Tertiary and including arrivals as recently as mid-Holocene. The immigrant taxa share an ability to disperse and a tolerance to drought. Rather than a process of steady accretion of taxa, local extinctions must have occurred through the millennia of climatic changes. We have more than a depauperate version of a late-glacial steppe; we have the current version of what, on a timescale of geologic history, is probably a continually changing community.

Steppes are restricted today to bluffs and terraces where extremes of summer drought occur. These sites also experience extremes of summer warmth, and carbonate-rich soils are common. The steep slopes show surface instability from mass wasting. This combination of physical features results in the formation of open plant communities for which bare ground is an important aspect. An inability to compete with other plants is usually presumed as a reason these plants are not found elsewhere.

The introduction of the late-glacial steppe into paleo-reconstructions was stimulated in large part by the need to provide a suitable trophic base for the grazing megafauna. Uncertainties remain: are the mammalian fossils contemporaneous and do they signify a diverse and abundant fauna? Is a true steppe consistent with such a fauna? Furthermore, although an herb-rich pollen zone is consistently a part of late-glacial pollen spectra taken from many areas of Alaska and Yukon, how geographically prominent was this vegetation? Could the pollen record have been produced if we invoke only the expansion of xeric sites under a hypercontinental climate? It is crucial to know whether or not the amount of Artemisia and grass in the vegetation changed dramatically in the Holocene.

SOIL-WATER DIFFUSIVITY OF UNSATURATED SOILS AT SUBZERO TEMPERATURES

Y. Nakano, A. R. Tice, J. L. Oliphant, and T. F. Jenkins

U.S. Army Cold Regions Research and Engineering Laboratory
Hanover, New Hampshire 03755 USA

The soil-water diffusivities of soils containing no ice were determined at -1°C by an experimental method recently introduced. The theoretical basis of the method is presented. The measured diffusivities of three kinds of soils are found to have a common feature in that the diffusivity increases with increasing water content, attains a peak, and increases again as the water content increases. This common feature of the soils at the subzero temperature is discussed in comparison with unfrozen soils. The experimental data appear to indicate that the basic transport mechanism of water in soils containing no ice at the subzero temperature is essentially the same as that in unfrozen soils containing a small amount of water.

It has long been recognized that accurate knowledge of water movement in frozen soil is very important for many practical applications. For example, the freezing of water transported to the freezing part of soil is known to provide the largest contribution to frost heaving (Anderson et al. 1978), and the damage of frost heave is of major concern to engineers.

Introducing a new experimental method, Nakano et al. (1982, 1983a-c) investigated the rate of water transport in unsaturated frozen clay under isothermal conditions and found that the rate of water transport is proportional to the gradient of total water content, which is generally the sum of the unfrozen water content and the ice content. In particular, when ice is absent, the flux of water F in one direction is given as

$$F = -D(\theta) \rho \frac{\partial \theta}{\partial x} \quad (1)$$

where θ is the weight of unfrozen water per weight of dry soil, x the space coordinate, ρ the dry density, and D the soil-water diffusivity.

EXPERIMENT

The two kinds of soil selected for this study were Fox Tunnel silt, obtained from Fairbanks, Alaska, and Regina clay from Saskatchewan, Canada. The specific surface area of Fox Tunnel silt determined by ethylene glycol retention is $31 \text{ m}^2/\text{g}$ and that of Regina clay $291 \text{ m}^2/\text{g}$. In a previous study (Nakano et al. 1982, 1983b) we conducted experiments similar to this by using a marine-deposited Morin clay from Maine with a specific surface area of $60 \text{ m}^2/\text{g}$. We will use the experimental data for Morin clay in this work for comparison.

The unfrozen water contents θ of the three kinds of soils at various temperatures in a warming cycle are presented in Figure 1. Measurements were made by the pulsed nuclear magnetic resonance method described in Tice et al. (1978). The total water content w and the dry density ρ of Fox Tunnel silt were 21.0% and 1.24 g/cm^3 , respectively. For Regina

FIGURE 1 Unfrozen water content θ (%) vs temperature $-T(^{\circ}\text{C})$ in a warming cycle for Fox Tunnel silt ($w = 21.0\%$, $\rho = 1.24 \text{ g/cm}^3$), Regina clay ($w = 22.6\%$, $\rho = 1.45 \text{ g/cm}^3$), and Morin clay ($w = 20.0\%$, $\rho = 1.42 \text{ g/cm}^3$).

clay $w = 22.6\%$ and $\rho = 1.45 \text{ g/cm}^3$, while for Morin clay $w = 20.0\%$ and $\rho = 1.42 \text{ g/cm}^3$. The three lines in Figure 1 are the approximate analytic expressions of data points for each soil.

The experiment consisted of connecting two long columns of soil of the same size (0.80 cm in diameter and 20.33 cm long) and the same specified dry density. One of them was uniformly dry with a negligibly small total water content b , while the other was uniformly wet with a specified total water content a . At time $t = 0$ we connected the two columns to make a single column 40.66 cm in length. While we maintained the column at -1°C , water was transported from the wet part to the dry part across the contact surface between the wet and dry soil columns. After 10 days passed, the soil column was quickly sectioned into a total of 64 equal thin column segments. The water content and the dry

TABLE 1 Experimental Conditions.

Exp. No.	Soil	Initial condition		Time duration (day)	Dry density (g/cm ³)	
		a(%)	b(%)		Mean	Standard deviation
1	Fox Tunnel silt	6.75	0.29	10	1.24	0.112
2	Fox Tunnel silt	6.80	0.35	10	1.23	0.105
3	Regina clay	18.1	0.49	10	1.45	0.150
4	Regina clay	17.9	0.52	10	1.45	0.141

density of each segment were determined gravimetrically.

We used 10-mL graduated plastic pipettes to enclose the soil columns. The dispensing end of each pipette was cut off and sealed with a stopper. For the preparation of wet columns, we thoroughly mixed water and soil and allowed the mixture to set for at least three days to attain moisture equilibrium prior to the packing. For the preparation of dry columns, oven-dried soil was packed into a pipette with slightly greater compactive force. During the packing, soil in the dry columns usually gained a small amount of water from the air, while soil in the wet columns lost a small amount of water to the air. We weighed each soil column after packing so that any gain or loss of water during the packing was accounted for when the initial water content was determined. All wet columns were frozen to -16°C and then warmed up to -1°C before each experiment so that they were in a warming cycle at $t=0$.

We conducted four experiments with the initial conditions given in Table 1. Experiments 2 and 4 were repeat experiments under nearly the same initial conditions as Experiments 1 and 3, respectively. Since the equilibrium unfrozen water contents for Fox Tunnel silt and Regina clay at -1°C are 8.62% and 20.6%, respectively, no ice was expected to be present in all these experiments at $t = 0$. The uniform packing of soil into a pipette was quite difficult. We examined the uniformity of the soil columns by using the measured dry density of all segments after each experiment. The mean and standard deviation of dry density are given in Table 1. Although these values are affected by errors involved in sectioning the soil columns into thin columns with ideally equal length in a relatively short time, they serve as an indicator of uniformity in packing and accuracy in sectioning.

Theory

When Equation 1 holds true, our experiment can be described in mathematical terms by the following initial value problem on the set $S = \{(-\infty, \infty) \times (0, T); T > 0\}$:

$$\frac{\partial u}{\partial t} = \frac{\partial}{\partial x} \left[D(u) \frac{\partial u}{\partial x} \right] \quad \text{on } S \quad (2a)$$

$$u(x, 0) = u_0(x) = \begin{cases} a - b & x < 0 \\ 0 & x \geq 0 \end{cases} \quad (2b)$$

where $u = \theta - b$, a and b are real numbers with $a > b \geq 0$, and soil columns in the experiment are approximated to be infinite. This approximation should remain accurate until the time when column end effects become significant. We also introduce a function $\phi(m)$ defined as

$$\phi(m) = \int_0^m D(u) u^{-1} du \quad (3)$$

where m is some positive number. It should be mentioned that the commonly used method (Bruce and Klute 1956) for the experimental measurement of diffusivities utilizes the mixed initial and boundary value problem of Equation 2a.

Equation 2a can be transformed into an ordinary differential equation by introducing a similarity variable $\xi = x(t + c)^{-1/2}$ where c is a positive real number. The similarity solution $u(x, t) \equiv h(\xi)$ should satisfy the equation:

$$[D(h)h']' + \frac{1}{2} \xi h' = 0, \quad -\infty < \xi < +\infty \quad (4a)$$

where primes denote differentiation with respect to ξ . We will seek a solution of Equation 4a satisfying the boundary condition, given as

$$h(-\infty) = a - b, \quad h(+\infty) = 0 \quad (4b)$$

Oleinik et al. (1958) investigated the initial value problem of Equation 2a for the case in which initial data $u_0(x)$ is continuous. Introducing a class of weak (generalized) solutions, they proved the existence and uniqueness of solutions in this class. These solutions can be classified into two types depending upon whether or not $\phi(m)$ is finite. When ϕ is infinite the solutions are continuously differentiable. However, when ϕ is finite, Equation 2a is parabolic near points where $u > 0$, but not near points where $u = 0$. Equations of this kind are often called degenerate parabolic. Because of this degeneracy, the transition between a part $u > 0$ and a part $u = 0$ is not smooth, and the solutions satisfy Equation 2a in the sense of distribution.

In soil physics the existence of a steep wetting front with finite propagating speed has been recognized for some time, based upon experimental observations (Swartzendruber 1969). A new theoretical interpretation of a wetting front was recently advanced (Nakano 1980a-c, 1981, 1982, 1983a-b) by

applying mathematical theorems of degenerate parabolic equations. A wetting front, defined as the interface between a part $u > 0$ and a part $u = 0$ in the solutions of Equation 2a for finite ϕ , is a singular surface in the sense of Truesdell and Toupin (1965), and propagates with finite speed. It is well established that the flow of water through unsaturated porous media is described accurately by Equation 1 when the inertial force is negligibly small in comparison to the viscous force (Raats and Klute 1968). Recently Nakano (1983a-b) has shown that the finiteness of ϕ defined by Equation 3 is equivalent to a physical condition that the inertial force is negligibly small at $\theta = b$ and $D(b) = 0$. Since in physical problems $D(\theta)$ tends to vanish as θ approaches zero, it is expected that ϕ is finite when b is negligibly small, and that under such conditions a wetting front with finite propagating speed appears.

It has been shown (Van Duyn and Peletier 1977a, Van Duyn 1979) that the problem of Equations 4a and 4b also has two types of solutions, depending upon whether or not ϕ is finite. When ϕ is infinite, $h(\xi) > 0$ for all ξ , and h approaches zero as ξ tends to infinity. When ϕ is finite, there exists a number ξ_0 such that

$$h(\xi) = \begin{cases} 0 & \text{for } \xi_0 < \xi \\ > 0 & \text{for } -\infty < \xi < \xi_0 \end{cases} \quad (5a)$$

We will consider a similarity solution of Equation 2a with a similarity variable of $\eta = xt^{-1/2}$. The similarity solution $u(x,t) \equiv f(\eta)$ should satisfy the equations:

$$[D(f)f']' + \frac{1}{2} \eta f' = 0, \quad -\infty < \eta < \infty \quad (6a)$$

$$f(-\infty) = a - b, \quad f(+\infty) = 0 \quad (6b)$$

We may consider $f(\eta)$ as a limit of $h(\xi)$ when c approaches zero.

A prevailing proposition states that similarity solutions are not only particular solutions, but, in many instances (Barenblatt and Zel'dovich 1971), are also asymptotic solutions to a wide class of the Cauchy problems of the original partial differential equation. There has been marked interest in the validity of this proposition applied to problems of porous media equations (Peletier 1971, Van Duyn and Peletier 1977b, Gilding 1979, Aronson and Peletier 1981). Van Duyn (1979) showed that similarity solutions of Equations 4a and 4b are indeed asymptotic solutions of the initial value problems of Equation 2a with continuous initial data.

From a strictly mathematical point of view, the discontinuity in initial data such as Equation 2b causes a serious complication. Applying Van Duyn's theorem (1979) and restricting the problem to the case in which the discontinuity in initial data disappears in some finite time, Nakano et al. (1983c) have recently shown that the solution of Equations 2a and b asymptotically converges upon the solution of Equations 6a and 6b. The extension of Van Duyn's theorem (1979) to the case of discontinuous initial data may not be mathematically exact, but should be an accurate approximation, from a physical point of view. We will use the similarity solution of Equations 6a and 6b to analyze the experimental data below.

When the solution of Equations 6a and 6b describes the asymptotic profile, we integrate Equation 6a to obtain

$$D[f(\eta)] = \frac{1}{2} \left[\int_{\eta_0}^{\eta} f(\eta) d\eta - \eta f(\eta) \right] / \frac{d}{d\eta} f(\eta), \quad \eta \leq \eta_0 \quad (7)$$

where $\eta_0 > 0$ is the location of a wetting front when ϕ is finite, and η_0 is infinite when ϕ is infinite. Once $f(\eta)$ is determined experimentally, $D(f)$ can be evaluated by Equation 7.

ANALYSIS AND DISCUSSION

The time duration of each experiment should be long enough for an initial profile to converge upon its asymptotic profile, but should not be excessively long so that column end effects are negligible. According to Van Duyn's theorem (1979), the deviation of a developing profile from the asymptotic profile is proportional to $t^{-1/2}$. Based on experimental data for Morin clay (Nakano et al. 1982, 1983a-c) and some preliminary experiments on Fox Tunnel silt and Regina clay, we set the time duration of 10 days. The results of the experiments are presented in Figure 2 and Figure 3, where the average water contents of the soils from two

FIGURE 2 Average water contents of two repeated experiments $\theta(\%)$ vs distance $x(\text{cm})$ for Regina clay.

FIGURE 3 Average water contents of two repeated experiments $\theta(\%)$ vs distance $x(\text{cm})$ for Fox Tunnel silt.

FIGURE 4 Diffusivities $D(\text{cm}^2/\text{day})$ vs water content $\theta(\%)$ for Fox Tunnel silt, Regina clay, and Morin clay.

repeated experiments are plotted versus the distance x (cm).

As discussed in the preceding section, a wetting front is expected to appear when $D(b)$ is negligibly small. A wetting front is clearly identifiable for Regina clay (Figure 2), but it is not easy to pinpoint for Fox Tunnel silt. Fortunately, this difficulty is of no serious concern in evaluating Equation 7 because no significant amount of error is introduced by using a value of η that is larger than the actual location of a wetting front η_0 for a starting point of the integration. Hence, one should select a starting point of η large enough so that $\theta = b$ in the neighborhood of this point. Numerical differentiation is generally considered to be a difficult operation. It is desirable to use formulas that include several neighboring data points so that the variation of data points due to experimental errors is smoothed over. Actual calculations of derivatives of $f(\eta)$ in Equation 7 were made by the standard finite difference method in which six neighboring points were used for interior points and three for end points (Nakano et al. 1983c).

The calculated values of $D(\theta)$ were plotted versus θ in Figure 4 where broken curves were drawn by visual inspection to show the trend of data points of Fox Tunnel silt and Regina clay. For the sake of comparison, the diffusivity of Morin clay with $\rho = 1.42 \text{ g/cm}^3$ at -1°C (Nakano et al. 1983c) is also presented as a solid curve in Figure 4. The common feature of these three kinds of soil is that D increases with increasing θ , attains a peak, and increases again as θ increases.

It has been recognized that the greatest amount of vapor diffusion occurs near the water content θ_c , when a monolayer of liquid water forms over soil surfaces, and that vapor diffusion levels off rapidly as the water content increases from this critical value (Jackson 1965, Nakano et al. 1982). Assuming the area of a water molecule to be $1.08 \times 10^{-15} \text{ cm}^2$, we calculated θ_c to be 0.86%, 1.66%, and 8.05% for Fox Tunnel silt, Morin clay, and Regina clay, respectively. On the other hand, from Figure 4 we find the water content θ_m at which the measured $D(\theta)$ attains a peak of about 0.8%, 1.2%, and 4.5% for Fox Tunnel silt, Morin clay, and Regina clay, respectively. Although θ_c does not coincide with θ_m , the soil with the greater specific surface area has the greater value of water content at which $D(\theta)$ attains a peak. From Figure 4 we also find that soil with less specific surface area has the greater peak. This is also the case for Jackson's data (1965).

We have found that the specific surface area is an important parameter affecting $D(\theta)$. However, the specific surface area does not seem to be directly linked to the mobility of water. Despite the difference in the specific surface area, the diffusivity of Fox Tunnel silt is close to that of Morin clay. In addition, the diffusivity of Regina clay is much less than those of the other two except at water contents ranging from 3% to 5%.

Although our experimental data are limited, the general behavior of $D(\theta)$ of soils at the subzero temperature is quite similar to that of unfrozen soils. Our data appear to indicate that the basic transport mechanism of water in soil containing no ice at the subzero temperature is essentially the same as that in unfrozen soil containing a small amount of water, although kinetic factors of transport are affected by the temperature.

ACKNOWLEDGEMENT

This work was supported by several Corps of Engineers projects.

SEISMIC VELOCITIES AND SUBSEA PERMAFROST IN THE BEAUFORT SEA, ALASKA

K. G. Neave¹ and P. V. Sellmann²

¹Northern Seismic Analysis, Echo Bay, Ontario, Canada

²U.S. Army Cold Regions Research and Engineering Laboratory
Hanover, New Hampshire 03755 USA

The distribution of high-velocity material was used as an indicator of ice-bonded permafrost. Observations from ice survey and marine seismic records, coupled with control from a small number of drill holes, suggest that ice-bonded permafrost is extremely widespread in the Beaufort Sea. Large areas of high-velocity material at shallow depths, 10-40 m below the seabed, were observed near Prudhoe and Harrison Bays. In some cases these zones extended up to 35 km from shore. It was also common to find that depths to the high-velocity material increased with distance from the shore. Observed depths were as great as 150-230 m below the seabed. Velocities also commonly decreased with distance from shore to a point where it was no longer possible to identify ice-bonded horizons. Reflection analysis revealed several deep near-horizontal reflectors that recurred along segments of the coastline from Harrison Bay to the Canadian border. Reflectors at approximately 200 m and 450 m could be permafrost-related, although no control exists for an evaluation of this interpretation. Locally these reflectors may extend out to the shelf edge to approximately the 100-m water depth.

Petroleum industry seismic data were used to obtain an improved understanding of the regional distribution of subsea permafrost. Our observations in the U.S. Beaufort Sea are based on data from Harrison Bay east to the Canadian border. The most detailed information is from the coast out to a water depth of approximately 15 m, with the greatest detail from the Prudhoe and Harrison Bay regions (Figure 1).

It has been demonstrated that refraction analysis of the upper part of deep seismic records can be useful in locating high-velocity zones that may be ice-bonded permafrost (Hunter et al. 1976, 1978). However, not all frozen materials can be located, due to their low velocities, which are caused by warm subsea permafrost temperatures, saline pore water, gas in voids, and the coarse resolution of this technique.

Reflection interpretations can also be used to acquire information on permafrost distribution and structure, but the lack of velocity data usually makes these interpretations more speculative than those from refraction analysis. Beyond the 15-m water depth, out to the shelf edge, our only information is from reflection analysis.

METHODS

The early-return data used for this study included nonproprietary records from Western Geophysical Company, Geophysical Service Inc., as well as data released by British Petroleum. Records from the land-sea transition were acquired during the winter over the sea ice. Examples of marine and ice survey records showing high-velocity zones interpreted as ice-bonded permafrost can be found in Neave and Sellmann (1982) and Hunter et al. (1976).

Control for these observations is very limited and it is virtually nonexistent beyond the 15-m water depth and in shallower water outside the Harrison and Prudhoe Bay regions. The existing control is from shallow drilling, penetrometer observations, and high-resolution seismic studies (Osterkamp and Harrison 1976, 1980, 1981; Harrison and Osterkamp 1981; Blouin et al. 1979; Sellmann and Chamberlain 1979; Miller and Bruggers 1980; Rogers and Morack 1980, 1981). Observations in the Canadian Beaufort Sea provide indirect control with a range of permafrost velocities, horizontal limits, and thicknesses (Hunter et al. 1976).

Error estimates were made to verify the analytical methods and measurements (Neave and Sellmann 1982). The consistency of results from duplicate coverage, often acquired during different years and seasons, also helped develop confidence in the results.

A model and appropriate equations are required to interpret the records and obtain depth and velocity data for the construction of maps and sections. The model used was a simple plane homogeneous layer over a half space, and our equations are derived from those provided by Grant and West (1965). Minor modifications to these equations are reported in Neave and Sellmann (1982).

A simplifying assumption was used for the refraction depth determinations: the water layer was combined with the low-velocity bottom sediments to make a single upper layer. An upper-layer velocity of 1.8 km/s was used for all profiles out to the 15-m water depth. In this zone, the upper-layer velocities were observed to range from 1.6 to 2 km/s. In deeper water an upper-layer velocity of 1.5 km/s was used.

The spatial resolution of data from this study is obviously not as great as could be obtained from

a seismic investigation specifically designed to study offshore permafrost. In general, the horizontal extent of a feature that can be detected should be a minimum of three detector spacings. This means that the minimum size of a target that can be resolved will vary from 150 to 300 m, depending on the source of the data used in this study. The minimum vertical thickness of a detectable high-velocity layer is usually determined by the wavelength of the refracted signal. Resolution is possible to approximately 1/2 wavelength, or about 50 m for most of these data (Sherwood 1967). However, shallow layers less than 30 m thick may also be detectable.

OBSERVATIONS

Our observations are influenced by a number of factors, including the amount of data examined for a region, its quality, the type of analyses that were possible, and the availability of control required to support the interpretations.

In the coastal zone, control has established a correlation between high-velocity zones and ice-bonded permafrost. Nearly all the records in the region have high-velocity refractors (greater than 2 km/s), but they are found at different depths. This great variability in the distribution of high-velocity material prompted us to outline coherent blocks of data that could be analyzed separately (Figure 1). The boundaries of the zones (A¹, A², etc.) were established by examining our seismic sections and isolating the segments with similar properties. The following results of our seismic analysis show the validity of these zones. It should be possible to find a geological explanation for the zones.

In area A¹, just north of the Sagavanirktok delta, refractors range from 0-40 m below sea level (Figure 2), with an average velocity of approximately 3 km/s. This area is part of a much larger shallow high-velocity patch, C¹, that extends north and east of Reindeer Island (Neave and Sellmann, in press). Rogers and Morack (1980) were the first to make observations on the southern edge of this zone, based on seismic data. Drilling and penetrometer observations confirm that shallow ice-bonded permafrost is present north of Reindeer Island and at several other locations in area A¹ near the Sagavanirktok delta (Miller and Bruggers 1980, Sellmann and Chamberlain 1979, Blouin et al. 1979).

In area A², which stretches from Foggy Island Bay to Flaxman Island with the exception of part of Mikkelsen Bay (Figure 1), high-velocity refractors are found in the range of 60-130 m below sea level. Velocities associated with this refractor are seen in Figure 3. The average velocity along this refracting layer is approximately 3 km/s.

In area A³, in Prudhoe and Mikkelsen Bays, high-velocity refractors occur between 160-230 m below sea level. The refractor velocities in this zone range from 2.5-4.5 km/s with an average of approximately 3.5 km/s (Figure 4). The position of this refractor in Prudhoe Bay is supported by logs from an offshore well (Osterkamp and Payne 1981). The refractor depth in this case corresponds to the top of the ice-bonded permafrost, and the structure appears to continue seaward in some parts of the study area as a reflector.

In addition to the deep refractor that occurs in the 200-m depth range, refractors are also found in area A³ at depths of 10-70 m (Figure 4). These shallow refractors have an average velocity of approximately 2.5 km/s, and may correlate with Horizon B reported by Reimnitz et al. (1971) around

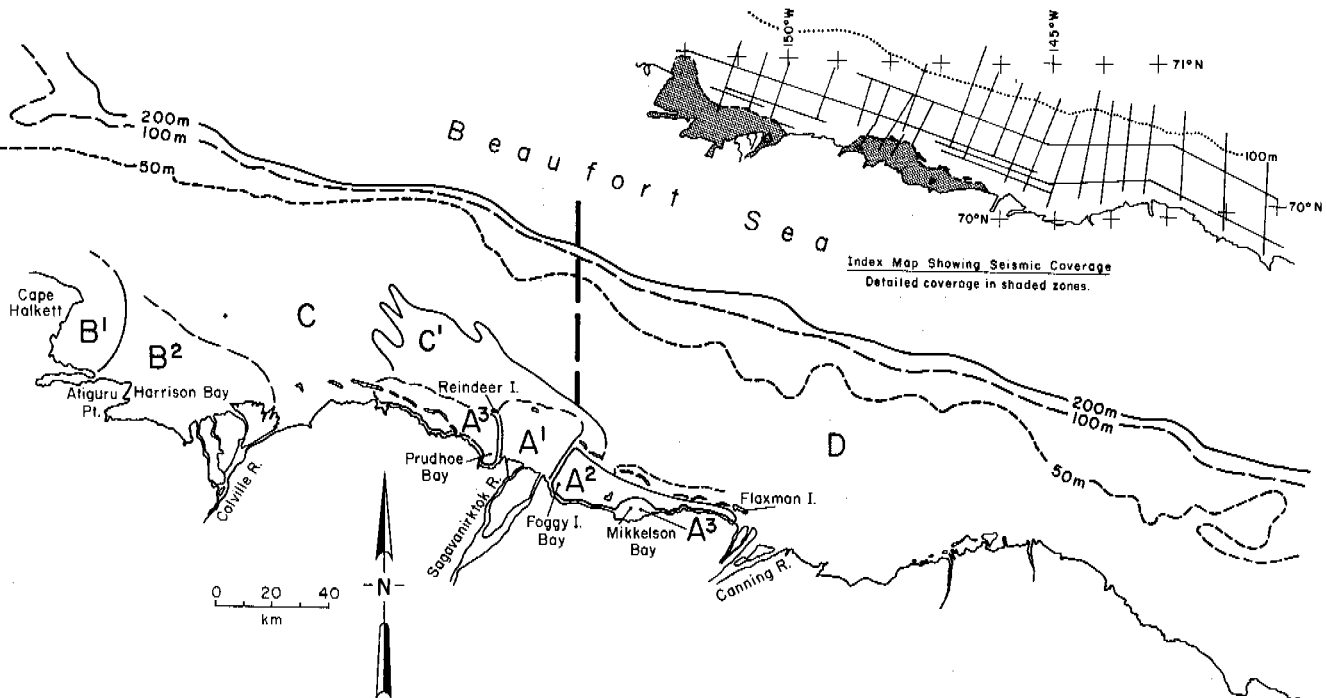

FIGURE 1 Index map showing the study area and zones with similar seismic velocity and depth structure.

FIGURE 3 Histogram of refractor depths and velocity depth plot for area A².

FIGURE 4 Histogram of refractor depths and velocity depth plot for area A³.

Pingok Island. It was part of their reflection survey, which covered the region between area A² and the Colville delta.

The depth histogram for the Harrison Bay data (Figure 5) is very similar to the one for area A³ in Prudhoe and Mikkelson Bays (Figure 4). There is a peak at the depth of 210 m and a grouping in the 10-

70 m range. Most of the shallow high-velocity refractors are west of Atigaru Point in area B¹ (Figure 1). The shallow refractors in this area are lower velocity, approximately 2.2 km/s, in contrast to 3 km/s for the shallow refractors in the Prudhoe area. This characteristic has been reported earlier by Rogers and Morack (1981), and they suggest it may

FIGURE 5 Histogram of refractor depths for areas B¹ and B².

FIGURE 6 Histograms of reflector depths for deep-water data. (a) Area C, west of the dashed line in Figure 1. (b) Area D, east of the dashed line in Figure 1.

be related to the occurrence of finer grained material in Harrison Bay. The deep refractors, at around the 210-m depth, are from the eastern two-thirds of Harrison Bay (area B²). The average velocity for this refractor is approximately 3.5 km/s.

On the lines north of the barrier islands, the refraction part of the records has a low signal-to-noise ratio along with low velocity readings. The only obvious high-velocity zone is the large area C¹, beyond Reindeer Island that appears to be an extension of area A¹ off the Sagavanirktok delta (Figure 1). This zone is discussed in greater detail in Neave and Sellmann (in press) and Rogers and Morack (1980).

Other zones are restricted to intermittent strips of marginally high velocity, in some cases just greater than 2 km/s. These zones can be found near shore and near the shelf edge. Reflection data for the lines west of Foggy Island Bay in area C (Figure 6a) define three distinct horizons, at 200 m, 450 m, and 750 m. The 200-m reflectors may be correlated with nearshore refractors in area B² and both parts of area A³. A tie seems likely between the 200-m reflector and the nearshore 200-m refractor that can be connected with onshore permafrost. This correlation, as well as that of the 450-m reflector with the bottom of ice-bonded permafrost, is discussed in Neave and Sellmann (in press).

The reflection data from the lines east of Foggy Island Bay (area D) are not of the same quality as the western lines. The resulting histogram for the eastern lines only shows the 450-m peak clearly (Figure 6b), but there are zones within this area that show shallower and deeper horizons. We therefore assume that these horizontal reflectors are common to the shelf from Harrison Bay to the Canadian border.

The most distinct transition observed in these records occurs just beyond the edge of the shelf. North of the 300-m water depth there is a noticeable increase in the quality and resolution of the reflection data.

CONCLUSION

The distribution of high-velocity material and possible related reflectors suggests that ice-bonded permafrost is extremely widespread and in some locations may even extend out to the shelf edge. It also indicates the variability of the materials in the permafrost zone.

The evidence for high-velocity zones in water depths less than 6 m being ice-bonded permafrost is good because of their connection with high-velocity material on shore. Drilling in the Prudhoe Bay region supports the conclusion that extensive shallow high-velocity material in this region is ice-bonded. This high-velocity zone is large (Figure 1) and may extend as much as 35 km from shore. A similar shallow zone (10-40 m below sea level) also exists in the western part of Harrison Bay. Other extremely shallow high-velocity zones may exist, but may not have been detected due to the resolution of this technique, the low velocities associated with warm ice-bonded material, and insufficient coverage. In areas where shallow high-velocity zones were not found, deeper high-velocity zones up to 230 m deep were observed. These zones were also thought to represent ice-bonded sediments, and in some cases the high-velocity material could be traced, with decreasing depth, back to shallow high-velocity material at the coastline.

Information on ice-bonded permafrost beyond the 15-m water depth is speculative, since no control exists beyond this point. However, deep reflectors at depths of approximately 200 m and 450 m may indicate that ice-bonded materials exist well out onto the shelf. The likelihood of the deep structures on the shelf being related to permafrost may be supported by similar observations in the Canadian Beaufort Sea, where deep layers thought to be ice-bonded permafrost persist more than 100 km from shore (Hunter et al. 1976). Additional weak evidence that permafrost may exist out to the shelf edge is suggested by a noticeable improvement in record quality beyond the shelf margin, indicating a considerable change in material properties.

ACKNOWLEDGMENT

This study was funded wholly by the Bureau of Land Management through inter-agency agreement with the National Oceanic and Atmospheric Administration, as part of the Outer Continental Shelf Environmental Assessment Program. We would like to thank the geophysical companies for their cooperative spirit in providing necessary seismic data.

PREVENTING FROST DAMAGE TO RAILWAY TUNNEL DRAINAGE DITCHES IN COLD REGIONS

Nei Fengming

The Third Survey and Design Institute of the Ministry of Railways
Tianjing, People's Republic of China

Cold weather and permafrost usually have an adverse effect on the drainage system of a railway tunnel. Based on several years' experience in railway construction and operation in the Great Xingan Mountains of China, the author discusses the effect of drainage ditches, deeply buried seepage ditches below tunnels, thermo-insulated drains, heated drains, etc., on the prevention of frost damage by using actual engineering examples. His conclusion is that, in cold regions where underground water is presumed to exist in winter, the drainage ditch is still preferable, even though it is difficult to construct and increase project costs. The seepage ditch is applicable only in regions where the frost depth is 2.7-4.8 m, because the ditch can affect the stability of the sidewalls if it is buried too deeply below the center of the tunnel. The thermo-insulated ditch and the heating ditch are more convenient and cheaper to construct, but should be used on only an experimental basis until more research can be done.

Because of cold weather and permafrost the drainage system in the railway tunnel usually does not work well. Based on experiences in railway construction and operation in the Great Xingan Mountains for many years, the author has introduced the effect of the drainage ditch, the seepage ditch buried deep in the centre of tunnel bottom, the thermo-isolated drain and the heating drain, etc., on the prevention of frost damage by using actual engineering examples. The detailed structure of the drainage ditch and the seepage ditch and their effect are presented with observed data.

PREVENTING FROST DAMAGE TO RAILWAY TUNNEL DRAINAGE DITCHES IN FOREIGN COUNTRIES

U.S.S.R.

The heating of railway tunnels in some places is provided by electric power using tubular heaters, while heat preservation in the ditch is effected by using modern and efficient thermal insulation materials, such as hard foamed plastics, cellular glass, pottery clay, etc. In some places, the ditch is warmed by the use of hot water or vapor.

Norway

Heating cables are installed in the tunnel drainage system. Some tunnels are equipped with frost-prevention double doors, which automatically open when the train approaches and close after it passes through.

U.S.A.

The primary measure adopted is to check carefully on every drainage ditch before the on-

set of winter and install heat preservation materials on the outlet. Heat is preserved in the drainage ditch by using foamed materials and heating cables are installed in the drainage pipelines.

Japan

Two in-situ experiments were undertaken in the Kamiwahore tunnel at Hokkaido, where the method used was to cover tunnel lining surface with thermal insulation materials, so as to reduce release of ground heat, in order to keep the tunnel lining surface at a temperature above the freezing point.

Type A: Use polyethylene corrugated plates installed on lining surface as waterproof plates; a gap of 18 mm between plates is left for drainage. Waterproof plates are coated with a 35 mm thick insulation layer of foamed urethane.

Type B: The concrete surface lining is coated directly with 13 mm thick waterproof mortar to serve as a waterproof layer, and then covered with 35 mm thick foamed urethane as an insulation layer.

Results obtained from the Japan experiments are: 1) In the severe cold region where the lowest temperature reaches -20°C and the yearly cumulative total negative temperature exceeds 510°C , the minimum surface temperature of the concrete lining of Type A can be kept at about 3°C ; 2) The minimum surface temperature of the concrete lining of Type B can be kept at about 4°C ; 3) The minimum surface temperature of the lining in the region where no heat preservation measures are adopted is -11°C , and the freezing period at the lining lasts 4 months.

PREVENTING FROST DAMAGE TO TUNNEL
DRAINAGE DITCH IN COLD REGIONS

Drainage ditch

The drainage ditch looks like a small tunnel and is constructed beneath the railway tunnel. The water table around the tunnel may be reduced by the use of the shaft, drilling or cracks, thus preventing lining from the effect of expansion caused by the freezing of the surrounding medium. Experiments show that the drainage ditch is a comparatively good drainage system in cold regions and is particularly suitable for regions where the mean monthly temperature is below -20°C and rock freezing depth is about 5-6 meters. A section of the drainage ditch is shown in Fig. 1. The section

of Type A, constructed with close-cut method, is suitable for the sector inside the tunnel; the section of Type B, constructed with open-cut method, is suitable for the sector outside the tunnel.

To make full use of the drainage capacity of the drainage ditch, at the time when it is being built, it is necessary to build an auxiliary drainage system, including a vertical blind drain, drain drilling and sub-ditch, as shown in Fig. 2.

Performance of the Drainage Ditch: Two kinds of drainage ditches are used in the railway tunnels in the permafrost region of the Great Khingan Mountains - those which pass through permafrost, and those which pass

through non-permafrost soil. These drainage ditches have been in operation for many years with good effect.

The drainage ditch in the mountain-top tunnel on the Yalin railway line has a section (about 190 m) passing through the permafrost soil (of the linking-up type, with mean ground temperature over many years at -1°C), thus resulting in freezing inside the drainage ditch each year. According to the survey data of July 1977, thickest ice in the drainage ditch is found in the permafrost soil region, and the thickness measures up to 80 cm. The freeze damage caused to the two kinds of drainage ditches which partly pass through permafrost soil is analyzed as follows: The drainage ditch passing through the permafrost soil and that passing through non-permafrost soil are located in different environs. The former is one form of heat source occurring in the frozen soil. Since the water temperature of the thawing region through which the tunnel passes is lower (1-3 $^{\circ}\text{C}$), the inner potential of this heat source is very small. There occurs heat exchange in the form of transmission between water at certain temperature and the surrounding frozen rocks, with the result that the inner potential of water, i.e., temperature drops. Besides, in the course of ground water flowing from the thawing region to the frozen soil region, the water temperature also drops gradually and when the water reaches the freezing point and releases all its potential heat, then freezing will occur.

Culling tunnel No. 2, for example, has all its drain ditches on permafrost soil. In February 1973 these were ice-bound, causing freezing inside the tunnel and affecting traffic safety. It was necessary to use a steam locomotive to thaw the ice and manpower to excavate it. In the winter of 1973, though measures had been strengthened, freezing still occurred when ice thickened up to 70 cm. The effect of thawing by electric stove was negligible. In 1977, 75 kW ventilators were used to blow hot air (from outside the tunnel) into the drain ditch, and it took seven days and nights to melt the ice of more than 400 m³ inside it. The fact that freezing occurred in both cases shows that to prevent frost damage it is necessary to take effective measures regardless whether the drain ditches pass wholly or partly through the permafrost soil.

The seepage ditch buried at center of tunnel bottom

The seepage ditch is buried deep in the ditch under the tunnel at a certain freeze depth with the aim of preventing frost damage by the use of ground temperature. The Chaoyang No. 1 tunnel is the first tunnel which has adopted the deep buried seepage ditch. The overall length of this tunnel is 420 m. The lowest mean temperature of the region is -27.9°C (in 1969), and annual mean temperature -3.2°C

(in 1969). Its elevation drawing is given in Fig. 3. Its buried depth (from roadbed to flow surface of the seepage ditch) ranges from 3.5 m to 4.5 m, and the actual freeze depth inside the tunnel is 5 m (where the rocks are rough-grained granite). Therefore, freezing occurs inside the ditch in winter season. However, since this kind of drainage system has a good drainage effect, frost damage is not liable to occur. In summer, when the covering slab of the inspection shaft is taken off, ice in the seepage ditch will thaw within several days, and normal operation is not affected. The seepage ditch is in Fig. 4.

The thermo-isolated drain

The thermo-isolated drain may generally reduce the ditch depth and raise the foot of the sidewall, thus making the cost cheaper and construction easier. For this reason, the thermo-isolated drain was constructed and tested in the Baikaer tunnel. There the freeze depth of the rock (Anshan rock) outside the tunnel is 7.4 m, and the minimum mean monthly temperature is -32°C (in 1973). Fig. 5 shows the section of the thermo-isolated drain. By testing the Baikaer thermo-isolated drain, we made the following observations: (1) The thermo-isolated drain costs less and is easier to construct. Thus it should be the object of research on the type of tunnel drainage in severe cold and permafrost soil regions; (2) If tunnels are provided with thermo-isolated drains, it is necessary to build such drains on both sides, because one-sided drain is liable to cause frost damage; (3) It is necessary to have thermo-isolation materials well treated to be dampproof, because the heat conduction coefficient increases with the increase of dampness; (4) It is also necessary to provide thermo-isolated layer at the bottom of the thermo-isolated drain. Only in this way is it possible to protect thermo-isolated drain from frost damage; (5) In construction it is necessary to reduce, as far as possible, the effect of air convection in the ditch, in order to minimize thermal loss due to the effect of air convection.

Heating drain

To prevent frost damage to the drain, in some tunnels different methods are used, such as hot air ventilation, hot wind ventilation, and stove heating. In the Aer Mountain tunnel hot air is used to raise the temperature. This tunnel has a total length of 3215 m and is sloped in the shape of an inverted V. The drain has a buried depth of 0.7 m inside it and 1.5 m at the opening. The mean annual temperature in the region is -3.5°C , and the minimum mean monthly temperature is -25.7°C (in January). Outside the tunnel, the minimum temperature is -48°C and maximum freezing depth is about 2.4 m. About 200 m inside the north end of the tunnel, the drain is provided with heating facilities, placed between the upper and lower covering slabs. The end of the heating pipe has a dia-

meter of 65 mm, without radiator or backwater pipe. Each year, from October 15 to April 20, heating is maintained with steam supplied three times a day. At the time steam is supplied, the temperature in the drain reaches beyond 20°C. Usually the temperature is kept at 7-8°C.

Thermo-isolated door-screen

This is installed at the tunnel opening for the purpose of preventing cool air from entering into the tunnel, preventing the drain from freezing and reducing frost damage. The tunnels which are equipped with thermo-isolated door-screen should have a watchman on duty to communicate with the railway station by means of signals. This method works better but is unfavorable for natural ventilation. It is applicable only when few trains pass through in opposite directions and when the tunnel is comparatively long. The effect of thermo-isolation door-screen used in the Xinan tunnel is as follows: the winter season in this tunnel lasts as long as seven months. The mean temperature in the coldest months is -26°C, and the minimum temperature is -54°C. The wind draft in winter blows directly to the door, at a velocity of 4.5 m/sec. on the average and 10 m/sec. at the maximum. Because it is a single slope tunnel, the difference in height between the two ends of the tunnel is 37 m. Therefore, there is considerable air convection inside the tunnel. When the temperature at the tunnel opening is below -15°C without the thermo-isolation door-screen, ice is formed along the entire 3000 meter length of the tunnel. With the thermo-isolation door-screen, air convection is greatly reduced. The minimum temperature in the middle of the tunnel is 2°C, usually at 5°C. The range of freezing is 500 m at one end, and 800 m at the other end. Sometimes, when the intervals between trains are short, and the door-screen is open for 30 minutes in one stretch, the range of freezing is 800 m and 1000 m respectively. After the thermo-isolated door-screen is installed, the amount of ice excavated is greatly reduced, so that maintenance work can be undertaken inside

the tunnel in winter time. The door-screen method has been used for 30 years with good effect. The thermo-isolated door-screen is made of thick canvas, size 6 X 8 m, opened and closed by hand. This tunnel has double-line clearance and single-line traffic. There is no mechanical ventilation.

SELECTION OF THE TYPE OF TUNNEL DRAINAGE

None of the types of drainage discussed is perfect, and any application should be made according to specific conditions in a flexible and comprehensive manner for purpose of economy and safety. Since the thermo-isolation door is questionable in terms of safety, it is seldom used. Even though the drainage ditch has problems such as difficult construction and high cost, it is still advisable to make preferential use of the drainage ditch in cold regions where underground water is presumed to exist in winter. The seepage ditch, if buried too deep in the center, would affect the stability of the sidewalls, and is therefore applicable only in regions where the freezing depth of rocks is 2.7 - 4.8 m. The thermo-isolated ditch and the heating ditch are more convenient and cheaper to construct, and should be used on an experimental basis. More research should be done on these two types of tunnel drainage in the cold regions.

DYNAMICS OF THE CRYOLITHOZONE IN THE NORTHERN
HEMISPHERE DURING THE PLEISTOCENE

I. A. Nekrasov

Permafrost Institute, Siberian Branch,
Academy of Sciences, Yakutsk, USSR

During a study of deep freezing of the lithosphere in various parts of the Earth, the concept of an extremely old cryolithozone (namely 2 mil. years old) was adopted. It was shown that the last phase of deep freezing of the lithosphere in the mountains of Northern Siberia and Alaska started in the Early Pleistocene (600-700 thousand years BP) and has continued from that time. During the last 50 thousand years four stages can be identified in the development of these frozen strata; during these stages the dynamics of the cryolithozone were closely linked to the progress of glacial events. Summarizing the information on traces of the past distribution of permafrost, the author has compiled a map of its maximum distribution. On the basis of the trends derived from this, a prognosis of the evolution of the cryolithozone for the next 100 years has been attempted. However, it is emphasized that man's industrial activities are starting to exert a critical impact on the course of natural processes.

A problem of geocryology is to determine the beginning of freezing of the upper levels of the lithosphere in various regions of the globe.

It is generally recognized that deep freezing of the Earth's crust has been a recurrent phenomenon. This is suggested by numerous traces of the old glaciations which are found within deposits ranging from Archean to Cainozoic in age. Glacial periods alternated with warmer periods, during which most of the Earth was dominated by subtropical climates. During the latter, the permafrost that had formed in previous glacial ages degraded completely. Present-day permafrost commenced forming during the Cainozoic fall of temperature.

The earliest ideas of the mechanism for deep freezing of the lithosphere are, in principle, correct. As early as 1886 Voeikov formulated the principle of equilibrium thermal state of the Earth's crust by demonstrating that heat losses of a crust layer with yearly varying temperatures are in equilibrium with the heat input from the Sun and from deeper layers of the lithosphere. The equilibrium between soil and atmosphere is, according to his view, represented by the annual average temperature at the depth of zero annual fluctuations (Voeikov 1952, p. 378).

Later, Shostakovich (1916) pointed out that the formation of "permafrost" starts when a soil layer, once frozen during winter, does not thaw out in summer, and a layer with subzero-temperature remains. One year later the phenomenon occurs again and the frozen layer grows in thickness. With every winter, the thickness of a frozen layer will increase until the freezing reaches the depth where the penetrating subzero-temperatures are in equilibrium with the warmth of deeper soil layers. Thus, the formation of permafrost is a current phenomenon, readily accounted for by existing conditions. Permafrost starts to form in conditions of ever-decreasing

heat input when the annual average magnitude of the radiation balance decreases to less than 30-35 kcal/cm² per year. It is at such values that the annual average ground temperature falls below 0°C, i.e. annual heat storage takes place at the subzero-temperature at the bottom of a layer of zero annual fluctuations.

General laws governing the permafrost history of the Earth have been subject to study by many researchers. These conclusions are summarized by Nekrasov (1976).

The concept of permafrost has been suggested by Sher (Sher 1971, Arkhangelov and Sher 1973). By identifying deposits of the Lower-Kolyma lowland (Olyorskaya suite) containing pseudo-morphs of wedge ice, and on the basis of faunal remains he attributes their formation to early Pleistocene. Sher believes that "... we feel that all these data taken together remove all doubts that in the early Pleistocene, in the formative stage of Olyorskaya suite deposits there existed on the Kolyma lowland conditions of severe continental climate that initiated the development of permafrost ..." (p. 63). Sher attributes the formation of the permafrost to 2 million years ago.

Another view is proposed by Velichko. By critically reviewing all earlier concepts (including that proposed by Sher), Velichko believes that "the permafrost zone in Eastern Siberia ... formed not at the end of the Pliocene but at least at the beginning of the second Pleistocene glacial stage" (Velichko 1973, p. 108), or about 700 thousand years ago. As far as Europe is concerned, he claims that "the first broad general-climatic wave of development of permafrost" (p. 47) is traceable only back to the beginning of the Würm, i.e. only 60-70 thousand years ago.

Explorers of the "Mamontova Gora" area attribute to approximately the same time, about 600 thousand years ago, the initiation of the permafrost in Central Yakutiya (Agadzhanian et al. 1973, p. 174).

"Once formed in lower Pleistocene, subterranean glaciation had existed throughout the entire Pleistocene, increasing simultaneously with increasing continentality of climate and vice versa."

Ravsky (1972) attributes the initiation of permafrost in Eastern Siberia to the Samara glaciation, which, according to Ravsky, started about 200 thousand years ago. Later, throughout the Messov inter-glacial period "the permafrost ... degraded completely south of the polar circle but remained, similar to present-day extent, north of it" (Ravsky 1972, p. 293). Then, during the Tazovsky stage permafrost aggraded and in the Kazantsevo interglacial degradation occurred over considerable territory of Inner Asia (p. 295). The present times (Holocene), according to Ravsky remains a period of permafrost degradation (p. 304).

The difference in dating of the start of deep freezing of the lithosphere in Eastern Siberia is nearly two million years. But if we take into account the latitude and altitude variation these differences are largely apparent. It should be emphasized that the data reported by Sher refer to the Kolyma lowland (70° N), those by Velichko and explorers of Mamontova Mountain to Central Yakutiya (63°N) while Ravsky refers to southern Siberia (52-54° N). The difference in latitude reaches nearly 20°.

It is known (Nekrasov 1976) that as one moves from north to south ground temperature increases by 0.7°C by every degree of latitude. Therefore, if we assume that this relationship still remained during the Pleistocene one can calculate that while on the Kolyma lowland the rock temperature had already dropped to -2, -3°C, it was still above +10°C in southern regions of Siberia in areas close to sea level. Exceptions were the high mountains of the southern part of Siberia. Owing to altitude variation the rock temperature decreased with height and therefore at altitudes in excess of 2000 m the permafrost formed simultaneously with that of the Kolyma lowland while at lower altitudes its development was close to that in Central Yakutiya. In depressions of Baikal-type its evolution was comparable to the history outlined by Ravsky.

During the colder epochs, the permafrost spread southward beyond the boundaries of its present position. For example, during the Samara glaciation of Siberia "perennial freezing covered the entire area of the Mongolian People's Republic, including its southern regions, the Gobi" (Gravis et al. 1973, p. 45).

On summarizing all data on the boundaries of maximum development of permafrost in Asia, Europe, and North America (Novoselskaya 1961, Popov and Kostyaev 1962, Flint 1963, Zeiner 1963, Brown and Péwé 1973, Huges 1973, Lorenzo 1969, Williams 1969) we have generated a map, showing the limits of maximum development of early permafrost within the northern hemisphere, by combining it with the one produced earlier (Nekrasov 1971) for present-day permafrost (Figure 1).

We have carried out paleogeographical reconstructions for the entire Quaternary era and more detailed reconstructions for the Upper Pleistocene and Holocene, including rock temperature fluctuations at the surface. The analysis of stratigraphical data on precipitation storage within

mountain depressions and an evaluation of neotectonic up-liftings and the modelling of deep freezing of the lithosphere (Nekrasov 1976) permit the following conclusions:

(1) The permafrost of the northern hemisphere started to form about 2 million years ago on lowlands along the Arctic Ocean and in watershed areas of the highest altitudes of the temperate zone. The permafrost of the southern regions originated only 200 thousand years ago, with its repeated complete or partial degradation during warming and new formation during colder periods. The latter was simultaneous with the formation of powerful cover and mountain-valley glaciers.

(2) During colder periods there was an expansion of permafrost so that its maximum advance in Europe reached 45° N, in North America, 35° N, and in Asia, 25° N.

(3) The evolution of permafrost of the northern hemisphere can be reconstructed with maximum reliability only since the Karginskoye interglacial age, i.e. for about the last 50-40 thousand years. During that period one can identify four stages, differing significantly from each other with respect to heat exchange between the lithosphere and the atmosphere:

(a) The first stage (Karginskoye interglacial) was from 50 to 25 thousand years ago. The Zyryan-skoe glaciation, which had lasted for over 50 thousand years, terminated about 50 thousand years ago. Of course, by the beginning of the Karginskoye interglacial, permafrost was widespread within Eurasia and North America and probably, its extent exceeded that of today. With the advent of the Karginskoye interglacial, together with a substantial warming, degradation of permafrost started. Permafrost degraded completely over most of Southern Siberia, and remained only on highlands. North of 60° N degradation in Western Siberia contributed to partial thawing of permafrost. In Eastern Siberia, this led to an increase of temperature and a substantial decrease of thickness. The coldness of the permafrost zone in near-polar regions is suggested by mammoth carcasses, found with well-preserved soft tissues, whose age, according to C¹⁴, reaches 40 thousand years.

(b) The second stage (Sartanskoe glaciation) was from 25 to 12 thousand years ago. About 25 thousand years ago, a cold period recurred, which, according to Velichko (1973b), was the coldest one in the Quaternary era. Glaciers in the mountains were reactivated. In Siberia that glaciation was presented at high-altitudes while the maximum length of glaciers of northern slopes reached 120 km, with ice up to 500-700 m thick. Uplands and large depressions in between mountains remained free from glaciers.

In the course of the fall of temperature, intense freezing occurred with an increase of thickness of permafrost in the mountains, particularly in watershed areas at high altitudes where its maximum thickness reached 1400-1500 m about 16-18 thousand years ago. Maximum thickness exceeded 600-700 m on uplands and over 1000 m in valleys in Arctic regions.

As the thickness and size of glaciers increased, there was a decrease in the rate of freezing of rocks within the bottoms of glacier trough-valleys. Where the thickness of cover glaciers was at a

maximum, partial degradation of permafrost started.

In the period of maximum development of glaciers the high-altitude regions were covered by 70-80% with ice. On tablelands, periglacial steppes, and tundras, sparse growth of birch trees was dominant.

(c) The third stage, from 12 to 5 thousand years ago, was associated with a warming of climate and a retreat of glaciers. Thawing gave rise to discharge carrying huge amounts of suspended materials from high-altitude regions into depressions and valleys of uplands. These processes occurred most intensively along northern slopes of ridges, where glaciers were large. For example, in Trans-Baikal sediment washed from the foothills of the Upper-Angara, Delyun-Uransky, North-Muisky and Kodarsky Ranges and the Longdor Mountain massif was carried away through the Patomsky and North-Baikal uplands. Outwash material from glaciers on the southern slopes of ridges generally did not move as far from the glacier edge because water discharges were less intensive.

Again, the most essential changes in the extent of the permafrost zone occurred in Europe and the mountains of Southern Siberia. Within the North-Baikal and Patomsky uplands and on the Selenga tableland a complete degradation of the permafrost occurred within river valleys and partial degradation in watershed areas. In Western Siberia deep thawing of permafrost occurred (Baulin et al. 1981).

Within depressions fluvio-glacial deposits from that stage infill the valleys and masses of mid-Pleistocene sands dominate their bottoms. Permafrost within the valleys also degraded partially. In most of the north-eastern part of Siberia, in association with a general warming of climate there was a gradual increase in temperature of the permafrost and a decrease of its thickness.

We associate the termination of this period with the warming maximum during a climatic optimum when glaciers had ablated to nearly their present-day dimensions.

(d) The fourth stage, of about 5 thousand years duration, is characterized by a gradual fall of temperature and establishment of the present-day climate and by an expansion of permafrost.

In high-altitude regions, the taliks within river valleys which were formed in the third period and which attained their maximum dimensions in the period of climatic optimum, start to contract. The higher parts freeze but their area still remains insignificant. There is the commencement of deep freezing in the bottom of glacier valleys (troughs) and small-size ice-collecting hollows. Intensive freezing of deposits also occurs within river valleys that drain depressions between the mountains, with the formation of ice wedges.

The permafrost zone within the tablelands and uplands of the north-eastern part of Siberia remains unaltered. In Southern Siberia the permafrost penetrates again farther south, into regions from which it had disappeared during the climatic optimum. An upper layer of permafrost was forming in Western Siberia at that time.

What are the main features of the present thermal equilibrium? Paleogeographical analysis shows that the present epoch refers to the fall of temperature that started about 5 thousand years ago after the climatic optimum. On the other hand,

we are witnessing a warming epoch that started following the "small glacial period" (the period of fluctuations of 1850 AD. During 500 years there has been an irreversible increase of annual average temperatures. This is complicated by short-term fluctuations. The glaciers on a world-wide scale are retreating and such a retreat of glaciers and the warming of climate has continued since at least 2300-2400 with a maximum meso-oscillation at a period of 1850 AD. Of course, owing to the general fall of temperature (of 40,000 years recurrence), the temperatures during the maximum period will be considerably lower than those at a maximum of the preceding stage that occurred in the III-VI centuries AD.

It is these basic trends in the thermal development of the Earth that should be used in evaluating the present-day extent of permafrost. But we should not omit the large inertia of the permafrost in comparison with the variations of thermal balance on the surface. Thus, with climatic fluctuations of a period of 40,000 years a time delay of 6-8 thousand years is present for permafrost 1000 m thick.

At the same time, interference of man in nature can abruptly change the picture presented above (Nekrasov and Balobaev 1982). Very hazardous is the increase of aerosols and carbon dioxide in the atmosphere. According to Budyko et al (1978), who made a prediction of climate changes for the coming 50 years, fuel burning will increase the atmospheric concentration of carbon dioxide by 30-40% by the year 2000 and 200% by 2025.

Similar to the past, this leads to an increase in the annual average air temperature by 0.5°C by 1990 and by 10-15°C by 2025. This means that the Arctic Ocean will be free from ice and its impact on climate will change. The predicted climatic changes are gigantic and at times provoke scepticism.

However, estimations made by American scientists (Energy ... 1977) are close to inferences of Soviet investigators. Objection may be caused only by the under-estimation of the self-regulating role of nature which must activate the mechanism of carbon dioxide absorption by plants and the ocean, which will greatly hinder the thawing of ice of the Arctic Ocean.

If we assume, however, that the predicted changes of climate are possible, then permafrost will be faced with a disastrous situation. In the greater part of its present-day range, an irreversible process of permafrost degradation will start. Thus, at temperate latitudes [the zone of the Baikal-Amur Railroad (BAM)] the thickness of the upper unfrozen layer will be 10-15 m by 2025. Farther to the north and at higher altitudes the thawing will be smaller. Where conditions still remain for the persistence of permafrost, the depth of seasonal thawing of soils will increase by 0.5-1.0 m. In turn, this will lead to an intensification of solifluction and thermokarst. Conditions will exist where structures supported by piles, constructed following the principle of a frozen foundation, will fail.

Deformations will occur in subgrades, and beneath roads and railroads wherever soils with high ice contents and with ice masses are present.

Since the process of phase transitions of ice

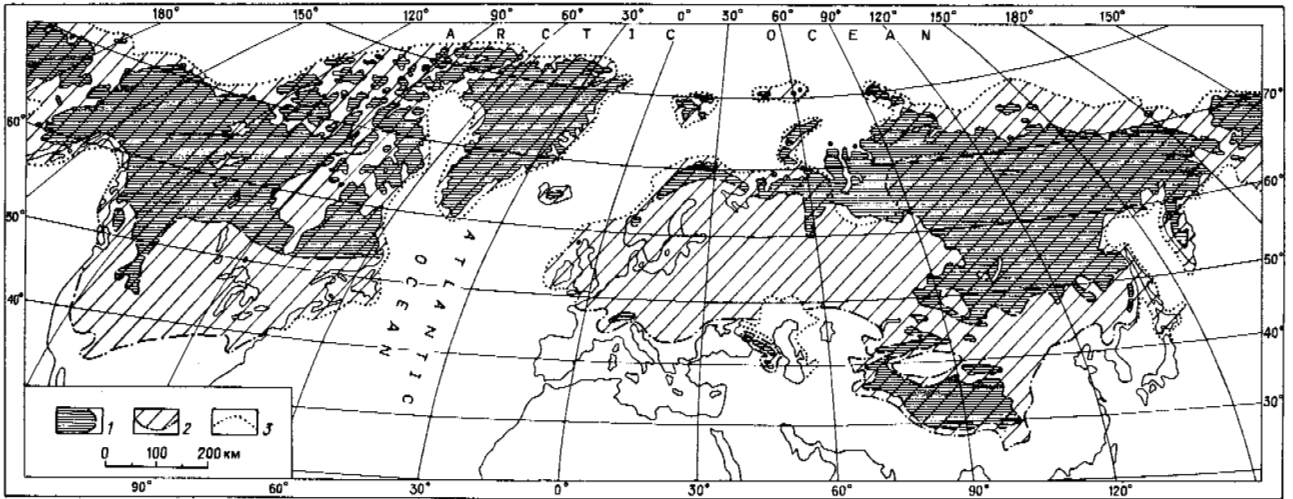

FIGURE 1 Extent of permafrost distribution in the northern hemisphere during different periods of the Quaternary: 1 - region of present-day permafrost; 2 - region of maximum development of permafrost; 3 - boundaries of sea basins during maximum development of permafrost.

into water proceeds slowly, mining structures, except for open cast operations, will not deteriorate in the near future. The principles of extracting deep ore deposits will not be altered within the next one hundred years.

A FROST INDEX NUMBER FOR SPATIAL PREDICTION OF GROUND-FROST ZONES

Fritz Nelson and Sam I. Outcalt

Department of Geological Sciences, University of Michigan
Ann Arbor, Michigan 48109 USA

Recent investigations of the relationship between the minimum and maximum mean monthly air temperatures along the trans-Alaska pipeline route indicate that good estimates of freezing and thawing degree days at a site can be obtained from these two extreme monthly mean values. The dimensionless ratio between the Stefan solution for the annual frost and thaw depths at a site can be obtained from the degree-day estimates, winter snow-cover data, and estimates of site thermal properties. The ratio of Stefan estimates of frost to thaw depths is termed the "frost number." Its value is much larger than unity in regions of continuous permafrost and descends to unity at the equatorward limit of the discontinuous permafrost zone. A preliminary mapping of the frost number in northwestern North America shows a very high spatial correspondence with observed permafrost distribution. The frost number can also be mapped using climate data in successive years, which yields information useful for correlation with such geomorphic processes as palsa growth and thermokarst development.

INTRODUCTION

Although numerous attempts have been made to regionalize permafrost through compilation of field observations and by means of computations involving climatic data, little effort has been made to incorporate calculations involving climatic data, substrate properties, and snow cover into an easily computed "permafrost index." Use of above-surface climate data alone can result in only a crude approximation of permafrost distribution, since the very large influences of snow, microclimate, and the thermal properties of the substrate are ignored. This paper presents a method which can incorporate spatial variations in some of these variables. Using this technique, an initial attempt is made to regionalize permafrost patterns in northwestern North America by combining degree-day estimates, winter-precipitation data, and, as a first approximation, simplified assumptions about subsurface thermal properties, topography, and vegetation cover.

PREVIOUS STUDIES

Many investigators have attempted to estimate and/or regionalize soil-frost conditions and permafrost distribution; these studies span a broad range of methods and scales but share the common objective of determining the nature and spatial or temporal extent of freezing conditions in the ground. Methods can be divided into two broad groupings. The first utilizes direct field-based observations on permafrost obtained from borehole, remote sensing, or geophysical methods, as reviewed by Ferrians and Hobson (1973). Trends can be extrapolated through time, as when fluctuations in a temperature profile are used to infer climatic change (Lachenbruch and Marshall 1969), and through space by delimiting ground-frost zones (e.g., Ferrians 1965), or mapping permafrost

thickness (Osterkamp and Payne 1981).

Of more relevance to this paper is a second group, which employs environmental information to make what are essentially "educated guesses" about spatial patterns of frost and/or permafrost. The major problem of such regionalization is treating the complex interactions between various factors such as snow and vegetation cover, terrain climate, substrate heterogeneity, soil moisture, and variations of geothermal heat flow, all of which can be quite variable within small areas. These problems have been addressed in a number of ways, ranging from ignoring most of the complicating factors to statistical analysis of a large number of variables.

Geographical scale is a critical consideration because the influence of local ground-cover, microclimate, and substrate-property variations is less discernible at smaller scales. For example, Brown (1967) used the -1.1° and -8.3°C mean annual air isotherms to delimit the equatorward boundaries of the discontinuous and continuous permafrost zones in areas of Canada where field measurements on permafrost were lacking. The resulting document is very useful for showing spatial variations of permafrost at the continental scale, but at large scales significant deviations from these boundaries appear, as shown by Zoltai (1971).

More recently, Harris (1981a, b) attempted to correlate freezing and thawing indices derived from screen-level climate data with permafrost occurrence and selected periglacial landform elements. His method consists of plotting freezing against thawing degree days and superimposing classes of observed ground-frost conditions or landforms for the same approximate locations on the resulting graphs. Although this procedure has revealed some interesting relationships, it is limited in its usefulness by its neglect of snow-cover effects and because the inherently spatial nature of the permafrost-distribution problem was largely ignored.

Many other investigators have attempted to

predict various frost and permafrost characteristics and their spatial variations by means of calculations involving environmental data, but the topics of many of these papers are only marginally related to those addressed in this investigation and will not be considered here.

DERIVATION OF THE FROST NUMBER

In this paper we develop an easily computed index of frost/permafrost conditions which reflects geographically variable climatic conditions, including snow cover, but which for present purposes is independent of variations in subsurface properties or conditions. The technique we propose could incorporate planimetric variations in the geothermal gradient, substrate thermal properties, and soil-moisture content although these variables are treated as constant in this study. Future studies could consider spatial variations in subsurface variables if reliable data become widely available for locations at which climate information is also collected.

In conjunction with a technique of spatial interpolation known as "lattice tuning," which takes maximum advantage of the spatial autocorrelation inherent in geographically distributed climatic data, the frost number can be used to predict ground-frost conditions over large areas in which common climatic data are available. Information yielded by the frost number pertains to permafrost conditions in equilibrium with the climatic data used as input; relict permafrost cannot be predicted by the method. Application of the frost number is restricted to sites experiencing thermal regimes in which the annual temperature amplitude exceeds that of the diurnal.

The well-known Stefan formula for predicting frost and thaw depths in soils has received wide use by engineers, agronomists, and geomorphologists (see, for example, Jumikis 1977 chapters 14-15). Although in unmodified form it can overestimate the depth of frost penetration because it ignores sensible heat, the Stefan formula provides an easily computed approximation of frost and thaw depths that is especially useful when little is known about site properties. The ratio of Stefan's frost and thaw estimates, modified for the effects of winter snow cover, can be used as an index of permafrost occurrence (cf. Lunardini 1981 p. 551). When used in conjunction with a simple method for abstracting climatic data and an efficient method of spatial interpolation, this frost index has potential for mapping permafrost distribution at small scales.

Analysis of the monthly mean air-temperature records of 19 stations in northern Alaska showed that their thermal regimes can be abstracted by three parameters: 1) mean annual temperature (T_m), 2) annual temperature amplitude (A), and 3) the phase angle (ϕ) in radians. Mean annual temperature and thermal amplitude can be approximated through simple manipulation of the mean temperatures of the extreme months (Haugen et al. 1983):

$$T_m = (T_h + T_c)/2 \quad (1)$$

$$A = (T_h - T_c)/2, \quad (2)$$

where T_h and T_c are the mean temperatures of the "hottest" and "coldest" months, respectively. These equations preserved 97.3 + 1.6% of the variance in the 19 series analyzed. The air temperature $T(d)$ for any day of the year can be estimated as a function of Julian date (d) by

$$T(d) = T_m + A \cos \{ (2 \pi d/365) - \phi \}. \quad (3)$$

In the absence of phase change, the solution for penetration of a periodic surface thermal disturbance into a homogeneous medium is given by

$$T(Z, d) = T_m + A \exp(-Z/Z_*) \cos \{ (2 \pi d/365) - \phi + (-Z/Z_*) \}, \quad (4)$$

where Z is depth and Z_* is the damping depth in the substrate (Ingersoll et al. 1954). The latter parameter is a function of the thermal diffusivity (α) of the substrate material and the wavelength (P) of the cyclic disturbance, expressed by

$$Z_* = (\alpha P/\pi)^{1/2}. \quad (5)$$

Decrease of amplitude with depth is given by

$$A(Z) = A \exp(-Z/Z_*). \quad (6)$$

The division between summer and winter occurs at the point on the cosine curve where the temperature crosses 0°C. This "frost angle" (β) is defined as

$$\beta = \cos^{-1} \{ (T_f - T_m)/A \}, \quad (7)$$

where T_f is the freezing point. When the temperature curve is symmetric, the mean summer (T_s) and winter (T_w) temperatures can be estimated by integration over only half the annual cycle (π radians):

$$T_s = T_m + A \frac{1}{\beta} \int_0^\beta \cos \theta d\theta = T_m + \frac{A}{\beta} \sin \beta \quad (8a)$$

$$\begin{aligned} T_w &= T_m + A \frac{1}{\pi - \beta} \int_\beta^\pi \cos \theta d\theta \\ &= T_m - \frac{A}{\pi - \beta} \sin \beta. \end{aligned} \quad (8b)$$

However, the winter temperature amplitude is compressed at the ground surface due to snow cover of "average" thickness Z_s . The winter surface amplitude A_w can be found by

$$A_w = A \exp(-Z_s/Z_{*s}). \quad (9)$$

The mean winter surface temperature must also be modified to reflect snow-cover effects; the mean summer surface temperature is for present purposes taken as the mean summer air temperature. This approximation could possibly be refined in future applications by Lunardini's (1981 p. 559-575) "surface n factor" using a surface-cover category representative of the vicinity of a station. In the equations that follow, the subscript (+) indicates effects attributable to snow cover. The mean winter surface temperature (T_{w+}) is given by

$$T_{w+} = T_m - \frac{A_w}{\pi - \beta} \sin \beta, \quad (10)$$

and the lengths of the summer and winter seasons in days can be calculated as functions of the frost cycle by

$$L_s = 365 (\beta/\pi) \quad (11a)$$

$$L_w = 365 \{(\pi - \beta)/\pi\}. \quad (11b)$$

A set of degree-day values adjusted for snow-cover effects can now be calculated as

$$DDT = T_s L_s \quad (12a)$$

$$DDF = |T_w L_w| \quad (12b)$$

$$DDF_+ = |T_{w+} L_w|, \quad (12c)$$

where the degree days of thaw (DDT) and frost (DDF) are the time-temperature integrals above and below the freezing point and T_s , L_s , T_w , and L_w are the mean summer temperature, length of summer (days), mean winter temperature, and length of winter, respectively.

Finally, by means of a formulation similar to that of Lachenbruch (1959), the mean annual surface temperature can be adjusted for snow cover:

$$T_{m+} = T_s (L_s/365) + T_{w+} (L_w/365) \quad (13a)$$

$$T_{m+} = T_m + (\sin \beta/\pi) A \{1 - \exp(-Z_s/Z_{*s})\}. \quad (13b)$$

Phase change, which cannot be easily incorporated into equations for periodic thermal disturbances in semi-infinite solids, is a very important consideration in frost/permafrost problems. The depth to which frost extends can be approximated by considering the thermal conductivity (λ) of the substrate, its volumetric water/ice content (x_w), the latent heat of fusion (L), and the degree days of thaw and frost. Frost and thaw depths can be obtained from

$$Z_t = \{(2 \lambda S DDT)/(x_w L)\}^{1/2} \quad (14a)$$

$$Z_f = \{(2 \lambda S DDF)/(x_w L)\}^{1/2}, \quad (14b)$$

where Z_t and Z_f are the thaw and frost depths, respectively, and S is a scale factor representing the appropriate units of time for the metric system employed.

If the seasonal differences in thermal properties $\{\lambda/(x_w L)\}$ are small, the ratio of frost to thaw depths at a site may be calculated with and without snow-cover effects, yielding a dimensionless ratio. These ratios are termed the air (F) and surface (F_+) frost numbers:

$$F = Z_f/Z_t \quad (15a)$$

$$F_+ = Z_{f+}/Z_t. \quad (15b)$$

Note that the surface frost number will always be equal to or less than the value calculated for air temperature because snow cover increases the mean annual surface temperature. If for mapping purposes substrate properties are assumed homogeneous, equations (14) and (15) reduce to

$$F = (DDF/DDT)^{1/2} \quad (16a)$$

$$F_+ = (DDF_+/DDT)^{1/2}. \quad (16b)$$

INTERPRETATION AND MAPPING

Interpretation of the frost number is straight forward. At locations where $F_+ < 1$, only seasonal frost is possible. Where F_+ is approximately unity, equilibrium permafrost should be near its climatic limit, and this value can be used to map the seasonal-frost/discontinuous-permafrost "boundary." Although delimitation of the continuous permafrost zone is always somewhat arbitrary, comparisons with empirical mappings indicate that a reasonable value for its equatorward limit may be taken as 1.5, which corresponds to a ratio of DDF_+ to DDT equal to 2.25.

A preliminary mapping (Figure 1) of the surface frost number F_+ was performed for northwestern North America using climatic data from Alaska (Searby 1978, Rieger et al. 1979), and the Yukon and Northwest territories (Hare and Thomas 1979, Canada 1967). The station records are of variable length but all represent at least part of the period 1941-1970. All but two of the records containing less than 10 years of observations are from DEW line stations and have been edited to eliminate extreme values (Canada 1967).

Four parameters were used as input: mean annual air temperature, the annual temperature amplitude, "average" snow depth, and a binary variable which indicates whether the snow cover is "packed" or "fresh" to facilitate calculation of the snow's thermal influence. The substrate was for preliminary purposes assumed to consist of a homogeneous, moderately wet silt.

The most problematic variable with respect to data availability was "average" snow-cover depth. Since such summary statistics are not readily available for a large number of stations, a surrogate method of obtaining such information was necessary. Our solution was to calculate an average snow depth Z_g by the formula

$$Z_g = 0.67 \{ \sum (P_i/D) (K - (i-1)) \} / K \quad (17)$$

where P is water-equivalent precipitation in those months i ($i = 1, 2, \dots, k$) in which the mean temperature is $\leq 0^\circ\text{C}$ and D is average snow density at the site (Bilello 1969 Figure 6). This procedure yields snow-depth estimates which are probably too low in the northern part of the study area and too high in the southern part. Nevertheless, the deviations are not extreme in cases for which average snow-depth data were available, and even this crude approximation is an improvement over ignoring snow-cover effects, as has been done in some other studies.

Locations of the data sites are given in Figure 1. The sites are largely restricted to coastal locations and a cluster of points in interior Alaska and Yukon, making some form of spatial interpolation necessary. A 34 x 24 grid (65-km mesh) was set up over the mapped area, and a technique known as "lattice tuning" (Tobler 1979) was employed to create a regular point lattice from the original irregularly spaced data points. Lattice

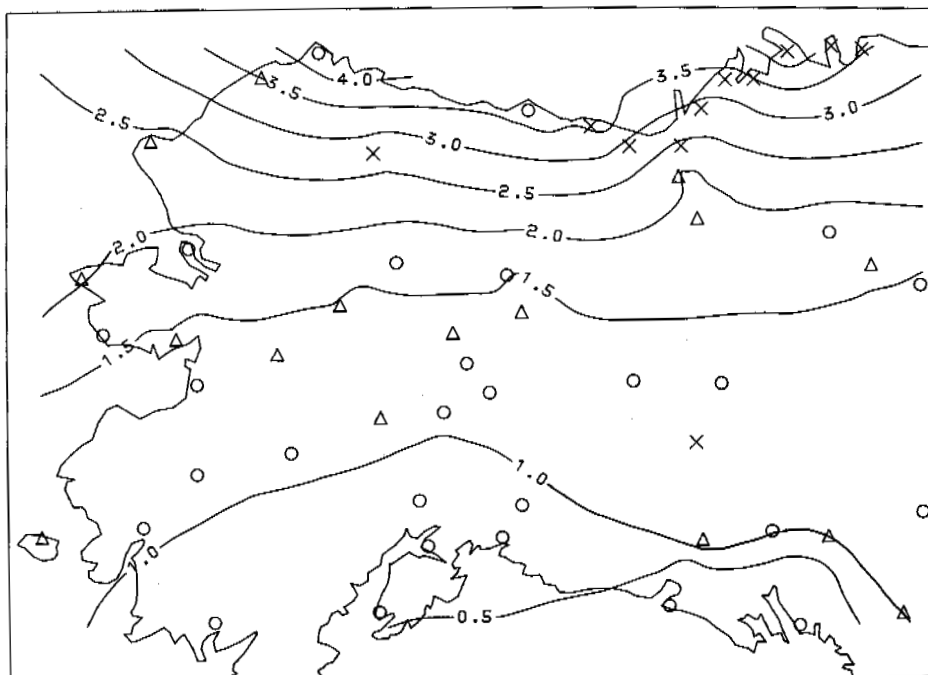

FIGURE 1 Map of the frost number in northwestern North America. Note strong increase from south to north. Locations of climate stations are shown by symbols denoting record lengths as follows: \circ , 30-year record; Δ , 10-29 years; \times , <10 years.

tuning is an iterative procedure in which estimated values at nodes lacking observations are adjusted to the original observations until successive operations yield no effective changes. The result is a smooth surface that interpolates correctly to the original data points from surrounding lattice nodes; in this respect the procedure is superior to more common gridding techniques which do not strictly preserve the integrity of the original values. The resulting lattice was then contoured and superimposed on a map of the study area (Figure 1).

A very strong, smooth increase in values of the frost number is apparent from south to north, and is consistent with trends of mean annual air temperature in the study area. The southward contour flexure in western Alaska is a response to reduction of thawing degree days near the Bering Sea coast. The southern boundaries of the discontinuous and continuous permafrost zones, delimited by the 1.0 and 1.5 contours, are well placed when compared with empirical delimitations (cf. Brown 1967, Ferrians 1965, Péwé 1975 Figure 23). The slight southward displacement of the continuous/discontinuous "boundary" relative to those of other authors' maps is a reflection of the simplifying assumptions made in this study about substrate properties, surface cover, and the lack of climate data in this part of the study area. The overall smoothness of the map and its lack of local peaks and pits show the importance of regional climate for permafrost distribution. If subsurface information was incorporated, the smoothness might be

reduced, but local sources of deviation could be treated analytically by trend-surface or map-comparison methods.

DISCUSSION

In addition to the difficulty of calculating good estimates of "average" snow cover, our method of obtaining degree-day estimates yields values for the thawing season which are somewhat low in northerly coastal locations. Values of the frost number in the northern part of the mapped area are therefore slightly higher than they would be if empirical values of DDT and DDF were used, although comparison with values obtained using data contained in Haugen (1982) indicates that the deviation is not extreme for the stations used here. For obvious reasons, the frost number can become very large when applied to locations with few thawing degree days. In such cases the values of DDT used must be as accurate as possible or gross errors in F_+ can result. An extreme example is Alert, N. W. T.; using the degree-day estimation techniques outlined in this paper, a value of nearly 27.0 is obtained for the surface frost number, whereas the value is about 5.5 if empirical degree-day values are used (data from Taylor et al. 1982). This is nearly as extreme an example as could possibly be found, however, and such large discrepancies are not possible at most low-land locations. However, this example does point

out the dangers of indiscriminate application of the estimation techniques employed in this paper. The frost number can be accurately computed only when reliable estimates of freezing and thawing indices are employed.

In addition to the use to which it was put in this paper, the frost number has some potential for use with annual climatic data at individual sites. Annual values of the number can fluctuate in response to variations in a wide range of natural and anthropogenic environmental influences, including snow depth, temperature, and soil moisture. Studies dealing with thermokarst development and palsa formation would be particularly appropriate for such applications. However, the frost number probably achieves its greatest utility in a spatial context; its simplicity and minimal input-data requirements make it an effective tool for mapping permafrost over large areas in which data lack detail or uniform spatial coverage. Mapping its variation in other parts of the earth may point to interesting environmental relationships recognizable only in a spatial context. A possibility not explored in this paper is use of statistical spatial-analytic techniques for comparing different years and/or the various environmental parameters involved in computation of the frost number.

THAW STRAIN DATA AND THAW SETTLEMENT PREDICTIONS FOR ALASKAN SOILS

R. A. Nelson^{1,4}; U. Luscher¹; J. W. Rooney²; and A. A. Stramler³

⁴Formerly with R&M Consultants, Anchorage, Alaska 99503 USA

To aid design of the trans-Alaska pipeline, a method was developed to predict thaw strain from correlations with simple frozen soil index properties. Laboratory thaw consolidation tests were made on about 1,000 representative soil samples recovered during subsurface exploration programs along the pipeline alignment. The test results were then grouped by sample soil type and landform profile. Various relationships among the soil index properties (frozen dry density and moisture content, specific gravity, gradation) and thaw strain measurements of samples within each category were examined to empirically determine a "best fit" equation by multiple variable regression analysis of the data. A computerized analysis procedure determined the set of regression coefficients to yield a unique equation for each soil category to predict thaw strain of a frozen soil sample with only borehole index property values. These estimated thaw strain values could be multiplied by stratum thickness and summed over an anticipated thaw depth to predict thaw settlement.

INTRODUCTION

Ground settlement resulting from thaw of permanently frozen ground is a problem often associated with civil construction in areas of discontinuous and continuous permafrost. One such construction project exemplifying a variety of thaw-inducing features is the trans-Alaska 1.22-m-diameter oil pipeline, constructed from 1974 to 1976, and in operation since its completion. Heat transfer from hot oil flowing through a buried pipe causes a generally cylindrical volume of permafrost surrounding the pipe to thaw. Disturbance of the natural vegetative regime by stripping of the organic mat from the pipeline right-of-way, construction equipment activity on the mat, and placement of embankment atop the organic mat alters the thermal and heat transfer properties of the ground surface, thereby effecting gradual thermal degradation (thaw) of the permafrost.

This paper presents laboratory thaw consolidation test results that were the basis for predicting thaw settlement along the entire 1,300-km pipeline alignment. These results were used in a multiple variable regression analysis with readily measured frozen soil index properties as the regression variables, ultimately producing a series of empirical equations used to predict thaw strain from those index properties. Once the thaw strain of a particular soil stratum was predicted, it was a simple matter to multiply the stratum thickness by the thaw strain to arrive at the stratum's thaw settlement. A summation of thaw settlements for the various strata encountered in a borehole to the total anticipated depth of thaw yields the total settlement for the borehole.

The analyses and procedures detailed in the following paragraphs were used to make borehole-by-borehole thaw settlement estimates for borings with permafrost from among the approximately 2,000

borings located along the pipeline centerline. As the boreholes were sited at an average spacing of about 0.5 km in permafrost sections of the alignment, settlement estimates for all borings along a short design section within a particular geologic landform (Kreig 1977) were considered together to express the range of anticipated settlements. Thaw settlement estimates were then used in such pipeline design functions as construction mode selection, elevated pipeline support design, and gravel workpad thickness requirements.

LABORATORY TESTING

Samples

Permafrost samples used in the laboratory test programs were collected in the field and handled in transport and preparation with attention to maintaining their frozen state. Borings were made using refrigerated drilling fluid. The samples were cored with various drill bits of approximately 76-mm inside diameter (i.d.). Field geologists classified the samples according to Pihlainen and Johnston (1963) field description of permafrost and the Unified Soil Classification system, and identified the geologic landform in which each boring was located as well. The samples were then transported under refrigeration from the field to testing laboratories in Fairbanks, Alaska, and Oakland, California.

There, sample ends were cut with a diamond saw in a cold room. Index properties of the still-frozen samples--dry density, moisture content, specific gravity, and gradation--were measured for each. Samples were generally 7-8 cm in diameter with a 2-2.5 height-to-diameter ratio, though some fine-grained samples with diameters as small as 4 cm were tested.

Thaw Consolidation Test Procedure

Thaw consolidation testing was done by R&M Consultants (R&M) in their Fairbanks laboratory and by Woodward-Clyde Consultants (WCC) in their Oakland laboratory. Though the test procedures used by these two organizations differed slightly, for the large magnitudes of thaw strain typically measured, the axial strain did not appear to be influenced by test method.

R&M implemented a uniaxial technique in performing thaw consolidation tests, using an 8.9-cm i.d. plastic cylinder to confine the samples. The frozen samples were first sheathed with a rubber membrane and fit with porous stones and filter paper on their ends. As the samples typically were not perfectly cylindrical nor of a single diameter, the plastic confining cylinder was slightly oversized, and any gap between the sample membrane exterior and the interior of the plastic cylinder was filled with rounded clean (Ottawa) sand. An axial stress equivalent to the overburden load at the sample's depth was maintained on the sample during thaw. Axial strain was recorded until all measurable deformation had ceased; however, where post-test diameter measurements denoted any lateral deformation, those values were then used to correct measured axial strain to a value corresponding to zero lateral strain.

WCC tests employed both uniaxial and triaxial techniques. Uniaxial tests, performed on clays, silts, and sands, were made in a standard 5-cm odometer device; triaxial tests, performed on coarse-grained sands and gravels, were made on 4- to 8-cm-diameter samples with height-to-diameter ratios of 2-2.5. Additional details of these tests are presented in Luscher and Afifi (1973).

Laboratory Test Results

The 1,024 thaw consolidation tests for the pipeline project were grouped into the following soil categories with the indicated Unified Soil Classifications:

- (1) Upland Silt - Upland Landforms (ML)
- (2) Lowland Silt - Lowland Landforms (ML)
- (3) Organic Soil (OL, OH, Peat)
- (4) High Plasticity Silt and Clay (CH, MH)
- (5) Low Plasticity Clay (CL)
- (6) Silty Sand (SM, SM-SC, SC)
- (7) Clean Sand (SW, SP, SW-SM, SP-SM, SW-SC, SP-SC)
- (8) Silty Gravel (GM, GM-GC, GC)
- (9) Clean Gravel (GW, GP, GW-GM, GP-GM, GW-GC, GP-GC)

Test results for these nine soil type categories are plotted as axial strain versus frozen dry density in Figures 1-9 in the order of the above listing. Axial strain includes any consolidation due to dissipation of excess pore water pressures in the thawed state; typically, consolidation while in the thawed state was considered a small proportion of the total measured thaw strain. Also shown in the figures are thaw strain prediction equations and the resultant curves, data produced by procedures to be discussed further.

MULTIPLE VARIABLE REGRESSION ANALYSES

Large geotechnical projects often make use of relationships between simple soil index properties and complex engineering property test results for certain design aspects, particularly when extremely variable subsurface soil conditions make prohibitive the time and cost of performing many complex tests. The more than 2,000 borings drilled along the trans-Alaska pipeline centerline showed soil conditions at some locations variable in soil composition and in distribution of moisture content and dry density within a single borehole as well. Use of correlations, then, proved a practicable geotechnical method, exemplified by the correlation of thaw consolidation tests with simple soil index properties.

Thaw Strain Prediction Equation

Thaw consolidation test results and associated frozen index properties were used as input to a multiple variable regression analysis. An equation of the form

$$\epsilon_t = A_1 n^2 + A_2 n + A_3 \frac{n^2 w}{S} + A_4 \frac{n}{S} + A_5 \frac{n}{w} + A_6 \quad (1)$$

where

- ϵ_t = predicted thaw strain,
 n = porosity of frozen sample (1-(frozen dry density / (specific gravity of soil particles x unit weight of water))),
 w = moisture content of frozen sample (weight of water / weight of dry soil),
 S = degree of saturation of frozen sample (specific gravity x w x (1- n) / n), and
 $A_1 \dots A_6$ = regression coefficients,

was used as the thaw strain regression equation. After an extensive parametric study of laboratory data and a number of empirical computer trials of different equation forms, Equation 1 was established as that algebraic expression yielding the most representative prediction.

A computerized mathematic analysis procedure determined the set of regression coefficients that made a predicted thaw strain, ϵ_t , most nearly equivalent to measured thaw strain, ϵ_{tm} . The mathematic procedure was similar to a least squares fit of a linear relationship with the exception that a nonlinear regression equation (Equation 1) was used, thereby allowing nonlinear data fits of several variables. Thaw strain was then predicted by this equation with only such simple index properties as frozen dry density, frozen moisture content, and specific gravity of a particular soil available.

Display of Thaw Strain Prediction Equation

The thaw strain (ϵ_t) predicted for any given combination of moisture content, dry density, and specific gravity is not obvious from examination of Equation 1 using the appropriate coefficients for each soil category. Therefore, the results of the regression analysis have been superimposed on the data displays in Figures 1-9 as curves based

on a representative specific gravity value and saturation values of 80% and 100%, bounding values for the saturation of most samples recovered from the field. A specific gravity of 2.70 was used for all display curves except those for lowland silt and organic soil, which were plotted for specific gravity of 2.65 and 2.30, respectively. The solid lines are curves calculated from the prediction equations shown in each figure. The short-dashed lines are linear extensions of the regression curves in high and low density ranges; these extensions are based on engineering judgment in the ranges where laboratory data are scarce.

Discussion of Prediction Curves Versus Laboratory Data

Each prediction curve resulting from the multiple variable regression analysis is drawn through a rather wide scatter of data points. Examination of a typical plot, such as Figure 1, then indicates that the thaw strain predictions may be in error by as much as 10% from what was measured in the laboratory. However, as not all data points on the figure have the same specific gravity or saturation range as for the curves drawn on the figure, the actual predicted strain may be closer to some of the outlying thaw strain results than that strain shown by the curves. The standard error of estimate (analogous to the standard deviation of the predicted versus measured error) and the multiple correlation of each of the nine thaw strain prediction equations are listed on Table 1. In the higher density ranges, the standard error of estimate decreases from this value, while, at the lower densities, the standard error of estimate is magnified.

TABLE 1 Prediction Error.

Primary Soil Type	Number of Samples	Multiple Correlation	Standard Error of Estimate (% Thaw Strain)
ML up	336	0.951	5.7
ML low	44	0.949	5.5
OL, OH	67	0.771	13.3
CH, MH	41	0.818	2.9
CL	122	0.886	5.1
SM, SC	196	0.890	5.3
SW, SP	90	0.829	2.1
GM, GC	59	0.921	3.8
GW, GP	69	0.913	3.0

The regression analysis results in a prediction equation that merely "averages" the data shown in the figures. Specific design problems at discrete locations may necessitate a more detailed examination of soil conditions and laboratory thaw consolidation results from a specific site.

Coarse-grained soils are subdivided into clean and silty fractions, for each displays a distinctive thaw consolidation behavior. Clean sands and gravels (less than 12% silt) exhibit some

measurable strains, though of generally lower value than those shown by siltier sands and gravels. Because the data are scarce in the low density range for clean soils, the short-dashed line for low density extrapolation is substantial. However, as few samples have low density and the estimated prediction curves roughly correlate with the lower density portion of the silty soil prediction curve, the prediction curves shown in Figures 7 and 9 are considered as representative.

BOREHOLE THAW SETTLEMENT ESTIMATES

The following procedure was then used to calculate thaw settlement. The representative alignment borings were chosen from the complete alignment boring program as those proximate to the pipeline centerline and generally containing the most detailed soils and geologic data. A typical boring and the associated tabulation of its predicted thaw settlements are used in explanation both of the assignment of frozen soil properties to each stratum and of the output from a thaw settlement prediction routine. Figure 10 illustrates typical information available for an alignment borehole, and Table 2 presents the thaw settlement predictions for that boring.

Frozen soil index properties were assigned to each meter of alignment borings according to the following systematic procedure. Though most boreholes were drilled to a depth of 15 m, thaw settlement estimates were extrapolated to a 30 m depth. The total borehole depth was generally subdivided by stratum thicknesses of approximately 1.5 m, corresponding closely to field sampling intervals, or at natural changes in soil type. Index properties were then determined. Laboratory test results were used when possible as the basis for designating index properties; however, as an exhaustive testing program was not feasible, soil properties were sometimes estimated for a stratum (data on Table 2 followed by an "E") by making comparisons with tested samples of similar soils.

The first two columns of Table 2 give the identifying number ("SAMP ID") and sampling depth ("SAMPLE INTERVAL") of a sample tested to determine index properties. Frozen dry density, frozen moisture content, frozen saturation, and specific gravity of soil particles of each stratum are entered to the right following "STRATA INTERVAL." The degree of saturation was calculated from the other three index property values (neglecting the 9% volumetric expansion of ice as discussed by Crory (1973)).

Once the frozen soil properties of dry density, moisture content, and specific gravity were determined and the Unified Soil Classification soil type assigned, these values were entered into a computer subroutine that calculated thaw strain and thawed soil properties. The calculation routine for each soil type includes the thaw strain prediction equation as shown in the appropriate one of Figures 1-9, as well as similar equations predicting thawed water content from the frozen soil index properties.

The thaw strain prediction equation (Equation 1) was not used over an entire range of frozen dry densities; rather, linear extrapolations from the

TABLE 2 Typical Thaw Settlement Prediction, Boring 84-3.

low density data to 100% strain at 0.0 kg/m³ (melting of pure ice) and from the high density data to a maximum dry density for each soil grouping were extended from the prediction curves as shown in Figures 1-9. These extrapolations were necessary, for the data were insufficient at the extremes of the density spectrum. After a stratum's thaw strain had been predicted, thaw settlement and thawed soil properties for that interval were calculated from the thaw strain and thawed moisture content predictions. The thaw settlement value for each stratum (thaw strain multiplied by the stratum thickness) is listed as "THAW SETTLE" on Table 2. A cumulative sum of these settlement values, commencing at the existing ground surface, is included in the table as the entry under "ACCUM THAW SETTLE"; those values represent the total ground surface settlement when thaw has advanced to each stratum's base.

CONCLUSIONS

1. Complete index properties (frozen dry density, frozen moisture content, specific gravity, gradation) of thaw consolidation samples were used in multiple variable regression analyses to relate measured thaw strain to each sample's index properties. After extensive trials, an equation was developed for each soil category that would predict representative thaw strain for the density range in which data were available. The predictions had a standard error of estimate generally within about 5% strain.

2. Thaw strain prediction equations can be used to estimate thaw settlement over an anticipated thaw depth using simple index properties of the frozen soil.

SHORELINE EROSION AND RESTABILIZATION IN A PERMAFROST-AFFECTED IMPOUNDMENT

R. W. Newbury and G. K. McCullough

Government of Canada, Fisheries and Oceans, Freshwater Institute
501 University Crescent, Winnipeg, Manitoba R3T 2N6 Canada

In 1976, an 850 m³/s river diversion was constructed through 300 km of permafrost-affected landscape in northern Manitoba. The diversion was accomplished by raising the level of a 1,977 km² riverine lake on the Churchill River (Southern Indian Lake) until the water spilled across a terrestrial drainage divide into a series of small valleys tributary to the Nelson River. Over 400 km² of permafrost-affected backshore area surrounding the lake were flooded. The mean annual temperature in the Southern Indian Lake region is -5°C. Three repeated phases of shoreline erosion in permafrost materials were observed; melting and undercutting of the backshore zone, massive faulting of the overhanging shoreline, and removal of the melting and slumping debris. At erosion monitoring sites in fine-grained frozen silts and clays, representative of over three-quarters of the postimpoundment shoreline, rates of retreat of up to 12 m/yr were measured. The index of erosion based on the wave energy impinging on the shoreline was 0.00035 m²/tonne. After 5 years of erosion, restabilization of the shoreline has occurred only where bedrock has been encountered on the retreating backshore. Clearing of the forested backshore prior to flooding did not affect the erosion rates. The rapidly eroding shorelines have increased the suspended sediment concentration in Southern Indian Lake water and have triggered degradation of the commercial fishery.

INTRODUCTION

Southern Indian Lake lies in shallow irregular Precambrian bedrock depressions on the Churchill River in northern Manitoba (latitude 57°N, longitude 99°W) (Figure 1). The climate of the region is continental, with long cold winters and short, cool summers. Average mean monthly temperatures vary from -26.5°C in January to +16°C in July.

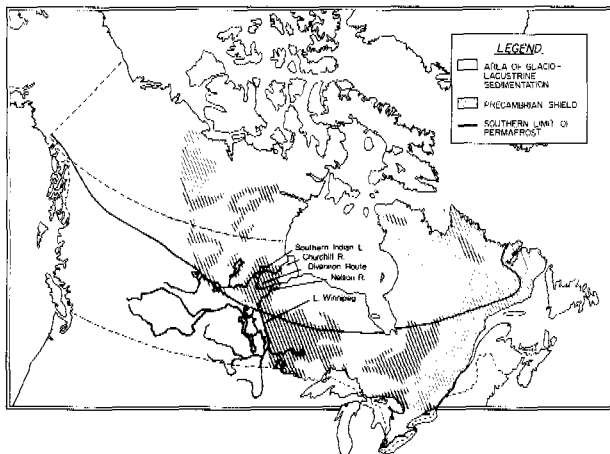

FIGURE 1 The 2,391 km² Southern Indian Lake reservoir is located on the Precambrian Shield in the discontinuous permafrost zone of central Canada. The lake lies on the northern boundary of the glacio-lacustrine deposits of Lake Agassiz.

The mean annual temperature is -5°C. One third of the annual precipitation of 430 mm occurs as snow-

fall during the average 200-day mid-October to late May snow cover period. The average accumulated depth of snow is 60 cm. Black spruce (*Picea mariana* (Mill.) B.S.P.), jackpine (*Pinus banksiana* Lamb.), and tamarack (*Larix laricina* (DuRoi) K. Koch) are the principal tree species of the boreal forest that covers the upland surrounding the lake. A layer of decaying mosses and lichens varying in thickness from a few cm to 5 m has accumulated since the final glacial retreat from the region 7,000 to 9,000 BP. During the deglaciation period, eskers, kames, and other proglacial landforms were deposited on the bedrock surface in the northern third of the region surrounding the lake. The deposits form a rolling upland with a local relief seldom exceeding 20 m. The uplands in the southern two-thirds of the basin lay within the area covered by glacial Lake Agassiz, a large proglacial lake that extended southward to the northern United States. Deposits of laminated silty clays up to 20 m thick occur throughout the region. In the southern region, the upland relief is greater and more abrupt, with exposed knolls and ridges of bedrock separated by poorly drained wetlands.

Permafrost is widespread in all terrain types surrounding the lake with the exception of the proglacial deposits in the northern region. The depth of the active layer varies from 0.5 to 2 m, depending upon local topography and the thickness of peat deposits. The temperature of the permafrost ranges from -0.2° to -0.8°C. Landforms associated with permafrost such as palsas, collapse scars, and peat plateaus occur frequently in the southern glacio-lacustrine region. Although the permafrost exceeds 10 m in depth in the upland areas (Brown 1973), it does not exist under the lake or under the narrow valleys of major tributaries.

In 1966, a program of hydroelectric development began in northern Manitoba to supply electrical energy to southern Manitoba and the central United States. A 927 km direct-current transmission line was constructed from southern Manitoba to hydroelectric dams at Kettle Rapids (1,272 MW capacity) and Long Spruce Rapids (980 MW capacity) on the lower Nelson River, 200 km southeast of Southern Indian Lake. Rather than extending the transmission line to potential dam sites on the Churchill River, a license was granted to Manitoba Hydro to divert 850 m³/s (about 85%) of the Churchill River waters southwards across a drainage divide, through a long series of small channels and lake basins in the Rat and Burntwood River valleys tributary to the Nelson River above the power dams. In June 1976, a dam was completed across the natural outlet of Southern Indian Lake at Missi Falls, and the mean lake level was raised 3 m to divert the flow across the drainage divide at the southern end of the basin (Figure 2). The area of the lake was increased from 1,977 to 2,391 km². Flooding extended beyond the sub-lake thawed zone into the permafrost-affected upland.

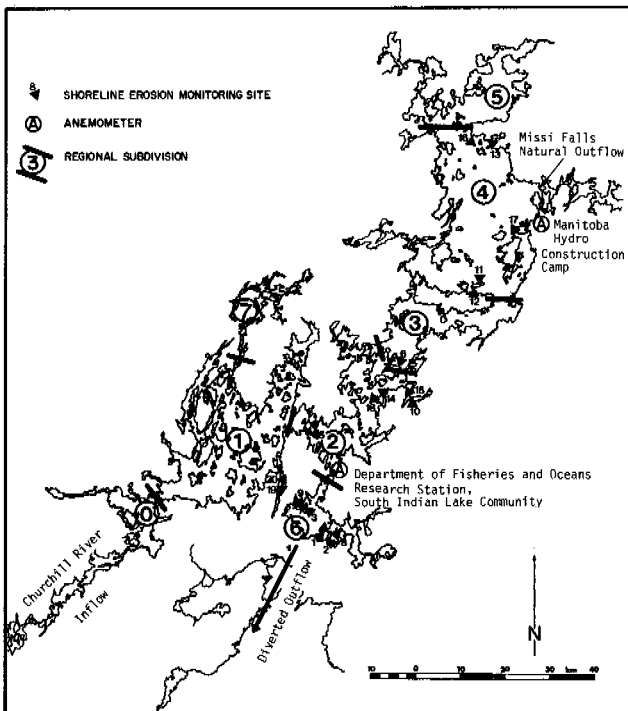

FIGURE 2 Southern Indian Lake is a series of bed-rock-controlled, riverine basins on the Churchill River. The basins have been numbered to facilitate limnological studies. Erosion monitoring stations in granular deposits and fine-grained permafrost materials are located at 20 sites of varying exposure throughout the lake.

Preimpoundment studies of the effects of flooding on shoreline stability predicted qualitatively that erosion and solifluction of the shoreline materials would occur (Underwood-McLellan 1970, Lake Winnipeg Churchill Nelson Rivers Study Board 1975). Quantitative estimates of the rates and

extent of shoreline erosion were not made, as analogous conditions had not occurred or had not been reported for such a large impoundment in permafrost.

METHODS

The study reported in this paper began in 1975, 1 year prior to the impoundment. Erosion monitoring sites were selected and surveyed at 20 locations having different exposures to wave conditions. The rates of erosion in the initial year of impoundment and the relative resistance to erosion of the permafrost materials have been previously reported (Newbury et al. 1978). The resistance to erosion was based on an index of erosion reported by Kachugin (1966) as a "washout coefficient, K_e ," which expressed the volume of backshore material eroded per unit of wave energy dissipated on the shoreline. Kachugin's units of the washout coefficient of m²/tonne are derived from the quotient of cubic meters of eroded materials per meter of shoreline length divided by the perpendicular component of the wave energy acting on the backshore expressed as tonne-meters per meter of shoreline length (m³/m)/(tonne-m/m). Eroded volumes have been surveyed annually since impoundment at erosion monitoring sites. Wave energies have been hindcast from wind speeds and directions recorded at 2 sites adjacent to the lake (Figure 2) using the modified Sverdrup-Munk procedure (U.S. Army Coastal Engineering Research Center 1966).

The lake was divided into eight sub-basins (Figure 2), for which the contribution of shoreline materials to the lake after impoundment was estimated. The washout coefficients determined from the monitoring sites were combined with the hindcast wave energies acting on 331 reaches of shoreline to determine the total erosion in each basin. The actively eroding shoreline reaches were mapped by aerial and boat reconnaissance of the whole lake in 1976 and 1978.

RESULTS AND DISCUSSION

Erosion Processes

Representative textures and ice contents of shoreline deposits at the monitoring sites are given in Table 1. An example of surveyed profiles showing annual erosion and nearshore deposition of lacustrine clay at a relatively high wave energy site is shown in Figure 3. The erosion of frozen fine-grained materials on shorelines surrounding the larger basins of the lake was observed to proceed in a repeated sequence of melting, slumping and removal phases. In the initial phase, melting occurs below and slightly above the water surface. In the second phase, the partially thawed materials flow out to form a silty-clay beach strewn with scattered frozen blocks. In some cases, caverns or melt niches are formed that are up to 1 m in height and extend up to 3 m into and under the frozen backshore materials (Figure 4). In this situation, the overlying cantilevered block splits away from the main land mass and falls onto the foreshore (Figure 5). In the final phase, wave erosion re-

^b Predominantly fine to coarse sand with some silty beds.

moves the fallen debris and the warm lake water is again brought in contact with frozen backshore materials. In the silty-clay glacio-lacustrine materials, the form of the slumping and eroding shorelines does not change substantially as the backshore retreats inland. If bedrock or coarse granular materials are encountered at the eroding face, the inland movement at the water level ceases but erosion of the backshore continues until a wave-washed bedrock zone or a stable beach is established.

At non-permafrost sites in coarse granular deposits (Sites 15 and 18), erosion and deposition processes agreed with those reported by Bruun (1962) for similar materials.

Erosion Rates at Monitoring Sites

The total volume of annual erosion and the washout coefficient, K_e , at each of the 20 monitoring sites surrounding the lake are summarized for 4 years of impoundment in Table 2. Where bedrock was not encountered, the mean washout coefficient for the permafrost materials was generally one-half of that reported by Kachugin (1966) for similar materials in the unfrozen state. Although this suggests that permafrost conditions may retard erosion, no data are supplied with the Soviet Union observations, and the magnitude of the washout coefficient may have been based on a different method of determining an index of the wave energy.

There was a wider range of K_e values observed during the first year of impoundment than in the following 3 years. At sheltered sites exposed to low wave energies, several open water seasons were required to destroy the protective moss and root cover at the water's edge. At exposed sites, large volumes of peat were quickly removed from the flooded foreshore, producing high K_e values in the first year. Because of the variability of early years, general K_e values were calculated using 1978-1980 data only. Also excluded from the general K_e determinations were values at sites after bedrock had been encountered at the eroding face (Sites 6, 8, 10, and 11). Based on the 16 shoreline sites which extend over the range of materials and fetches encountered on Southern Indian Lake, the general K_e value found by linear regression was $0.00035 \text{ m}^2/\text{tonne}$ ($r^2 = 0.71$, $n = 42$, Figure 6).

FIGURE 3 A typical consecutive annual sequence of eroding shoreline profiles at Site 1 (Figure 2). Slumped material from the initial 1975-76 period was removed in the following year.

FIGURE 4 The sequence of erosion in permafrost materials begins with the thawing and removal of backshore materials at the reservoir water level. Deep niches and caverns may be formed under the backshore zone as shown here at an island in region 4. The portion of the survey boat protruding into the cavern is 5 m in length.

FIGURE 5 As the thawing and eroding niche proceeds under the backshore zone, the length of the cantilevered block of frozen materials overhead increases until the entire backshore zone splits and tumbles onto the foreshore. The block is then thawed and removed by waves, and the formation of a new niche commences under the freshly exposed frozen bank.

The erosion index, K_e , is shown in parentheses for each period ($\times 10^{-3} m^2/tonne$). Arrows indicate cumulative erosion at shorelines not surveyed in 1978.

FIGURE 6 The linear relationship between eroded materials and wave energy for the 1978-1980 period on Southern Indian Lake is similar to that proposed by Kachugin (1966) for reservoirs in the Soviet Union. The scattered data points and wide confidence limits (95%) at high erosion and high energy sites suggest that the relationship may be curvilinear.

Sediment Contributed by Shoreline Erosion

The total dry weight of mineral materials eroded in the years 1976, 1977, and 1978 for each basin excluding the limited exposure shorelines of region 7 of the lake, is summarized in Table 3. Estimates were not extended beyond 1978, as that was the last year in which a reconnaissance survey was undertaken to determine the portions of the total shoreline in overburden and bedrock materials. Post-impoundment bank erosion dramatically increased the turbidity of the lake (Hecky and McCullough 1983). The long-term preimpoundment sediment input to the whole lake, estimated from Churchill River inflows, is 200×10^6 kg/yr. The sediment input from eroding shorelines following impoundment exceeds $4,000 \times 10^6$ kg/yr.

Time Required for Shoreline Restabilization

In the first 5 years of impoundment on Southern Indian Lake, restabilization in permafrost-affected fine-grained materials has occurred only on shorelines where bedrock underlying the backshore zone was exposed at the water's edge. Where bedrock was not encountered, there has been no change in the melting, slumping and eroding sequence of shoreline migration. The annual erosion indices at monitoring sites in fine-grained materials have shown no diminishing trend following the first year of impoundment (Table 2). The clearing of shorelines up to the impoundment level did not affect erosion rates.

Because sub-surface exploration of the bedrock topography surrounding the lake is prohibitively expensive, the time required for shoreline re-

^bAfter Hecky and McCullough (1983).

stabilization can be estimated only from the frequency of occurrence of bedrock at the monitoring sites scattered throughout the lake. Eighteen of the monitoring sites occur in fine-grained materials which are representative of over three quarters (2,841 km) of the postimpoundment shoreline. In the initial 4 years of impoundment, bedrock was encountered in the retreating backshore of the 4 most exposed monitoring sites. Assuming that the bedrock distribution is similar at less exposed sites, the rate of bedrock encounters should decrease, because more time will be required to remove the overburden. If the rate decays geometrically, 4/18 of the remaining eroding shoreline will strike bedrock every 4 years until the preimpoundment condition is restored.

Prior to impoundment, 76% of the shoreline was bedrock controlled. Following impoundment, bedrock was exposed on only 14% of the shoreline. Because the wave energy distribution on the lake and the bedrock topography were not changed by the impoundment, the same proportion of shoreline will ultimately be bedrock controlled. At the assumed geometric recovery rate of the sample shorelines, it would take 35 years to restore 90% of the fine-grained permafrost shorelines to their preimpoundment condition. Although this is an approximate estimate, it is likely that the instability of the Southern Indian Lake shoreline will not change for several decades. The discharge of bank sediment into the lake will continue to disrupt the fishery resources upon which the local residents are dependent (Bodaly et al. 1983a,b).

ACKNOWLEDGMENT

For over 20 years, the late R. J. E. Brown of the National Research Council of Canada undertook permafrost research in Manitoba and throughout northern Canada. In 1978, following the Third International Conference on Permafrost, he conducted a memorable tour of the Freshwater Institute project on Southern Indian Lake, which focused international attention on hazards of extensive flooding in permafrost terrain. The research staff of the Southern Indian Lake project wish to acknowledge his support, encouragement, and significant contribution to the understanding of permafrost phenomena.

GEOTHERMAL DESIGN OF INSULATED FOUNDATIONS FOR THAW PREVENTION

J.F. Nixon

Hardy Associates (1978) Ltd., 221-18 St. S.E., Calgary, Alberta, Canada T2E 6J5

As development in the North American Arctic proceeds to more northerly remote regions, the demand for reliable and thermally acceptable foundations for heated structures on permafrost will increase. In subarctic areas, or regions where the permafrost ground temperatures are close to melting, some method of ventilation or heat removal is necessary to provide a stable, frozen subsoil condition for support of the structure. However, in more northerly areas, communities or new energy developments are located where the mean ground temperatures are colder than -5°C or so, and another foundation alternative is available to the designer. It is possible using insulation alone, to retain the melting isotherm above the thermally unstable permafrost layer. In some cases, a distinct economic advantage may exist (particularly for smaller structures) to placing the foundation on a thicker layer of insulation, and omitting any active form of heat removal altogether. In this way, the capital costs of an elevated structural floor, or costs for ventilation or other heat removal systems can be omitted. In many remote northern areas, regular maintenance cannot be relied upon, and the use of a pure insulated foundation system does not require any long-term maintenance, and may have more than simply economic advantages. A thermal analysis for rectangular insulated structures is reviewed, and a new solution for a heated circular insulated structure is presented. A convenient chart allows the designer to select the insulation thickness that will prevent the 0°C isotherm (or any other isotherm) from entering the permafrost subsoil. In addition, an available solution for an insulated buried pipe in permafrost is reviewed for comparison.

INTRODUCTION

Foundations for heated structures on permafrost have traditionally employed ventilation as well as insulation to preserve the frozen condition beneath the structure. (See for example Tobiasson (1973) or Nixon (1978).) This is likely the most economical method of preserving permafrost beneath a building placed on grade in areas where the mean ground temperatures are within a few degrees of the melting point. Industrial and community development has proceeded further north into remoter and colder areas of the North American continent. In such areas, the requirement for essentially maintenance free foundation systems becomes more acute. In addition, the mean ground temperatures may be several degrees colder than some of the subarctic or discontinuous areas where development has been traditionally more active in past decades. Therefore, the use of a foundation system involving insulation alone as a means of permafrost protection becomes more attractive, where it is necessary to place a structure directly on grade. This removes the need for pile placement equipment and a costly structural slab, or the installation and maintenance of costly subfloor ventilating systems.

This paper reviews an existing thermal solution for insulated rectangular structures, and introduces a new solution for circular heated areas placed on grade. It is assumed that thawing of the subgrade must be completely prevented in the long term, and the thaw line maintained within the insulation layer, or layer of stable granular fill beneath the structure. It is stressed again that such foundation systems are only attractive for

areas where the mean ground temperature is several degrees below the melting point, and become particularly useful where the lateral dimension of the heated area is not large.

GEOTHERMAL SOLUTIONS FOR THAW PREVENTION

Porkhaev (1963) has presented charts for the calculation of thaw depth beneath a two-dimensional heated strip area on permafrost. Based on a later review by Tsytoich (1975), the solution for zero thaw depth can be written as:

$$a = 0.5 \cotan \left\{ \frac{\pi\beta}{2(1+\beta)} \right\} \quad (1)$$

where $\beta = k_f(T_f - T_g) / k_u(T_s - T_f)$

$a = k_u h_i / B k_i$, a dimensionless insulation parameter

$(T_s - T_f)$ = structure temperature in $^{\circ}\text{C}$ above melting point

$(T_g - T_f)$ = mean ground temperature in $^{\circ}\text{C}$ below melting point

h_i = insulation thickness (m)

B = total width of foundation (m)

and k_i , k_u and k_f are the conductivities of insulation, unfrozen and frozen ground in $\text{W/m}^{\circ}\text{C}$.

This solution provides the required insulation thickness to prevent thaw beneath the center of a long strip heated area on permafrost of width B . Porkhaev (1963) provides further approximate methods of modifying this two-dimensional solution

for square or rectangular shaped structures. The basis for these is not apparent and the following solution handles the three-dimensional case more accurately.

For heated circular areas such as tanks (or approximation to square areas), a similar method to Porkhaev's "quasi-static" method can be used to obtain the temperature field and thaw depth beneath a circular area. Although physically a three-dimensional problem, it is made simpler by considering it as a two-dimensional case in radially symmetrical coordinates. The author has based this solution on the work of Ruckli (1948) and others. It is beyond the scope of this paper to present the complete derivation of this new solution for circular heated structures. For zero thaw depth, the thickness of insulation can be written in non-dimensional form as

$$a = \frac{\pi}{8} \frac{1}{\beta} \tag{2}$$

with the same notation as before.

Equations (1) and (2) can then be plotted as shown in Figure 1, and may be used to obtain the insulation requirements beneath the center of a long rectangular or circular structure.

FIGURE 1 Required Insulation Thickness For No Thaw Beneath Heated Building On Permafrost - General Solution

DISCUSSION

It is of practical interest to note that the thickness of insulation increases in direct proportion with the minimum lateral dimension of the

structure. The foundation requirements are also heavily dependent on the ratio of the structure temperature to the ground temperature, as one would expect. A circular or square area will require somewhat less insulation than a long heated strip area, other conditions being equal. This is due to the differences between heat flow in two- and three- dimensions.

Figure 2 shows a specific solution for a typical set of soil thermal properties, and for a typical polystyrene insulation. As an example, a tank heated to +15°C continuously, and founded on a permafrost subsoil having a mean ground temperature of -8°C, would require 20 cm of insulation for a tank 20 m in diameter. At first sight this may appear to be a large insulation thickness, but may be economically attractive when one considers the great reduction in complexity during construction, and the significantly reduced maintenance effort during operation, as compared with a ventilated or piled foundation.

The insulation requirements toward the edge of the heated area might be reduced somewhat, and more detailed thermal analysis using a two-dimensional thermal simulator could be carried out to optimize the insulation thickness across the structure (see Nixon and Halliwell (1982) for a description of a two-dimensional thermal program operating in radial symmetry).

Figure 2 shows a specific solution for circular and rectangular heated areas, where typical or representative values for the thermal conductivity of frozen soil and insulation have been selected. The insulation conductivity is a recommended design value for rigid polystyrene insulation used in such applications. When the ratio of the structure temperature to the ground temperature becomes greater than about 2:1, the figure illustrates the sharp rise in insulation thickness that would be required to prevent thaw beneath the centre of the structure.

Experience with thermal analyses of this nature shows that thermal equilibrium is usually approached or reached within about 20 years. However, structures that are designed to function for much less than this might employ less insulation, depending on a more detailed time dependent thermal analysis, i.e., Porkhaev (1963) or Nixon and Halliwell (1982).

The freezing temperature, T_f , given in equations (1) and (2) is normally assumed to be the melting point of bulk fresh water, 0°C. However, for this foundation type, it would be prudent to adopt a somewhat lower temperature (say, -1°C) for the maximum temperature at the underside of the insulated pad. This allows some safety factor to be incorporated in the design, and reduces some of the frozen soil strength or creep problems that might result if the subsoil remained too close to its melting point for much of its design life. Design in saline soils would require the use of a lower freezing temperature, T_f .

Cross-drainage and the flow of meltwater through the granular pad beneath the insulation pose a major hazard for the success of this foundation type, and steps must be taken to limit or prevent this completely using surface grading or placement of impervious layers.

FIGURE 2 Specific Solution for Required Insulation Thickness to Maintain Permafrost Frozen

This form of foundation design allows a large depth of soil beneath the loaded areas of the structure to warm up close to the melting point. Large, persistent structural or live loadings may introduce time-dependent bearing capacity or soil creep problems. Granular pads should normally underlie the insulation layer to distribute concentrated surface loadings, and should be of a sufficient thickness that soil creep, in particular, does not progress on a continuing basis. Normally, surface loads imposed by a hanger, tank, or warehouse on a ventilated or piled foundation might not induce stresses that would cause creep or time-dependent bearing capacity problems. For these insulated foundation types, a large "bowl" of permafrost has been subjected to increasing temperatures in the long term. Unfortunately, the region of highest stresses coincides with the region of warmest temperature, and the designer must be very conscious of the foundation design issues (such as creep settlement) that remain.

No documented case histories of this foundation type are available to the author, and it will become a high priority to instrument foundations constructed using this design method to obtain some field verification of the design approach presented here. However, the above relationships will be of value to the design engineer as no straightforward chart exists, to the author's knowledge, that summarizes the geothermal design for heated foundations using insulation alone to prevent thaw.

INSULATED PIPES

Finally, a solution given originally by Thornton (1976) has been reworked to obtain the insulation thickness for no thaw beneath a buried pipe. His solution can be rearranged into a similar format as previous solutions for heated structures to become:

$$a = \frac{k_u}{k_i} \frac{h_i}{B} \tag{3}$$

$$= \frac{1}{2} \frac{k_u}{k_i} \left\{ \exp \left[\left(\frac{k_u}{k_i} \right)^{-1} \beta^{-1} \ln \left(\frac{D}{r_o} + \sqrt{\left(\frac{D}{r_o} \right)^2 - 1} \right) \right] - 1 \right\}$$

where B is now the pipe diameter, D is the depth of burial to the pipe axis, and r_o is the radius of the insulated pipe.

The insulated pipe radius is related to the pipe diameter and insulation thickness by

$$r_o = 0.5 B + h_i \tag{4}$$

The function expressed by equation (3) is plotted in Figure 3.

The solution is only weakly dependent on the ratio D/r_o, and the insulation thickness can be obtained explicitly from equation (3) as long as the approximate ratio D/r_o is known.

For β greater than about 0.3, equation (3) can be greatly simplified to

$$a = \frac{1}{2} l_n \left(\frac{D}{r_o} + \sqrt{\left(\frac{D}{r_o}\right)^2 - 1} \right) \cdot 1/\beta \quad (5)$$

NOTE: CONDUCTIVITIES OF INSULATION, FROZEN SOIL AND THAWED SOIL ARE k_i , k_f AND k_u RESPECTIVELY. ABOVE IS BASED ON SOLUTION FOR INSULATED PIPE BY THORNTON (1976)

FIGURE 3 Required Insulation Thickness for No Thaw Beneath Heated Pipe in Permafrost-General Solution

For example, with a burial depth ratio, D/r_o of 3, the natural log function is 1.763, and the insulation thickness is simply obtained from

$$a = 0.881/\beta \quad (6)$$

This function has therefore a similar form to the circular heated area on the ground surface.

Replacing a and β by their usual representation, the equation for insulation thickness is

$$\frac{h_i}{B} = 0.881 \frac{k_i}{k_f} \left(\frac{T_s - T_f}{T_f - T_g} \right) \text{ for } D/r_o = 3 \quad (7)$$

If $k_i/k_f = 1/65$, then

$$\frac{h_i}{B} = 0.014 \left(\frac{T_s - T_f}{T_f - T_g} \right)$$

For a 60°C pipe buried in -6°C permafrost, the required insulation thickness is about 14% of the pipe diameter.

It appears, as for the heated structures considered earlier, that insulation on its own may provide a viable design option, provided the permafrost is cold, and the structure is not excessively hot. It is also worth noting that with all other things being equal, the required insulation thickness goes up in direct proportion to the pipe diameter.

Finally, it should be noted as before that these sections should be used only as a rough guide to insulation requirements, and detailed numerical analysis accounting for actual soil stratigraphy and surface heat transfer conditions should be undertaken to refine these preliminary predictions.

It is further noted that all of the solutions presented here can be used equally well for determining insulation requirements for chilled structures on unfrozen ground, provided the subscripts for frozen and unfrozen soil are interchanged.

DRIVEN PILES IN PERMAFROST: STATE OF THE ART
Dennis Nottingham and Alan B. Christopherson

Peratrovich, Nottingham & Drage, Inc., Anchorage, Alaska 99503 USA

File driving techniques in permafrost have developed rapidly over the last 5 years, to a point where the driven pile method using thermally modified drilled pilot hole now offers a fast and economical solution to many frozen foundation problems. Most types of piles, including H-shape, pipe, and sheet piles, now can be driven, assuming that there is a knowledge of soil conditions and that the correct procedure is followed. Presented in this paper are the latest research, testing, and production pile driving developments in Alaska. Current proposed pile design approaches will be discussed as related to short-term loading and long-term creep. The scope of this paper is based largely on actual practical experience with about 5,000 piles recently driven in cold and warm permafrost soils; as well as recent laboratory work and field testing experience on a large number of driven piles. The proposed criteria presented in this paper are primarily addressed to the practicing design engineer, including design and construction considerations. As more research and experience accumulate, factors presented in this paper may change.

INTRODUCTION

In the past, piles used as structural support in permafrost have consisted primarily of the drilled and slurry backfill type. Early pile driving efforts in Alaska by the U.S. Army Corps of Engineers, the State of Alaska, oil companies, and others had varying success. Although piles had been driven in permafrost, the methods used were not entirely reliable or economical. Conversely, development of slurry backfill pile placement was advanced through extensive use on the Trans-Alaska Pipeline and North Slope oilfield projects.

Pile driving in permafrost using thermally modified pre-drilled pilot holes has now developed to the point where predictability, reliability, and economy make it a viable method in most applications. Current research efforts have helped define characteristics associated with the general soil types encountered. Contractors also are becoming aware of these methods and advantages, particularly after recent experience with piles driven into permafrost on the North Slope and other locations in Alaska.

Driven pile placement requires less equipment and support. When properly planned, installation placement rates of possibly 2 to 3 times the rate for slurry piles can be achieved. Driven piles can be loaded after placement much sooner than slurry backfill piles. Principal limitations of driven piles are location tolerances and present lack of refined driving equipment, although many good components do exist.

This paper is directed primarily toward design engineers who must apply the results of knowledge gained to date in a practical manner. A design concept is presented that uses short-term loading criteria to define maximum adfreeze limits under any condition including long-term, followed by long-term loading to establish long-term pile adfreeze strength limits based on creep deflection. This approach clarifies a past area of confusion to many engineers concerning the appropriate values to use for long-term strength.

DRIVEN PILE PLACEMENT METHODS

Piles, including H-shape, pipe and sheet, can be, depending on soil conditions, driven with both impact and vibratory hammers and the more sophisticated sonic hammers. Where extremely hard driving is encountered, an impact hammer and cast-steel pile driving tips are necessary. Experience has shown that even with relatively easy driving, pile tips should probably be used with an impact hammer to prevent tip damage. Pipe piles are particularly subject to tip ovaling and flattening during impact driving into pilot holes. Pile tips on pipe piles should be of the open, flush exterior type, and H-pile tips should be flush on the exterior. Vibratory hammers are particularly good in fine-grained saturated thawed soils or weak frozen soils, such as those produced by the thermally modified pilot hole method. They have been used for slow driving in warm frozen silts without the use of pilot holes. Vibratory hammers may have difficulty driving piles into cold dense frozen soils or where there is a predominance of coarse gravels and cobbles, or hard layers. It should be noted that driven piles made of mild steel (i.e., A36, A252, etc.) have not been observed to fail due to fracture while driving with impact hammers in extremely cold environments; however, they may fail from improper structural design considerations or driving methods. To more clearly identify various hammer types suitable for use in cold weather and permafrost, the following discussion is presented.

Impact Hammers

Impact hammers rely on falling mass to produce energy and have many forms and types. Practice in Alaska now centers primarily on diesels, with air hammers and hydraulic impact hammers also in use. Diesel hammers work well if kept warm, and meet resistance to driving to assure ignition. When used with pilot hole thermal modification

and short piles, driving is often too easy for efficient diesel operation. Air hammers offer very controllable driving, but during cold weather line heaters or heaters may be needed to prevent freezeup. Hydraulic impact hammers are small, fast-hitting devices that offer tremendous potential for driving small piles, such as for remote building foundations. Mounted on tracked vehicles, they are highly efficient and mobile machines. As with all hydraulic systems in cold weather, attention must be given to use of proper fluids and to keeping components warm and protected from the environment.

Typical driving rates in permafrost for properly sized impact hammers are 300 mm (1 ft) per minute in warm fine-grained soils, 300 mm (1 ft) per minute in dense warm granular soils with the use of a pilot hole, and up to 1524 mm (5 ft) per minute by use of thermally modified pilot holes in most soil types and temperatures.

Vibratory Hammers

Vibratory hammers are either hydraulic or electric and operate on a principle which uses two counter-rotating eccentric weights. Even the largest vibratory hammer has driving energy only equivalent to a small impact hammer, and will perform the same should difficult driving be encountered due to coarse granular or dense material. They are particularly good in fine-grained saturated soils or under conditions where soil particles can be displaced. As a result, vibratory hammers are highly efficient when used with thermally modified pilot holes.

Properly sized vibratory hammers have achieved driving rates in permafrost of less than 150 mm (0.5 ft) per minute at best in some warm fine-grained soils, but approximately 6 m (20 ft) or more per minute in most cold permafrost soils when the thermally modified pilot hole method is used properly.

Sonic Hammers

Often confused with vibratory hammers, sonic hammers and drills are inherently capable of tremendous driving rates. These high frequency devices offer great potential, but at the present time they are expensive, few in number and have many significant operational problems, particularly in cold weather. In most frozen fine-grained soils without pilot holes, driving rates comparable to vibratory hammers using thermally modified pilot holes have been achieved. To date, frozen granular soils have presented difficult driving for this type of pile hammer and thermally modified pilot holes have been used under these conditions to speed pile installation. Without the use of thermally modified pilot holes, voids have been noted around the pile near the ground surface, and typically pile embedment is increased to account for loss of strength in these upper sections.

DRIVEN PILE INSTALLATION TOLERANCES

Designers specifying driven piles must recognize that placement tolerances are to be expected, and plans must be detailed accordingly. Horizontal tolerances of piles installed with an impact hammer can be ± 50 mm (2 in), with an extreme of ± 76 mm (3 in) in plan, while variation from plumb may be up to 2%. Vibratory hammers are somewhat better in this regard, and can usually drive piles to within a 12 mm (0.5 in) horizontal tolerance and virtually plumb. This is because piles can be vibrated up and down the thawed pilot hole until desired tolerances are achieved. Piles driven by impact hammers cannot be adjusted in this manner. An important factor in achieving specified design tolerances if pilot holes are used is to drill an accurate pilot hole, since the pile follows hole alignment during driving. At times it may be desirable to drill the pilot hole 0.5 - 1 m (1 - 2 ft) deeper than pile tip elevation, particularly if driving to close vertical tolerances.

To reduce potential accumulations of soil and water pressures within driven pipe piles, placement of a small diameter weep hole in the pile wall prior to driving just above final ground line elevation is recommended. From the authors' experience, this hole need not be greater than 25 mm (1 in) in diameter. It has been noted on several driving jobs that water will spray out of these weep holes many feet as the pile nears grade; when welded pile cap is attached to pile top.

EXPERIMENTAL TESTING

Split Spoon Frozen Soil Penetration

Experiments using standard penetration tests (SPT) in frozen ground are shown in Figure 1. Analysis of these data and subjective comparison to past pile driving and soil sampling experience show that suitably designed piles probably can be driven in fine-grained soils as cold as -3°C (26.6°F) and in coarse-grained soils of possibly -1°C (30.2°F) using pilot holes. Piles probably cannot be driven efficiently without pilot holes in frozen soils much colder than -0.5° to -1.0°C (31.1° to 30.2°F), depending on soil type. With this information, parameters are established for potential driven pile foundations in permafrost. Obviously, in permafrost colder than these temperatures, some method such as pilot hole thermal modification must be used to achieve suitable soil temperature in the immediate pile area during driving.

Pilot Hole Thermal Modification

The technique of modifying permafrost temperature by use of a small pilot hole and non-circulated hot water allows easy pile driving where previously it seemed impossible. A pilot hole is a drilled hole generally extending to the desired pile tip depth. Pilot hole thermal modification has proven to be a more reliable and

controllable method than other methods of thawing, including steaming, and if used properly affects the soil regime significantly less than drill and slurry methods.

Use of water-filled pilot holes in permafrost may have other important implications. Water offers a noncompressible media which when subject to shock tends to transfer vibrations, causing soil particles to temporarily loosen and then densify against the pile thereby promoting good adfreeze bond between the pile and soil. Water also fills all voids in material around the pile, thus assuring a strong pile/soil/ice bond. Regardless of the exact mechanism, water-filled pilot holes in general allow piles to be driven easily and improves placement accuracy.

Drilled pilot hole diameter can be determined for any size pile by equating the pilot hole diameter to the pile diameter and subtracting $2d$. Where d is the desired isotherm distance from the edge of the pilot hole in mm (in). For H-piles, an equivalent diameter equal to slightly larger than the section depth may be appropriate.

Using concepts taken from Nottingham (1981) concerning early discoveries relating to pile driving with water-filled pilot holes, and curve fitting techniques, the following approximate relationship was established:

$$d = k(T)^{1/2} \quad (1)$$

here: d = isotherm distance from the pilot hole edge in mm (in)

k = constant for various soil types and isotherm desired

T = ground thaw time in minutes

Considering a -3°C (26.6°F) isotherm for silty soils and a -1°C (30.2°F) isotherm for gravelly soils, k will be approximately 0.3 - 0.5 for most conditions, using British units. For a thaw time of 60 minutes, d from the equation above will be approximately 50 - 101 mm (2 - 4 in).

In practice, vibratory pile driving tends to cause soil to be vibrated from the sides of the hole and be displaced to the pile tip. This will cause the pilot hole water to rise along or in the pile, depending on type and results in the following:

1. Soil refreezes near the pile tip faster because of lower heat requirements, as verified by field measurements.

2. The water-soil mixture created by driving action acts to effectively slurry the pile into place.

To date, field observations in -5°C (23°F) soils indicate freezeback in less than 2 days and in -7°C (19.4°F) soils in about 1 day. Structural strength for most load applications is achieved after this period. To the authors' knowledge, no significant frost jacking during the refreeze process has been observed or measured in the Prudhoe Bay area.

Based on laboratory tests and field experience, initial temperature of pilot hole water does not appear to be critical. Water temperatures between $15-27^{\circ}\text{C}$ ($60-80^{\circ}\text{F}$) may be suitable for warmer permafrost, while water temperatures between $65-100^{\circ}\text{C}$ ($150-212^{\circ}\text{F}$) appear to be appropriate for cold permafrost. Generally, water in actual installations has been placed in pilot holes 40-60 minutes before pile driving with good success.

PILE LOADING CRITERIA

Presented in Figure 2 is an idealized mode of pile action in ice-rich permafrost under constant loading. After a load increment is applied, for a period of a few hours to a few days and depending on pile length, a load adjustment period will be required for stresses to be uniformly distributed over the pile surface. This period is often described in literature as primary creep. Steady state creep is of interest for the low long-term adfreeze stresses normally used in design, and is often referred to as secondary creep. For most structural applications, it is usually necessary to limit long-term creep of piles to less than 12 - 25 mm (0.5 - 1 in); thus pile failure within the tertiary creep region is of less interest to the design engineer.

Four specific conditions are of importance to the design engineer:

1. short-term vertical loading
2. long-term vertical loading
3. frost jacking loading
4. lateral loading

Conditions 1 and 2 are discussed in this paper.

Short-Term Vertical Loading

Short-term pile tests in cold permafrost have demonstrated tremendous adfreeze resistance values, but values rapidly decrease near 0°C (32°F). Short-term has been conservatively taken in this report to be loads of generally less than 5 hours' duration. This loading group contains the following categories:

1. building live loads (other than permanent loads such as furniture, files, etc.)
2. wind loads
3. earthquake loads
4. moving vehicle loads
5. ice impact forces
6. other loads applied for short duration

By accurately assessing these loads, the design engineer can reduce pile lengths where short-term loads are a significant factor because of potentially higher allowable adfreeze stress in most cases, and where creep is not an important factor. Figure 3 depicts the authors current recommended design adfreeze stresses with an approximate safety factor of 3 for the short-term condition. It is important to note that for driven piles the adfreeze of coarse-grained soils to steel is much lower than for fine-grained soils. The thermally modified pilot hole approach helps to assure a kind of slurry bond; however, high allowable adfreeze stresses are not advisable in coarse soils. Tests on slurry piles indicate little difference in strength compared to similar size driven piles in fine-grained soils, but slurry piles exhibit greater short-term strength in coarse-grained soils.

Design charts shown in this paper do not account for end bearing, which may be significant for some conditions, such as gravel. However, end bearing is ignored in favor of a more conservative approach at this time.

When designing piles, engineers should disregard pile embedment in the active zone as contributing to pile strength.

The graphs used here do not account for saline soil conditions. The design engineer confronted with this situation should perform additional tests, which are beyond the scope of this paper.

Long-Term Vertical Loading

Piles in permafrost are subject to creep-related settlement when loads are of a sustained nature. This cannot be overemphasized in designing significant structures such as water tanks, heavy machinery supports, or other critical structures. The phenomenon is not unlike creep, which engineers commonly consider for design of concrete or timber structures.

Conversely, failure of the designer to separate short-term loads from long-term loads may lead to uneconomical foundation solutions.

Long-term creep is sensitive primarily to these aspects:

1. sustained loading
2. soil temperature
3. pile diameter
4. soil type and moisture content
5. vibrations
6. adfreeze stress

Long-term deformation of ice and ice-rich soils may be approximately represented by steady-state creep where the flow law for ice provides the upper limit for ice-rich soil. Limited numbers of long-term tests on driven piles in various soil types and temperatures have produced a series of approximate creep rates for various adfreeze values.

Pile displacement rate is very dependent upon the applied shaft shear stress. However, the effect of temperature is also clearly important, with pile displacement rates changing by as much as one order of magnitude for soil temperature changes of a few degrees.

The effect of pile diameter is also important, as found by several other researchers (Nixon and McRoberts 1976, Weaver 1979). Increasing pile diameter appears to lower allowable stress for equal creep rates. In other words, under equal adfreeze stress, a large diameter pile will settle faster than a smaller pile.

In piles supporting sustained loads, long-term deformation is highly sensitive to adfreeze stress, and design loads must be held to low levels for supports which are critical with respect to deflection.

Figure 4 was constructed from the best data currently available for ice-rich soils. The chart is based mainly on soil temperature and pile size, and only generally considers soil type and moisture content. This chart can be used conservatively for most soil types, including granular soils, but pure ice will have greater creep rates. Soils with ice content greater than 50% should be viewed with consideration given to potentially greater creep rates and reduced adfreeze strength.

Long-term creep calculations should consider average soil temperature over the pile length, excluding the active layer. Where average temperature varies with the season, it may be desirable to evaluate time increments to reflect these variations. Where unusual conditions such as heavily long-term loaded closely spaced piles are used, group creep action should be given special consideration; this aspect is beyond the scope of this paper.

Driving Methods

The authors recommend the use of driven piles in thermally modified pilot holes for the following reasons:

1. Foundation soil can be logged and examined for exact conditions at each pile.
2. Difficulties in achieving driving tolerances are reduced.
3. Driving stresses and pile installation time are reduced.
4. Soil slurry is developed around the pile thus assuring a more complete adfreeze bond.
5. Impact on the permafrost thermal regime around the pile is minimized, compared to slurry methods.
6. Discontinuous permafrost, taliks, and perched water tables present few construction problems when compared to slurry piles in similar conditions.

CONCLUSIONS

Driven piles in permafrost can offer an attractive alternative to many foundation systems. Suitable design procedures recognizing permafrost peculiarities must be used, with attention to loads, creep, and frost jacking over the design life. Currently driving procedures and techniques presented in this paper are being implemented during production driving tests on the North Slope.

For more detailed information the reader is referred to the paper by Nottingham and Christopherson (1983). Additional reference data can be found in the paper by Victor Manikian (1983).

ACKNOWLEDGMENTS

The authors are grateful to ARCO Oil and Gas Company for their cooperation and dedication to the further development of driven pile techniques in permafrost on the North Slope. Also the authors wish to thank Todd Nottingham for his technical assistance in experiments for this project.

Temperature data for Mars suggest the existence of global permafrost. Due to the low pressure of water vapor in the Martian atmosphere the frost point lies at about 198K. Consequently, ground ice can only be in diffusive equilibrium with the atmosphere at relatively high latitudes (poleward of about 40°). Slow diffusion rates through fine-grained regolith, however, may permit ground ice to have existed for billions of years anywhere within the permafrost zone.

The climatic changes on Mars, on time-scales of millions of years, appear to be directly controlled by astronomical variables. Climatic changes on time-scales of billions of years are probably of geological nature. It appears likely that an early phase of intense outgassing could have produced global temperatures considerably in excess of those at present.

Probably more than 100 m of precipitable water was released during this early phase of outgassing. The water may have charged a global ground water system which subsequently froze during a period of cooling climate. The downward progression of the freezing front may have increased the pressure of the underlying ground water system. Locally, the artesian pressure could have exceeded the lithostatic pressure, fractured the ground ice seal and released water at enormous discharges. Alternatively, the pressure build-up in the confined aquifers could have liquefied subsurface unconsolidated materials leading to fracturing of the overlying ground ice layer. Both mechanisms would explain the large channels as results of catastrophic discharge. Smaller-scale morphologic features indicative of deterioration of near-surface ground ice occur over vast areas on Mars.

INTRODUCTION

The morphology of channels, valleys, chaotic and fretted terrains and many smaller features on Mars, is consistent with the hypothesis that localized deterioration of thick layers of ice-rich permafrost has been a dominant geologic process on the Martian surface. Such ground ice deterioration may have given rise to large-scale mass movement, including sliding, slumping, and sediment gravity flowage, perhaps also catastrophic floods. In contrast to Earth, such mass movement processes on Mars lack effective competition from erosion by surface runoff. Therefore, Martian features due to mass movement have grown to reach immense size without being greatly modified by secondary erosional processes.

The Viking mission to Mars in 1976 provided adequate measurements of the relevant physical parameters to constrain models for Martian permafrost. The temperatures on Mars suggest thick global permafrost and models for planetary evolution indicate abundant water. Consequently, the most reasonable conclusion based on the probable physics of the Martian regolith is that it does contain a thick layer of ice-rich permafrost, a conclusion consistent with the observed surface geology.

GLOBAL DISTRIBUTION OF PERMAFROST

Permafrost, as originally defined by Muller (1947), refers to "a thickness of soil or other superficial deposit, or even of bedrock, at a variable depth beneath the surface of the earth in which a temperature below freezing has existed continually for a long time (from two years to tens of thousands of years). Permanently frozen ground

is defined exclusively on the basis of temperature, irrespective of texture, degree of induration, water content, or lithologic character". Unfortunately, some confusion exists in the planetary literature regarding the use of "permafrost", hence the need to explicitly state the above definition.

Muller's definition appears consistent with the view that 0°C is the criterion for permafrost. Most workers currently use this definition (Washburn 1980), rather than the actual freezing point which varies with a number of factors including water content, lithology, and salinity.

Permafrost on Mars plays a potentially major role in the cycling of volatiles and in its effects on crustal geological processes. The mean annual surface temperature on Mars is everywhere below 273 K. Thus, permafrost is global. The lower boundary of the permafrost layer is controlled by the geothermal heat flux. Fanale (1976) determined the present rate of heat production on Mars by assuming that, in bulk, the planet had the same ⁴⁰K, ²³²Th, ²³⁸U, and ²³⁵U concentrations as chondrites (a type of stony meteorite with small rounded bodies of olivine and enstatite called chondrules). Based on this he found a near-surface heat flux of 29.3 ergs/cm²/s. Assuming perfect temperature equilibrium with the atmosphere, Fanale's model showed that the 273 K isotherm would be encountered at a depth of 1 km at the equator, at 2 km at 40° latitude and at greater depths at higher latitudes (Figure 1). These numbers probably give the maximum thickness of the global permafrost. Toksoz and Hsui (1978) calculated a heat flux of 35 ergs/cm²/s. This higher value would correspond to a steeper temperature gradient and somewhat thinner permafrost

FIGURE 1 Theoretical distribution of ice and sub-freezing (< 273 K) temperatures on Mars. Ground ice is in equilibrium with respect to the present atmosphere in lenticular regions extending from the poles equatorward to about 40° latitude. Ice may also be present in the remaining permafrost zone because of slow water vapor diffusion through fine-grained regolith. Modified from Fanale (1976).

zone than the one calculated by Fanale (1976). Rossbacker and Judson (1981) have computed the permafrost distribution based on this revised heat flux value.

The zone in which ground ice could exist in equilibrium with the atmosphere is much smaller than the permafrost zone, because of sublimation of ice in diffusive contact with the atmosphere wherever the temperature exceeds the frost point (the temperature at which ice will begin to precipitate out of atmospheric water vapor). The upper boundary of the zone containing permanent ice intersects the ground surface at the edge of the permanent ice cap. The base is at a depth of 1 to 1.5 km at the poles. The zone of equilibrium ground ice narrows to zero at about 40° latitude (Figure 1).

The pattern depicted in Figure 1 is highly idealized. It assumes perfect diffusive contact between the ground ice and the atmosphere. The soil, however, is probably not in perfect diffusive contact with the atmosphere at all depths. Due to slow diffusion rates of water vapor, ground ice could exist for billions of years at nearly any depth within the permafrost layer (Smoluchowski 1968).

Measurements of the atmospheric water vapor by the Mars atmospheric water detector (MAWD) onboard the Viking orbiters, demonstrated diurnal and seasonal variability within a range of 5 to 40 precipitable μm in equatorial and mid-latitudes (Farmer et al. 1977). Using the equatorial average of 12 pr. μm , and assuming a well-mixed atmosphere, Farmer and Doms (1979) calculated the associated frost point temperature to be 198 K. Figure 2 illustrates the results of their calculations of the depth below the surface at which temperatures during the diurnal cycle never exceed this frost point temperature. In this figure the regions labeled "cold" refer to regolith which never rises above the frost point temperature any time during the year, i.e. these are the zones of equilibrium ice. The central hatched area, labeled "hot" is characterized by temperatures which do exceed the atmospheric frost point at some time during the day in all seasons. Farmer and Doms' (1979) investigation shows that between latitudes 35°S and 46°N the near-surface temperatures are always above the frost point, so that ice can never be present in equilibrium with the atmosphere. The near surface regolith at these latitudes is therefore

FIGURE 2 Stability of water ice in the Martian regolith as a function of latitude. The results are based on assumed perfect diffusive exchange between the ground ice and an average well-mixed Martian atmosphere containing 12 μm of precipitable water. Such an atmosphere gives a frost point of 198 K. Regions labeled "cold" may retain permanent ground ice, that labeled "hot" will never retain equilibrium ice. In intervening areas water ice is stable during part of the year. Numbers on the vertical boundaries (270, 0, 90 ...) refer to areocentric longitude (L_s). $L_s = 0$ corresponds to northern vernal equinox. From Farmer and Doms (Journal of Geophysical Research, v. 84, p. 2881-2888, 1979, with permission).

"desiccated", or free of ice and water, at least within layers which maintain diffusive contact with the atmosphere. At latitudes higher than about 45° the regolith at a depth of one meter never reaches the frost point at any time of the year; this is the region of potential permanent ice. The upper boundary of the zone of permanent ice intersects the surface at the edge of the ice caps ($\sim 80^\circ$).

CLIMATIC CHANGE

The global permafrost distribution discussed in the preceding chapter is based on the currently observed Martian climate. The Martian temperature regime, however, is variable. Kieffer et al.'s (1977) surface temperature model for Mars calls for wide diurnal and seasonal temperature fluctuations. At equatorial latitudes the daily maxima range from 290 K to 260 K. Daily minima range from 180 K to 170 K (Figure 3). The equatorial zone is warmest during southern hemisphere summer. Surface temperatures observed by the infrared thermal mapper (IRTM) during the Viking primary mission ranged from 130 to 290 K (Kieffer et al. 1977).

After decades of controversy the idea of primary astronomical control of periodic fluctuations in the Earth's climate now appears to have been firmly established (Berger 1977, Imbrie and Imbrie 1980). The Earth's climatic history, however, is exceedingly complex because the signature of the astronomical variations is overprinted by factors controlled by oceanic circulation and global tectonics. Also, of the orbital parameters responsible for climatic change, axial obliquity and orbital eccentricity vary relatively little for the Earth.

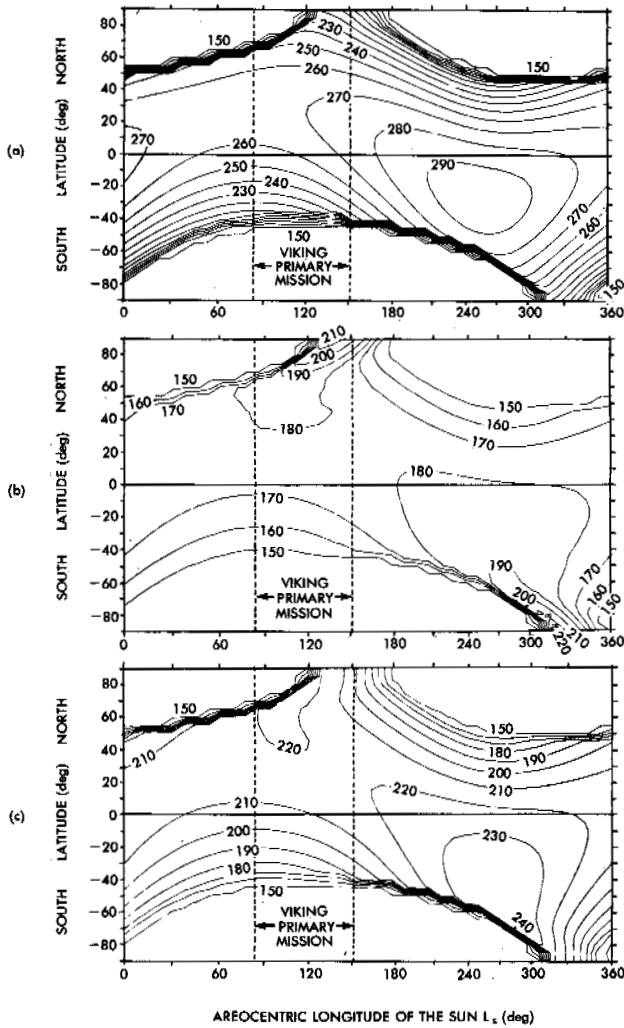

FIGURE 3 Diurnal surface temperature means and extremes for the primary Viking thermal model. (a) maximum temperatures, (b) minimum temperatures and (c) mean temperatures. Modified from Kieffer et al. 1977.

For Mars the situation seems to favor a much stronger astronomical control on climatic change. The absence of oceans will probably produce a much more stable global circulation pattern, and orbital parameters are subject to great change. The obliquity of the Mars spin axis varies on a time scale of 10^5 years (Ward 1974). The amplitude of this behavior is itself modulated on a 10^6 year time scale by changes in orbital inclination (Figure 4). Together with orbital eccentricity variations and changes in the heliocentric longitude of perihelion of Mars' orbit, the obliquity variations will produce great changes in the intensity and distribution of insolation on Mars. The climatic response is likely to be great and geological evidence should be discernible. It is commonly thought that the layered terrain near the Martian poles preserves a record of cyclic aeolian sedimen-

FIGURE 4 Calculated time series for the variation in eccentricity, precession index and obliquity for Mars. (a) presents results for the last 10 million years, (b) presents, with greater resolution, the variations within the last 1 million years. Based on analysis by Ward (1974). Figure reproduced from Cutts and Lewis (Icarus, v. 50, p. 216-244, 1982, with permission).

tation probably caused by periodic changes in global climate (Pollack and Toon 1982, Carr, 1982, Cutts and Lewis, 1982).

As on Earth, longer-term climatic change driven by geological factors has probably also occurred on Mars. One such factor is possible polar wandering in response to a reorientation of the Mars spin axis following the growth of the Tharsis volcanic province.

The climate on Mars early in that planet's geological history may have been dramatically different from the present because of possible "greenhouse effects" in the early atmosphere. Mars today has an atmosphere which does not lead to appreciable self-enhanced warming. However, if a primordial

reducing atmosphere occurred, greenhouse warming could have been substantial (Sagan, 1977). Pollack (1979) proposed that abundant water was available in the primordial source materials, and that Mars had been subject to a brief period of intense outgassing early in its history. The resulting atmosphere would have been rich in both oxidized gas species (carbon dioxide) and reduced ones (ammonia). Such an atmosphere would have produced both high atmospheric pressure and high temperatures.

The depth penetration of the thermal wave corresponding to these temperature variations depends on the wave frequency. The daily thermal wave probably affects only the upper few centimeters, the annual changes the upper 1-10 m. These fluctuations produce a layer which is subject to alternating ice formation and desiccation on an annual basis. In mid-latitudes this layer is from 10 cm to 1 m thick, in the equatorial zone it extends down to 10 m (Figure 2). Temperature changes on time scales of 10^5 - 10^6 years should penetrate to depths of a few hundred meters to 1 km. Temperature changes over geologic time scales of billions of years may affect the entire regolith (Table 1).

TABLE 1 Climatic changes on Mars: Factors, Time Scales, and Depths of Penetration of the Associated Thermal Wave

Time Scale	Cause	Penetration Depth of Thermal Wave
Daily	Planetary Rotation	cm
Year	Orbital revolution	1-10 m
10^5 - 10^6 years	Obliquity and eccentricity variations	100 m-1 km
$1-4 \times 10^9$ years	Polar wandering Greenhouse effect Solar luminosity	km

The depth-porosity relationship of the Martian upper crust is still subject to conjecture because of the absence of relevant seismic data. Based on comparisons with Earth and the moon, Carr (1979) suggested that the base of the porous layer on Mars should be in the 10-20 km range. Pore space for the containment of interstitial ice would, therefore, be expected to exist throughout the permafrost zone. Pore fluids could exist down to considerable depth below the permafrost boundary.

FORMATION OF ICE-RICH PERMAFROST

Prior to the Mariner 9 mission in 1971-1972 Mars was considered a planet greatly impoverished in water. Morphological evidence for flowing water in the form of large channels, discovered by Mariner 9 (McCauley et al. 1972), completely changed that perception. As stated by Pollack (1979), "Water is the only plausible, cosmically abundant substance that meets all the morphological constraints imposed by the many channels on Mars." Water is probably present in frozen interstitial form in the permafrost zone, some is tied up in the polar caps, and some is tied up in hydrated minerals or ad-

sorbed onto clay particles in the regolith.

Fanale (1976) estimated that for reasonable porosities and thickness of the impact-generated regolith one could easily accommodate the equivalent of 400 m of water evenly spread over the surface of the planet. Anders and Owen (1977), basing their analysis on the atmospheric abundance of the primordial noble gas isotope ^{36}Ar , concluded that the outgassing of Mars should have produced the equivalent of 9.5 m of water, distributed globally. This is the lowest estimate available. Pollack and Black (1979) predicted a Mars water inventory in the range of 80-160 m.

One commonly held model for planetary accretion implies an increasing volatile abundance with distance from the early sun. Presumably, this was controlled by the temperature gradient in the solar nebula. Accordingly, one should expect more primordial water on Mars than on Earth. As we have seen, however, available estimates imply that Mars has outgassed much less water than Earth. Ringwood (1978) has addressed this problem in a comprehensive study of water in the solar system. He argues that Mars probably did have a much greater amount of water-rich condensates in its primordial composition, but due to a low accretion energy which prevented complete differentiation of that planet, the water remained trapped in the mantle. The differentiated Earth with its active tectonic system has a mechanism for effective release of mantle water to the surface. Such a mechanism does not exist on Mars. As stated by Baker (1982), "The question is not why we see an abundance of water-related surficial features on Mars. Rather, the question is why there is not much more evidence for water on the planet's surface". The answer, according to Ringwood (1978), lies in the incomplete degassing of the planet.

The temperatures on Mars suggest thick global permafrost. Models for planetary evolution indicate abundant water. Consequently, a most reasonable conclusion is that the Martian regolith contain large amounts of ice-rich permafrost. In all probability, additional water is available in the liquid phase in pore spaces beneath the ice-rich zone.

This layer of ice-rich permafrost could have formed, as in the terrestrial case, from downward percolation of meteoric water precipitated as the planet's atmosphere cooled after an initial high-temperature stage (Carr 1979). This would be the most likely scenario if the planet experienced an early phase of massive outgassing, with consequent "greenhouse" warming, as assumed in Pollack's (1979) model.

Instead of producing an ocean of liquid water, as on Earth, the outgassing of the planet Mars may have generated a subsurface reservoir of water and ground ice. Although this reservoir may play the role as both source and sink in the Martian water cycle, it does not drive a regular hydrologic system as on Earth. The geological effects of the Martian water reservoir differ greatly from those on Earth; the sculpted surface features differ accordingly.

INFERRED GEOLOGICAL CONSEQUENCES

Excellent papers by Carr and Schaber (1977) and

Lucchitta (1981) and books by Carr (1981) and Baker (1982) present an abundance of pictorial evidence for morphological features on Mars strongly indicative of ice-rich permafrost. Small-scale features include patterned ground, and a range of thermo-karst features. Larger-scale features include areas of collapsed ("chaotic") terrains (Sharp 1973), abundant in the "headwater" regions of the large outflow channels (Sharp and Malin 1975) of the Chryse Basin, and many regions of dissected ("fretted") terrain along the edge of the Martian uplands (Sharp 1973, Gatto and Anderson 1975). Sapping, due to ground ice deterioration, is probably a global phenomenon; the process may have been particularly important in development of the valley networks of the old Martian terrains (Pieri 1980).

Soderblom and Wenner (1978) considered some of the geological implications of global permafrost. If, indeed, a thick ice-rich permafrost is underlain by a layer where water does reside in liquid form, a global discontinuity in regolith strength may have developed. Diagenetic processes would have progressed much more rapidly within this liquid zone than within the permafrost, perhaps producing tightly cemented rocks below the interface. This discontinuity subsequently controlled the development of scarps bounding the chaotic and fretted terrains. The lower zone would be much more resistant, allowing the overlying impact breccia and volcanic deposits to easily erode down to the common base level of that diagenetic interface. The escarpments along the fretted terrain margins have heights in the 1 to 2 km range with very slight regional variations (Sharp 1973).

Carr (1979) suggested that venting of subsurface water reservoirs through fracture of the ground ice seal might be a mechanism for the release of vast floods. Morphologic evidence for such floods are the large outflow channels. Carr's (1979) proposal calls for a regional system of confined aquifers. These were created by the progressive downward freezing of ground ice during a period of cooling climate. Liquid water between this freezing front and the base of the porous regolith would gradually increase in pressure. In regions downslope of high potential head differences the artesian pressure could have exceeded the lithostatic pressure, fractured the ground ice seal, and caused water to rush to the surface at enormous discharge rates. Carr's calculations yield discharge rates commensurate with the hydraulic geometry of the Chryse outflow channels.

Nummedal (1978) called on liquefaction of subsurface unconsolidated materials to explain the Chryse channels and associated chaos. This scenario was developed because of striking morphological similarities between the Martian chaos-channel systems and liquefaction slide scars in Norwegian quick-clay terrain (Bjerrum 1971) and submarine slides subsequently discovered on the Mississippi delta front (Nummedal and Prior 1981). If the Martian features are due to liquefaction, then most of the channel volume is due to overburden collapse rather than erosion by running water. The apparent headward growth of many outflow channels is consistent with headscarp retrogression, a common mechanism in terrestrial liquefaction (Prior and Suhayda 1979).

Liquefaction in unfrozen terrain is normally limited to very fine-grained materials where internal pore water pressure can reach the vertical confining pressure without substantial fluid leakage. In permafrost terrain, however, an ice-rich cap may provide the necessary seal such that even gravels may become liquefied (Finn et al. 1978). In fact, Carr's (1979) proposed system of confined aquifers is likely first to reach an internal pressure adequate for liquefaction of unconsolidated materials before the artesian pressure can rupture the overlying seal. Once such a highly sensitive subpermafrost layer was formed, a seismic shock (internal or impact) could have triggered the liquefaction, with consequent collapse and fluid release.

Terrestrial morphologic features formed by the collapse of ice-rich permafrost are generally of small scale. This appears to be due to their rapid modification by surface runoff. On Mars, on the contrary, such modification would be insignificant as it probably has not rained since the initial formation of ground ice collapse features. Consequently, the surface morphology on Mars has evolved through the continued action of mass movement. The related features have grown to reach immense size. Channels, valleys, chaos, and fretted terrains on Mars have grown to assume scales and morphologic characteristics similar to those found in the only terrestrial morphogenetic province where mass-movement is dominant: the submarine continental slope and rise (Nummedal and Prior 1981, Nummedal 1982).

CONCLUSIONS

Observed temperatures and calculated internal heat flux for Mars suggest the existence of global thick permafrost. The layer is probably 1 km thick near the equator and substantially thicker in higher latitudes.

Changes in the thermal regime of the Martian regolith have occurred in response to cyclic astronomical perturbations (time scales of a day to 10^6 years) and the geologic evolution of the planet ($\sim 10^9$ years). The consequent distribution of ice within the permafrost zone may be very complex.

Existing models for Martian outgassing yield an adequate amount of water to have produced a global ice-rich permafrost. Water may have entered the regolith either as meteoric water during a planetary warm phase or directly as juvenile water from below.

This ice-rich permafrost is commonly thought to be the cause of abundant "cold-region" morphologic features seen in Viking images. It is proposed that some of the large-scale channels and chaos areas derive from catastrophic failure of a permafrost seal above deep artesian aquifers or liquefaction of unconsolidated materials beneath such a seal.

PRACTICAL APPLICATION OF UNDERSLAB VENTILATION SYSTEM:
PRUDHOE BAY CASE STUDY

William B. Odom

Sohio Alaska Petroleum Company, Pouch 6-612, Anchorage, Alaska 99502 USA

When designing buildings at grade on permafrost, consideration must be given to maintaining the frozen subgrade. One foundation system cools by ventilating ambient air through ducts in the subgrade. This paper responds to the need for documented results correlating performance of underslab ventilation systems to theoretical thermal analysis for operating facilities at Prudhoe Bay, Alaska. Experiences from the design and construction of a 7200 sq. ft. Fabrication Shop in Prudhoe during the 1981 summer construction season are the basis for the discussion. Design criteria recommendations are presented for slab-on-grade underslab ventilation systems for thermal analysis and system design. Aspects of construction specifications which contribute to ensuring good system performance are highlighted. The article concludes with a case study for Sohio's Fabrication Shop. Thermal analysis calculations to determine ventilation rates which contrast F. J. Sanger's method to J. F. Nixon's approach using the Fabrication Shop's design criteria are appended. Instrumentation data is tabulated for intake and exhaust duct temperatures, and subgrade temperatures over an eighteen (18) month period covering initial freeze-back, winter operation, and summer thaw. From information presented, correlations are made on how well theoretical analysis approximates actual performance of a slab-on-grade underslab ventilation system.

INTRODUCTION

When designing buildings at grade on permafrost, consideration must be given to maintaining the frozen subgrade to prevent excessive differential settlement. One method of ventilating a foundation system is by forced ventilation using ambient air through ducts in the subgrade.

This paper responds to the need for documented results correlating performance of underslab ventilation systems to theoretical thermal analysis for operating facilities at Prudhoe Bay, Alaska. Design criteria and aspects of construction specifications are presented. The article concludes with a case study of an underslab ventilation system for Sohio's Fabrication Shop.

ANALYSIS

Two thermal analysis methods are commonly used to determine subgrade ventilation rates. One method was authored by Sanger (1967). A more current and conservative method was presented by Harlan and Nixon (1978); the basis for this method was originally published by Nixon (1978) and includes some charts and two case histories. After applying each method to the Fabrication Shop's design criteria (see section on case study) and using a 3°C temperature difference between inlet and outlet duct temperatures for both methods, Harlan and Nixon's approach provided approximately a factor of 3 greater ventilation than that computed using Sanger's method. Furthermore, for our design criteria, Sanger's method suggested using a temperature difference between inlet and outlet duct tempera-

tures of 15.4°C. When strictly applying Sanger's method with a 15.4°C design temperature difference, and using a 3°C design temperature difference with Harlan and Nixon's method, Harlan and Nixon provided a factor of 21 greater ventilation than Sanger.

In reviewing the two methods, Harlan and Nixon's approach is based on peak heat flux consisting of heat from the structure and heat gain from the pad subjected to a sinusoidal change in surface temperature, maintaining a small temperature difference between inlet and outlet air, and shutting ventilation off when ambient temperatures are above -4°C (25°F). Sanger's method is based on average heat flux consisting of heat gain from the structure and heat that must be removed to refreeze pad, and considers larger temperature differences between inlet and outlet air. Although Sanger's method does not consider a ventilation shutoff temperature, it does consider ducts closed during the summer thaw season. Harlan and Nixon's method appears to yield more conservative results because peak heat flux is used to design ventilation rates, and the heat gain from the pad is significant.

SYSTEM DESIGN

Subgrade Ducts

Helical, corrugated metal pipe (culvert material), hot dipped in aluminum was used for the Fabrication Shop subgrade ducts. Although an economical product, it is difficult to field weld should the seams leak. The Fabrication Shop corrugated ducts failed a 0.25 N/m² hydrotest,

causing a 2 week delay while the system was reexcavated and repaired. Mild, thin-walled steel pipe would have allowed for field welding of joints and repair of seams. Another advantage of continuous mild steel pipe would be the ability to electrically thaw any plugged ducts; however, the high cost of steel pipe generally limits its use. Ducts should be sloped toward a collection point where access can be made to pump out any water which may infiltrate the system.

System Controls

As a safety precaution, it is desirable to supercool the foundation subgrade to insure that the summer thaw below the slab does not propagate into the tundra. Ideally, to take advantage of the annual cooling cycle, the fan system should operate when subgrade temperature is warmer than ambient air. This requires a subgrade thermal probe, ambient air thermal probe, and comparator. Location of the subgrade probe should be evaluated to determine a representative depth. This system will achieve maximum super cooling of subgrade. The Fabrication Shop, however, only uses an ambient air thermal probe; the system is set to operate when ambient air is -4°C (25°F) or colder. Although simple in operation, this system does not use the entire annual cooling cycle and can actually cause warming of the subgrade.

The most desirable system from a maintenance standpoint is a simple system such as one with a single fan for all ducts, access to each duct, and an on/off switch. Because we have experienced electrical component failures, controller malfunctions, and nonfunctioning dampers, careful selection of system components is required.

Intake and Exhaust Ducts

Location of intake/exhaust ducts should be a minimum of 3.7 m above grade. Systems with intake/exhaust ducts at low elevations are experiencing drifting snow problems. Intake/exhaust ducts located at roof line appear to perform well.

The exhaust ducts for the Fabrication Shop have a gooseneck profile and are detachable for inspection and maintenance. Dampers were installed to allow for balancing the system, and bird screens cap both intake and exhaust ducts.

Insulation

Extruded polystyrene is recommended over expanded polystyrene, or any of the urethane board insulations for below grade applications under permanent structures. Studies have shown that extruded polystyrene maintains its thermal characteristics better than urethane when subjected to freeze/thaw cycles in saturated soils conditions; in addition, urethanes tend to disintegrate. From a cost standpoint, extruded polystyrene is generally competitive with urethane when comparing cost per "R" value (thermal resistance coefficient). Where polystyrenes are used beneath buildings when spilled solvents such

as diesel fuel could come in contact with the insulation, an impervious membrane should be used to protect the polystyrene.

Instrumentation

The subgrade should be instrumented in order to monitor the thermal performance of the subgrade. The Fabrication Shop used 3 nonreplaceable thermistor strings evenly spaced along the longitudinal centerline of the building. Each string had 4 nodes at 1.5 m on center with the first node located 1.5 m below grade. Each string was placed in a small diameter plastic pipe which was filled with a water and glycol mixture. Thermistors were chosen because of their high degree of accuracy, stability, and simplicity in obtaining readings. If thermistor strings cannot be replaced, a minimum of three thermistor strings should be located beneath any major building to cross check data. A digital ohm meter is required to read thermistor resistance, which is converted to temperature with a simple equation. Thermocouples were not used for the Fabrication Shop because of the difficulty in obtaining the proper instruments to read the sensors and the lack of knowledge of the parameters that affect the accuracy of the readings.

Radiant Heat

Typically, the heat loss computations for a ventilation system are based on slab temperature of approximately 15°C (60°F). Monitoring of the Fabrication Shop floor confirmed that this was a reasonable assumption for that building. The use of radiant heat can increase the slab temperature to 27°C or greater. If the slab temperature is not accurately determined, the long-term performance of the foundation system could be jeopardized. Radiant heat is not recommended as a method of heating buildings with subgrade ventilation systems. During the summer months, the ventilation system is inactive and the abnormally high heat input caused by radiant heat may thaw the subgrade below the theoretically computed depth.

Duct Spacing

Underslab ducts for the Fabrication Shop were arbitrarily spaced 10 times the diameter of the duct and ventilation rates were computed based on this duct spacing. A more rational approach to determine duct spacing would be to evaluate the maximum freeze radius of the duct subjected to the anticipated thermal load.

Thawing Provisions

Should the subgrade ducts become plugged with frozen water, provision should be made to easily thaw the plug. For one North Slope building, we used a steam probe and small pump which worked well; it is imperative that there be access to each duct. Heat tracing or installing a continuous small diameter pipe to inject steam would also work.

CONSTRUCTION SPECIFICATIONS

Installation Specifications

Specifications should explicitly state "how" and "when" the contractor is to install the ventilation ducts. The time of year is a significant parameter in the construction of an under-slab ventilation system. During construction of the Fabrication Shop, the duct trenches filled with water, and because construction duration was not specified for excavation and backfill, the contractor was not required to expedite his work. Duct trenches were left open during the warmest season and for a longer period than anticipated. Ideally, the best procedure is to install the ducts during one construction season and to construct the building the subsequent construction season. However, as an alternate, we recommend a stringent installation specification which will require the contractor to perform in a short period of time. This will limit thaw bulb propagation.

Pressure Test

The ventilation system should be pressure tested prior to placement of backfill to eliminate the problem of water intrusion into the ducts during the summer thaw. The Fabrication Shop specifications required an air pressure test of 0.25 N/m² (one-in. water gauge) for 1 hour without an allowance for bleed-down. However, the contractor had difficulty in capping the ducts and in connecting the air pressure equipment to the ducts. Consequently, an equivalent hydrotest was substituted.

Temporary System Operation

Performance of a subgrade ventilation system assumes a full season of operation. As the construction of a major building may require 6 months, we recommend that provisions be made in the construction contract to require temporary operation of the underslab ventilation system when ambient air temperature is -4°C (25°F) or colder. Temporary heat in the building will be approximately the same as normal operating temperature. Therefore, it is essential that the ventilation system operate as soon as practical to ensure long term performance of the foundation system.

CASE STUDY

Synopsis

The Sohio Fabrication Shop is an 18 x 37 m preengineered building with a slab-on-grade foundation in conjunction with an active subgrade ventilation system. Figure 1 shows building plan dimensions and subgrade duct locations.

Figure 2 shows a typical section through floor slab. The existing gravel pad was approximately 1.2 m thick. In order to maintain access to adjacent buildings and roads, pad elevations could not be raised. Foundation construction

started in June 1981, and Figure 3 illustrates water intrusion and sloughing of trenches during placement of subgrade ducts. The subgrade ventilation system was commissioned in November 1981.

FIGURE 5 Air Duct Temperatures

Building and system performance has been good to date. As our thermal analysis indicated that thaw bulb depths were marginally safe, the total subgrade ventilation rate was increased from 0.189 m³/s (400 ft³/min) to 1.89 m³/s (4,000 ft³/min). During freezeback, 1.6 mm cracks developed in the slab and were thought to be a combination of concrete shrinkage and expansion of the saturated subgrade during freezing. However, the cracks did not propagate, and the floor's serviceability remains intact. Figure 4 shows thermal profiles over a 1 year period. Figure 5 presents inlet and outlet duct temperature readings taken during the first and second year of operation. Figure 6 illustrates system simplicity using a single fan on the intake manifold. Figure 7 shows the problem of drifting snow over duct outlets. This problem was later rectified by raising the duct outlet elevations to approximately 3.7 m.

Design Criteria

Freezing index (F.I.)	4166°C days (7500°F days)
Thaw index (T.I.)	555°C days (1000°F days)
Mean annual air temperature	-12.2°C
Mean annual temperature variation	17.8°C
Freezing season	265 days
Building temperature (Ts)	15.6°C
Insulation Thickness	0.15 m
Thermal conductivity insulation (K ₁)	0.0311 W/mK
Thermal conductivity gravel pad (K ₂)	1.80 W/mK
Dry density gravel pad	2,020 kg/m ³
Moisture content pad (w)	3%
Volumetric heat capacity air (C _a) @ -12.2°C	1.355 kJ/M ³ K
Time ambient air above -4°C	126 days
Temperature rise through ducts	3°C (Harlan and Nixon or 15.4°C (Sanger))
Mean annual ground temperature (zero amplitude @ -14 m below existing grade)	-9°C

Thermal Analysis--Harlan and Nixon's Method

Substituting the Fabrication Shop's design criteria into formulas presented by Harlan and Nixon, and using a temperature difference between inlet and outlet duct temperatures of 3°C, the following thermal quantities are computed.

Thaw depth @ 126 days	1.31 m
Peak heat flux to ducts occurs	@ 237 days
Heat gain from structure	7.9 J/m ² s
Heat gain from pad	13.9 J/m ² s
Maximum heat flux	21.8 J/m ² s
Total required ventilation rate	3.6 m ³ /s (7622 CFM)

Thermal Analysis--Sanger's Method

Substituting the Fabrication Shop's design criteria into formulas presented by Sanger and using a temperature difference between inlet and outlet duct temperatures of 15.4°C, the following thermal quantities are computed.

Thaw depth (modified Berggren equation)	1.06 m
Average heat flow from pad	0.103 J/m ² s
Average thaw index	77.8°C days
Average surface temperature	-0.3°C
Average air inlet temperature	-15.7°C
Average temperature rise in ducts	15.4°C
Average heat flow from floor	0.432 J/m ² s
Average total heat flux	0.535 J/m ² s
Duct velocity	0.391 m/s
Total required ventilation rate	0.171 m ³ /s (363 CFM)

CONCLUSION

Thermal analysis methods are most sensitive to the temperature difference between inlet and outlet ducts. Air temperature measurements at inlet and outlet ducts indicate an average temperature difference during the first year of operation around 10°C based on random readings over a 4 month period. During the second year, one reading taken when ambient air temperature was -29°C indicated a temperature difference between inlet and outlet ducts of 6°C. Therefore, use of a design temperature difference of 3°C in Harlan and Nixon's method provides a conservative ventilation rate for the first year of operation, and may be a realistic number after several years of operation. Increasing ventilation rate simply requires an increase in fan size, which insignificantly affects the total system cost. Although the Fabrication Shop's actual ventilation rate was approximately 10 times greater than that computed by Sanger, and 50% less than that required by Harlan and Nixon, the system has performed well. The success of the Sohio Fabrication Shop is attributed to the high ventilation rate which supercools the subgrade, the low mean annual air temperature (-12.2°C), and the relatively cold permafrost temperatures (-9°C @ -14 m depth).

UNIAXIAL COMPRESSIVE STRENGTH OF ICE SEGREGATED FROM SOIL

Takahiro Ohrai, Tsutomu Takashi,
Hideo Yamamoto and Jun Okamoto

Technical Research Laboratory, Seiken Co., Ltd.
2-11-16 Kawaraya-machi, Minamiku, Osaka, Japan

Segregated ice (ice lens), which was columnar grained, was subjected to uniaxial compression tests. Specimens of such ice (5 cm in diameter and 9 cm in height) were prepared by freezing a soil composed of a frost-susceptible clay collected in Tokyo. The main factor thought to influence the strength of frozen clay is either unfrozen water or segregated ice. Therefore, the strength of segregated ice constitutes an important element in the clarification of the strength of the frozen clay. When a load is applied in the direction of ice growth, the uniaxial compressive strength increases with decreasing temperature, giving values of 18.6 Mega Newton/square meter at -10°C and 24.5 MN/m^2 at -20°C . When it is applied perpendicular to the growth direction, the uniaxial compressive strength, which is about 4.9 MN/m^2 at -20°C , is approximately equal to the strength of commercial ice. When the loading angle ranges between 20° and 90° to the growth direction, the strength is nearly constant and decreases at -10°C to one-fifth of the strength in the growth direction.

INTRODUCTION

The artificially frozen wall has come to be widely applied to the technique of supporting earth pressure as well as of preventing water from seeping into an area to be excavated. In recent years the ground-freezing technique has become more important due to increased number of large scale works and increased depth of work sites, e.g., 50 m depths. The need to save energy and to reduce the amount of frost heaving calls for the frozen soil wall to be made as thin as possible. Accordingly, knowledge of the bearing strength of the frozen soil wall is required.

The uniaxial compression test is relatively simple for obtaining data on the mechanical properties of frozen soils so that we have studied them consistently, limiting our study to the uniaxial compressive strength (Takashi et al. 1980, 1981a). The reason the uniaxial compressive strength of frozen clay is lower than that of sand is considered to be the existence of segregated ice, the so-called ice lens, as well as unfrozen water, which is one characteristic of frozen clay.

The authors have succeeded in forming large specimens of segregated ice, which contain no trace of soil particles, by applying the knowledge that the frost heave ratio increases with decreases in both effective stress and frost penetration rate (Takashi et al. 1978).

The experimental results, presented in this paper, were obtained systematically with respect to the dependence of the uniaxial compressive strength of segregated ice on temperature, loading direction, and

strain rate, which are discussed below.

The results thus obtained will serve as an attempt to understand the mechanical behavior of frozen clay.

PREPARATION OF SPECIMENS

Soil Collection

The soil, from which specimens of segregated ice were later prepared, was collected in Tokyo. The soil is a Manaita-bridge clay, undisturbed and saturated, markedly frost susceptible, and diluvial (Takashi et al. 1981b). The grain-size distribution curve and properties of the soil collected are shown in Figure 1 and Table 1, respectively.

Technique

Shown in Figure 2 is the schematic diagram of the apparatus used to prepare specimens of segregated ice. Uniaxial upward freezing was achieved by lowering an acrylic cylinder, which contains the soil collected, into a chilled brine bath, described as an antifreeze bath in the figure. The lowering speed was about 2 mm/hr. This arrangement made it possible to provide nonload freezing in an open system because only the weight of the unfrozen part of the soil above the freezing front exerted pressure on the frozen part. The portion of sand above the bottom of the cylinder was designed to eliminate the shock of violent freezing, which comes about the moment that the cylinder bottom touches the surface of the chilled bath.

Thus, the thickness of sand was selected to be more than 40 mm. When the soil was thick, rhythmic ice banding (Martin 1959), which produced frost heaving in the soil, was found, as shown in Figure 3. With the frost line penetrating further up, the thickness of the unfrozen part of the soil decreased; and then, with the resultant decrease in resistance to water movement in the unfrozen soil, segregation of ice

FIGURE 1 Grain-size distribution curve.

increased gradually. Finally, the segregation reached a stage of so-called perfect ice segregation (Arakawa 1966), in which the formation of segregated ice continued, being free from soil particles, as shown in Figure 4. Once perfect ice segregation started, it occurred continuously in the space between the unfrozen part of the soil and the sand at the bottom in the cylinder by repeating the same process as seen in Figures 2 and 4.

FIGURE 3 Vertical section of rhythmic ice banding.

FIGURE 4 Exterior appearance of a cylinder in the process of perfect ice segregation.

FIGURE 2 Apparatus for preparing specimens.

Structural Characteristics of Ice Specimens

Photographs of a vertical thin section and a horizontal thin section obtained from a segregated ice specimen (5 cm in diameter and 9 cm in height) are shown in Figure 5. Segregated ice was columnar

FIGURE 5 Photographs of (a) horizontal and (b) vertical thin section of a specimen (5 cm^φ × 9 cm^H).

grained ice, and its grain diameter on a plane perpendicular to the growth of the columnar grains was approximately 1 mm.

Usually, columns of bubbles as fine as a thread were found throughout the specimen in parallel with the growth direction, while small bubbles about 1 mm in diameter were found at the center of the specimen. The density of the specimens ranged from 0.877 to 0.904 g/cm³, the average for 35 specimens being 0.893 g/cm³.

No trace of soil particles was detected in the segregated ice through a magnifying glass of 50 magnifications.

TEST PROCEDURE

The shape of the specimens was cylindrical, and their standard dimensions were 5 cm in diameter and 9 cm in height.

The uniaxial compression apparatus used was capable of applying a load for compression at a constant strain rate ranging from 1.0×10^{-5} to $6.7 \times 10^{-3} \text{ s}^{-1}$, the maximum loading capacity being 98 Kilo Newton. The apparatus was set up in a walk-in room with a temperature range of -0.2° to -30° C (about $\pm 0.2^\circ \text{ C}$ accuracy).

A loading platen was a rigid acrylite disk. Specimens were exposed to the test temperature for at least 24 hours before testing. Axial load and displacement during the test were recorded by an X-Y recorder.

RESULTS AND DISCUSSION

Stress-Strain Curve and Uniaxial Compressive Strength q_u

Stress-strain curves which are typical at different temperatures and strain rates are shown in Figures 6 and 7, respectively.

FIGURE 6 Stress-strain curves at various temperatures.

FIGURE 7 Stress-strain curves at various strain rates.

The peak of the curves becomes sharp with decreasing temperature or increasing strain rate. When the temperature was low or the strain rate was large, the specimen collapsed into fine pieces with explosive rupture. This mode of failure, shown by arrows in both figures, is called "brittle failure" in this paper. On the other hand, the mode of failure in which the specimen remains whole without rupture after the stress reaches its maximum, is called "ductile failure."

The uniaxial compressive strength is defined as the maximum stress q_u under each condition. In this paper, $q_{u//}$ represents the q_u when the load is applied in the direction of segregated ice growth and $q_{u\perp}$ when applied perpendicular to the direction.

Temperature Dependence of q_u

Shown in Figure 8 is the relation between the uniaxial compressive strength q_u and temperature θ under conditions of two strain rates and two loading directions. In all cases, q_u increases with decreasing temperature under the same conditions.

Values of $q_{u//}$ at a strain rate of $1.0 \times 10^{-4} \text{ s}^{-1}$ are fairly large, giving values of 9.8 MN/m² at -1.5° C , 18.62 MN/m² at -10° C , and 24.5 MN/m² at -20° C . These values are larger than those of various types of ice. At temperatures close to freezing, it seems that the relation between the value of $q_{u//}$ and temperature agrees with the relation between the pressure and freezing point calculated from the Clausius-Clapeyron equation. On the other hand, the values of $q_{u\perp}$ are much smaller than those of $q_{u//}$ and are equal to the strength of commercial ice, ranging from 1.96 to 6.86 MN/m² (Butkovich 1954).

Referring to the gradient of q_u/θ , that of $q_{u//}/\theta$ is larger than that of $q_{u\perp}/\theta$.

It is found that the shape of stress-strain curves varies with the temperature as seen in Figure 6. In the case of $q_{u//}$, the mode of failure was brittle at -1.9°C , whereas even at -26.5°C it was ductile in the case of $q_{u\perp}$.

FIGURE 8 Uniaxial compressive strength q_u vs. temperature θ . Open symbols represent brittle failure; solid symbols, ductile failure.

Loading Direction Dependence of q_u

A great difference exists between values of $q_{u//}$ and $q_{u\perp}$ under the same temperature and strain rate, as seen in Figure 8. It is considered from photographs in Figure 5 that the value of q_u may depend on the loading direction.

The relation between uniaxial compressive strength and loading direction at -10°C is shown in Figure 9, in which the abscissa represents angles ψ between loading direction and ice growth direction. In the range $0^\circ - 10^\circ$, the value of q_u decreases markedly with increasing ψ . In the range $20^\circ - 90^\circ$, its value is nearly constant and is equal to that of $q_{u\perp}$. The mode of failure was ductile except when $\psi = 0^\circ$. In this case it was presumed from the state of deformation and how cracks formed, which is described later, that the dominant cause is the gliding of the grain boundary.

The value of q_u is larger at an angle of 10° than in the range $20^\circ - 90^\circ$. The main reason is presumed to be differences in angle, or friction of grain-boundary glides, or both.

Strain Rate Dependence of q_u

Shown in Figure 10 is the relation between the uniaxial compressive strength q_u and the strain rate $\dot{\epsilon}$ at two tempera-

FIGURE 9 Uniaxial compressive strength q_u vs. loading direction ψ . Open circles represent brittle failure; solid circles, ductile failure.

FIGURE 10 Uniaxial compressive strength q_u vs. strain rate $\dot{\epsilon}$. Open symbols represent brittle failure; solid symbols, ductile failure.

tures, -3°C in the case of $q_{u//}$ and -10°C in the case of $q_{u\perp}$, chosen on the basis of expected occurrences of both brittle and ductile failures. In the figure, maximum and minimum $q_{u//}$ values at each strain rate are shown by two broken lines because of wide scatter in the data.

It is apparent that a maximum value of q_u exists at a certain strain rate. It can be seen that the compressive strength has a maximum at a strain rate between 8.3×10^{-5} and $3.3 \times 10^{-4} \text{ s}^{-1}$ in the case of $q_{u//}$ and between 1.2×10^{-4} and $5.0 \times 10^{-4} \text{ s}^{-1}$ in the case of $q_{u\perp}$. In two series of previous tests, a strain rate of $1.0 \times 10^{-4} \text{ s}^{-1}$ was

used, at which the maximum measured strengths were consequently observed.

It was found that the shape of stress-strain curves varies with the strain rate, as seen in Figure 7. The variations are similar to those with the temperature. The mode of failure was brittle at $5.5 \times 10^{-5} \text{ s}^{-1}$ at -3°C in the case of q_{uII} ; and at $4.8 \times 10^{-4} \text{ s}^{-1}$ at -10°C in the case of q_{uI} .

Characteristics of q_{uII} at near 0°C

Shown in Figure 11 is the relation between uniaxial compressive strength q_{uII} and strain rate $\dot{\epsilon}$ at about -0.4°C . Room temperatures recorded during the test varied by no more than $\pm 0.05^\circ\text{C}$. Temperatures at points in contact with both ends of the specimen were measured by means of copper-constantan thermo couple measurements that have a sensitivity of $\pm 0.003^\circ\text{C}$.

In Figure 11, with an increase in strain rate the temperature of the specimen is lowered and the value of q_{uII} increases.

It is considered that part of the specimen melts and that the specimen temperature is lowered by latent heat. The freezing-point depression of an ice-water system is expressed by the Clausius-Clapeyron equation as follows:

$$\Delta P = - \frac{L}{V_i - V_w} \frac{\Delta T}{T} = -13.41 \Delta T \text{ (MN/m}^2\text{)} \quad (1)$$

where P, T, L, V_i , V_w are pressure, absolute temperature of freezing, latent heat of fusion, and specific volume of ice and of water, respectively; ΔT is the freezing-point depression. The value of ΔP calculated from equation (1) using the temperature that was lowered during the compression is shown by triangle symbols in Figure 11. The value of ΔP coincides with the value of q_{uII} , approximately.

Only near 0°C did the phenomenon of decreasing temperature occur; at -5°C and

FIGURE 11 Uniaxial compressive strength q_{uII} vs. strain rate $\dot{\epsilon}$ at about -0.4°C .

-10°C , the temperature rose. The cause remains unexplainable at present.

Transition from Ductile to Brittle Failure

Shown in Figure 12 is the dependence of the strength of each of the brittle and the ductile failure, q_{uII} , on temperature, for which the data have different strain rates. Open and solid circles represent brittle and ductile failure, respectively. Half-open circles represent the brittle failure in which the specimen collapsed immediately after the peak in the stress-strain curve. Data near 0°C and at large strain rates such as $5.0 \times 10^{-3} \text{ s}^{-1}$ were omitted in the figure. It is clearly seen from the figure that regions of brittle and ductile failure are separated by a straight line. The transition from ductile to brittle failure occurred at strain rates of 1.0×10^{-4} , 3.3×10^{-5} , and $6.7 \times 10^{-6} \text{ s}^{-1}$ at constant temperatures of -1.7° , -3° , and -18°C , respectively.

FIGURE 12 Zones of ductile and brittle failure in the case of q_{uII} .

Cracks

In the case of brittle failure, visible crack formation did not occur until the specimen collapsed into pieces with explosive rupture.

In the case of ductile failure, however, visible cracks occur when the stress is near maximum, when the strain is about 1×10^2 , as seen in Figures 6 and 7. Typical cracks are shown in Figure 13. These cracks appear perpendicular to the direction of segregated ice growth.

In the case of data adjacent to the straight line in Figure 12, the cracks appear regularly in the growth direction and perpendicular to it, as seen in Figure 14. Near 0°C , cracks in the growth

direction dominated.

When the load was applied perpendicular to the growth direction, failure was mostly ductile. In this case, the horizontal section of the specimen after compression was in the shape of an ellipse, which had a short axis in the growth direction, and the majority of cracks appeared in the growth direction.

As mentioned above, it was characteristic of segregated ice that visible cracks appeared regularly in the growth direction, or perpendicular to it, or both.

FIGURE 13 Photograph of typical cracks ($\theta = -0.6^\circ\text{C}$, $\varepsilon = 1\%$, $q_{ul} = 7.25\text{MN/m}^2$).

FIGURE 14 Photograph of cracks in transition zone from ductile to brittle failure ($\theta = -16^\circ\text{C}$, $\varepsilon = 1\%$, $q_{ul} = 15.4\text{MN/m}^2$).

CONCLUSIONS

The experimental results with respect to the uniaxial compressive strength q_u of segregated ice are as follows:

- 1° When the load is applied in the direction of ice growth, the longitudinal uniaxial compressive strength q_{ul} increases with decreasing temperature, giving values of 18.62 MN/m^2 at -10°C and 24.5 MN/m^2 at -20°C . These values are larger than those of various types of ice.
- 2° When the load is applied perpendicular to the growth direction, the lateral uniaxial compressive strength q_{ul} , which is about 4.9 MN/m^2 at -20°C , is approximately equal to the strength of commercial ice.
- 3° In the case of a loading direction in the range $0^\circ - 10^\circ$, which is the angle ψ between the loading and the ice growth direction, the value of q_u decreases markedly with increasing ψ . In the range $20^\circ - 90^\circ$, its value is nearly constant.

4° The compressive strength has its maximum at a strain rate between 8.3×10^{-5} and $3.3 \times 10^{-4}\text{ s}^{-1}$ in the case of q_{ul} , and between 1.2×10^{-4} and $5.0 \times 10^{-4}\text{ s}^{-1}$ in the case of q_{ul} .

5° Near 0°C , part of the specimen melts and the specimen temperature is lowered by the latent heat corresponding to the melting. With an increase in strain rate, the value of q_{ul} increases with a resultant fall in temperature.

6° The transition from ductile to brittle failure occurred at strain rates of 1.0×10^{-4} , 3.3×10^{-5} , and $6.7 \times 10^{-6}\text{ s}^{-1}$ at constant temperatures of -1.7° , -3° , and -18°C , respectively. Visible cracks appeared regularly in the direction of ice growth, perpendicular to it, or both.

WATER MIGRATION DUE TO A TEMPERATURE GRADIENT
IN FROZEN SOIL

J. L. Oliphant, A. R. Tice, and Y. Nakano

U.S. Army Cold Regions Research and Engineering Laboratory
Hanover, New Hampshire 03755 USA

Closed soil columns at an initially uniform total water content were subjected to a nearly linear and constant temperature gradient along their length. At various times, the columns were sectioned and water content as a function of position was determined gravimetrically. Unfrozen water content vs. temperature curves were also determined with a nuclear magnetic resonance technique on separate samples of the same soil at the same dry density. It was found that the water migrated from the warm to the cold end and two zones developed in each of the tubes, one that contained only liquid water and the other containing ice and water. The boundary between the two zones also migrated toward the cold end as the experiment progressed, and the water content of the zone containing only water fell while that of the zone containing ice and water increased. The free energy of the liquid water was calculated as a function of position, assuming the validity of a form of the Clausius-Clapeyron equation. Hydraulic conductivity coefficients were then calculated from the free energy gradients and water migration data. Values ranged from 4.5×10^{-12} m/s at -0.3°C to 3.5×10^{-13} m/s at -2°C for the Morin clay soil tested.

It has been known for many years that a portion of the water in soils remains unfrozen at temperatures below 0°C . Methods of measuring the unfrozen water content as a function of temperature have been discussed in a recent paper by Oliphant and Tice (1982). Details of the nuclear magnetic resonance technique developed at USA CRREL for accurately measuring unfrozen water contents are given in a report by Tice et al. (1982). The existence of unfrozen water in frozen soils allows for significant rates of ice and water migration in frozen soils along water free-energy gradients. This causes ice lensing, frost heave, breakup of roads and foundations, and loss of soil strength when the soil thaws. Thus, it is important to understand the mechanisms of water migration and ice formation in frozen and freezing soils.

Free energy gradients of water in frozen soils can be caused by temperature gradients, water or dissolved salt concentration gradients, or pressure gradients. To understand the movement of water due to each of these causes, we are carrying out a series of experiments in which the gradients causing water migration are carefully controlled and separated so that, as nearly as possible, only one type of gradient acts on the free energy of the water in a given experiment. The data from these experiments can then be used to validate models concerning the migration of water in frozen soils. An understanding of both the driving forces for water migration and the responses to these driving forces, or conductivities, is needed to model water migration in soils under natural conditions.

The results of experiments on water migration in frozen soils due to water concentration gradients have been reported by Nakano et al. (1982, 1983). The purpose of this paper is to report the initial results of an experiment that measures water migration due to a temperature gradient. Water migration due to a temperature gradient in porous materials

containing ice has previously been measured by Dirksen and Miller (1966), Hoekstra (1966), and Williams and Perfect (1980). In the experiments by Dirksen and Miller and by Hoekstra, a closed moist soil column was subjected on one end to a temperature below freezing and on the other end to a temperature above freezing. The soil column itself was used to conduct heat from the warm end to the cold end. The soil columns, initially unfrozen, would begin to freeze at the cold end, and the temperature gradient along the column would change as the experiment proceeded. This changing temperature gradient was caused by the initial constant temperature of the soil column and by changing thermal diffusivities in the column as water migrated and ice rearranged. Although this type of experiment is good for obtaining a qualitative idea of what happens when moist soil is subjected to a temperature gradient, it is difficult to obtain quantitative data on moisture migration as a function of temperature and the temperature gradient in the soil.

In the more recent experiment by Williams and Perfect, a saturated frozen soil column was connected on either end to water reservoirs containing a lactose solution. Semipermeable membranes were placed between the lactose solution and the ends of the soil column to help slow the migration of lactose into the soil. The two reservoirs were kept at two different temperatures and the rate of water movement from the reservoirs to the soil column was monitored. Again, in this experiment heat was conducted from the warm reservoir to the cold reservoir through the soil column, so a completely linear temperature gradient could not be established. After a long time a steady-state temperature gradient and water flow rate through the column were established, and an average value of water migration through the column due to the overall temperature gradient was obtained.

Williams and Perfect (1980) discuss how to calculate hydraulic conductivity coefficients from the water migration data by using a form of the Clausius-Clapeyron equation to convert temperature gradients to effective pressure gradients in frozen soil. The coefficients they calculate show considerable scatter but agree on an order-of-magnitude basis from sample to sample. More importantly, the calculated coefficients seem to be compatible with data obtained from the same apparatus using a pressure gradient instead of a temperature gradient between the two reservoirs (Burt and Williams 1976). This seems to indicate that the applied form of the Clausius-Clapeyron equation is valid for ice and water in a frozen soil. If this is the case, then accurate measurements of water migration due to temperature gradients will also yield accurate values of the hydraulic conductivity of frozen soils.

The experiment described herein was designed to allow accurate measurement of moisture migration in soil columns due to carefully controlled temperature gradients. The assumptions involved in deriving hydraulic conductivity coefficients from these data are discussed. In addition, methods of comparing the coefficients with those derived from direct pressure and moisture content gradient experiments are given.

EXPERIMENTAL PROCEDURE

The apparatus shown in Figure 1 was used to maintain a constant and nearly linear temperature gradient along the soil column. It consists of two aluminum blocks A, 30.5 cm long by 11.2 cm across by 2.54 cm thick. Five semicircular grooves 0.95 cm in diameter were machined along one face of each

block. These grooves were spaced 1 cm apart across each block so that when the blocks are bolted together, five holes 0.95 cm in diameter are formed. The soil is packed into 10-mL plastic serological pipettes that fit snugly into the holes.

Two aluminum blocks, B, bolt to either end of the combined blocks, A, as shown in the figure. These blocks are 5.08 cm by 5.08 cm by 11.2 cm. Each has a 2.54-cm diameter hole drilled into it through which an antifreeze mixture from a temperature-controlled bath is circulated. The four aluminum blocks, when bolted together, are then surrounded by a box of 5.08-cm thick fiber-impregnated plastic, which acts as thermal insulation and damps out short-term temperature changes in the laboratory room.

Aluminum has a thermal conductivity about 90 times higher than that of ice and thus about two orders of magnitude higher than a partially frozen soil-water mixture. When antifreeze mixtures at two different temperatures are circulated through the B blocks, heat is transferred at a high rate through the A blocks, from the warm end to the cold end. Most of this heat is transferred through the aluminum blocks and only a small amount through the embedded soil columns. The diameter of the soil columns is small compared with their length, so the temperature profile that obtains along the aluminum blocks is impressed on the soil columns, keeping them at the same constant and nearly linear temperature gradient as the surrounding aluminum. Temperatures are monitored by a row of copper-constantan thermocouples placed through the bottom aluminum block, A, flush with the inside surface of the middle groove.

The soil selected for the initial experiment, called Morin clay, was a marine-deposited clay obtained from the Morin brickyard, Auburn, Maine.

FIGURE 1 Apparatus for obtaining a constant temperature gradient along a soil column.

The area was uplifted and original solutes were leached by natural seepage. The clay is non-swelling and has a specific surface area of $60 \text{ m}^2/\text{g}$. It is the same soil used in the experiments reported by Nakano et al. (1982, 1983).

For the initial experiments, the ends of five plastic serological pipettes were trimmed, leaving plastic tubes 27.8 cm long with 0.95 cm o.d. and 0.79 cm i.d. A rubber stopper was placed in one end of each tube filling 0.5 cm of the tube. Morin clay with a nominal water content of 20% of the dry weight was then packed into each tube in layers approximately 1 cm thick. This packing was done carefully to achieve the same average dry density in each tube. The average dry densities in tubes 1 through 5 were 1.46, 1.50, 1.46, 1.47, and 1.48 g/cm^3 . These dry densities are almost the same as those used in the water migration experiments reported by Nakano et al. (1982, 1983). A rubber stopper was then placed in the last 0.5 cm of the tube, leaving a packed soil column 26.8 cm long.

The five packed tubes were set aside for several days at room temperature to allow moisture equilibration in the soil. They were then placed in a -20°C cold room and allowed to freeze quickly. Meanwhile, a temperature gradient was established along the apparatus shown in Figure 1 by circulating antifreeze at two different temperatures through the end blocks. Five less carefully packed soil columns were placed in the apparatus while the temperature gradient was being established. The thermocouple temperature readings obtained for the first experiment are shown graphically in Figure 2. They range from -0.25°C at the warm end to -2.05°C at the cold end of the soil columns. It can be seen that the temperature gradient is almost linear except near the warm end. After a stable temperature gradient was established, the five less carefully packed tubes were quickly removed and the five soil columns frozen at -20°C were placed in the apparatus. It was noted that in about 45 minutes the thermocouple readings along the apparatus returned to those obtained for the first experiment.

Tubes 1 through 5 were removed after being subjected to the temperature gradient for 2, 4, 8, 16, and 32 days, respectively. As each tube was removed it was replaced by one of the blank tubes.

FIGURE 2 Temperatures and unfrozen water contents along the soil column.

It took about 30 minutes for the original temperature readings to be reestablished after each tube was removed. The removed tubes were quickly placed on their side back in the -20°C cold room and allowed to freeze for 30 minutes. Each soil column was then sectioned into 44 segments and the total water content of each segment was determined gravimetrically.

RESULTS AND DISCUSSION

The measured water content of each of the 44 segments of each tube is shown in Figure 3. The total water content seems to divide qualitatively into two sections for each of the tubes. On the warm end there is a section of relatively flat and even water content that is below the average for the tube. The length of this section increases and the water content falls slightly as time goes on. On the cold end there is a section, which initially covers most of the tube, that has a relatively uneven total water content. The total water content of this section is above the average for the tube and it appears that, as time goes on, two peaks are formed in the total water content curve, one close to the cold end and one close to the boundary between the even and uneven sections. The curves shown in Figure 3 look qualitatively similar to those reported by Dirksen and Miller (1966) and Hoekstra (1966). Both of these reports show curves that are relatively flat on the warm end, dipping slightly toward the cold end, and eventually forming two peaks in the cold end section.

A qualitative explanation of the shape of the curves shown in Figure 3 can be given. The smooth section toward the warm end is made up of segments that contain only unfrozen water, while the section toward the cold end is made up of segments that contain both ice and unfrozen water. The unevenness of the cold end section is probably due to the inherently uneven distribution of small ice lenses forming in the soil. The peak that forms at the far cold end is due to the closed boundary condition of

FIGURE 3 Final total water contents along the soil column.

FIGURE 4 Unfrozen water contents as a function of temperature for Morin clay at a dry density of 1.45 gm/cm³ and a total water content of 21.8%.

the tube at this end. The peak that forms at the boundary between the two sections probably forms because the hydraulic conductivity is higher close to the boundary than it is farther along in the tube where the soil is colder and there is less unfrozen water.

The unfrozen water content vs. temperature curves determined by NMR on a separate sample of the Morin clay at the same dry density as the other samples are shown in Figure 4. Both the freezing and thawing curves are shown; the hysteresis between them is evident. Using the curves in Figure 4 and the temperature measured along the soil column as shown in Figure 2, the expected unfrozen water content as a function of position along the tube can be obtained. The values obtained from the freezing curve in Figure 4 are plotted in Figure 2. It can be seen from Figure 2 that if the boundary between ice-containing and ice-free parts of the tube is to move gradually toward the cold end, as it does in Figure 3, then the total water content, which is equal to the unfrozen water content in the ice-free sections, must decrease in these sections. This is seen to happen on a qualitative basis in Figure 3, although the decrease is less than that expected from Figure 2.

The data shown in Figure 3 can be analyzed quantitatively by first calculating the water fluxes across the boundaries of adjacent segments. The average water content of all the segments was calculated and then the individual mass balances were calculated for each segment. Water fluxes away from the warm end and toward the cold end were counted as positive. For example, if the first segment on the warm end had a total water content less than the average, then the amount of water making up the difference has moved across the boundary from the first to the second segment. A mass balance around the second segment shows that the flux from the second to the third segment must

FIGURE 5 Total fluxes of water across segment boundaries for the soil column.

FIGURE 6 Average fluxes of water across segment boundaries and calculated hydraulic conductivity coefficients for the soil columns.

be equal to the flux from the first to the second segment plus the difference between the average water content, which is assumed to be the initial water content of all the segments, and the final measured water content. In general, for the *i*'th segment, the flux from that segment to the next, *f_i*, can be calculated from the equation

$$f_i = f_{i-1} + (W_i - W_{ave}) \tag{1}$$

where *W_i* is the water content of the *i*'th segment and *W_{ave}* is the average or initial water content. Flux values calculated according to Equation 1 are shown for the boundaries between each of the segments of each of the five tubes in Figure 5. These values were then divided by the number of days that each tube was exposed to the temperature gradient to obtain an average flux per day at each segment boundary. These values are shown in Figure 6.

Comparing Figure 3 with Figure 5, it can be seen that the position of maximum flux corresponds to the boundary between the sections of each tube that contain ice and water and only water. Figure 5 also indicates that fluxes through the section that contains only liquid water increase only gradually with time. Comparing Figure 5 and Figure 6, it can be seen that most of the flux calculated for the segments in the section that contained only liquid water at the end of the experiment came at a time when there was both ice and water in the segments, before the boundary between the two sections had passed these segments. After the boundary passed, only a small amount of flux moved through the ice-free segments. This is especially evident when comparing data on the 2-, 4-, and 8-day tubes (Figure 5).

In Figure 6, it is evident that in the cold end section, where both ice and water were present in the soil, the flux at a given position in the tube and thus at a given temperature and temperature gradient remained relatively constant for all of the tubes as the experiment progressed. In other words, a frozen soil containing both ice and unfrozen water that is subjected to a temperature gradient acts as a pump, pumping water toward the cold end. The rate of pumping can depend on the type of soil, the temperature, and the temperature gradient, but as long as ice is present it does not depend on the total water content. Similar conclusions were reached by Williams and Perfect (1980).

A line has been drawn in Figure 2 that approximates the temperature profile over most of the length of the temperature gradient apparatus. This line has a slope of $0.082^{\circ}\text{C}/\text{cm}$. If we assume, as do Williams and Perfect (1980), that the form of the Clausius-Clapeyron equation that applies is

$$H = \frac{L}{Tg} \Delta T, \quad (2)$$

where H is suction in cm of water, L is the latent heat of fusion of pure water equal to 3.33×10^9 ergs/g, T is temperature in $^{\circ}\text{K}$, ΔT is the freezing point depression or degrees below 0°C , and g is the gravitational acceleration equal to $981 \text{ cm}/\text{sec}^2$, then an effective pressure gradient can be calculated from the temperature gradient. Evidence that Equation 2 does apply is given by Williams (1967). Using Equation 2 and the temperature gradient given above, we can calculate that the driving force for water movement in the part of the soil column that contains both ice and water is 1020 cm of $\text{H}_2\text{O}/\text{cm}$. The fluxes in Figure 6 are given in percent of dry soil wt/day. To convert these values to cm^3/day , multiply by the dry density of the soil, then by the volume of an individual segment (0.30 cm^3), and divide by 100%. Hydraulic conductivity coefficients, K , can then be found by solving a form of Darcy's law

$$q = -K A \frac{dP}{dX}, \quad (3)$$

where q is the flux of water in cm^3/day , A is the cross-sectional area in the tube available for flow (0.49 cm^2), dP/dX is the effective driving force calculated above to be 1020 cm of $\text{H}_2\text{O}/\text{cm}$, and K has units of cm^2/cm of $\text{H}_2\text{O}/\text{day}$. To convert K to the more usual units of m/s, divide by the number of

centimeters in a meter (100) and by the number of seconds in a day (86,400).

Carrying out all of the above calculations, we find that if the numbers given for the flux values in Figure 6 are multiplied by 1.0×10^{-12} , they are equal to the hydraulic conductivity coefficient, K , in m/s. By comparing Figures 2 and 6, we can see that the hydraulic conductivity coefficients range from about 4.5×10^{-12} m/s at -0.3°C to about 3.5×10^{-13} m/s at -2°C . Williams and Perfect (1980) report values of the average hydraulic conductivity coefficients on several silts that range from 4×10^{-12} m/s at an average temperature of -0.23°C to 6×10^{-14} m/s at an average temperature of -0.40°C . If it is remembered that the Morin clay is a finer material and thus has a higher surface area and a higher unfrozen water content at a given subfreezing temperature, then the higher hydraulic conductivity coefficients at a given temperature reported in this paper are not surprising. It is also not surprising that, as temperature decreases, the hydraulic conductivity coefficient values decrease at a slower rate for the Morin clay than for the silts. What is remarkable about the conductivity values shown in Figure 6 is the reproducibility of the values from sample to sample. In addition, values could be calculated over a broad temperature range using just one soil column. It appears that by using the experiment given in this paper, values of hydraulic conductivities down to at least -10°C can be measured.

If, in the future, values of hydraulic conductivity coefficients in frozen soils can be directly measured using some type of direct pressure gradient apparatus, such as that used by Burt and Williams (1976), then those values could be compared with values obtained from temperature gradient experiments such as those reported in this paper, and the assumption that the correct form of the Clausius-Clapeyron equation is being used could be checked. At present, there are no direct methods available accurate enough to allow a quantitative comparison. Harlan (1973) has suggested that hydraulic conductivity values obtained for unsaturated, unfrozen soils could be used for frozen soils at like unfrozen water contents. The experiments reported by Nakano et al. (1982, 1983) give values for the soil-water diffusivity, $D(\theta)$, for Morin clay at various water contents. The form of Darcy's law used was

$$q = -D(\theta) A \frac{\partial \theta}{\partial X} \quad (4)$$

where θ is the water content and $D(\theta)$ is the diffusivity. If the soil-water characteristic curve, i.e. suction or pressure in the soil as a function of water content, is known, then Equation 4 can be written as

$$q = -D(\theta) A \frac{\partial \theta}{\partial P} \frac{\partial P}{\partial X} \quad (5)$$

where P indicates soil-water suction. Equation 5 is analogous to Equation 3 with K equal to $D(\theta) \partial \theta / \partial P$. Thus, a comparison can be made between the temperature gradient and water concentration gradient experiments. We do not yet have good soil-water characteristic curves on the Morin clay, but these can be obtained. We will make these comparisons in the future.

CONCLUSIONS

In this paper we have presented a method for measuring water migration due to a temperature gradient in frozen soils. The important part of the experimental technique that is new is that long and thin soil columns are embedded in an aluminum block and the temperature gradient created in the block is impressed upon the soil columns. This allows the temperature gradient in the soil to be controlled even though water and ice migrate. Hydraulic conductivity coefficients were calculated for a Morin clay sample down to a temperature of -2.0°C . This calculation involves the assumption that a specific form of the Clausius-Clapeyron equation is valid for relating the pressure or chemical potential of the water in the soil to temperature as long as both ice and liquid water phases are present.

It appears that experiments can be done down to at least -10°C to determine hydraulic conductivity coefficients. We are presently doing further experiments with Morin clay, using steeper temperature gradients and going to lower temperatures, and we plan to run other soils in the future. We hope that the method becomes a quick and convenient way to determine the hydraulic conductivities of frozen soils over a wide temperature range.

Hydrologic Characteristics of Small Arctic-Alpine Watersheds
Central Brooks Range, Alaska

Lawrence J. Onesti and Steven A. Walti

Indiana University, Bloomington, Indiana 47405 USA

A hydrologic investigation of six watersheds was conducted during three summer runoff seasons (1978, 1979, and 1980) in the central Brooks Range. The orographic effect produced by the Brooks Range significantly affects both summer and winter precipitation patterns and consequently stream runoff characteristics. Summer precipitation north of the continental divide is normally greater than that to the south, which is reflected in the volume of runoff per surface area for the small watersheds near the divide. The largest percentage of seasonal runoff takes place from breakup to early summer and is attributed to snowmelt and to the significant proportion of summer precipitation which occurs during this period. Precipitation discharge calculations suggest that the major portion of annual precipitation becomes stream discharge representing a large water yield in proportion to total precipitation. These yields are attributed to low evaporation rates and to the presence of continuous permafrost.

INTRODUCTION

The hydrologic characteristics of six arctic-alpine watersheds ranging in size from 4.8 to 125 km² were monitored during three consecutive runoff seasons (1978, 1979, 1980) at Atigun Pass in the central Brooks Range. Atigun Pass, having an elevation of 1,400 m, is located in the Endicott Mountains of the Phillip Smith quadrangle (68°N latitude, 150°W longitude) and crosses the east-west trending continental divide of the Brooks Range (see Figure 1). Three of the watersheds under investigation drain south to the Yukon River system, while the remainder flow to the north. Relatively small watersheds were selected in an attempt to limit the variability in geologic, morphometric, and climatic factors which could affect the stream's hydrologic regime.

SURFICIAL CHARACTERISTICS OF WATERSHEDS

The Brooks Range is an arctic-alpine periglacial environment located within the zone of continuous permafrost (Péwé, 1975). The active permafrost layer is highly variable in the study area. Ellis (1979) documented a lower limit of the active layer which rarely exceeds 1.5 m during the thaw period.

Pleistocene glacial deposits are present along all the valley floors, interrupted only by recent fluvial deposits associated with the present streams. The valley walls both north and south of the continental divide are covered with more recent talus cones, aprons of colluvium and/or alluvial fans, slushflow deposits, protalus ramparts, and lobate rock glaciers.

VEGETATION

Arctic-alpine tundra is the characteristic vegetation throughout the watersheds of the study

area. The low relief valley floors are host to a wide variety of tussock, sedge, and grass communities. Inhabiting the stream banks of the larger valleys are extensive stands of dwarf birch and shrub willows. This shallow rete of vegetation dominates valley floors, and low relief fans, providing adequate protection against surficial runoff.

Recent glacial activity, frost action, prolific mass wasting, and rapid erosion of the steep mountainsides have left the valley hillslopes unstable and constantly changing. The shallow soil and coarse debris found on the valley floors, create drastic changes in vegetation. Lichens, ferns, grasses, small herbs, and saxifrages are scattered among the coarse debris, offering little resistance to surficial runoff and erosion.

CLIMATE

Weather conditions in this alpine region are influenced primarily by the radiation balance and the movement of air masses, both of which are highly variable during the runoff season. Air temperature normally remained above freezing; however, intrusion of arctic air masses during the runoff period would inhibit snowmelt runoff.

Four Belfort Universal weighing bucket-type recording snow and rain gages were installed at sites N-1, N-2, S-1, and S-2 (see Figure 1) to record summer precipitation. Although this network of gages could be considered rather thin, it was determined to be representative for the purposes of this study.

The orographic effect produced by the Brooks Range gives this area the highest annual precipitation values along the trans-Alaska pipeline from the Yukon River to Prudhoe Bay (Haugen, 1979).

FIGURE 1 Study area and location of gages.

Precipitation data from a network of gages distributed over a distance of 60 km both North and South of Atigun Pass for the period of record suggest that summer rainfall varies considerably from year to year as well as north and south of the continental divide. This network is not shown in Figure 1. Precipitation north of the divide is normally greater than that to the south.

The largest total summer rainfall recorded during the study period was 332.74 mm at Station N-1 in the Atigun Pass during the 1980 field season and the least 74.00 mm at station N-2 in 1978. However, the 1978 value may be somewhat misleading, since this period of record is much shorter than the 1979 and 1980 seasons (see Table 1). The average total summer precipitation for the 1979 and 1980 seasons was 227.72 mm for stations north of the divide and 186.06 mm for stations to the south (see Table 1). Considering that all the periods of record terminate in mid-August and freezeup normally occurs in late September or early October, these rainfall values would be higher if precipitation for the latter half of August and September were included.

Unlike the reported significant influence of evaporation in the middle and low latitudes, in arctic regions it has been reported to account for only a 0.5-2.0% reduction in total runoff (Hösvind 1965). Thus evaporation has been disregarded in the calculations pertaining to the study.

TABLE 1 Precipitation Values North and South of Continental Divide (in millimeters).

Year	Length of Record	Stations (North)	
		N-1	N-2
1978	6/20-8/12	97.00	74.00
1979	5/13-8/18	245.13	151.63
1980	5/26-8/13	332.74	181.37
Average 227.72			

Year	Length of Record	Stations (South)	
		S-1	S-2
1978	6/20-8/12	102.7	102.7
1979	5/14-8/17	166.89	166.13
1980	5/26-8/10	185.17	226.06
Average 186.06			

FIELD METHODS

Six continuous recording gages were used to monitor the stage of the streams under investigation. Stage recorders were operational within a few days of the initial spring flow; however, icing and slushflow conditions as well as winter snow accumulation in the channels inhibited early installation. A Marsh-McBernie velocity meter was

used to record flow velocities. Velocity measurements were used to establish a representative rating curve for stream discharge. Six seasonal hydrographs were derived from stage values taken at 2 hour intervals from each stage recorder chart.

NATURE OF THE DATA

The period of record for both precipitation and discharge does not extend through the entire runoff season. Data collection normally ended in mid-August due to university commitments (see Tables 1 and 2 for length of records). In the Atigun Pass area freezeup normally occurs in late September or early October (G. Elliot, personal communication). Since the 1978 record does not include the breakup period, no conclusions will be drawn for this period but the data will be reported.

The 1979 and 1980 period of record are rather similar in length and do include most of the breakup period; however, approximately 1.5 months of the precipitation and discharge data are missing. Nevertheless the authors feel the major portion of the seasonal runoff was recorded and only late summer low flows and perhaps a few precipitation events are missing. Due to the paucity of hydrologic information for this area, these data merit comment; however, it is recognized that the record is incomplete.

DISCHARGE PATTERNS

The patterns of precipitation and runoff for the period of record are highly skewed toward late spring and early summer in the central Brooks Range. On the average, approximately 30% of the recorded summer precipitation occurred during the first 30 days of this period. The large proportion of summer precipitation which occurs in the early portion of the runoff season in combination with snowmelt contributes to the exceptionally large runoff experienced.

Seasonal hydrographs for the streams under investigation indicate that 50% of the stream flow was discharged in the first 30 days of the 1980 runoff season, while 85% of the recorded flow occurred in the seven week period after June 1 in both 1979 and 1980. These values correspond well to values documented by Pissart (1967), Church (1972), McCann and Cogley (1973), and Collins (1979) for other arctic watersheds.

Daily stream flow fluctuations seen in June are somewhat more uniform than those experienced in the latter portion of the runoff season and may be attributed to snowmelt response to diurnal fluctuation in air temperature (see Figure 2). Snowmelt rates increase during the early portion of the runoff period. This acceleration of snowmelt is brought on by discontinuous or patchy snow cover characteristic of south facing slopes, which receive a disproportionate amount of radiation during the early spring. Gray and O'Neill

(1974) established that during a 6 day interval, 44% of the energy supplied to an isolated snow patch was by sensible heat transfer. During a period of continuous snow cover the corresponding figure for the same location was 7%.

Diurnal peak flows on the average occur from approximately 7:00 P.M. to 10:20 P.M., and minimum flows are recorded between approximately 9:30 A.M. and 12:30 P.M. depending upon basin size and location within their individual drainage networks. The degree of diurnal flow variation ranges from 0.35 to 3.15 m³/s again depending primarily on basin size. A rapid and short-term decline in the hydrograph is normally related to an intrusion of arctic air with temperatures at or below freezing (see Figure 2). The gradual decline in the seasonal hydrograph reflects the melting and final disappearance of practically all of the snowpack by mid-July, with a few large late summer frontal or convectional showers producing peak discharge events which are in some cases larger than events experienced in the earlier part of the runoff season but are of shorter duration (see Figure 2). The highest peak discharges recorded occurred during the 1978 period of record in the larger basins, while in the smallest basins June Bug and Sediment Creek, the peak discharges occurred in 1979 and 1980 respectively. Since both peak flows recorded in the latter two basins are associated with precipitation events, this would appear to suggest that smaller basins are somewhat more sensitive to individual rainfall events.

TABLE 2 Total Recorded Basin Runoff.

Streams	Year	Length of Record	Seasonal	Peak
			Runoff (m ³ / record x 10 ³)	Dis- charge (m ³ / s)
Dietrich River	1979	5/22-8/17	14,778	286.5
	1980	5/29-8/14	19,718	239.0
Chandalar River	1978	6/26-8/13	10,678	644.0
	1979	5/28-8/17	17,114	437.0
Thunder Creek	1980	5/30-8/14	23,499	459.0
	1978	6/15-8/13	5,413	166.5
Sediment Creek	1979	5/30-8/18	5,790	127.5
	1980	5/29-8/14	5,645	134.0
June Bug Creek	1978	6/13-8/13	888	65.6
	1979	5/25-8/18	1,784	58.9
Atigun River	1980	5/26-8/14	1,800	91.8
	1978	6/18-8/13	1,484	44.0
Atigun River	1979	5/29-8/18	2,962	106.5
	1980	5/29-8/14	3,287	62.5
	1978	6/14-8/13	50,504	1020.0

	1980	5/30-8/14	53,957	932.8

- a) Nival freshet with remarkable diurnal flow.
 b) A cold spell with a dramatic decline in flow.
 c) Late summer period, little precipitation and little runoff.
 d) Large peaks due to frontal precipitation.

FIGURE 2 An example of a seasonal hydrograph and associated precipitation.

TOTAL RUNOFF CALCULATION

Precipitation-runoff calculations represent the contribution of rainfall and snowfall to stream runoff (Langbein 1949). The equation used to calculate total annual runoff (R_p) is as follows:

$$R_p = P_t \times (A_b \times C_f),$$

where (P_t) is seasonal precipitation in mm, (A_b) is basin area in km^2 , and (C_f) the correction factor for time. Calculated values are expressed in cubic meters per season.

For the period of record summer rainfall accounts for approximately 42% of stream discharge in the study area, suggesting that approximately 58% of the seasonal discharge is attributable to nonrecorded snow and ice melt as well as to groundwater contribution.

The above percentages are in fair agreement with annual frozen versus unfrozen precipitation values indicated by Haugen (1979). However, since discharge and precipitation for late August and September were not recorded by this study, precipitation-runoff values attributed to summer rainfall may be considered underestimates.

TABLE 3 Precipitation/Runoff Calculations.

Stream	Area (km ²)	Year	Sea- sonal Pre- cip. (mm)**	Runoff	
				Total Runoff (m ³ / record x 10 ³)	per km ² (m ³ / km ² x 10 ³)
Atigun River (N-2)*	125.2	1978	74.0	8,989	71
		1979	151.6	13,792	110
		1980	181.4	23,553	188
June Bug Creek (N-1)*	5.9	1978	97.0	1,152	195
		1979	245.1	1,237	210
		1980	332.7	1,939	329
Thunder Creek (S-1)*	12.3	1978	102.7	1,259	102
		1979	166.9	1,636	133
		1980	185.2	2,387	194
Sediment Creek (S-1)*	4.8	1978	102.7	495	103

		1980	185.2	8,790	195
Dietrich River (S-2)*	44.9	1978	102.7	4,617	103
		1979	166.1	6,944	155
		1980	226.1	8,166	182

*Rain gage site used in calculation.

**See Table 2 for length of record.

Total water yield for the period of record indicates that the seasonal volume of discharge is directly related to drainage basin size, as would be expected; however, water yield per km² does not show this relationship. Small watersheds near the continental divide have greater volume yields per surface area than larger watersheds (see Table 3). The precipitation gage N-1 normally records the highest summer rainfall values (see Table 1) while Calkin and Ellis (1980) reported greater depth of snowpack with decreasing distance from the continental divide; both of these factors most likely contribute to this variation in volume discharge per unit area.

SUMMARY

Four distinct runoff periods characterize stream flow in the arctic-alpine environment of the central Brooks Range. Spring breakup is short and associated with penetration of warm air masses into the study area in combination with high inputs and longer durations of radiation as the summer solstice approaches. The largest volume of discharge occurred during the snowmelt runoff period.

Low stream discharge characterizes the late summer period; however, sporadic intense rainfall events develop peak flow conditions in all streams. The major portion of all rainfall and snowmelt becomes runoff due to the continuous nature of the permafrost and to low evaporation

rates. Precipitation-runoff values for the period of record indicate that 42% of stream runoff is attributed to summer precipitation and the remaining 58% to snowmelt and baseflow.

ACKNOWLEDGEMENTS

FIELD MEASUREMENTS OF ELECTRICAL FREEZING POTENTIALS IN PERMAFROST AREAS

V. R. Parameswaran¹ and J. R. Mackay²

Electrical potentials developed during freezing of natural soils have been measured in two permafrost areas: one in a saturated sand in a drained lake (Illisarvik) on Richards Island where permafrost was aggrading downward 5.65 m below ground; the other, in a mud hummock in the active layer at Inuvik. Peak potentials of up to 1350 mV were measured on electrodes located on the advancing freezing front at Illisarvik. At Inuvik, maximum freezing potentials of up to 700 mV were measured as the active layer froze in winter. There was also evidence of downward water migration and freezing as the ground started to thaw at the surface in spring.

INTRODUCTION

The phenomenon of electrical potentials generated during freezing of aqueous solutions and other systems such as moist soils has been known for some time, although the exact mechanism of development is not fully understood. Several plausible explanations have been proposed for pure water and dilute aqueous solutions, but no such theory has been suggested for soils.

When water freezes on the surface of a solid, the dipole field of the oriented water molecules in the initial ice layer causes rotation and reorientation of the molecules in the liquid adjacent to the ice. An electrical double-layer of a few nanometers is formed at the interface between the frozen and unfrozen parts. It behaves like a semipermeable membrane, allowing one kind of charge to pass through more readily than the other, and causes selective incorporation of an excess charge of one sign in the frozen part and an equal and opposite charge in the unfrozen part. The potential developed in this way is commonly called the freezing electrical potential. During freezing, there is a tendency for water to migrate to the freezing front, and thus several electrokinetic effects (such as electrophoresis, electro-osmosis, streaming potential, and sedimentation potential) may also arise as a result of the relative motion between water and solid phase.

Early measurements of freezing potentials were carried out in water and in dilute aqueous solutions containing different kinds of ions, for example, alkali metals, ammonia, halogens, and hydroxyl ions (for early references, see Parameswaran 1982). The early investigations showed that the magnitude and sign of the freezing potential depend upon various factors, including the type of ion in solution, type and distance between electrodes, concentration of electrolyte solution, and rate of cooling.

Reports on the observation of freezing potentials in soils and rocks are meagre and inconclusive. Jumikis (1958) measured potentials of 40-120 mV during freezing of Dunellen silty soil (a glacial till) and suggested that such potentials could enhance moisture transport in the material.

Korkina (1975) studied the freezing electrical potentials in suspensions containing particles of less than a micron and saturated with different kinds of ions such as Fe^{3+} , Ca^{++} , Na^+ , and NH_4^+ . The magnitude and polarity of the induced voltage depended on the density of the suspensions, type of particles, and type of ions. Under laboratory conditions, Borovitskii (1976) measured freezing voltages of 150-200 mV in argillaceous rocks, and Yarkin (1974, 1978) measured freezing voltages of up to 325 mV in powdered sand containing about 23% moisture and smaller freezing voltages in other soils. More recently, Hanley and Ramachandra Rao (1980, 1981) studied the effects of various cations on the generation of freezing potentials in a bentonite clay. The maximum potentials were in the range of 30-50 mV, and they concluded that the development of freezing potential and migration of moisture are closely associated phenomena, each influencing the other. Parameswaran (1982) has also reported laboratory measurements of electrical freezing potentials in water and soils under various rates of cooling. Ice-positive potentials of 4-12 V developed in pure water under rapid cooling; and in moist sands and soils ice-negative potentials of 100-200 mV were measured. Under slow cooling at $-2.2^\circ C$ reconstituted natural soils from permafrost areas showed freezing voltages of 200-300 mV. The freezing potentials in water could be due to a combination of those related to the phase change of water and those arising out of charge separation and ion incorporation from traces of impurities (known as Workman-Reynolds effect). In addition to polarization of water molecules and alignment of dipoles across the potential barrier at the freezing boundary, charges inherently present at the surface of mineral particles in soils could also contribute to the development of freezing potentials by exchange absorption processes.

The development of contact electrical potentials during freezing is of considerable importance in many construction problems in northern North America, the USSR, and Europe, where vast areas are underlain by perennially and seasonally frozen ground. Under the influence of an electrical gradient such as that caused by freezing, water is

transported through frozen clay and silt towards the freezing front where segregated ice can form (Verschinin et al. 1949, Hoekstra and Chamberlain 1963). Such movement of water under the influence of geoelectric fields in the presence of a thermal gradient could also cause electro-osmotic drainage of unfrozen and frozen soils (Nersesova and Tsyrovich 1966). The additional heave caused by such processes could necessitate special construction techniques for pipelines, foundations for buildings, and other structures in permafrost areas. Geoelectric fields generated near buried pipelines could also affect their cathodic protection.

FIELD STUDIES

Very few measurements of electrical freezing potentials under natural conditions have been published. The only documented report to the authors' knowledge is that of Borovitskii (1976), who measured the inherent electrical fields developed in the active layer between frozen and thawed parts in a permafrost region of the USSR. The measured values did not exceed 50 mV, although the value of the potential varied with depth in the ground. This he attributed to differences in quantity and direction of moisture movement. Mackay has also carried out measurements of the potentials developed in electrodes embedded to different depths in the active layer and in perennially frozen ground in three different areas of the Northwest Territories. When electrodes were placed in the active layer, he observed a potential change as the freezing front passed the electrodes. Values of potentials measured in the field were of the same order of magnitude as values measured in the laboratory on natural soils (Parameswaran 1982). This similarity of the freezing potentials measured in the laboratory and in the field prompted the authors to install field electrode assemblies in two permafrost areas and to measure freezing potentials in an attempt to understand the physical processes that occur during freezing of the ground. One chosen area was the middle of an artificially drained lake (Illisarvik) on Richards Island, N.W.T., where permafrost was aggrading from the top down (Mackay 1981). The other area was at Inuvik, N.W.T., where the active layer in a mud hummock was monitored. This paper describes the equipment and some of the results.

Illisarvik Lake Site, Richards Island

An electrode probe consisting of five plexiglas tubes, each 1.93 m long, 38 mm OD and 25 mm ID, was installed at the site, the middle of a drained lake, on 20 June 1981. Twenty-two copper electrodes in the form of circular bands (12.5 mm wide) were installed on the probe in suitable grooves 1 mm deep. The bottom electrode (numbered zero) was 89 mm from the tip of the plug closing the first tube. All the others, numbered 1 to 21 from the bottom upwards, were set 150 mm apart. A shielded coaxial cable (RG 174/U) was connected to each electrode through a slanted hole in the wall of the tube and the soldered joints were protected by epoxy

resin. The tubes were designed to be joined with plexiglas couplings as they were installed.

Wires from the electrodes were connected to a rotary switch having 24 terminals (Figure 1b). The bottom electrode was connected to the common point (-); the others were connected to switch points 1 to 21. The central switch contact point was made the (+) terminal. The shields from all the cables were connected to the ground terminal, which was in turn connected to a grounding steel post at the lake site.

Two thermistor cables were installed near the electrodes for temperature measurements. The first cable had 12 thermistors (YSI 44033, calibrated to $\pm 0.01^\circ\text{C}$ at 0°C), each inside a soil salinity sensor (Soilmoisture No. 5100-A). These were embedded in a 30 mm diam PVC rod at 500 mm intervals. The rod (with salinity sensors) was installed in a hole drilled by water-jet 0.4 m from the electrode assembly (Figure 2). A second temperature cable with 26 thermistors (YSI 44033) spaced 150 mm apart was installed 4 m from the electrode assembly.

Depth of permafrost was 5.65 m when the electrodes were installed in June 1981. The uppermost electrode (21) was at a depth of 6.11 m and the bottom electrode (0) was 9.31 m below ground level (lake bottom). This placement ensured that the 0°C isotherm would soon reach the uppermost electrode. The material in which the electrodes were installed was a saturated sand with medium-to-fine grain size.

Inuvik Site

This site is about 3 km north of the town of Inuvik in an area of colluvium that has developed a pattern of mud hummocks. The electrode probe consisted of a PVC tubing (20.6 mm OD, 12.7 mm ID, 3 m long, closed at one end) on which 12 copper electrodes in the form of bands or rings (12.7 mm wide and about 1 mm thick) were installed in suitable grooves 150 mm apart. Coaxial cables were soldered to the electrodes and the wires were led out through a central hole and connected to the terminals of a rotary switch. The outer shields of the cables were grounded to a steel post at the site. A thermistor cable with 13 thermistors (YSI-44033) was also made. The electrode probe and the thermistor cable (Figure 3) were installed (by hand drilling) in August 1981 in the centre of a mud hummock about 2 m in diameter.

RESULTS AND DISCUSSIONS

Illisarvik Lake Site, Richards Island

Owing to the thermal disturbance of the ground caused by drilling and the resulting freeze-back, the readings taken in August 1981 are questionable and are not reported here. The Illisarvik site is relatively inaccessible and frequent readings were impossible, so that the next readings were taken 23 March 1982, 8 June 1982, and 12 August 1982. The temperature and freezing potential profiles for these dates are plotted in Figure 4(a-c). None of the three temperature profiles shows any change in gradient in crossing 0°C , from positive to negative

temperatures. In Figure 4(a) there is a gradual change in the profile at about -0.1°C ; and in Figure 4(b, c) a definite inflection point at -0.1°C . With little doubt this marks the freezing point depression so commonly observed in soils. The Illisarvik sediments consist mainly of sand, and the freezing point depression is slightly lower than might be expected. Since the sub-permafrost pore water has an increased salinity from ion rejection during permafrost aggradation, however, a freezing point depression below that of the original sands is to be expected. To illustrate, in the summer of 1982 the specific conductance of the pore water just below permafrost, as measured with the soil salinity sensors, was about $300\ \mu\text{ohm}^{-1}\ \text{cm}^{-1}$; salinity had increased appreciably since the previous summer. Nearby measurements of heave of the ground surface suggest that most of the ice formed during the downward growth of permafrost was pore ice and not segregated ice.

Figure 4(a-c) shows plots of peak potentials and temperature gradients. On 23 March 1982 there was a very pronounced peak in the potential at 1.08 V at a depth just 15 cm below the 0 deg isotherm. As the temperature measurements were taken 0.4 m from the electrodes, the agreement seems good. By way of contrast, on 8 June 1982 the peak potential (about 1.35 V) occurred at a ground temperature of -0.1°C , the peak coinciding closely with the inflection point on the temperature curve. By 12 August 1982, however, the peak potential was unchanged at the same depth as on 8 June 1982, although permafrost had aggraded 50 cm and the ground temperature had decreased to about -0.4°C . In summary, the results from the Illisarvik site indicate that freezing potentials develop on electrodes located at the freezing front, but these results are by no means conclusive.

Inuvik Site

The Inuvik site contrasts with the Illisarvik site in soil type and the placement of the electrodes. Here the soil is a silty clay, with particles about 50 % finer than 0.002 mm and a specific surface area of about $120\ \text{m}^2/\text{g}$. The amount of unfrozen pore water in the clay, using the specific surface area method of Anderson and Tice (1972), is estimated at about 9 % at -5°C and 7 % at -10°C . Voltage and temperature readings were taken every two weeks by the staff of the Inuvik Scientific Resource Centre. Variations of voltage and temperature with depth below surface were much more predictable and systematic than those at the Illisarvik Lake site. Figure 5(a-e) shows the variations of voltage and temperature at various depths as the ground froze and thawed in the 1981-1982 season. At depths of 0.05 and 0.20 m, respectively, a freezing potential developed as the temperature passed through 0°C in the month of October 1981 (Figure 5(a,b)). The maximum freezing potentials developed were as high as 650 mV. As the ground temperature at these locations dropped in winter, the potential dropped too and remained at the lower level. In spring (May 1982), as the ground started to thaw and the temperature rose above 0°C , the potentials again rose to values of up to 700 mV. The interpretation of this potential is uncertain, but there is considerable evidence that

during the summer thaw period water may migrate from the thawed active layer into the still-frozen active layer to freeze and increase the ice content (Cheng 1982, Mackay, in press; Parmuzina 1978, Wright 1981). A minor freezing potential may thus develop during the summer thaw period. This behaviour of meltwater, possibly percolating downwards and freezing to generate a freezing potential, was not observed at the electrodes at lower levels. For example, in Figure 5(c) the freezing potential on the electrode at a depth of 0.51 m below surface level rose to 700 mV as the ground temperature passed through -0.1°C . With further decrease in ground temperature the freezing potential remained unchanged. A slight drop in potential was noted when the temperature passed through 0°C in June 1982 as the ground thawed, but essentially the voltage was constant around 700 mV even when the ground started to freeze again in October 1982. The same type of behaviour was observed 0.96 m below ground level (Figure 5(d)).

Figure 5(a,b) shows the development of pronounced freezing potentials at depths of 0.05 and 0.20 m, respectively, in the upper part of the active layer where ice lensing commonly takes place. In addition, potentials at 0.51 and 0.96 m remained at 600-700 mV during the winter, after temperatures dropped below 0°C . Measurements carried out at Inuvik for many years have shown a prolonged and very gradual frost heave in the winter months long after the temperature has dropped below 0°C (Mackay et al. 1979). This suggests that, in winter, upward migration of unfrozen water from the freezing front into the frozen active layer could cause a minor freezing potential to develop. At levels close to the permafrost table, where ground temperature is maintained at or below 0°C , no freezing potentials developed on the electrode 1.42 m below ground level (Figure 5(e)). Figure 5(a-e) also shows that as depth increases below ground level the minimum temperature, as expected, becomes higher. For example, at 0.05 m the lowest ground temperature measured was -10°C , whereas at 0.96 and 1.42 m the lowest soil temperatures measured were -3.5 and -2.5°C , respectively.

CONCLUSION

Freezing potentials appear to have developed on electrodes installed in saturated sand at Illisarvik where the 0°C isotherm was that of an aggrading lower permafrost surface, but the results are inconclusive. Peak potentials of up to 1350 mV were measured on electrodes located on the advancing freezing front. At Inuvik, the electrodes were placed in the active layer on top of permafrost, in a silty clay. The electrodes in the upper part of the active layer where lens ice forms in the freeze-back period registered substantial increases in potential as the freezing front passed the electrodes. The maximum freezing potential measured here was about 500 mV when the ground temperature was about -0.1°C . There was also evidence of downward water migration and freezing, as evidenced by a rise in freezing potential at levels below the surface as the ground thawed at the surface. These field measurements indicate that by suitably modifying electrode probes and improving measuring

techniques it is possible to locate and study the advancing freezing front and water migration at different levels below the surface as ground freezes and thaws.

ACKNOWLEDGEMENTS

The authors would like to express their sincere thanks to the following: C. Hubbs, J.C. Plunkett, and G.H. Johnston; the DBR/NRCC Workshop staff, and the staff of the Inuvik Scientific Resource Centre. Field support for J.R. Mackay from the Geological Survey of Canada, the Polar Continental Shelf Project (Department of Energy, Mines and Resources) and the Natural Sciences and Engineering Research Council is gratefully acknowledged. This paper is a contribution from the Division of Building Research, National Research Council Canada, and is published with the approval of the Director of the Division.

MEASUREMENT OF UNFROZEN WATER CONTENT IN SALINE
PERMAFROST USING TIME DOMAIN REFLECTOMETRY

Daniel E. Patterson and Michael W. Smith

Geotechnical Science Laboratories, Geography Department,
Carleton University, Ottawa, Ontario Canada, K1S 5B6

Time Domain Reflectometry has been previously used to determine volumetric unfrozen water contents, θ_u , in frozen soils. This paper presents laboratory results which indicate that the technique can be extended to use in saline permafrost samples. TDR determined values of θ_u for samples at the same salinity, are generally reproducible to within 2.5%. Measured θ_u data, for the soil at its natural salinity, were used to calculate values at other salinities, by accounting for the freezing point shift. The measured and calculated values generally agree to within 2-5% in θ_u . Finally, some field data are presented.

INTRODUCTION

Ice-bonded permafrost is found extensively beneath the floor of the Beaufort Sea, and its presence requires special attention in offshore engineering. To reliably predict the behaviour of permafrost for engineering purposes, accurate data on the volumes of ice and water are required. Since seabed permafrost may not be in a state of thermodynamic equilibrium, it is not possible to simply calculate the proportions of ice and water present in the soil based on temperature, salinity and pressure. The phase composition can only be determined by direct measurements on actual core samples, carried out immediately upon recovery. This paper presents preliminary results on the use of Time Domain Reflectometry (TDR) to determine the volumetric unfrozen water content in saline soils. If total water content is also known (e.g. by gravimetric means or by TDR on the thawed sample), the complete phase composition of the sample can be determined.

THE TDR TECHNIQUE

Previously we have reported on the use of TDR to determine volumetric unfrozen water contents of soils, θ_u , from the measured dielectric constant, K_a (Patterson and Smith 1981). Background information on the TDR technique can be found in the literature (e.g. Topp et al. 1980, Patterson and Smith 1981, Smith and Patterson 1982). Briefly, the technique is used to determine the apparent dielectric constant (K_a) of a soil, from measurement of the travel time (t) of the TDR's step-voltage along a transmission of known length (L). Parallel rod or coaxial lines are the two types of transmission line most commonly used, where the former is embedded in the sample and the latter is used to contain the sample. Figures 1 and 2 show sample TDR traces for each type respectively. The A point on these figures is the start of the line in the soil, and the B point (where recognizable) is the response of the open circuit termination. K_a is determined from the following equation:

$$K_a = \left[\frac{c \times t}{L} \right]^2 \quad (1)$$

where c is the free space velocity (3×10^8 m/s) and t is measured on the horizontal axis of the TDR trace.

Topp et al. (1980) determined an empirical relationship between K_a and volumetric water content, θ_v , for unfrozen mineral soils, which is largely insensitive to soil type, temperature or other physical properties:

$$K_a = 3.03 + 9.3 \theta_v + 146.0 \theta_v^2 - 76.7 \theta_v^3 \quad (2)$$

This relationship has also been found to apply to the determination of volumetric unfrozen water content in frozen soils (Patterson and Smith 1981). Figure 3 presents a comparison of θ_u data determined via the TDR technique, and by other methods for the same soils. In general, the data agree to within +/-2.5% in θ_u . In addition, the authors have also shown that TDR determined freezing characteristic data agree well with published data for soils of similar texture and physical properties (Patterson and Smith 1981, Smith and Patterson 1981, 1982). An example is shown in Figure 5, for two Kaolinite soils.

The use of TDR in highly saline soils (salinity > 5 g NaCl/l) can be difficult due to the large electrical losses associated with the conductive pore water. Under certain conditions, the losses can make it difficult to distinguish the open circuit response (B point), making K_a measurements impossible. The ability to determine K_a will depend upon water content, pore water salinity, temperature and the length of the transmission line. Some of these aspects are illustrated in Figures 1 and 2.

The traces shown in Figure 1 are for an unfrozen saline sand at two temperatures using parallel rod lines. At 0°C, the open circuit response for the 5 and 10 cm lines is quite clear, but it cannot be located for the 20 cm line. At 25°C, the B point is still clear for the 5 cm line, however, it is

somewhat uncertain for the 10 cm line. This example shows that the conductive losses, at any salinity, are temperature dependent and that the ability to determine K_a is a function of line length.

Figure 2 shows TDR traces for frozen Kaolinite samples, at initial salinities of 10 and 20 g NaCl/l, in 5 cm coaxial lines. In these examples, liquid water content decreases and pore water salinity increases as the soil freezes. As this occurs, the open circuit response improves, even though the pore water salinity increases as more water turns to ice.

When using TDR in saline soils, the combined effect of pore water salinity, water content and temperature will dictate the line length to be used. To obtain K_a measurements over a wide range of freezing temperatures, several line lengths can be used. As a guide, we recommend using the longest line that gives a recognizable B point (see Smith and Patterson 1982). Further, Figure 1 suggests the possibility of using a dual length probe to determine B points in very lossy materials.

PROCEDURES

Sample Preparation

A silty clay (Allendale) and a clay (Kaolinite #3) were used in laboratory experiments with precision 50 ohm coaxial lines serving as sample containers, of lengths 5-15 cm (depending upon initial pore water salinity). To prepare the samples, a coaxial line was placed in a low temperature chamber and a soil slurry, at the desired pore water salinity, added in small incremental amounts and frozen until the line was completely filled. In this manner, a sample without ice lensing or variations in salinity can be obtained. The sample containers were then covered in an impermeable latex membrane, and immersed in a controlled-temperature bath.

TDR traces were recorded on an x-y recorder at various temperatures on warming cycles. K_a and θ_u were determined from equations (1) and (2) respectively.

Determining the Freezing Point Shift

If freezing characteristic data (θ_u versus temperature) for a soil at its natural salinity are known, then values at other salinities can be calculated using the method described in Banin and Anderson (1974). The assumptions of this analysis are: 1. all the salts are in solution, 2. they are uniformly distributed in the pore water, and 3. the salts do not precipitate out during freezing. For samples containing only NaCl in the pore water, and with unfrozen water contents expressed on a volumetric basis, the method of Banin and Anderson can be simplified as follows:

$$T_n = T_i + S_o \cdot \Delta \frac{\theta_i}{\theta_o} \quad (3)$$

where T_n is the new temperature at which an unfrozen water content θ_i will occur, θ_i is the unfrozen water content at temperature T_i for the soil at its

natural salinity, θ_o is the water content of the thawed sample, S_o is the pore water salinity (g NaCl/l) of the thawed sample and Δ equals $-5.8675 \times 10^{-2} \text{ } ^\circ\text{C}/(\text{g NaCl/l})$. This formulation can be used if $S_o/(\theta_i/\theta_o)$ is less than about 90 g NaCl/l (see Wolf et al. 1978).

Sources of Error

In these experiments, travel times in the samples were between 0.5 and 3.0×10^{-9} s (depending upon θ_u and line length). The authors have verified that in this range, travel times measured in coaxial lines filled with low loss materials (air, dielectric powders and liquids of known properties) are within +/-2% of expected values, as given by the time base accuracy of the TDR used. In saline soils, the open circuit response (B point on Figures 1 and 2) may become rounded, creating uncertainties in travel time measurements (hence K_a and θ_u determinations). The authors estimate that the travel time can be measured to within +/-2.5% of the available time window. This implies an uncertainty in θ_u estimates of +/-3.5% (from equations (1) and (2)).

The error in calculating the temperature shift in a soil freezing characteristic curve is a function of the certainty in water content and pore water salinity. Ignoring uncertainty in the pore water salinity, the error in calculating the freezing point shift will be due to uncertainties in the θ_i/θ_o ratio in equation (3). For example, if θ_i/θ_o is assumed to be 0.5, +/-5%, then the uncertainty in the freezing point shift will be about 5%. The error in the calculated freezing point shift increases with the salinity of the thawed sample. Depending upon S_o , θ_i , θ_o and T_i , calculated values for T_n can be in error by several hundredths to one or more degrees.

RESULTS AND DISCUSSION

Figure 4 presents the freezing characteristic data for the Allendale silty clay soil, measured at salinities from 0.6 g NaCl/l (natural salinity) to 10.6 g NaCl/l. The curves at various salinities were calculated from the data at 0.6 g NaCl/l, accounting for the freezing point shift. At salinities of 5.6 g NaCl/l or less, the agreement between measured and calculated θ_u is within +/-2%. At 10.6 g NaCl/l, the measured values are between 1 to 5% lower than calculated.

Figure 5 shows freezing characteristic data for Kaolinite #3 determined from four samples. The data generally agree within 2.5% in θ_u with the largest difference of 5% at -0.2°C . This reproducibility in TDR results has been noted previously in Patterson and Smith (1981). The dashed line in Figure 5 is a power curve fit to the freezing characteristic data for Kaolinite #7, from Anderson and Tice (1973) (see also Anderson et al. 1973 and Tice et al. 1978). The agreement in the mean unfrozen water content data (either expressed gravimetrically or volumetrically) is good for these soils of similar properties.

Figure 5 shows the comparison between measures and calculated θ_u values for Kaolinite

#3 at initial salinities of 10 and 20 g NaCl/l. The calculated values were derived from the data for the sample at its natural salinity, by the method discussed previously. The right hand axis denotes calculated pore water salinity, which increases as θ_u decreases.

The measured and calculated values agree well, although the measurements tend to be about 2-5% higher, with the largest differences found for the 10 g NaCl/l sample. This aspect was not present in the 10.6 g NaCl/l Allendale silty clay results; however, data in Yong et al. (1979) for a Kaolin, show that measured values also were higher than calculated.

It is estimated that the error in the measured θ_u data for the saline samples is about $\pm 3.5\%$ (based upon possible errors in K_a), although data from different runs at any given temperature are within about 2.5%. Other factors, such as the effects of salt on soil hydrologic properties, or modification to the $K_a-\theta_u$ relationship, cannot be ruled out as contributing to the observed differences. The authors have noted some effect of salinity on travel time when salinities are large. This aspect is presently under investigation using a combined TDR-dilatometer experiment to simultaneously obtain phase composition data for saline samples (cf. Patterson and Smith 1981). These experiments should provide information for refinement, if necessary, to the use of the TDR technique in saline permafrost materials.

FIELD OBSERVATIONS

The TDR technique has recently been used in the field, during a core logging program in the Beaufort Sea. θ_u data were obtained using a 10 cm parallel rod line which was inserted into the core within minutes of recovery. The probe could generally be pushed into the sample; however, if there was sufficient ice-bonding, pilot holes could be made using a hand drill. An x-y recorder trace of the TDR display was made for data analysis. Values of the apparent conductivity, σ , were also determined via TDR (see Smith and Patterson 1982). The results for one core are shown in Table 1. The data in the table indicate two distinct layers in the profile. The values of θ_u in the 15-48 m layer, determined from the thawed sample and via TDR, agree to within 5%. Below this, the differences are between 8 and 26%. There is also a three-fold difference in the apparent conductivity between these layers. In view of this, the differences in θ_u in the 60-90 m layer could be interpreted as ice contents.

CONCLUSIONS

The TDR technique has been used to obtain phase composition data in saline frozen soils. TDR determined values of θ_u for different samples at the same salinity are generally reproducible to within 2.5%. This reproducibility has been noted previously for soils at low salinity (Patterson and Smith 1981).

For the silty clay samples, measured and calculated θ_u values generally agree to within $\pm 2\%$, for salinities less than 5.6 g NaCl/l. At 10.6 g NaCl/l, the measured θ_u data are 1 to 5% lower than calculated. For Kaolinite #3 samples, the measured θ_u data are up to 5% higher than calculated but with most differences in the 2 to 3% range.

TABLE 1 Summary of Field Observations

SONIC AND RESISTIVITY MEASUREMENTS ON BEREA SANDSTONE
CONTAINING TETRAHYDROFURAN HYDRATES:
A POSSIBLE ANALOG TO NATURAL GAS HYDRATE DEPOSITS

C. Pearson, J. Murphy, P. Halleck, R. Hermes, and M. Mathews

Earth and Space Sciences Division, Los Alamos National Laboratory
Los Alamos, New Mexico 87545 USA

Deposits of natural gas hydrates exist in arctic sedimentary basins and in marine sediments on continental slopes and rises. However, the physical properties of such sediments, which may represent a large potential energy resource, are largely unknown. In this paper, we report laboratory sonic and resistivity measurements on Berea sandstone cores saturated with a stoichiometric mixture of tetrahydrofuran (THF) and water. We used THF as the guest species rather than methane or propane gas because THF can be mixed with water to form a solution containing proportions of the proper stoichiometric THF and water. Because neither methane nor propane is soluble in water, mixing the guest species with water sufficiently to form solid hydrate is a difficult experimental problem, particularly in a core. Because THF solutions form hydrates readily at atmospheric pressures it is an excellent experimental analog to natural gas hydrates. Hydrate formation increased the sonic P-wave velocities from a room temperature value of 2.5 km/s to 4.5 km/s at -5°C when the pores were nearly filled with hydrates. Lowering the temperature below -5°C did not appreciably change the velocity however. In contrast, the electrical resistivity increases nearly two orders of magnitude upon hydrate formation and continues to increase more slowly as the temperature is further decreased. In all cases the resistivities are nearly frequency independent to 30 kHz and the loss tangents are high, always greater than 5. The dielectric loss shows a linear decrease with frequency, suggesting that ionic conduction through a brine phase dominates at all frequencies, even when the pores are nearly filled with hydrates. We find that the resistivities are strongly a function of the dissolved salt content of the pore water. Pore water salinity also influences the sonic velocity, but this effect is much smaller and only important near the hydrate formation temperature.

INTRODUCTION

Hydrates are a crystalline form of water containing voids or cavities that can trap other (guest) molecules which play an important role in stabilizing the hydrate structure. Two types of hydrates (types 1 and 2) are known to form. The first type contains only relatively small cavities ($>8.6 \text{ \AA}$ in diameter) that can trap guest species smaller than ethane, whereas the second type contains a mixture of small and large (9.5 \AA in diameter) cavities that can trap molecules as large as isobutane. Most of the common constituents of natural gas form hydrates, usually type 1, but type 2 hydrates can also form if significant amounts of C_3H_8 , C_4H_{10} , or CO_2 are present.

Until recently, natural gas hydrates were widely known only as a nuisance that condensed in gas transmission lines. Then Soviet investigators reported natural gas hydrate deposits in the Siberian Arctic. These early reports were confirmed with the discovery of large natural gas hydrate deposits in arctic North America and in marine sediments. Research interest in hydrates increased as hydrates became not only a potential engineering problem in the Arctic, but also a potential energy resource. Although a considerable body of experimental data exists on the

electrical properties of pure crystalline hydrate (see Davidson 1973, for a summary) these measurements are usually conducted at frequencies far higher than those used in exploration geophysics and surprisingly little is known about the physical properties of sediments containing hydrates in their pores except for the pioneering work by Stoll and Bryan (1979).

In this paper, we present laboratory sonic and resistivity measurements on Berea Sandstone cores containing tetrahydrofuran (THF) hydrate. Tetrahydrofuran was used as a guest species instead of methane or some other constituent of natural gas because THF hydrate is stable at moderate temperatures ($+4^{\circ}\text{C}$) and atmospheric pressures, which greatly simplifies experimental procedures. A second major advantage of THF hydrate is that the guest is mixable with water. This eliminates the problem of ensuring complete mixing between the guest species and water, which is a formidable problem inside the pore spaces of sedimentary rock. Because the crystal structure of hydrates is largely independent of the guest species, the physical properties of THF-hydrate-containing samples are probably similar to the physical properties of a natural gas hydrate deposit formed in similar rocks. This is particularly likely if the natural hydrates form from gas-containing molecules large enough to form type 2 hydrates.

This paper focuses on sonic and electrical measurements because preliminary calculations (Pearson 1982) show that sonic velocities and resistivities are more strongly affected by the presence of hydrates than are other physical properties such as densities or thermal conductivities. In addition, seismic and electrical methods are the most commonly applied exploration geophysical techniques. Clearly a detailed understanding of the electrical and acoustic properties of hydrates is necessary to design and interpret geophysical surveys over natural gas hydrate deposits.

During this study we restricted our electrical measurements to the frequency range from 10 Hz to 30 kHz because most exploration geophysical surveys are conducted at these relatively low frequencies. In addition Olhoeft (1977) demonstrates that the electrical properties of permafrost at higher frequencies are very variable. If hydrated sediments are similar in this respect, then even if surveys could be conducted at higher frequencies, the results would be very difficult to interpret.

EXPERIMENTAL METHOD

The samples were cylindrical cores approximately 5 cm long and 2.54 cm in diameter cut perpendicular to the bedding plane from a block of Berea sandstone. The ends were ground parallel to ensure good contact between the ends of the samples and the electrodes or transducers. Samples were saturated with a stoichiometric mixture of THF and water (18 parts water to 1 part THF; Gough and Davidson 1971) under vacuum. As part of the study, various amounts of NaCl were added to the fluid. The concentration of salt is reported by the molarity of the water NaCl solution before THF was added to the mixture. Because temperature is an important variable in our study, all measurements were conducted in a NESLAB RTE-8 constant temperature bath. We left the sample in the bath for 24 hours, well after a temperature change, to ensure the sample had equilibrated with the bath. Because the crystalline water that formed in the pores disassociated near 4°C which is near the disassociation temperature of THF hydrates (Gough and Davidson 1971) and significantly above the melting point of ice, THF hydrate apparently formed in the pore spaces of the rock, not water ice.

The electrical measurements were conducted using a two-electrode system similar to that described by Collett and Katsube (1973). We used a Princeton Applied Research model 5204 lock-in analyzer, which can measure the in-phase and quadrature components of the voltage drop across the precision resistor, and were able to calculate the real and imaginary components of the resistivity, the phase angle, and the complex relative permittivity. The complex electrical properties (i.e., the complex permittivity (K^*) and the loss tangent (D) were calculated using the following equations presented by Collett and Katsube (1973).

$$D = \frac{P''}{\sqrt{[P'']^2 - (P')^2}}, \text{ and} \quad (1)$$

$$K'' = \frac{1}{\omega [P''] \epsilon_0}, \quad (2)$$

where $[P'']$ and P' are the magnitude complex resistivity and the real part of the complex resistivity respectively, ω is the frequency, and ϵ_0 is the permittivity of free space. The real (K') part of the relative permittivity can be calculated from K^* using

$$K' = \frac{K''}{1+D^2}. \quad (3)$$

Two-electrode systems of this type are subject to several systematic errors, among which are inductive and capacity coupling between the leads, current leakage around the sample, transfer impedances between the sample and the electrodes and contact polarization (Olhoeft 1975). We minimized coupling between the leads by using shielded wires. Calibration using known resistors showed that coupling and resistance in the leads had a negligible effect on our measurements. Current leakage was minimized by jacketing the samples tightly in shrink tubing before conducting measurements. We minimized transfer impedance between the electrode and the sample by spring loading the electrodes and using a conducting brine as an interstitial fluid. Polarization processes at the electrodes can also cause errors in two-electrode measurements, particularly if the sample is highly resistive or the measurement frequency is high. These effects may cause the small-frequency dependence above 1 kHz in the high resistivity curves in Figures 1 and 2. However we always used 200-Hz measurements when comparing resistivities because, at these frequencies, the

FIGURE 1 Resistivity as a function of temperature and frequency for a Berea core saturated with 0.5 N NaCl THF solution.

FIGURE 2 Resistivity as a function of frequency and salinity at -24°C .

resistivities were frequency independent. Rust (1952) compared resistivity measurements on porous sedimentary rocks using both two- and four-electrode (which avoid most of the experimental problems described above) techniques. He concluded that, as long as the sample is saturated with a conductive fluid, either method gives an accurate measure of the complex resistivity.

Sonic measurements were conducted using the pulse transmission described by Mattaboni and Schreiber (1967). We used Valpey Fisher LTZ-5 quartz 1-MHz piezoelectric transducers that were attached to the sample by a spring-loading device. All measurements (both sonic and electric) were conducted at atmospheric pressure, except for a small axial load, >0.1 MPa, which was applied to ensure that the electrode or transducer remained in contact with the sample. Olhoeft (1977) found the electrical properties of permafrost to be strongly pressure dependent from 10 Hz to 10 kHz. Thus, care must be taken when using our results to interpret geophysical surveys over natural hydrate deposits because the *in situ* pressure will always be much greater than atmospheric pressure.

ELECTRICAL RESULTS

As shown in Figures 1 and 2, the resistivities of Berea cores containing THF hydrates are functions of both temperature and salinity at which the measurements were made. However, to 30 kHz, the resistivities are nearly independent of frequency. Figures 1 and 2 plot the complex resistivity, but because the imaginary component of the resistivity was always very small, usually less than 10% of the real component, the real and complex resistivities are nearly equal. As a result, loss tangents are very high, often in excess of 100. Both the real relative permittivity and the imaginary part which is proportional to the dielectric loss are linear functions of frequency. The log linear relationship between the dielectric loss and frequency (Figure 3) is particularly important because the dielectric loss is a parameter that describes the motion of electric charge. If the material displays

conduction that arises not from the effect of polarization on the displacement current but from actual charge transport, Hasted (1974) shows that

$$\epsilon = \epsilon_{\text{dielectric}} + \frac{\sigma}{4\pi\omega\epsilon_0} \quad (4)$$

Here $\epsilon_{\text{dielectric}}$ is the component of the dielectric loss associated with loss from polarization currents. With a dielectric loss mechanism such as that from water molecules and in the absence of conductors, will normally show a strong peak when plotted vs. frequency. However, if conduction dominates the polarization effects, ϵ will be inversely proportional to frequency. Thus, the slope of the line from Figure 3, which is (0.994) calculated using least square regression techniques, implies that conduction is much more important than polarization effects in determining the electrical properties of hydrate-containing Berea sandstone cores.

FIGURE 3 Imaginary part of the relative permittivity $\times 10^{-4}$ vs. frequency for a Berea core saturated with a 0.5 N NaCl THF solution at -24°C .

The effect of temperature and salinity on the resistivities of the Berea cores also suggests that the electric currents flow because of ionic conduction in an unfrozen brine phase, which is present in the rock even after hydrates start to form. The exponential increase in resistivity with temperature occurs because lowered temperatures cause the proportion of hydrates in the pores to increase, further constricting the brine phase. The decrease in resistivity as the salinity increases (shown in Figure 2) is caused by an increase in the ionic concentration of the brine phase. The additional ions present probably also inhibit the formation of hydrates increasing the amount of brine present in the pores.

The electrical properties of hydrate-containing sediments can be quantitatively understood using Archie's law ($\rho = a\rho_w\phi^{-m}S_w^{-n}$), an empirical

relationship between water content and the resistivity of water-saturated sediments. Here ρ is the resistivity of the sediments, ρ_w is the pore water resistivity, S_w is the fraction of the porosity occupied by liquid water, and a , m , and n are empirically derived parameters. This equation also applies to rocks where the pore spaces are partially filled with ice or hydrates. However, as the amount of liquid water decreases, S_w and ρ_w are both reduced, S_w because some of the available pore space is now filled with a solid nonconductor, and ρ_w because the dissolved salts are concentrated in the remaining unfrozen brine. If the brine is not very near saturation, the effect on hydrate or ice formation of ρ_w is relatively easy to quantify because an increase in salt concentration causes a linear decrease in ρ_w . Because hydrates of ice exclude all of the dissolved salts as they form, the salt concentration of the brine inclusions is inversely proportional to the volume fraction of liquid water, if we assume that the sediments were initially water saturated. In addition, the resistivity of aqueous solutions increases exponentially with decreasing temperatures. Including both the temperature and concentration effects, the resistivity of a partially frozen brine at temperature T is thus proportional to $(C)^T S_w$, where C is a constant. Substituting this relationship into Archie's equation and dividing by the resistivity at 0°C , we find that the ratio of frozen (ρ_f) and thawed (ρ_t) resistivities is

$$\rho_f / \rho_t = C^{-T} S_w^{1-n} \quad (5)$$

Archie's law accounts for the rapid decrease in resistivity as a function of temperature (see Figure 4). Because N is usually equal to 2, the

resistivity is inversely proportional to S_w . As the temperature decreases, the concentration of the brine at equilibrium with hydrates increases, causing S_w to decrease and the resistivity to increase. Increasing the molarity of the salt solution causes the resistivity to decrease because the increased salinity of the pore water inhibits the formation of hydrates, which increases the amount of unfrozen water (S_w) present.

In order to compare the electrical properties of partially frozen sediments with the measurements on hydrate containing sediments described above, we performed a series of electrical measurements on a Berea sandstone sample saturated with an 0.5 N NaCl solution. Because this sample did not contain any THF, ice rather than hydrates formed when the temperature of the sample was reduced below freezing. As was the case with hydrates, the complex resistivities were frequency independent and a linear relationship existed between $\log(E)$ and \log frequency. The relationship between hydrate and ice containing samples is shown in Figure 4. Note that the curves are similar in that both curves show an exponential decrease in resistivity with temperature. The quantitative difference between the curves is probably caused by differing amounts of crystalline hydrates and ice in the pore spaces. Such differences are not unexpected because ice and THF hydrates have different stability curves and dissociation temperatures. The resistivity of ice reaches a nearly constant value at -4°C , the freezing point of a 0.5 N NaCl solution, whereas the THF-containing sample does not reach plateau until $+2^\circ\text{C}$, presumably the dissociation temperature of THF hydrates in a 0.5 N NaCl solution.

SEISMIC RESULTS

Sonic P-wave velocities, measured on hydrate-containing Berea sandstone cores as a function of temperature, are shown in Figure 5. This figure

FIGURE 4 Resistivity as a function of temperature for two Berea sandstone samples, one saturated with 0.5 N NaCl THF solution and one saturated with a 0.5 N NaCl solution without THF.

FIGURE 5 Sonic velocities vs. temperature for two Berea cores showing the effect of salinity.

shows results from cores saturated with two different NaCl solutions. Note that in both cases the sonic velocities increase from 2.5 to 4.5 km/s when hydrates begin to form in the pore spaces. Once hydrates form, the velocities reach a plateau where further cooling produces very little change.

As shown in Figure 5 the salinity of the saturating liquid has very little effect on the sonic velocities once hydrates have formed in the cores. However cores saturated with saline water and THF approach the high-velocity plateau more gradually than do samples saturated with pure water and THF. Thus the behavior of sonic velocities as a function of temperature contrasts with the electrical resistivity measurements in that electrical resistivities decrease rapidly as a function of temperature even after the pore spaces of the sample are probably nearly full of hydrates, while sonic velocities rapidly increase when hydrates start to form in the pore spaces. Then the velocities reach a plateau where further cooling produces very little change in sonic velocities. The difference in the temperature dependence of sonic velocities and resistivities illustrates a fundamental difference in the mechanism by which electrical and acoustic signals are transmitted in rock. Electrical signs are transmitted through the brine phase so electrical properties remain sensitive to the amount of brine present, even when the fraction of the pore volume containing brine becomes very small. In contrast, acoustic pulses are transmitted primarily through the solid matrix, so once the pore volume is largely filled with hydrates, a further decrease in the small brine fraction produces only a negligible change in velocity. However the slower asymptotic approach in the brine-rich sample suggests that amount of fluid in the unfrozen brine phase does have some effect on velocity when the brine phase consists of a relatively large amount of fluid.

The compressional velocity of hydrates forming in a sediment can probably be understood using a three-phase time-averaged equation, first proposed by Timur (1968) for partially frozen sediments and since tested by several other authors. The compressional velocity (V_p) is related to the velocity of ice (V_s), the velocity of the brine inclusions (V_b), and the velocity of the solid matrix (V_m) by

$$1/V_p = \frac{\phi(S_w)}{V_b} + \frac{\phi(1-S_w)}{V_s} + \frac{(1-\phi)}{V_m} \quad (6)$$

Because of the similarities between the seismic velocities of ice and hydrates, this equation can probably be used to calculate the velocity of a mixture of hydrates and brine in sedimentary rock. Note that Equation 6 depends linearly on S_w , in contrast to Equation 5 which, if $n = 2$, is inversely proportional. The difference in electrical and sonic properties as a function of temperature can be explained by the difference in the dependence of Equations 5 and 6 on S_w . The electrical properties are inversely proportional to S_w so the electrical resistivity remains sensitive to changes in S_w even when very little unfrozen water remains in the rock. In contrast,

in Equation 6 S_w enters directly as a term added to other quantities. Thus as S_w becomes small it has a negligible effect on the seismic velocity.

We performed no sonic measurements on Berea samples that did not contain a THF hydrate mixture so we could not compare the effect of THF hydrates and ice on the sonic velocities. However because our measurements are very similar to results published by Pandt and King (1979) for partially frozen sediments, we expect ice and hydrates to have nearly the same effect on the sonic velocities.

CONCLUSIONS

Several significant conclusions can be drawn from this study: (1) the resistivities and sonic velocities of Berea sandstone cores are strongly affected by the presence of either ice or hydrates. Resistivities increased by an order of magnitude and continued to increase rapidly as further decreases in temperature reduced the amount of unfrozen brine present in the rock. The sonic velocities, in contrast, rapidly increased when hydrates began to form in the cores but soon approached a limiting value. Further cooling produced only a very small increase in sonic velocities. (2) Ice and hydrates produce very similar changes in the sonic and electrical properties of Berea sandstone. Any differences can probably be ascribed to differing amounts of unfrozen brine present in the pores. This suggests that it may be difficult to distinguish permafrost and hydrate-containing layers using ordinary geophysical techniques. (3) The salinity of the pore water in which the hydrates form has a strong effect on the resistivities but a very small effect on the sonic velocities. We suggest that the effect of temperature and salinity on resistivities and sonic velocities can be explained if the samples obey Archie's law for resistivities and the three-phase rule for velocities. (4) Resistivities of hydrate containing cores are nearly frequency independent in the range from 10 Hz to 30 kHz. However, both the dielectric constant and the dielectric loss decrease rapidly as a function of frequency. The log linear relationship between frequency and dielectric loss suggests that the electrical properties of the hydrate containing samples are controlled by ionic conduction in a frozen brine phase.

Our experimental results show that the presence of hydrates has a strong effect on the acoustic and electric properties of sediments compared to unfrozen or unhydrated sediments. An increase of several orders of magnitude in electrical resistivities can easily be detected using a variety of electrical exploration techniques. Also an 80% increase in sonic velocity is sufficient to produce a very strong reflection in seismic reflection data and can easily be detected in seismic refraction surveys. This very strong velocity contrast may account for strong reflections that are often observed at the bottom of possible hydrate bearing horizons in marine seismic surveys (Shipley et al. 1979).

ADFREEZING STRESSES ON STEEL PIPE PILES, THOMPSON, MANITOBA

E. Penner and L. E. Goodrich

Geotechnical Section, Division of Building Research
National Research Council of Canada, Ottawa, Ontario, K1A 0R6

Studies of uplift forces on steel pipe piles in frost-susceptible varved clays were carried out near Thompson, Manitoba, over three consecutive winters. The installation consisted of pipe piles, 169, 323 and 458 mm in diameter and 3.3 m long. Each pile size was replicated three times on the same site, and all piles had separate reaction frames anchored to bedrock. For the first winter, when the thick gravel layer that was placed over the site was allowed to freeze to the piles, high uplift forces were measured. The pile was isolated from the gravel in the two subsequent winters and the adfreeze values corresponded more closely to those determined previously.

Adfreezing of frost-susceptible soil to foundations and subsequent uplift is an important engineering problem. Special precautions are required for structures that must function in this environment, to avoid destructive displacement forces. The question that arises in the consideration of various design possibilities is the magnitude of the force generated and how it varies with soil type, soil moisture content, climate and foundation material. Crory and Reed (1965) and Vialov (1959) have shown the importance of such uplift forces and that they can be substantial in the active layer of permanently frozen ground. Earlier adfreezing studies in seasonal frost areas were described by Trow (1955), Kinoshita and Ono (1963), Penner and Irwin (1969), Penner and Gold (1971), and Penner (1974). The work of Penner, and Penner et al, involved field measurements on piles of wood, concrete, and steel pipe of various diameters from 7.6 to 30.5 cm.

Displacement of foundations in frost-susceptible soils may occur because the wet soil freezes to the foundation during frost penetration. The formation of ice lenses, the main cause of frost heaving, may lift structures unless special precautions are taken. Preventative measures may simply involve replacing the frost-susceptible soil, preventing freezing by insulating, special heating techniques, isolating the structure from the heaving soil or controlling the water supply. Loading of the structure is rarely used in practice.

The technique commonly used in the measurement of adfreeze forces is to place a force gauge between a suitable reaction frame and the structure, e.g., foundation walls or piles. Normally, characteristic surface displacements develop in the surrounding soil (Penner and Gold 1971).

Primary heaving forces always develop in the same direction as the heat flow, normal to the direction of ice lens growth. Complex thermal patterns sometimes develop due to differences in the thermal properties of the structure and the soil. For example, a steel pile often projects above the ground surface. In areas of seasonal frost, the depth of freezing is greatest at the pile. This pattern is enhanced further when snow accumulates on

the site and the pile projects above the insulating snow layer.

A field study was undertaken in 1971 at Thompson, Manitoba, where a Division of Building Research (DBR) field station is located, to extend investigations carried out at Ottawa on the performance and behaviour of various foundation structures. The initial objective of this study was to measure uplift forces on steel piles.

SITE SELECTION AND PREPARATION

The main site requirements were easy accessibility, a nearby power line, shallow bedrock for anchorage of the steel reaction frames, and surface soil characteristics common to the region. Islands of permafrost occur at Thompson, so a site was chosen where no permafrost was present.

The test site was about 3.2 km south of the town. Site preparation consisted of removing the trees and placing a layer of gravel over the ground surface to provide good trafficability for construction equipment with a minimum of soil disturbance. A thin layer of asphaltic concrete was placed over the gravel to improve local working conditions during pile and rock anchor installations. A schematic diagram of the site with installations in place is shown in Figure 1.

Following the development of unusually high forces during the first winter's operations, the gravel layer on the ground surface was isolated from the pile with a metal shield. A layer of grease was placed between the pile and the metal shield to reduce friction and the possibility of adfreezing. The influence and importance of this design change in the profile next to the pile cannot be overemphasized. The experience might well serve as a caution wherever piles are used in cold climates. The effect on the force measurements and adfreeze stresses will be included in the section on results and discussion.

INSTALLATION OF STEEL PIPE PILES AND ROCK ANCHORS FOR REACTION FRAMES AND BENCHMARKS

The surface of the piles was sandblasted to remove the anticorrosion treatment. Piles were stored outside for several months to allow surface rust to form. The ends of the piles were capped with steel plates, 2.54 cm thick on top and 1.25 cm on the bottom. All nine piles, three of each diameter, 169, 323 and 458 mm, were prepared this way. These piles were nominally 6, 12 and 18 in. in diameter and are referred to as S6A, S12A, and S18A, respectively. Copper-constantan thermocouples were placed at 0.3 m intervals on the surface of one pile of each diameter for temperature measurement. Lead wires were placed in a 1.9 cm diameter conduit welded along the length of the pile. To reduce thermal conduction errors along the leads on temperature measurements, the thermocouple wires and tip were embedded with epoxy resin in a 15 cm long horizontal groove around the circumference of the pile at each measurement location. This procedure also ensured good thermal contact between pile and thermocouple.

The piles were randomly located on the site in machine-augered holes 15 cm larger than the pile diameter. Backfilling was done immediately with the augered soil to avoid large moisture changes. The surface gravel layer was replaced to conform with the rest of site, for the first year only.

The steel reaction frame consisted of two steel beams (S150 x 19) 0.91 m long, crossed at 90°, and tied down at the four ends with 1.9 cm diameter high-strength steel anchor rods. Stelco expansion shells (3.2 cm "S" type) were placed at a depth of 0.46 m into bedrock (Figure 2). The strength of each anchor and rod assembly was tested by applying a tensile load of 0.1 MN. Two benchmarks, BM 1 and BM 2 (Figure 1), were installed in bedrock in the same way.

Thermocouple cables were placed to a depth of 3 m in augered vertical holes at various distances (0.15, 0.30, 0.61, 1.22, and 3 m) from the three temperature-instrumented piles. Fine-grained dry mine slag was used for backfilling around the cables.

Snow was allowed to accumulate on the site during the winter. Lightweight elevated wooden catwalks were built along the main row of ground survey stakes, to the nearby benchmark, and to the instrumented weather centre, to avoid snow disturbance by the survey crew. A photograph of a portion of the site is shown in Figure 3.

Other Instrumentation

Dillon force gauges, placed between reaction frame and pile, were used to measure uplift forces. The gauge capacity selected was based on the Ottawa experience, with suitable provisions for the higher forces expected. During the first winter the reaction frames had to be adjusted at critical times, to reduce the forces and avoid damaging the gauges by exceeding their rated capacity; hence the maximum uplift forces were not measured. For the second and third winters (1973/1974 and 1974/1975), vibrating wire force gauges capable of measuring a force of 0.44 MN were installed. The new gauge could be read remotely in addition to having a high capacity. As

will be discussed later, the layer of gravel placed over the site was thought to be the main cause of the very high forces measured in the first year, so gravel and pile were isolated for the second and third winters.

Observations

Ground temperatures were recorded at least once a day using a multipoint L & N recorder for the main points; others were recorded by hand. The overall accuracy of the temperature measurements, including installation errors, was believed to be within $\pm \frac{1}{4}^{\circ}\text{C}$. All force gauges were calibrated and checked before installation and read daily. Level surveys were done weekly or bimonthly for the center of the reaction frame, the piles and surface gauges. Air temperatures were measured with a thermocouple inside a Stevenson screen at the site. Temperatures from maximum/minimum thermometers were used to determine the freezing index. Snow depths were measured daily at two locations, using permanently placed snow stakes.

SOIL, CLIMATE, AND PERMAFROST CONDITIONS

The town of Thompson (55°45'N, 97°50'W), a recently developed industrial settlement, lies within the discontinuous permafrost zone (Johnston et al 1963). Although the site did not contain any permafrost, there were patches of it within a few hundred metres. The mean annual air temperature at Thompson, based on very limited data, is about -3.9°C . This value is consistent with that determined for nearby settlements from 7 years of observations. The mean annual precipitation, based on measurements made between 1968 and 1972, was 44.6 cm of water, 33 cm as rain, and 116 cm of snow.

The Thompson area was extensively glaciated during the Pleistocene epoch. Varved clays and glacial tills constitute the surficial deposits throughout this region. At the test site the overburden ranges in thickness from 3.7 m in the NW corner to 6.1 m in the SW corner. It consists of varved clays with the exception of a thin layer of pebbly sandy silt overlying the bedrock. There was a thin layer of peat at the SE corner, through which one pile passed (Figure 1, S6A).

The clay size content determined on augered samples was about 50%, with most of the remaining coarser materials passing the 200 sieve. Moisture contents ranged from 20 to 30% by weight. The grain size at the site falls within the grain size envelope for the Thompson soil (Johnston et al 1963).

RESULTS AND DISCUSSION

Figure 4 shows the 1972/1973 and 1973/1974 maximum heave along a NS line through the temperature-instrumented piles, S6A, S12A, and S18A. The maximum frost penetration in the vicinity of the piles is also shown. This figure illustrates the contrasting results, to which special attention is directed.

The cause for the high adfreeze results was the adfreezing of the gravel layer during the first winter, 1972/1973. The large vertical displacements

LAWS GOVERNING INTERACTIONS BETWEEN RAILROAD ROADBEDS AND PERMAFROST

N. A. Peretrukhin¹ and T. V. Potatueva²

¹Institute of Transport Construction, Moscow, USSR

²Institute of Civil Engineering, Tomsk, USSR

In southern areas of permafrost occurrence interactions between railroad roadbeds and permafrost are characterized by changes through time both in the intensity of the thawing of permafrost and settlement of the grade as deformation of the foundation materials occurs. These interactions may be divided provisionally into three periods: those of intense deformation, moderate deformation, and complete stabilization. The first period is characterized by an irregular regime of thawing and settlement of the foundation materials. Initially thawing and settlement are very intense but towards the end of the period this intensity declines markedly. The beginning of the period coincides with that of construction and it ends 1-2 years after completion of the grade. These trends are dictated by the changes in the natural permafrost conditions provoked by construction of the roadbed. The second period is characterized by a relatively low intensity of thawing and settlement which tends to die away with time. The duration of this period is dictated by the degree of disturbance of the natural local conditions and the deformability of the thawing permafrost materials under the influence of the completed grade. The third period is characterized by complete stabilization of the roadbed which corresponds to the needs of normal operation of the line. Depths of thaw and amounts of settlement display no linear correlation. The thaw depth depends on the degree of disturbance of the natural thermal regime, and on hydrological, permafrost, and other natural conditions, whereas total settlement depends on the composition and ice content of the thawing permafrost and also on the compressibility of the permafrost materials under a given operating load.

INTRODUCTION

In past years, construction of railway roadbeds in southern areas of permafrost required relatively complicated engineering decisions, such as removal of soft active layer soils and permafrost to depths of 3 m under the embankment and backfilling the excavation with granular material; increasing the embankment width to account for settlements caused by thawing of the underlying permafrost, and also the construction of berms. These measures are taken to prevent or control the large, differential settlements and other embankment deformations that occur, and result in an increase of 30-100% in the volume of earth work and a complicated and labor-intensive construction operation. Experience has shown, however, that such measures do not result in a stabilized roadbed, and, even when some permafrost has been excavated, the roadbed experiences long-term, large and irregular settlements. It is very difficult to control both permafrost thawing and roadbed settlement. Field experiments were carried out, therefore, to study the mechanisms of roadbed-permafrost interaction, to observe the effectiveness and anti-deformation measures, and to accumulate data characterizing roadbed stability of typical sections (Peretrukhin 1978).

RESEARCH METHOD

Values of the active layer in natural conditions,

the depth to the permafrost table under the embankment, roadbed settlements caused by compression of soft active layer soils and thawing permafrost are the main quantitative indices of roadbed-permafrost interaction. These indices are generalized parameters of the process considered. They indicate the overall effect of a great number of variable natural factors (climatic, geomorphological, hydrogeological etc.) on the thermal regime and the condition and properties of the perennially frozen ground, as well as changes in them resulting from roadbed construction. At the same time, these indices characterize the thermal and mechanical interaction of embankments and perennially frozen ground during the construction and operating periods, as well as the consequences of such interaction—the permafrost thaws and embankment settlements occur.

The field research included a detailed study of the natural frozen soil and engineering-geological conditions at typical locations and embankment sections, as well as changes that occurred prior to, during, and following construction of the railway. The engineering-geological work and geocryological survey were conducted using standard methods. In doing so, values of the generalized indices that characterize the roadbed-permafrost interaction were measured. Investigations were conducted at five locations on a railway being constructed in the southern part of the permafrost region.

NATURAL CONDITIONS AND DESIGN DECISIONS

Permafrost occurs in scattered patches along the route. It was found on north-facing shady slopes and in river valleys and dells where the ground was covered by moss and vegetation. The active layer thickness is as much as 0.4-1.2 m in undisturbed areas. The roadbed design was chosen, taking into consideration the operating experience of railways constructed in regions having similar natural conditions. In doing so, it was assumed that all permafrost would thaw and that long-term and irregular roadbed settlements would occur. The total settlement was calculated taking into account the permafrost ice content. The embankment width was increased and berms were constructed on both sides of the embankment as anti-deformation measures (Table 1). In addition, at test section 4 the soft foundation soil (a loam of medium plasticity) was excavated to a depth of 0.5-0.8 m and replaced by gravel.

TABLE 1

Section Number	Length (m)	Embankment (m)		Berms (m)		Earth work time
		Height	Increase in width	Height	Width	
1	260	2.0	0.7-1.5	-	-	Winter
2	290	1.8-4.0	-	1.5-3.6	3.0-5.0	Winter & summer
3	150	2.0-1.5	2.0	-	-	Summer
4	123	14.0	2.0	5.0	10.0	Summer
5	50	6.0	5.6	2.0	6.0	Winter

The embankments were to be constructed of fine to medium sands (sections 1-3) and gravels (sections 4 and 5). The upper part of the embankment was constructed of clayey loam with gravelly inclusions (sections 1-3) and of clayey loams with stones and cobbles (sections 4 and 5).

RESEARCH RESULTS

Natural frozen soil conditions began to change during the preconstruction works period. The active layer thickness increased by 2.2-2.7 times compared to that in undisturbed areas and reached 1.2-1.4 m in sections 1, 2 and 3, and 1.0-1.2 m in section 5. During and after construction of the embankment the depth to the permafrost table under the embankment continued to increase at all sections following a definite pattern: the rate and depth of permafrost thaw attenuated with time (Figure 1).

During the first two years of railway operation the rate of permafrost thaw under the embankment centerline was 0.4-0.5 m/yr at sections 1 and 2, constructed in winter, and to 0.8 m/yr in sections 4 and 5, constructed in summer. During the next two years the thaw rate decreased almost by half. In the 4th year following construction the depth to the permafrost table exceeded 3 m and by the 12th year it was almost 5 m (Figure 1, curve 1).

The permafrost thawed completely in places where the permafrost thickness was less than 5 m

before the preconstruction period. In places where the permafrost thickness exceeded 5 m, the depth of thaw was somewhat greater than 5 m. The calculated settlement differed from that actually measured by not more than 10% (Table 2). During the first 3 years the embankment settled 0.10 m and in the next 8 years it settled very little (Figure 1, curve 4). At section 4 the permafrost thawed more rapidly (Figure 1, curve 2). This was due to the comparatively higher temperature of the permafrost as well as the warming influence of water that filled a trench excavated in order to replace the soft foundation soils under the embankment. Water filled the trench during the summer construction period. In the first year the permafrost thawed to a depth of 0.7 m under the embankment centerline and to 2.4 m under a berm on the west side. Three years after the embankment was built the permafrost table was at a depth of 4 m below the embankment centerline, at a depth of 5 m under

a berm on the east side. During the following 8-9 years the depth of thaw exceeded 11 m (Figure 1, curve 2).

The considerable difference between calculated and actual values of the permafrost thaw depth at this section (Table 2) can be explained as follows: the effect of both time (summer) and method of construction, and also of the warming influence of water in the trench, were not taken into account in the calculations. In spite of the rapid, irregular and deep permafrost thaw, the actual embankment settlement proved to be negligible (0.05 m). It occurred only in the first few years after construction of the embankment when compressible soils were thawing. The underlying frozen soils, including shales, did not deform when thawing. As a result, during the 12 years of railway operation, the actual dimension of the roadbed and the ballast layer did not change significantly from that measured before the railway was put into regular operation.

At section 5 the change in depth to the permafrost table followed a regular pattern from the time construction started (Figure 1, curve 3). The rate of thaw in the first two years was greater compared to that in the following years and the thaw rate under the roadbed centerline was approximately half that occurring under berms and embankment slopes. By the end of the 3rd year the permafrost table was at a depth of about 1.2 m under the centerline and 1.6-2.8 m under berms. In this period the embankment settlement due to thaw

TABLE 2

Section number	Permafrost		Depth to permafrost table in 12th year (m)			Embankment settlement by 12th year (m)		
	Thickness (m)	Temperature (°C)	Calculated		Actual	Calculated		Actual
			In design	More precise		In design	More precise	
1	3-10	0.02	complete thaw	-	-	to 1.0	0.4	0.15
2	3-10	1.4	"	5.0	5.0-5.5	1.06	0.4	0.15
3	3-10	1.4	"	5.0	5.0-5.5	0.67	0.4	0.16
4	>9	0.13	"	5.0	to 11.5	0.55	0.15	0.05

Note: More precise calculated values of the depth of thaw and settlements were determined using methods specified by the authors (1974).

consolidations of both active layer and permafrost soils about 0.55 m under the centerline (Figure 1, curve 6) and 0.35-0.70 m under berms. After 10 years of railway operation the permafrost table under the embankment centerline was just below the original moss cover. The latter appeared to have settled to a depth of 1.75 m below the original ground surface. In this case, the more precise calculated value of the depth of thaw under the embankment did not differ significantly from that actually observed.

The curve showing the rate of thaw at section 5 indicates that thawing ceased under the embankment (Figure 1, curve 3). At the same time, the high rate of embankment settlement at this section, compared to that occurring at the other sections, is worth noting (Figure 1, curve 6). Moreover, settlement was observed not only in the first two years, when the frozen active layer soils thawed, but also in the following 8 years, when thawing of permafrost had ceased. This was due to compression of the permafrost soils, which originally were in a plastic-frozen state at a temperature of -0.3°C . The actual total settlement of the roadbed at this section was about 2.5 times less than the design value and about 12% less than the more precise value calculated using methods specified by the authors (1974).

The research showed that properties of the foundation soils change significantly as settlement occurs. During 11 years of observation the moisture content of the thawed permafrost under the embankment at sections 1-3 decreased by 5% with a corresponding increase in density. At section 5 the moisture content of the foundation soils decreased by as much as 50% and the density increased 1.3-1.8 times. Present calculation methods do not take these changes into account.

Analysis of the research results shows that permafrost thaw and embankment settlement follow a predictable pattern. The permafrost thaws more rapidly during construction and in the first 1-2 years thereafter. Under certain conditions it decreases by approximately 70-80% in the first 2-3 years and by 20-30% in the following 8-10 years. This pattern is not followed, however, in cases where the moss-vegetative cover is disturbed or removed and especially when soft formulation soils

are excavated and replaced under an embankment. The length of the thaw period under such conditions is dependent on the permafrost thickness and temperature, the embankment height and structure and also on the local frozen soil, hydrological and hydrogeological conditions and changes that occur in them prior to and during construction. Embankment settlements may cease long before thawing of permafrost ends, if compressibility of the thawing soil appears to be insignificant. At the same time, settlements of high embankments are possible due to compression of plastic perennially frozen soils, thawing of which has practically ceased.

Differences between actual and calculated settlement values were observed at all sections. These were due partly to the incorrect design assumption that, regardless of its thickness, all permafrost would thaw under railway embankments in areas where high-temperature permafrost occurred in scattered islands. The lack of good data on the ice content and compressibility of the perennially frozen foundation soils also introduced errors in the calculations. The roadbed at all test sections, as well as at other embankment sections constructed on permafrost along this railway route, was as stable as necessary. Most settlements occurring in the construction period were compensated for before putting the railway into regular operation. The small settlements that occurred later were corrected by placing more ballast during maintenance operations.

One factor that deserves special mention is that the effectiveness of berms on improving both the stability and condition of embankments was not determined even though the warming effect on foundation soils was ascertained sufficiently well under all conditions considered. Thus, increasing the embankment width and construction of berms can be considered as expedient anti-deformation measures. However, the increased width at all test sections appeared to be excessive and the use of berms on both sides of the embankment at section 2 was not well founded. Increasing the roadbed width based on calculated settlement values would be more expedient for this section.

CONCLUSION

The results of the field research described in this paper were used in the design of embankments for another railway situated in similar natural conditions. In that case, excavation of peat at "mari" (bogs) was not undertaken when embankments were greater than 3 m thick and the width of embankments and berms were prescribed taking into consideration the condition and properties of perennially frozen soils. The roadbed at such sections remained sufficiently stable and ensured railway traffic could proceed at established speeds.

APPLICATIONS OF THE FAST FOURIER
TRANSFORM TO COLD REGIONS ENGINEERING

W. F. Phillips

Utah State University, Logan, Utah 84322 USA

The utility of using the fast Fourier transform as a means of consolidating climatic data into a form useful for cold regions engineering design is presented and discussed in this paper. It is shown that a 20-year data set consisting of 175,320 hourly values of a climatic variable can be represented by only 118 Fourier coefficients with little loss of information content. Complete consolidated climatic data sets are presented for Barrow and Fairbanks, Alaska. In addition, some other applications of the Fourier transform to the field of cold regions engineering are discussed and specific examples are presented.

INTRODUCTION

Construction and maintenance of structures in the arctic and subarctic regions are characterized by a wide range of problems in addition to those experienced elsewhere. Most of these problems are directly related to some type of thermal interaction between the structure, the environment, and the underlying permafrost. An engineer must be able to predict such thermal interactions in order to design structures which perform satisfactorily in such an environment. Because the performance of such structures is coupled so closely to climatic conditions, the design engineer often needs data which describe how the ambient temperature and solar radiation vary with time at the design location. Such data are available for several Alaska locations through the National Climatic Center (1978, 1979).

Because of the variable nature of climatic conditions, a very large volume of data is needed to adequately describe these climatic variables. For example, 8,760 data points are needed to describe the hourly variations in temperature for 1 year at a single location. Furthermore, because climatic conditions change somewhat from year to year, 10 - 20 years' data are needed to obtain meaningful statistics. Thus, something on the order of 100,000 data points are needed to describe a single climatic variable at a single location. However, a data set of this volume has only very limited usefulness in routine engineering design.

There is a need for some means by which climatic data sets can be consolidated into a more manageable form. The consolidated data must retain all the information required for design and yet it should be compact enough to be handled with small desk top computers. It is the purpose of the present paper to show that the fast Fourier transform can be used to achieve such a consolidation.

The Fourier transform has long been a principal tool in many diverse fields of science, and with the development of the modern fast Fourier transform, many facets of scientific analysis have been completely revolutionized. The Fourier transform

identifies or distinguishes the amplitude and phase of the different frequency sinusoids which combine to form an arbitrary function of time. Mathematically, this relationship is stated as

$$F(v) = \int_{-\infty}^{\infty} f(t) \exp(-i2\pi vt) dt, \quad (1)$$

where f is the function of time, t ; $i = \sqrt{-1}$; and F is the Fourier transform expressed as a function of frequency, v . The function of time can likewise be expressed in terms of its Fourier transform

$$f(t) = \int_{-\infty}^{\infty} F(v) \exp(i2\pi vt) dv. \quad (2)$$

If $f(t)$ is a periodic, band-limited function of time, sampled $2N$ times over some integer multiple of the fundamental period with a sampling frequency that is more than 2 times the largest frequency component of $f(t)$, then the Fourier transform becomes a set of $2N$ Fourier coefficients which can be calculated from the $2N$ sampled values of $f(t)$:

$$F_n = \frac{1}{2N} \sum_{k=0}^{2N-1} f(kt_s) \exp(-i\pi nk/N); \begin{cases} n = 0, 1, \dots, 2N-1 \\ k = 0, 1, \dots, 2N-1 \end{cases}$$

where t_s is the sample interval. The function $f(t)$ is expressed in terms of these Fourier coefficients as

$$f(t) = \sum_{n=0}^{2N-1} F_n \exp(i\pi nt/Nt_s); \quad n = 0, 1, \dots, 2N-1$$

Also, in view of the facts that $\exp[i\pi(2N-n)k/N] = \exp(-i\pi nk/N)$ and the Nyquist component, F_N , is zero for the class of functions described above, equation (4) may be rewritten as

$$f(t) = \sum_{n=-N+1}^{N-1} F_n \exp(i\pi nt/Nt_s), \quad (5)$$

where,

$$F_{-n} = F_{2N-n}; \quad n = 1, 2, \dots, N-1 \quad (6)$$

FIGURE 1 Fourier transform of solar flux data for Fairbanks, Alaska.

FIGURE 2 Fourier transform of ambient temperature data for Fairbanks, Alaska.

Furthermore, if $f(t)$ is a real valued function, then F_{-n} is the complex conjugate of F_n and $f(t)$ may be equivalently written as

$$f(t) = \sum_{n=0}^{N-1} [A_n \cos(\pi n t / N t_s) + B_n \sin(\pi n t / N t_s)], \quad (7)$$

where A_n is twice the real part of F_n and B_n is the negative of twice the imaginary part of F_n , for n greater than zero, and A_0 is the real part F_0 .

For a detailed discussion of Fourier transforms, discrete Fourier transforms and fast Fourier transforms, see Brigham (1974).

Meteorologists and climatologists have used the Fourier transform as an analytical tool for many years. The hope of finding some predictable element in the year-to-year variations of climate has long inspired the search for dependable periodicities in climatic data. Harmonic analysis has been a standard tool in this search.

The usual procedure has been to remove the annual and diurnal variations from a data set through averaging or some other filtering process. Fourier analysis is then used to identify any low frequency oscillations which may still be present in the data set. From analysis of this type almost every conceivable period from 1 to 36 years has been suggested by investigations of one observation series or another. For detailed bibliography and description of methodology see Panofsky and Brier (1958) and Lamb (1978).

More recently, spherical harmonic analysis has been used to identify two-dimensional spatial periodicities in global temperature and pressure fields (see Christidis and Spar 1981). Analysis of this type has aided in improvement of the sophisticated space-time models used for short term weather prediction.

In the present paper harmonic analysis is applied to climatic data with a different objective.

The Fourier transform is used here as a means of restructuring a climatic data set into a form that is more useful for engineering analysis and design.

FOURIER TRANSFORMS OF HOURLY DATA

To demonstrate the utility of transforming climatic data from the time domain to the frequency domain, transforms for two different Alaska stations will be presented. These two stations are Barrow and Fairbanks.

Fourier transforms were computed for both solar flux and ambient temperature using 20 years of hourly data for both of the above locations. These data were obtained on magnetic tape from the National Climatic Center (1978), Asheville, North Carolina. For each climatic variable at each location, 175,320 hourly readings for the period 1957 - 1976 were used to generate a Fourier transform. These Fourier transforms each contain 87,661 complex pairs, comprising the amplitude and phase information for the 87,661 different frequency sinusoids that combine to exactly form the original data set. It is interesting to note, however, that in each case, at most, 59 frequencies were found to have magnitudes detectable above a low noise level. Furthermore, it was always the same frequencies that were found to have significant magnitudes, independent of the climatic variable or the location for which the transform was computed. The magnitudes of the Fourier coefficients in equation (5), for the Fairbanks transforms, are plotted in Figures 1-2. Similar results were obtained for the Barrow transform.

Further examination reveals that each of the spikes shown in Figures 1-2 are actually formed by a set of closely spaced frequencies and not by a single frequency. The low frequency spike, that appears at zero cycles per day, may consist of up to five separate significant frequencies. These are the zero frequency and the fundamental annual frequency and its first three harmonics (0, ± 1 , ± 2 , ± 3 , ± 4 , cyc/yr). For example, Figure 3 shows the

FIGURE 3 The low frequency harmonics of the solar flux transform for Fairbanks, Alaska.

low frequency portion of the same transform plotted in Figure 1. The expanded scale of Figure 3 allows one to distinguish between the many different frequencies, that all appear as a single line in Figure 1. Notice that the transform has a significant component at the zero frequency. This is simply the average value of the climatic variable. There is also a significant component at the annual frequency ± 1 cyc/yr. It should be pointed out that a year is taken here to be a solar year, that is, 8,766 hours or 365.25 days. This annual component was found to have a period of exactly 8,766 hours. There is also a small, but definitely detectable, component at the first harmonic of the annual frequency ± 2 cyc/yr. In Figure 3 the higher order harmonics are not detectable, however, when the numerical values are examined, these harmonics are found to have magnitudes slightly above the noise level. All of the intermediate frequencies were found to have only very low noise level magnitudes. In Figure 3 the computer has plotted the magnitudes of 240 different frequencies; however, only those mentioned above appear significant.

When the low frequency portions of the other transforms are expanded, the results are very similar to Figure 3. In all cases the only significant frequencies were found to be 0, ± 1 , ± 2 , ± 3 , ± 4 , cyc/yr. The Fourier coefficients for these frequencies describe the annual periodic variations in the climatic data.

From Figures 1-2 it can be seen that the daily frequency and its first five harmonics (± 1 , ± 2 , ± 3 , ± 4 , ± 5 , ± 6 cyc/day) are also significant. This is to be expected, since the Fourier coefficients for these frequencies describe the daily variations in the climatic data. What might be less obvious is that there are eight other significant frequencies in the neighborhood of each of the daily harmonics. For example, that portion of the transform shown in Figure 1, consisting of the frequencies very near 1 cyc/day, is shown in Figure 4 on an expanded scale. Notice that the primary frequency occurs at 365.25 cyc/yr. The frequencies nearest to this fundamental harmonic, on either side, are found to have only a very low noise level magnitude, barely

FIGURE 4 The near-daily frequencies of the solar flux transform for Fairbanks, Alaska.

detectable in Figure 4. Then two more significant frequencies occur, one on each side of the primary frequency, at 364.25 and 366.25 cyc/yr. Then, at twice this spacing, two more frequencies with small but detectable magnitudes are observed. These frequencies, which flank the fundamental frequency at intervals of 1 cyc/yr, will be called "beat frequencies."

In a similar manner, each of the harmonics of the daily frequency is found to be flanked by four pairs of beat frequencies. The spacing between these frequencies is always exactly one cycle per solar year. Similar results are found for the other transforms. It is the daily harmonics and their associated beat frequencies that contain the information which describes the daily variations in the climatic data and how these daily variations change with the seasons of the year.

PREDICTABLE CLIMATIC VARIATIONS

It seems reasonable to assume that variations in a climatic variable at a particular location can be adequately described by the 175,320 hourly values which make up a 20-year data set. Such data sets contain two different types of variations. There are predictable variations, that result primarily from the motion of the earth relative to the sun, and there are random variations, resulting from random motions in the earth's atmosphere. All of the information about the predictable variations in a climatic data set is contained in the 59 complex pairs which are the Fourier coefficients for the 59 significant frequencies described above.

When these 59 sinusoids are recombined, one obtains the climatic variable as a function of time, excluding all of the random variations. Each of the component frequencies contributes to the temporal distribution in a way that can be related to physical observations. The role of the annual harmonics and the daily harmonics is rather straightforward. However, the importance of the beat frequencies, associated with the daily harmonics, may be less obvious.

FIGURE 5 The daily variations in Fairbanks solar flux as predicted from the Fourier transform excluding the noise frequencies.

To demonstrate the role which the beat frequencies play in the Fourier transform, consider a function of time, $f(t)$, formed by combining a primary sinusoid of amplitude A and frequency ω with two secondary sinusoids of amplitude B and frequencies $\omega-\delta$ and $\omega+\delta$, respectively,

$$f(t) = B \sin(\omega t - \delta t) + A \sin(\omega t) + B \sin(\omega t + \delta t) \quad (8)$$

Recalling that

$$\sin(\theta \pm \phi) = \sin\theta \cos\phi \pm \cos\theta \sin\phi, \quad (9)$$

equation (8) can be rewritten as

$$f(t) = [A + 2B \cos(\delta t)] \sin(\omega t). \quad (10)$$

Thus it is seen that the function described by equation (8) is an amplitude modulated sine wave. In a similar manner, each of the daily harmonics combines with the associated beat frequencies to form an amplitude modulated sinusoid.

Just as constant amplitude sinusoids can be combined to produce a repeating but nonsinusoidal wave form, these amplitude modulated sinusoids combine to produce daily variations which have a wave form that changes over the year. This can best be demonstrated by recombining the Fourier components shown in Figure 1. This result is shown in Figure 5.

It can be seen from Figure 5 that recombining these harmonics results in the prediction of small nighttime oscillations in the solar radiation, when the flux should remain constant at zero. These small inaccuracies result from the fact that the Fourier series was truncated to contain only five harmonics of the daily frequency.

NUMERICAL RESULTS

For future work it will be convenient to have each transform, expressed in a numerical form. One

has the option of expressing any Fourier series either in complex form or in sinusoidal form. Each form has certain advantages and one form can be easily computed from the other. Because many small computers and hand held calculators do not easily handle complex functions, the sinusoidal form will be presented here.

The Fourier transforms of the solar flux and ambient temperature data for Fairbanks and Barrow, Alaska are presented in Tables 1 and 2. Column one is the frequency in cycles/year; columns two and three give the cosine amplitude and the sine amplitude, respectively, for the corresponding frequency in the Fourier series representation of the solar flux data; and columns four and five give the same information for the ambient temperature data.

The average or most probable value of either solar flux or ambient temperature, at any time during the year, can easily be determined from the results given in Tables 1 and 2. Suppose, for example, that the average value of the solar flux in Fairbanks on a particular Julian day, D , at some solar time, t , is desired. This is computed from the equation,

$$q_s = \sum_{n=0}^{58} \{A_n \cos[2\pi\omega_n(D - 1 + t/24)/365.25] \quad (11)$$

$$+ B_n \sin[2\pi\omega_n(D - 1 + t/24)/365.25]\},$$

where ω_n , A_n , and B_n are taken from Table 1, columns 1, 2, and 3, respectively. Thus the average solar flux on June 21, $D = 172$, at 2:15 p.m. solar time, $t = 14.25$, is 460 W/m^2 . The average ambient temperature at the same time would be 20.5°C .

DISCUSSION

This paper has pointed out some of the advantages of using Fourier analysis on climatic data. It has been shown that a 20 year data set can be consolidated by more than 1,000:1 through use of the Fourier transform. This result alone seems very significant. There are, however, other advantages to Fourier analysis which may be even more significant. Perhaps the biggest advantage to be gained from transforming climatic data from the time domain to the frequency domain is the simplification achieved by using the transformed data for engineering analysis.

Consider, for example, the problem of computing the change in ground temperature which results from a change in surface conditions. In order to simplify this example, the earth will be taken as a homogeneous semi-infinite solid and the effects of any phase change will be ignored. The equation that governs the temperature in the earth is

$$\frac{\partial \theta}{\partial t} = \frac{k}{\rho c} \frac{\partial^2 \theta}{\partial x^2}, \quad (12)$$

where θ is the earth temperature as a function of depth x and time t and where k , ρ , and c are the thermal conductivity, density, and specific heat of the earth, respectively. Assuming a ground cover

Table 1 Fourier transform from hourly climatic data for Fairbanks, Alaska.

with thermal conductance u , solar absorptance α , and a surface film coefficient h , the boundary condition at $x = 0$ is

$$h \theta(0,t) - \left(\frac{h}{u} + 1\right)k \frac{\partial \theta}{\partial x}(0,t) = \alpha q(t) + h \phi(t) \quad (13)$$

where q and ϕ are the solar flux and ambient temperature. The remaining boundary condition is

$$k \frac{\partial \theta}{\partial x}(\infty,t) = q_{\infty} \quad (14)$$

where q_{∞} is the steady heat loss from the earth's core.

Thus, to predict the temperature variations in the earth as a function of surface conditions, it is necessary to express the solar flux and ambient temperature as a function of time and then solve a partial differential equation which involves these forcing functions. However, if we introduce the

Fourier transforms,

$$q(t) = \sum_{n=-N}^N Q_n \exp(i\omega_n t), \quad (15)$$

$$\phi(t) = \sum_{n=-N}^N \Phi_n \exp(i\omega_n t), \quad (16)$$

$$\theta(x,t) = \sum_{n=-N}^N \Theta_n(x) \exp(i\omega_n t), \quad (17)$$

then the transform of equations (12)-(14) is

$$i\omega_n \Theta_n = \frac{k}{\rho c} \frac{d^2 \Theta_n}{dx^2}, \quad (18)$$

$$h \Theta_n(0) - \left(\frac{h}{u} + 1\right)k \frac{d\Theta_n}{dx}(0) = \alpha Q_n + h \Phi_n \quad (19)$$

FIGURE 6 Predicted ground temperature in the Fairbanks area with moderate ground cover ($u = 1.5 \text{ W/m}^2\text{°C}$).

$$k \frac{d\theta_n(\infty)}{dx} = \begin{cases} q_\infty, & n = 0 \\ 0, & n \neq 0 \end{cases} \quad (20)$$

Thus, what was a partial differential equation in the time domain becomes an ordinary differential equation in the frequency domain.

Equation (18) is easily solved subject to equations (19) and (20) to give

$$\theta_n(x) = \begin{cases} \phi_0 + \frac{\alpha Q_0}{h} + \frac{(h+u)q_\infty}{hu} + \frac{q_\infty}{k} x, & n = 0 \\ \frac{(\alpha Q_n + h \phi_n) \exp(-\gamma_n x) \exp[-i(\gamma_n x + \beta_n)]}{\{[h+(h+u)k\gamma_n/u]^2 + [(h+u)k\gamma_n/u]^2\}^{1/2}}, & n \neq 0 \end{cases}$$

where

$$\gamma_n = (\omega_n \rho c / 2k)^{1/2}, \quad (22)$$

$$\beta_n = \tan^{-1} \left[\frac{(h+u)k\gamma_n}{hu + (h+u)k\gamma_n} \right]. \quad (23)$$

The Fourier transforms given in Table 1 or 2, can be used in equation (21) and the result can be transformed back to the time domain, using equation (17), to give the desired solution.

A typical solution using the Fairbanks data is shown in Figure 6. The four curves shown in this figure are the predicted ground temperature distributions at solar noon on March 21, June 21, September 21, and December 21. For this solution, a ground cover with thermal conductance of $1.5 \text{ W/m}^2\text{°C}$ was assumed. Note that the permafrost extends to a depth of about 60 m with this ground cover present. Figure 7 shows the solution for the

FIGURE 7 Predicted ground temperature in the Fairbanks area with no ground cover ($u \gg h$).

same conditions with the ground cover removed ($u > h$). Note that removal of the ground cover will completely thaw the permafrost and greatly increase the thickness of the active layer.

This example points out how much of the heat transfer analysis associated with cold regions engineering can be simplified through the use of Fourier transforms. This was a very simple example; however, a similar approach can be used in the analysis of more complex problems that involve thermal interaction with the environment.

LONG-TERM CREEP DEFORMATION OF ROADWAY EMBANKMENT ON ICE-RICH PERMAFROST

Arvind Phukan

Department of Civil Engineering, University of Alaska
Anchorage, Alaska, 99508 USA

Six different combinations of insulation layers, toe berms, and air-ducting systems were installed at an embankment near Bonanza Creek to study thermal degradation at side slopes and toe sections. The performance of these design measures has been monitored since the completion of construction in 1974. Though some of these measures show encouraging results in minimizing long-term thaw settlements, creep settlements are recorded at some of the central sections of the embankment where soil conditions consist of generally frozen ice-rich organic soils to fine-grained soils. In this paper, the long-term creep deformations recorded for the roadway embankment near Bonanza Creek are evaluated. Based on all data recorded for the last 8 years, a long-term creep deformation behavior of the roadway embankment (about 7.6 m height) in ice-rich permafrost is formulated. Based on theoretical analyses, the vertical creep movements (within the central portions of the embankment) are calculated, and they show reasonable qualitative agreement with the measured data. Measured movements indicate that the primary creep movements occurred within the first 3 years after the construction. The analysis presented provides a rational basis for embankment design on ice-rich permafrost.

INTRODUCTION

Roadway embankments built on permafrost have encountered significant deformation with time (Esch, 1973, 1978, Johnston, 1969, Phukan, 1981). Previous studies (Figure 1) by the Alaska Department of Transportation on the roadways embankment constructed over permafrost have shown that relatively deeper thawing beneath the roadway side slopes occurs, even in areas where the embankment thickness beneath the roadway centerline is sufficient to prevent thawing into the underlying permafrost. Because of snow cover, the side slopes will not freezeback the thawed portions near the toe sections, and therefore, annually deeper thawing of underlying permafrost often occurs beneath the roadway side slopes. Those problems are further intensified by increased embankment heights and steeper side slopes which are constructed over ice-rich permafrost. In 1974, the Alaska Department of Transportation installed six different combinations of insulation layers, toe berms, and air-ducting system at a newly constructed highway section near Bonanza Creek to study the embankment slope design in controlling thaw of permafrost beneath roadway side slopes (Esch, 1978). Details of these design measures are illustrated in Figure 1, and measurements have been monitored since the completion of construction in 1974. Though some of the design measures show encouraging results in minimizing long term thaw settlements, creep settlements are recorded at most of the central sections of the embankment where the subsoil conditions consist of generally frozen ice-rich organic soils to silty soils. Limited data are available on the creep deformation behavior of roadway embankment constructed on these ice-rich soils.

This paper evaluates the creep deformations recorded for the roadway embankment constructed near Bonanza Creek, which is located approximately 25 miles west of Fairbanks on the Parks Highway, Alaska, USA. Based on the data, a creep theory is formulated to predict the long-term deformation. Results of the laboratory studies on ice-rich frozen soil samples as well as some of the available information on ice, are used to determine the magnitude of creep parameters. The predicted creep settlement agrees closely with the measured movements.

SITE CONDITIONS AND INSTRUMENTATION

The site located at Bonanza Creek lies within the discontinuous permafrost regions of Alaska, and the thickness of permafrost is of the order of 30-40 m in the regions. Esch (1978) reported the detailed information regarding the construction and design measures for this embankment section.

The embankment was built on about 0.6 m of ice-rich organic soils underlain by ice-rich silt. The variation of frozen moisture content of the underlying soils is presented in Figure 2. The natural vegetation near the site consists of scattered black spruce, tamarack, willow, and alder, which is typical of the interior muskeg environments in Alaska. The mean annual permafrost temperature recorded in an adjacent undisturbed forest area is in the range of -1° to -1.5° C at a depth of 10 m.

Three hundred and fifty-two thermocouples and 20 thermistors were installed both in horizontal strings and in 18 vertical borings drilled through

the embankment. Readings of both thermocouples (accuracy +0.2°C) and thermistors (accuracy +0.03°C) are made monthly. Details of these Temperature readings are given by Esch (1978). For this study, the recorded temperature readings by the Alaska Department of Transportation are evaluated, and the data at two different sections, at sta. 170+00 and sta. 166+75, are shown in Figures 3 and 4.

Survey measurements are made annually in late September to monitor annual settlements at different cross sections. Centerline settlements recorded from 1976 to 1981 at cross sections sta. 166+75 and sta. 170+00 are presented in Figure 5. Deformations recorded at other cross sections of the embankment lie within the shaded portion of the envelope shown in this figure.

THEORETICAL SETTLEMENT ANALYSIS

It can be seen in Figure 5 that the embankment built on ice-rich permafrost shows typical creep behavior with distinct primary and secondary stages. As shown in Figures 3 and 4, the temperature at the midpoints of the embankment was changing and approached steady state conditions after 6 years of construction. The effect of berm at the toe of the embankment on the temperature distribution is reflected (see Figures 3 and 4). The settlement reached the secondary creep stage after 3 years of construction, (2 years after the end of construction) and in practice one is mainly concerned with the deformation during this stage.

The following equation may be written:

$$S(t) = S(i) + \dot{S}(c)t, \tag{1}$$

Where: $S(t)$ = time-dependent settlement;
 $S(i)$ = pseudo-instantaneous settlement;

$S(c) = \frac{ds}{dt}$ = steady state settlement rate;
 t = time.

At a given frozen soil temperature, both $S(i)$ and $S(c)$ are functions of the applied stress.

Based on previous works (Landanyi, 1972, Johnston and Ladanyi, 1972, Hult, 1966, Vyalov, 1965), an approximation of the plane-strain condition equation (1) can be written as

$$S(t) = C_1 S_k \left(\frac{\sigma_1 - \sigma_3}{\sigma_k} \right)^k + C_2 S_c \left(\frac{\sigma_1 - \sigma_3}{\sigma_c} \right)^n t, \tag{2}$$

where $C_1 = \left(\frac{(3)^{1/2}}{2} \right)^{k+1}$

$C_2 = \left(\frac{(3)^{1/2}}{2} \right)^{n+1};$

σ_1 and σ_3 are the major and minor principal stresses, respectively; σ_k, σ_c, K, n are creep parameters dependent on temperature and
