NATIONAL ACADEMY PRESS 2101 Constitution Avenue, NW Washington, DC 20418

The National Research Council was established by the National Academy of Sciences in 1916 to associate the broad community of science and technology with the Academy's purposes of furthering knowledge and of advising the federal government. The Council operates in accordance with general policies determined by the Academy under the authority of its congressional charter of 1863, which establishes the Academy as a private, nonprofit, self-governing membership corporation. The Council has become the principal operating agency of both the National Academy of Sciences and the National Academy of Engineering in the conduct of their services to the government, the public, and the scientific and engineering communities. It is administered jointly by both Academies and the Institute of Medicine. The National Academy of Engineering and the Institute of Medicine were established in 1964 and 1970, respectively, under the charter of the National Academy of Sciences.

Library of Congress Catalog Card Number 83-63114

International Standard Book Number 0-309-03435-3

Permafrost: Fourth International Conference, Proceedings

Printed in the United States of America

National Academy Press

The National Academy Press was created by the National Academy of Sciences to publish the reports issued by the Academy and by the National Academy of Engineering, the Institute of Medicine, and the National Research Council, all operating under the charter granted to the National Academy of Sciences by the Congress of the United States.

Preface

Perennially frozen ground, or permafrost, underlies an estimated 20 percent of the land surface of the earth. It affects many human activities, causing unique problems in agriculture, mining, water supply, sewage disposal, and construction of airfields, roads, railroads, urban areas, and oil and gas pipelines. Therefore, understanding of its distribution and behavior is essential.

Although the existence of permafrost has been known to the inhabitants of Siberia for centuries, not until 1836 did scientists of the Western world take seriously the accounts of thick frozen ground existing under the forests and tundra of northern Eurasia. In that year, Alexander Theodor von Middendorf measured temperatures to a depth of approximately 107 m in permafrost in the Shargin Shaft, an unsuccessful well dug in Yakutsk for the governor of the Russian-Alaskan Trading Company. It was estimated that the permafrost there was 215 m thick. For over a century since then, scientists and engineers in Siberia have been actively studying permafrost and applying the results of their research in the development of the region. Similarly, prospectors and explorers have been aware of permafrost in northern North America for many years, but not until World War II were systematic studies undertaken by scientists and engineers in the United States and Canada.

As a result of the explosive increase in research into the scientific and engineering aspects of frozen ground since the late 1940s in Canada, the United States, the USSR, and, more recently, the People's Republic of China, and Japan, among other countries, it became apparent that scientists and engineers working in the field needed to exchange information on an international level. The First International Conference on Permafrost was therefore held in the United States at Purdue University in 1963. This relatively small conference was extremely successful and yielded a publication that is still used throughout the world. In 1973 approximately 400 participants attended the Second International Conference on Permafrost in Yakutsk, Siberia, USSR. By that time

it had become apparent that a conference should be held every 5 years or so, to bring together scientists and engineers to hear and discuss the latest developments in their fields. Thus in 1978 Canada hosted the Third International Conference on Permafrost in Edmonton, Alberta, including field trips to northern Canada. Approximately 450 participants from 14 nations attended, and Chinese scientists were present for the first time. The published proceedings of all three of these conferences are available (see p. 1524).

In Edmonton it was decided that the United States would host the fourth conference, and a formal offer was made by the University of Alaska. Subsequently, the Fourth International Conference on Permafrost was held at the University of Alaska at Fairbanks, July 17-22, 1983. It was organized and cosponsored by committees of the Polar Research Board of the National Academy of Sciences and the State of Alaska. Local and extended field trips to various parts of the state and northwestern Canada, to examine permafrost features, were made an integral part of the conference.

Approximately 900 people participated in the numerous activities, and 350 papers and poster displays from 25 countries were presented at the conference. Many engineering and scientific disciplines were represented, including civil and mechanical engineering, soil mechanics, glacial and periglacial geology, geophysics, marine science, climatology, soil science, hydrology, and ecology. The formal program consisted of panel discussions followed by paper and poster presentations. The panels considered the following themes: pipelines, climatic change and geothermal regime, deep foundations and embankments, permafrost terrain and environmental protection, frost heave and ice segregation, and subsea permafrost.

The U.S. Organizing Committee is indebted to the many sponsors for their financial support, to the technical and professional organizations which participated in the program, and to the local Fairbanks organizers for their efforts, which resulted in a highly successful meeting.

R & M Consultants	Unwen Scheben Korynta Huettl
Anaconda Copper Company	

Conference Publications

The official proceedings of the conference consist of: (1) the Abstract and Program volume, which was published prior to the conference and is available from the University of Alaska; (2) the present volume of 276 contributed papers by authors from 22 countries; and (3) a final volume that will contain the panel and plenary presentations, additional contributed papers, and a list of participants.

A review group, acting under the U.S. Organizing Committee for the Fourth International Conference on Permafrost, was responsible for reviewing the abstracts submitted in response to the initial call for papers, and later for reviewing the papers themselves. To accomplish these tasks within the span of the year preceding the conference, strict deadlines were imposed and enforced. The review group met twice at the National Academy of Sciences, first in the fall of 1982 and again in April 1983.

The objective of the group was to ensure the preparation of scientifically and technically sound camera-ready copy on a schedule consistent with the desire to have the contributed papers published by late 1983. The task was greatly facilitated by the ability of the authors to prepare their own camera-ready copy within the deadlines.

More than 200 reviewers were called on to ensure an adequate and timely critique of each manuscript. These reviews were carried out with generous cooperation from Canadian specialists. The papers from the USSR were accepted on the basis of Soviet review prior to submission to the U.S. Organizing Committee. The Soviet camera-ready copy was prepared in the United States following revision of their English-language manuscripts. An additional 30 Soviet papers are being prepared for publication in the final proceedings volume. The authors from the People's Republic of China were provided review and editorial comments, and their papers were then returned to them for final preparation.

The members of the review group were:

Robert D. Miller, Chairman, Cornell University
Duwayne M. Anderson, State University of New York, Buffalo (Remote Sensing and Planetary Geophysics)

Robert F. Black, University of Connecticut (Periglacial and Permafrost)
Joseph M. Boyce, National Atmospheric and Space Administration (Lead Reviewer, Remote Sensing and Planetary Geophysics)
Robert F. Carlson, University of Alaska, Fairbanks (Hydrology)
John Dennis, U.S. Park Service (Ecology)
Hugh M. French, Ottawa University (Lead Reviewer, Periglacial and Permafrost)
Laurel E. Goodrich, National Research Council of Canada (Thermal and Mechanical Engineering)
William D. Harrison, University of Alaska, Fairbanks (Geothermal and Subsea)
Hans O. Jahns, Exxon Production Research Co. (Lead Reviewer, Geothermal and Subsea)
C. William Lovell, Purdue University (Lead Reviewer, Civil Engineering)
Virgil Lunardini, Cold Regions Research and Engineering Laboratory (Lead Reviewer, Thermal and Mechanical Engineering)
Howard Thomas, Woodward-Clyde Consultants (Civil Engineering)
Leslie Viereck, U.S. Forest Service (Lead Reviewer, Ecology)
Ted S. Vinson, Oregon State University (Civil Engineering)
John R. Williams, U.S. Geological Survey (Lead Reviewer, Hydrology)
Louis DeGoes, Secretary

The generous editorial assistance of the Cold Regions Research and Engineering Laboratory and the National Research Council during various stages of manuscript review and preparation is gratefully acknowledged. A special note of appreciation is due to Louis DeGoes for his dedicated efforts throughout the planning and review stages of the preparation of the proceedings.

In addition to the proceedings, a series of field trip guidebooks was published by the Alaska Division of Geological and Geophysical Surveys and is available from that agency in Fairbanks. A special permafrost bibliography of over 4,000 citations was published by World Data Center A for Glaciology in Boulder, Colorado, as Glaciological Data Report GD-14. The bibliography covers much of the world literature on permafrost published during the last five years.

R.D. Miller, Chairman
Paper Review and Publications

U.S. Organizing Committee

Troy L. Péwé (Chairman), Arizona State University
Gunter E. Weller (Vice-Chairman), University of Alaska
Amos J. Alter, Technical Council on Cold Regions Engineering, ASCE
Jay Barton, University of Alaska
Jerry Brown, Cold Regions Research and Engineering Laboratory
Oscar J. Ferriars, Jr., U.S. Geological Survey
Hans O. Jahns, Exxon Production Research Company
John R. Kiely, Bechtel Corporation
Arthur H. Lachenbruch, U.S. Geological Survey
Robert D. Miller, Cornell University
Richard D. Reger, Alaska Division of Geological and Geophysical Surveys
A. Lincoln Washburn, University of Washington
James H. Zumberge, University of Southern California
Louis DeGoes, Fourth International Conference on Permafrost

Program Chairman: William D. Harrison, University of Alaska
Paper Review and Publication Chairman: Robert D. Miller, Cornell
University
Field Trips Chairman: Oscar J. Ferriars, Jr., U.S. Geological Survey
Local Arrangements Chairman: William M. Sackinger, University of Alaska

Participating Technical Organizations

Alaska Academy of Engineering and Science
Alaska Council on Science and Technology
Alaska Oil and Gas Association
American Association for the Advancement of Science (Arctic Division)
American Geophysical Union (Committee on Space Hydrology)
American Society of Civil Engineers (Technical Council on Cold Regions
Engineering)
American Society of Mechanical Engineers (Low Temperature Heat Transfer
Committee)
American Meteorological Society (Committee on Polar Meteorology)
Cold Regions Research and Engineering Laboratory
Comité Arctique International
International Geographical Union (Periglacial Commission)
U.S. Man and the Biosphere Program (MAB, Project 6B)

PERMAFROST
Fourth International Conference
PROCEEDINGS

ON THE RELATIONSHIP BETWEEN THE STRUCTURE AND CHARACTERISTICS
OF BEDROCK MASSES AND THEIR PERMAFROST HISTORY

V. E. Afanasenko, V. N. Zaitsev, V. E. Romanovskii,
and N. N. Romanovskii

Geology Department,
Moscow State University, Moscow, USSR

Comprehensive investigations in the areas of permafrost hydrogeology and engineering geology within the Stanovoy and Mongol-Okhotsk folded systems revealed the presence of horizons and zones of severe jointing in the bedrock. They occurred both where there was no permafrost and at the top and bottom of the permafrost. The thickness of the zones involved reaches 100 m and more, and the ice content where the rock is frozen reaches 6-10% by volume. The formation of these horizons of severely-jointed rock is related to the dynamics of permafrost development during climatic changes in the Late Pleistocene and Holocene, specifically to intense frost shattering caused by repeated freeze-thaw. These horizons and zones of severe jointing exert a major influence on the formation of the existing subsurface drainage and of talik zones which operate both as recharge and discharge zones in terms of groundwater and also as lateral transfer zones beneath the permafrost.

The blocks of mountain bedrock in the zone of sporadic permafrost distribution have specific structural characteristics, i.e. the highly jointed horizons of exogenous origin. In the hydrogeological aspect these are hydrogeological blocks of insular and sporadic freezing. Their highly jointed horizons are most commonly the highly saturated zones, the water of which is of great economic value for industrial and municipal water supply.

The structure and characteristics of bedrock blocks were studied in the central part of the Baikal Amur Railway zone, an area subjected to multiple and substantial changes of the frozen state in Pleistocene and Holocene time. Those are Stanovaya and Mongol-Okhotsk mountain regions composed of rocks of the Early Proterozoic age, as well as Paleozoic and Mesozoic folded belts. Similar to other regions of the Baikal region, the Transbaikalian region, and the Verkhoyano-Kolymskaya mountain-folded regions, subjected to substantial transformation of the total frozen state in the Quaternary period, it is suggested that the state and characteristics of the hard and semihard rock blocks of the territory in question have been changed by the dynamics of permafrost.

To identify regional characteristics of cryogenic disintegration near the upper and lower boundaries of permafrost, special investigations based on electrical prospecting methods were carried out. The distribution of the most typical structural characteristics of the zone of exogenic jointing of bedrock blocks within the study area, the permafrost thickness, and the density of the component rocks, were primarily established. The techniques suggested by Piotrovskaya and Romanovsky (1982) were used. The most probable values of the thickness of the exogenic density zone and specific electric resistance of the unfrozen jointed bedrock, characterized by extensive areal occurrence, are given in Table 1.

Usually, a normal field of thickness distribu-

tion of the exogenic jointed zone of the study area has apparent anomalous areas of two types, within which the values are higher by two or more times than the background ones.

The first anomalous type includes linear zones having faults with a break in continuity. The anomalous areas of the second type are confined to the valleys of large rivers such as the Gilyui, Ilikan, etc., formed within a relatively long period of Early-Mid Pleistocene entrenchment (Piotrovskaya and Romanovsky 1982). Such areas commonly extend one or more km across the whole width of these valleys.

The formation and further development of high thickness of dispersion zones, in the aforementioned valleys, were caused not only by initial jointing along the linear tectonic disturbances, but also by subsequent processes of cryogenic disintegration causing formation of a jointed weakened zone in the upper part of the bedrock blocks. The anomalously great thickness of such jointed zones was observed by us only in ancient-stage valleys and did not occur in younger valleys formed as a result of Holocene entrenchment. Thus, the upper and oldest part of the Gilyui River valley is characterized by a great thickness of jointed zones. The downstream part of the valley was shaped later. The zones of exogenic jointing were either insignificant or absent.

Regional analysis of ice-filling of the jointed zones in the frozen part of the bedrock blocks, using the electrical prospecting techniques and prototype observations, made it possible to identify zones of complete ice saturation, up to their "bulged" state, in the section of frozen bedrock. The latter is indicative of intensive processes of cryogenic disintegration in these parts of bedrock blocks. The disintegration processes are confined to specific relief forms having different terrain expression.

Upon studying regional variability of rock ice-

TABLE 1 Thickness parameters for the dispersion zone and specific electric resistance of the thawed jointed bedrock.

Elementary geological body	Dispersion zone thicknesses (m)			Specific electric resistance of rock		
	Total number of measurements n	Medium θ , m	Standard $S \hat{\theta}$, m	Total number of measurements n	Medium θ , k .m	Standard $S \hat{\theta}$, k .m
1) Dispersion zone of metamorphic rock blocks of Archean age. The surface corresponds to the Pliocene/Mid-Pleistocene relief stage (upper horizon)	26	53.6	1.2	166	1.1	0.02
2) The same (lower horizon)	-	>100	-	85	4.6	0.07
3) Dispersion zone of similar blocks, but the surface formed as a result of the Upper-Pleistocene-Holocene entrenchment cycle (lower horizon)	8	53.3	36	4	4.3	0.25
4) Dispersion zone of Proterozoic granitoid blocks (PR) within the Pliocene/Mid-Pleistocene surfaces	38	51.2	1.0	93	2.3	0.04
5) Dispersion zone of Mesozoic granite blocks (Mz), whose surface corresponds to Pliocene/Mid-Pleistocene stage	7	44.0	2.8	7	4.0	0.38

filling, we used the values of specific electric resistance (SER) of frozen jointed bedrock, obtained in geophysical studies and confirmed by prototype observations. In this case, it seems convenient to use the index of rock ice-filling rate, introduced by us as a function:

$$P_{ric} = \frac{P_j^{fr}}{P_{mon}^j}$$

where P_j^{fr} = SER of frozen jointed rocks;

P_{mon}^j = SER of the unfrozen "monolith" part of the same rock block.

According to the data, the value of the P_{ric} parameter is different for divides and valley areas, thus confirming the substantial differences in conditions of permafrost formation and its cryogenic structure within the limits of these relief forms.

The values $P_{ric} = 0.35 - 0.95$ are most characteristic of the lowest part of the section of frozen jointed bedrock on slopes and low (to an altitude of 1100-1300 m) on interfluves. P_{ric} rarely exceeds 1.0 here. It means that the frozen rocks of such areas are, as a rule, characterized by inherited cryogenic structures and low ice content. The joints of such rocks, in the belt of weathering, are only partially filled with ice. This cryogenic structure of jointed rocks points to the weakening of cryogenic disintegration here at present.

The frozen jointed bedrock, at the lower permafrost boundary in the ancient-stage valleys, is most commonly characterized by the values of $P_{ric} =$

1.2 to 2.3. The values of P_{ric} below 1.0 are extremely rare. Most of the joints are entirely filled with ice, and, in many cases, the rocks occur in the "bulged" state. The high ice content seems to give unequivocal evidence of active cryogenic disintegration both recently and at present.

Studies of the intensity of cryogenic disintegration at the base of permafrost within the so-called bald mountain belt are of particular interest. Due to the effects of altitudinal zonality, such areas were distinguished by the most severe temperature conditions during the whole period of perennial frozen ground existence and development. It resulted in deep freezing of bedrock blocks. It is supported by the results of our geophysical studies on the bald mountain divide surfaces above the altitude of 1400 m in the Soltakhan range, as well as within the Stanovoi range at an altitude of 1300-2000 m. Permafrost thickness in these areas reaches between 200 and 500 m. The presence of highly jointed bedrock immediately under the permafrost layer is characteristic of the section. Besides, in many areas the perennially frozen rock series has a more complex structure. Two intervals of high ice content, upper and lower, interbedded with ice-poor frozen rocks, are common in the section. The structure of this section suggests that cryogenic disintegration of the rock near the base of bedrock blocks of the bald mountain belt, as well as in the upper part of the perennially frozen rock section was most intensive during the Pleistocene and Holocene.

To understand fully the scope of our findings on the intensity and total development of dispersion zones in the cryogenic series, it is necessary to approach the problem from a historical aspect and

to relate the principal structural characteristics and properties of bedrock blocks to "permafrost" history. As mentioned above, cryogenic disintegration of bedrock blocks in the "permafrost" zone was caused by multiple processes of partial or complete freezing or thawing of rocks at the base or in the upper part of the frozen section. These processes result in a substantial increase in rock jointing and porosity.

It is common knowledge that one of the basic indicators of continuous existence of frozen series during the Pleistocene was the presence of syngenetic multiple-veined ice in sections in Quaternary deposits of different ages. In our studies and also in those of Alekseyev (1968), Maksimova (1971), Kaplina et al. (1975), Vtyurin (1976), the occurrence of syngenetic multiple-veined ice in sediments of the first, second and third terraces above the floodplain on the floors of the Olekma, Ust-Nyukzha, Zeya, Gilyui, G. and M. Olda and other river valleys, i.e. approximately up to 54° N has been established. The upper surface of the ice veins is, as a rule, "detached" from the present base of the active layer by 0.8-1.5 m. The space over the vein is filled with peaty sandy loam, sand, peat or ice of thaw-lake origin. This structure of the upper parts of syngenetic ice wedges is indicative of the fact that in the warmest periods of Upper Pleistocene and Holocene some parts of valley floors and intermountain areas were characterized by a considerable increase in the mean annual rock temperature within the range of their values below 0°C and in the depth of seasonal thawing (2-3 fold as compared to the present levels). The frozen series did not thaw everywhere or completely. It was largely controlled by high ice content (up to 50-70%) of the mantle of unconsolidated deposits, substantial heat-insulating effects of surface moss-peat covers, the effect of the negative temperature shift at the base of the seasonally-thawed layer and the present inversion in distribution of the mean annual air temperatures from divides to valley and depression floors. The long-term (secular and millennial) increases and decreases of mean annual rock temperature should result in substantial shifts (up to 100 m) in the lower frozen ground boundary. Besides the valley floors, the most favorable conditions for long "preservation" of perennial frozen rock in the periods from the Mid-Pleistocene to the present have occurred within the limits of the cooling belt, most persistent in time, coinciding with the bald mountain part of the Stanovoi, Dzhugdyr, Tukuringra, Suktakhan and Dzhagdy ranges, confined to altitudes of over 1300-1500 m. Multiple and substantial displacements of the lower permafrost boundary occurred here, as in the valley floors. The displacements are indicated by new electric prospecting data on the frozen zone structure of the mountain structures, mentioned earlier, as well as by the data presented by Kaplina et al. (1975). Most high-temperature frozen rock series are formed within the belt, transitional from the inversion to the altitudinal-zonal one. We place in this category the low, smoothed interfluves and gentle slope areas adjacent to the mountains and bordering the Upper-Zeya and Uda depressions, as well as the Amur-Zeya plain. In the Late Pleistocene and Holocene, these areas were evidently noted for

multiple neogenesis of frozen series and their thawing. The thawing is indicated by the absence of syngenetic multiple-veined ice on these relief forms, as well as by the present wide occurrence of sporadic frozen series and areal zones with high bedrock jointing traced to a depth of over 50 m, as already mentioned. The syngenetic multiple ice wedges did not occur in either relief form of Amur-Zeya plain, i.e. south of Tukuringra-Suktakhan-Dzhagdy mountain range, although cases of pseudomorphism occurrence have been described for them in the literature. The thawing is most likely indicative of a complete areal degradation of perennial frozen rocks on the Amur-Zeya plain during the Holocene climatic optimum. The thawing is also supported by wide occurrence of large relict thermokarst forms there (up to a few km across), on the interfluves of the upper reaches of the Onon, Ulmin, Olga and Tu rivers, and also by the presence of hummock-and-sink hole micro-relief in the Selemdzha and Byssy river basins. According to Mordvinov (1940), the formation of such forms was caused by complete thawing of multiple ice wedges during the Holocene climatic optimum. Our calculations of perennial freezing support the idea that the maximum thickness of frozen ground observed at present on the Amur-Zeya plain (about 50-80 m) could have formed between 3000 and 4000 years ago in the period of Late-Holocene cooling that followed the climatic optimum.

The principal changes in the physical state of hard rock (thawed and frozen) had a substantial effect on rock jointing and porosity in those intervals where the changes were most substantial and recurrent.

Rather extensive weathering crusts were recorded by us and a number of other researchers in the upper part of the MFR section within a wide strip of the submontane area bordering the Upper Zeya and Uda depressions, and Amur-Zeya plain. This weathering crust type, with a thickness reaching 40-50 m, has attracted attention from experts in different fields. Thus, it was reported by Alekseyeva (1978) that vermiculite weathering crusts were found on intermediate and basic igneous rocks that are enriched with biotite and phlogopite. The formation of such weathering crusts is related by the researcher to rock disintegration and leaching. The occurrence of the weathering crusts formed on the account of cryogenic disintegration is supported by the recent findings of "Mosgiptans" Institute. Thus, weathering crusts were discovered in the sections of a number of mountain hollows and quarries along the foothills bordering the Upper-Zeya depression, commonly with high-pressure ground water that causes active ice formation in winter.

The development of intensive jointing and cryogenic disintegration zones affects the saturation of bedrock, its permeability and the capacity for subsurface drainage. Areas with well washed joints and high rock porosity are developed in areas of intensive subsurface drainage with infiltration and pressure filtration. Additional ground water pressure is developed in the same areas with an attenuated subsurface drainage and joints filled with a fine-dispersed filler, because these rocks constitute poorly conducting media.

In areas adjoining the linear persistent large

faults with a break in continuity, the thickness of dispersion zones and those with highly jointed rocks may reach 100-150 m.

The thickness of the upper horizon of high jointing and rock weathering beyond tectonic disturbances changes within 10-30 m, reaching sometimes over 50 m. The rocks of this horizon are irregularly saturated in their thawed state, because they commonly contain a great amount of finely-dispersed material and serve as confining beds in this case. In cases where the horizon's rocks constitute highly broken hard rocks, but with a small amount of finely-dispersed filler ("collapsible" rock), they have good filtration characteristics and are, as a rule, saturated.

Our electrical prospecting suggests that the zones of cryogenic disintegration are confined to the lower permafrost interval of the rock blocks. The dispersion zones below the base of the permafrost, discovered within the valleys of large and medium rivers of "pre-Holocene" occurrence, as well as within the bald mountain belt (at over 1300 m altitude), are 40-100 m thick. In the frozen part of the section, the rocks of these zones are characterized by relatively high ice content, but in the unfrozen state they are characterized by high saturation.

The principal movement of artesian water takes place at the base of permafrost in highly jointed zones of cryogenic origin within the limits of all hydrogeological blocks of the investigated region, both of sporadic and continuous shallow freezing. They are fed through infiltration taliks in interfluvial and from the upper courses of small river valleys, although the discharge occurs through the pressure-filtration taliks in river valleys. The latter results in intensive icing formed by ground water discharge in winter.

MEASUREMENT OF PERMEABILITIES OF FROZEN SOILS

Jaime Aguirre-Puente and Jacques Gruson

Laboratoire d'Aérothermique, Centre National de la Recherche Scientifique
4 ter, route des Gardes, F92190 Meudon, France

A method for the measurement of the permeability of frozen soils is proposed. It consists of applying a temperature below 0°C only to the central portion of a cylindrical specimen of a porous medium and a positive temperature to the other two portions. To fix and know the position of the 0°C isotherm it is necessary to impose the same absolute value to the two temperatures. It is possible to use this method without limitation of the explored domain of temperatures. The first apparatus that was constructed is described, and the results of permeability measurements on a silt at -0.3°C are given and discussed. The experience acquired has led to the construction of a second, improved permeameter and to foresee new supplementary protections against small variations of temperature in the experimental room, which were found to have an important influence on the stabilization of the thermal and flowing regimes and reproductibility of experiments.

INTRODUCTION

In a porous medium of fine texture the water contained in the pores undergoes a phase transformation process that is progressive with the evolution temperature below zero degree Celsius. For a given temperature in an isothermal system the ratio of the quantity of liquid water to the mass of the solid matrix adopts a value which corresponds to thermodynamic equilibrium. This equilibrium is assumed to exist in each pore of the system; it depends on the interface phenomena and on the sense of the thermal variation which the medium has undergone to attain an isothermal condition. Water in the liquid state is normally assumed to be present as adsorbed water in a film between the solid matrix and the ice in the pores. A particular characteristic of this water film is its apparent high stress-bearing capacity in a direction perpendicular to the film (Vignes-Adler 1975) despite of the high mobility of the molecules of water.

On the other hand, when a moist porous medium is subject to freezing, a cryogenic suction appears near the ice-water interface existing in the pores. On a macroscopic scale this suction results in a depression of the interstitial water and causes a water flow from the warmer to the colder portions of the system; this moving water solidifies on the ice interfaces encountered during the flow. The water flow takes place through the unfrozen porous medium and also through the films of adsorbed water (Aguirre-Puente et al. 1977). Distillation across the ice crystals formed in the pores also allows the transfer of mass (Miller 1970).

During the freezing of a porous medium a distribution of temperature is established, and a phase-transformation layer appears the thickness of which depends on the texture and the nature of the matrix. Complex interactions between the thermal, physico-chemical, and mechanical parameters determine the intensity of the cryosuction, the rate of water movement, and the position and rate of increase of the ice lenses (Aguirre-Puente et al. 1977). In general, it may be stated that these phenomena are much

more intense if the porous medium has a fine texture, if the temperature gradients are small, and if the duration of the phenomena is extended in time.

To acquire a better understanding of the zones of phase transformation and the regimes of water migration induced by thermal gradients, it is necessary to determine the laws governing the cryosuction and also the characteristics of permeability of soils at temperatures below 0°C (Aguirre-Puente et al. 1977).

The purpose of this paper is to propose a method for the measurement of the permeability of frozen soils, and to describe the permeameters fabricated in the Laboratoire d'Aérothermique. The preliminary results obtained for a silt soil, and the difficulties experienced during our research are discussed.

PROBLEMS ENCOUNTERED IN THE MEASUREMENT OF PERMEABILITY

For the measurement of the permeability of frozen soils, the use of a classical permeameter, maintained below 0°C, is excluded because the free water at the inlet and outlet reservoirs of the apparatus will freeze. The ice will then block the flow despite the persistence of capillary and adsorbed water around the particles of the medium.

However, the principle of a classical permeameter may be used under isothermal conditions if temperatures only slightly below 0°C are employed in order to maintain the free water of the reservoirs in a supercooled state. In this case, to obtain the freezing of the soil it is necessary to produce nucleation of ice in the interstitial water by introduction of a nucleating agent that initiates the phase transformation. Membranes permeable to water but impermeable to ice must be placed at the extremities of the test sample to prevent freezing of the supercooled water in the reservoirs. In this method, used by Miller et al. (1975), the temperature range of utilization is limited by the degree

of supercooling achieved.

A more elaborate system for eliminating the solidification of water in the reservoirs at the extremities was conceived by Burt and Williams (1976). The system consists of immersion of the permeameter

FIGURE 1 First permeameter constructed

in a thermostatic bath. The central portion of the permeameter contains the soil saturated with pure water, and two semipermeable membranes are provided at the extremities to separate the central portion from the end reservoirs. The supercooling of the liquid bath and of the end reservoirs is obtained by using a solution of lactose. The semipermeable membranes permit water to pass through but restrict the passage of dissolved molecules, thereby allowing the water of the sample to remain pure. Freezing of the porous medium is accomplished by a nucleating agent introduced from the exterior. The temperature domain that may be explored with this system is limited by the freezing point of the lactose solution. Despite this limitation however, the lactose system may also be used for the study of nonisothermal systems and to draw conclusions concerning the mechanism of freezing (Williams and Wood 1982).

DESCRIPTION OF THE METHOD AND APPARATUS EMPLOYED

At the Laboratoire d'Aérothermique du CNRS an apparatus for the measurement of permeability of frozen porous media based on the principle of

the classical permeameter was constructed. Pure water is used to saturate the porous medium and to supply the reservoirs and channels of the permeameter during the experiment. To eliminate freezing of the free water present at the extremities of the apparatus, only the central portion of the test specimen is kept at the desired negative temperature, while the two extreme portions and the end reservoirs are maintained at a positive temperature. The effective length of the frozen portion to be considered for the calculation of permeability is defined by the two freezing fronts formed in the porous medium. To impose the position and to prevent any major displacement of these freezing fronts, the two extreme portions of the specimen are maintained at a positive temperature having the same absolute value as the negative temperature of the frozen portion. If the precise temperature of the freezing front in the porous medium is known, the symmetry must be accomplished in relation to this temperature.

The system consists of a copper cylinder containing the specimen, which is enclosed by a coaxial cylindrical sleeve. Two plastic plates in the form of a hollow disc having low thermal conductivity (celeron) are placed perpendicular to the axis in order to divide the annular space into three compartments. Cryostats and thermostats are used to maintain the two temperatures symmetrical with respect to 0°C (or the characteristic temperature of the freezing front) in the compartments of the annular space by means of the circulation of liquids.

Figure 1 shows the first apparatus constructed. It was used for the experiments discussed in this paper. The diameter of the test specimen and the effective length of the frozen portion are approximately 3 cm and 10 cm, respectively.

The test material was compacted layer by layer in the cell, and its moisture content and the degree of compaction were rigorously controlled. Pistons provided with porous plates were tightly fixed at the extremities of the specimen after the compaction.

FIGURE 2 Water-supply system

In the preliminary experiment a rapid freezing was used as a first step to avoid the phenomenon of supercooling in the central portion of the sample and the resulting modification of the soil structure. For this purpose temperatures of about -40°C and $+40^{\circ}\text{C}$ were imposed on the central and end portions, respectively. Once thermal stabilization had been obtained, the temperature were increased and decreased progressively in stages up to the desired values always keeping them symmetrical with respect to 0°C .

Temperature control was accomplished systematically in order to verify the position of the 0°C isotherm. For this purpose, thermocouples were placed on the internal wall of the specimen holder, primarily near the insulating plates defining the three compartments and midway along the length of each portion.

The use of water free of dissolved gases is necessary in such experiments. The supplying of water at the desired pressure to inlet of the permeameter is done with the aid of an airtight system (see Fig. 2). This system consists of a cylinder and piston in which the pressure is applied by a lever arm. The length of the lever arm and the weight suspended at its extremity determine the pressure exerted. Finally, observation with a cathetometer of the meniscus formed across a capillary of small diameter by the water leaving at atmospheric pressure allows the measurement of water discharge from the specimen.

EXPERIMENTAL EXAMPLE

Preliminary measurements were conducted on a silt. It was the same soil used at the freezing station of Caen (France) to simulate roads studied during the 1970's by the Laboratoire Central des Ponts et Chaussées and the Centre National de la Recherche Scientifique (Philippe et al. 1970).

Due to the high sensitivity of the freezing phenomena of the porous media of fine texture, long durations are required for the stabilization of the thermal and hydraulic regimes. Despite the poor control of ambient conditions in our experimental room, the experiments performed presented several periods of stabilization during which the rate of water flow was reproducible.

To illustrate the determination of the permeability, the case corresponding to a frozen portion of soil at -0.3°C is presented here.

The characteristics of the soil after compaction in the cell were as follows : density $\rho = 2120\text{kgm}^{-3}$, dry density $\gamma_d = 1820\text{kgm}^{-3}$, water content $\omega = 0.166$ (16.6%), porosity $\varepsilon = 0.32$, total length of the sample $L = 0.336\text{m}$, length of the portion at -0.3°C and $l = 0.107\text{m}$ (supposing that the isotherm 0°C corresponds to the frozen line).

The pressure imposed on the water in the inlet reservoir during this experiment was 0.55 bar. Figure 3 represents five periods of evolution of the meniscus in the fine capillary of the outlet. Regularity and reproducibility are quite satisfactory. The velocity of displacement of the meniscus equal to the slope of the straight line drawn on the experimental points. Taking into account the 2mm-diameter of the capillary, it is possible to determine the rate of water flow going through the

FIGURE 3 Relative position of the meniscus in the capillary vs. time, for five periods of good reproducibility.

specimen. This information is presented in Table 1.

The expression of the generalized Darcy law used in fluid dynamics is

$$\vec{v} = - \frac{K}{\mu} \text{grad } \hat{P}, \quad (1)$$

where \vec{v} is the filter-velocity, K the permeability, μ the dynamic viscosity, and $\hat{P} = p + \rho gh$, the

driving pressure of the water in the pores (with p , interstitial pressure and h , the level of the considered point with reference to an arbitrarily fixed horizontal plane). In the case of our experiment, we can neglect the gravitational influence.

$$K = 10^{-18} \text{ m}^2 \text{ for } T = -0,3^\circ\text{C}. \quad (5)$$

For comparison the values obtained by Burt and William (1976) for Slims Valley silt and Leda clay

18					
Mean rate of water flow				2.0124×10^{-13}	

One point of our research program consists of analyzing the different thermodynamic aspects governing the behavior of the water during its passing through the fine porous media. Indeed, it is probable that the Darcy law is not absolutely valid in the case of media having very fine interstices and when the influence of interstitial pressure could have effects in the phase transition processes concerning, for example, the equilibrium temperature ice-water and the distillation through the ice crystal. Despite the absence of study, we can use the Darcy law and determine an effective of apparent permeability:

$$K = \frac{v \mu}{\text{grad } p} = \frac{v \mu \ell}{\Delta p} \quad (2)$$

We can also neglect the influence of the unfrozen portions that have a very much higher permeability than the frozen portion. The value of this permeability was obtained with the same specimen under isothermal conditions corresponding approximately 20°C and was

$$K_{\text{unfrozen}} = 1.14 \times 10^{-16} \text{ m}^2. \quad (3)$$

The filter-velocity (v) is the rate of flow (q) divided by the surface of the circular section (A) of the specimen, and we can therefore calculate the permeability in the frozen portion by the formula:

$$K = q \mu \ell / A \Delta p, \quad (4)$$

with $\mu = 1.8$ centipoise = $1.8 \times 10^{-13} \text{ kg m}^{-1} \text{ s}^{-1}$ for $T = 0^\circ\text{C}$, $\ell = 0.107 \text{ m}$, $\Delta p = 0.55 \times 10^5 \text{ Pa}$, $q = 2.0124 \times 10^{-13} \text{ m}^3 \text{ s}^{-1}$, and $A = \pi(0.03)^2/4 = 7.0686 \times 10^{-4} \text{ m}^2$:

were, respectively, $K = 10^{-16} \text{ m}^2$ and $K = 2 \times 10^{-18} \text{ m}^2$ approximately.

DISCUSSION

The principal problems encountered during the measurements were mainly those coming from the small variations in temperature occurring frequently during the night. Indeed, even small thermal perturbations may cause considerable variations in the quantity of unfrozen water, resulting in a sensible additional flow due to the change of density in the water-ice or ice-water transformations. On the other hand, a small change in temperature will produce a change of temperature of the frozen portion and the unfrozen portions that are in the same sense; consequently, the thermal symmetrical conditions will be disturbed, producing a supplementary displacement of the frozen line, which will take a long time to arrive at a new stabilized condition.

Some practical problems were inherent to the long periods required for stabilization of temperatures: for instance, there were breakdowns in the electric current and in the temperature-regulating apparatus (cryostats), which disturbed the progress of the experiment.

Finally, we emphasize the need for a more elaborate and complete study of the flow of water in a porous medium when ice is present in the pores and when the interstices are very fine.

CONCLUSION

The apparatus that was constructed and used to determine the permeability of frozen soils confirms the validity of the method proposed, which consists of applying symmetrical temperatures in relation to 0°C (or to the characteristic temperature of

the frozen line) to prevent the solidification of the free water present in a permeameter. With this method there is no limitation to the domain of temperature that can be studied. Due to the necessity of reducing the duration of thermal and mechanical stabilization, we have recently constructed the permeameter shown in figure 4 which is an apparatus similar to the one used for the measurements presented in this paper, but which has smaller dimensions. We also foresee the use of a supplementary thermostatic guard at 0°C to protect the system against the thermal variations of the experimental room.

NOTES ON CHEMICAL WEATHERING, KAPP LINNÉ, SPITSBERGEN

Jonas H. Åkerman

Department of Physical Geography, University of Lund, Sölvegatan 13, S-22362 Lund, Sweden

Surface karst features upon outcrops of dolomitic limestone are described from an area in the western part of Spitsbergen (78°04'N, 13°38'E). The morphometric characteristics of karrenforms are compared with the height above sea level, position in the terrain and upon the outcrops, exposure to prevailing winds, the snow cover. The best developed forms are found between 50 and 150 m a.s.l upon gently sloping rock surfaces where there is a thick snow cover which can provide water during the melt season. Signs of differential chemical weathering are common in the area in the form of elevated quartz-filled joints forming complex patterns on the surfaces of the outcrops. A good correlation is found between the height of these quartz veins and the height above sea level. As the isostatic uplift history of the area is well known, it is possible to estimate the denudation rate of the dolomitic limestone to be 2.48 mm/1000 yr.

INTRODUCTION

Chemical weathering under periglacial conditions has received relatively little attention. Though several authors have remarked that chemical processes have been neglected, very few studies have been devoted specially to the subject (Cailleux 1962, 1968, Corbel 1959, Helldén 1974, Rapp 1960b, Troll 1944, Washburn 1969). The opinion that chemical weathering in the periglacial environment is unimportant is, however, today gradually dispelled. It should be observed that Rapp (1960a) in his studies of slope processes in Spitsbergen and, especially in Kärkevåg in northern Sweden has showed chemical denudation processes to be quantitatively dominant (Rapp 1960b p.184-185).

Observations of surface karst features, exfoliation forms, alveoles and taffoni, oxide rinds, carbonate coatings, desert varnish and case hardening as well as active grus weathering are today commonly reported from various periglacial environments, indicating the importance of the chemical processes. In the genesis of the abovementioned features, the chemical action is only a part of a complex mechanism. The karst processes are better known and less complex. The number of studies and observations from the Arctic is limited and the intensity of the karst processes in the arctic environment compared with other climatic regions is still under discussion (Corbel 1952, 1957, Bügeli 1956, 1960, Helldén 1974, Sweeting 1964, Jennings 1971).

Corbel initially estimated very high denudation rates for the arctic regions, 40 mm/1 000 yr in Spitsbergen (Corbel 1957, 1959), but later, after more field studies, he changed the rate to 15.75 mm/1 000 yr. Helldén (1974) studied a part of the strandflat south of Kapp Linné (the same area dealt with in this study), and found values which are very close to Corbel's estimates (11.4 - 15.5 mm/1 000 yr. Studies from northern Canada indicate considerably lower denudation rates - 5.0 mm/1 000 yr (Corbel 1959) and 2.05 mm/1 000 yr (Smith 1965). Great differences in the precipitation climate - Spitsbergen is comparatively wet (200-400 mm) and the Canadian area studied is comparatively dry (130 mm) - make a comparison between the areas difficult. The

observations by Helldén (1974) in Spitsbergen are the most reliable figures from this area despite the fact that the investigation area was small and the observation period short.

INVESTIGATION AREA

In the area south of Kapp Linné (Figure 1) Helldén observed that the area was very poor in karst features (Helldén 1974 p.124). Other investigators have also commented on the lack of karst features in this area despite the presence of a suitable bedrock. During the course of studies on periglacial geomorphology and processes the author noted several examples of karst features (Åkerman 1980 p.70-75) and some time was devoted to the subject, although it was not a part of the investigation program.

A major part of the investigation area lies upon the Hecla Hoek series, which here consists of Precambrian-Ordovician rocks (Flood et al. 1971). Like elsewhere along the west coast, the Hecla Hoek series strike more or less parallel to the coast, and the rocks consist of vertical to nearvertical thin strata of schists, quartzites, tillites, dolomites, limestones and conglomerates. The eastern part of the area lies upon younger sedimentary rocks of which Upper Carboniferous limestones are the most important.

The area has an arctic, humid climate, with a mean annual air temperature of -4.8°C (1912-1975) and a mean annual precipitation of 400.8 mm (1934-1975) (cf. Åkerman 1980 p. 14-46). The annual course of air temperature and precipitation is given in Table 1, and from these figures we find that the summer climate is cold and that the period during which the chemical processes may act is short.

OBSERVATIONS

During the geomorphological inventory and mapping of the investigation area, surface karst features were observed in many places. The forms found were not large and conspicuous but common and characteristic of the limestone outcrops. The distribution

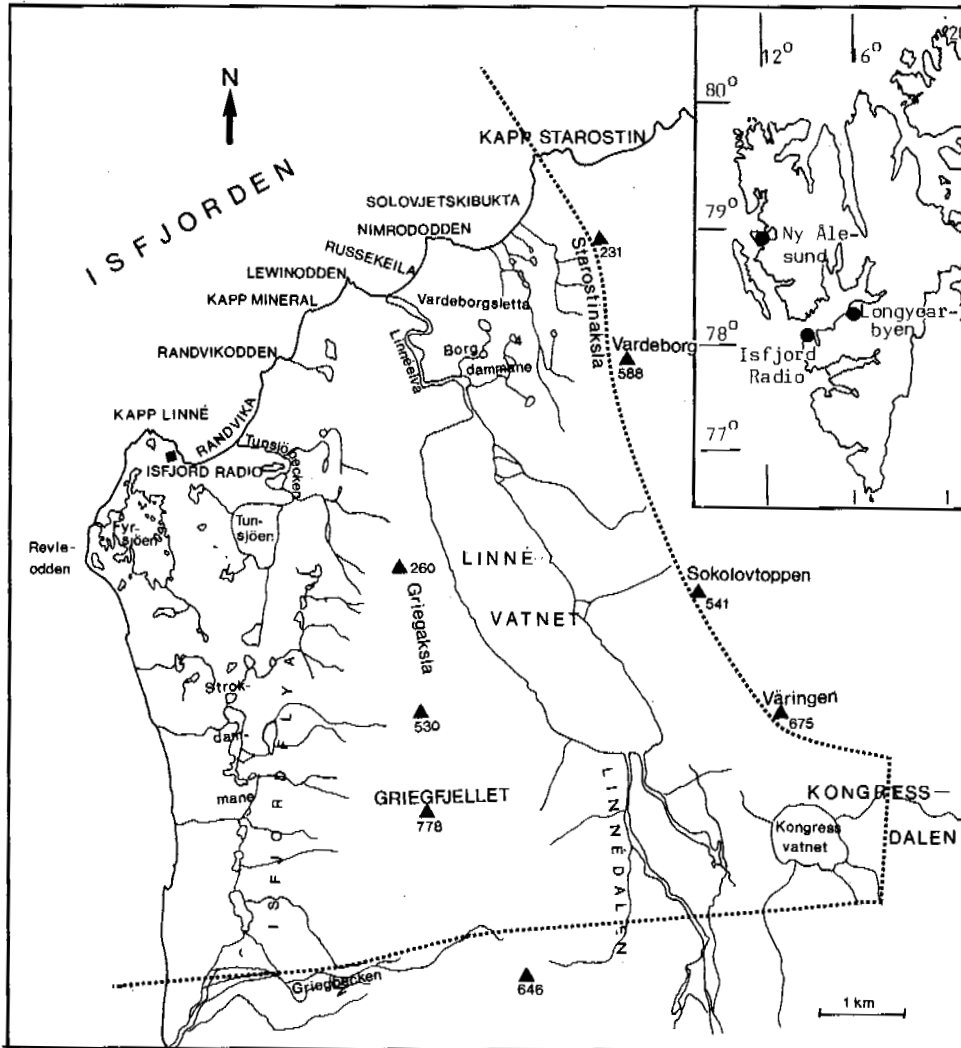

FIGURE 1 Orientation map of the investigation area near Kapp Linné, Spitsbergen. Place names and heights (m) according to Norsk Polar-institutt Map no. B9, Blad ISFJORDEN, original scale 1:100 000.

of the observations, the more important ones of which were included in the geomorphological maps, shows that two separate areas can be distinguished: (1) the central part of the strandflat west of the Linnévatnet Lake and (2) the west facing slopes of the Wardeborg-Våringen mountain ridge and the area around the Kongressvatnet Lake (Figure 2). The observations on the strandflat are connected with the outcrops of dolomitic limestones and the surface karst features east of the Linnévatnet Lake are found in soft Cyatophyllum limestones.

The Kongressvatnet area

The surface forms observed in this area are mainly karren forms, but also weakly developed doline forms were observed around the Kongressvatnet Lake. The karren forms are generally found on fairly steep to vertical surfaces on the mountain walls. They consist of furrows, running in sets straight down the steepest inclination with sometimes sharp, but in most cases rounded, ribs in between. The width ranges between 1 and 10 cm, and the length rarely exceeds 40 cm (Table 2). In figure 4 an example of this type of karren forms from the area around the Kongressvatnet Lake is shown. Also common are small

grikes (solution slots), which are solution-widened joints in the limestone.

To obtain a picture about the surface karst features and their relations with some environmental factors, some simple observations regarding their

FIGURE 2 The occurrence of surface karst features within the investigation area south of Kapp Linné, Spitsbergen.

position in the terrain were performed. The factors concerned were height above sea level, association with flowing water, rock walls and their exposure, loose blocks, rock outcrops (level surfaces, sloping surfaces, summits), and snow depth.

In figure 3 the relation between the width of the observed karren forms and their height above sea level is shown. There is a tendency for the widest karren forms to occur between 100 and 200 m a.s.l. Below and above this height the number of wide karren forms is decreasing. This may be explained by a shorter time for formation at the low levels (the valley was earlier filled with a glacier), and less favorable formation conditions at the higher levels (the physical weathering dominating?). The exposure and orientation of the rock wall may be an important factor in the chemical weathering processes, sun, wind and precipitation exposure (cf. Dunkerley 1979 p.333). However, the majority of the rock walls of the area are exposed to the west and southwest, and only a small percentage of the rock walls face other directions. Therefore it is difficult to obtain a picture about whether in this area the occurrence of karren forms may be related to orientation and exposure or not.

The karst forms found on the more level sites have been related to their occurrence in association with flowing water, their position upon rock outcrops, the occurrence upon loose blocks, and snow depth (Table 3).

TABLE 3 Occurrence of Surface Karst Features on the More Level Sites in the Area East of the Linnévatnet Lake, Spitsbergen

Flowing water	Rock outcrops			Loose blocks
	level surfaces	sloping surfaces	summits	
7.2%	16.6%	51.3%	32.1%	9.7%

The surface karst features found in association with the small streams of the area are few and mainly restricted to the Kongresselva River ravine. The observations upon loose blocks are also few but here the figure is probably an underestimate as only larger blocks were incorporated in the observations. Rock outcrops dominate the observation material, and sloping surfaces or sides of the outcrops are the places where karst features are most frequently found. There are many factors determining this distribution, but in this area the snow depth is of great importance. Level surfaces at the tops of outcrops and more rugged outcrops or summit surfaces are generally blown free of snow. They will therefore be comparatively dry, and are furthermore subject to a more intensive frost shattering which will destroy forms created by chemical processes.

The sites which have a medium thick snow cover (0.5-1 m) are those which have the best developed surface karst features. Here there is a fairly large amount of water released during the snowmelt season. Snowmelt occurs early in the summer, after which the surfaces are exposed to precipitation. Snow insulation affords protection from frost shattering during late spring and late autumn, the periods with the highest frequency of freeze-thaw cycles.

FIGURE 4 Karren forms on a dolomitic limestone outcrop southeast of Kapp Linné, Spitsbergen.

FIGURE 5 Complex net pattern of quartz filled veins in a dolomitic limestone outcrop at 35 m a.s.l. 4 km east of Kapp Linné, Spitsbergen.

The Strandflat Area

Surface karst features are found on the dolomite outcrops, but here the forms are generally smaller and less well developed than was the case in the softer limestones east of the Linnévatnet Lake. In general the karren forms are weakly developed solution flutes, small solution facets or a chaotic, rugged ridge system a few centimetres high and preferably on the flat or gently sloping summits of the outcrops. Welldeveloped Rillenkarren are rare, but some examples are found in the eastern and highest part of the strandflat (Figure 4).

Differential Weathering

More interesting than the weakly developed karren forms is the differential weathering of the dolomitic limestones with quartz veins. The dolomitic limestones of the strandflat have in many cases complex joint systems which are filled with a white or yellowish white quartz. As the weathering rate in the limestone is considerably higher than that in the quartz, the quartz filled joints are left as a complex pattern of elevated veins on the surface (Figure 5). Since it was observed that these veins seemed to be higher and better developed on higher levels, it was concluded that the veins might be used to estimate the limestone denudation of the area (cf. Dahl 1967, Birkeland 1982).

There is a progressive increase in vein height with elevation (Figure 6). The differences in height of the veins at each site are great, but as both the mean and the maximum show a good correlation, it is reasonable to conclude that the correlation with the height above sea level as indicated in Figure 6 is relevant. In the discussion below, the maximum values are used as probably being the most significant in the discussion about denudation rates.

There is a fair amount of data available concerning the isostatic uplift of the area and thus the number of years each outcrop has been above the sea level (Büdel 1968, Schytt et al. 1967, Ståblein 1978 and the author's ^{14}C datings). In Figure 7 the

FIGURE 6 The relation between the mean and maximum height of the quartz veins upon dolomitic limestone outcrops and the height above mean sea level for the strandflat area east of the Linnévatnet Lake, Spitsbergen.

correlation between the maximum height of the quartz veins and the estimated number of years the outcrops in question have been above the sea level is shown. If we assume that the height of the quartz veins is a measure of the limestone denudation and use the results above and estimate the denudation rate, we obtain a mean of 2.48 mm/1 000 yr. The maximum value is 3.78 mm/ 1 000 yr and the minimum is 1.5 mm/1 000 yr. These values are considerably lower than those obtained by Corbel (1960) and Hellden (1974), who calculated values between 11.4 and 15.74 mm/1 000 yr. The difference is due to the fact that Corbel and Hellden based their estimates upon hydrochemical data -the amount of $\text{CaCO}_3 + \text{MgCO}_3$

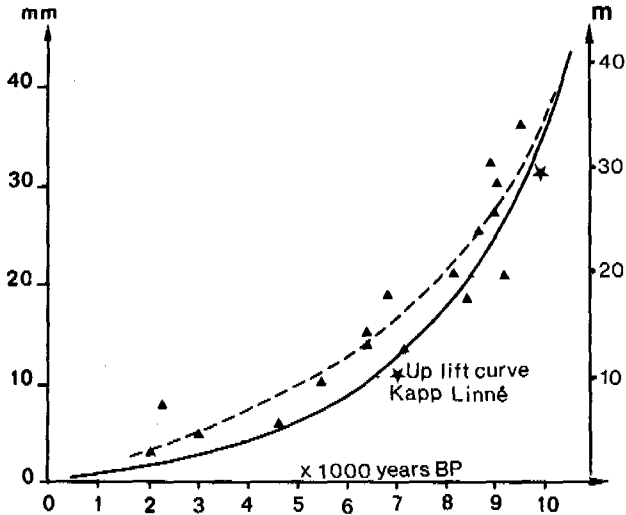

FIGURE 7 The relation between the height of the quartz veins and years each site has been above sea level. The isostatic uplift curve according to Schytt et al. (1967). Two of the authors ^{14}C datings (Lu-1722 and Lu-2020, Dep. of Quaternary Geology, Univ. of Lund) have been added (\star).

transported in solution in the streams. The water in the streams comes partly from rainwater and partly from snow and has been in contact with the bedrock and limestone particles in the soil for a longer time. Therefore the solution/denudation rates based upon this kind of measurements must be considerably higher than that on exposed rock. The rock outcrops are exposed to running water during snowmelt and during rainfall, dew deposition and fog wetting only so solution/denudation is less. Taking this into account, the result obtained is probably fairly representative.

Another result which ought to be considered is that the denudation rate seems to have decreased during the 10 000 yr period the processes have acted in the area (Figure 8). The lowest denudation rates are found for the sites which have been above the sea level during the last 2 000 to 4 000 years. During this period the denudation rate is about 1.5 mm/1 000 yr while those sites which have been above the sea level during 4 000 to 9 000 years have denudation rates of up to 3.5 mm/1 000 yr. This may be explained by (1) the change in surface roughness over time or (2) the climatic optimum during the post glacial warm period.

The first possibility must always be a part of the explanation but it will probably be of great importance only during the earliest stages. The well documented climatic changes during the post glacial thermal optimum provided warmer summerclimates with more and longer periods with precipitation in the form of rain, drizzle and fog wetting each year. The vegetation was also more ample which made the surface water more aggressive as a result of a higher concentration of humus acids. This will increase the limestone solution considerably (cf. Heilddén 1974).

CONCLUSIONS

The study area, which is representative of the strandflat areas of central west Spitsbergen as regards the geological, geomorphological, climatological and hydrological factors, is rich in forms and features created directly or indirectly by chemical weathering and associated processes. The majority of the forms are small and thereby easily overlooked. Still, the processes and the forms resulting from them are an important part of the periglacial environment.

The most common and widespread process in this respect is the limestone solution and the surface karst features associated with it. There is a clear relation between the karst features observed and their localization in the terrain as well as with the height above sea level. This latter is related to age of exposure.

The correlation found between the height of quartz veins upon dolomitic limestones and the time available for their formation allows of an estimation of the limestone denudation during the last 10 000 years. The figure obtained is 2.5 mm/1 000yr and is considerably lower than earlier studies have shown for the area (11-15 mm/1 000 yr), however, these latter studies were based upon hydrochemical measurements, result from processes active 4-5 months per year. The rock outcrops here studied are exposed to running water only a few days during the snowmelt season and during those days with rain precipitation, surface condensation and fog. Taking this into account (15 days during snowmelt and 46 days of rain -the average number of rainy days June to September), the period during which the process can be active will be restricted to some 1.7 months only. Further, the water acting on the rock outcrops is less aggressive than the soil/ground water acting upon the level rock surfaces and on the soil particles. Regarding these factors, the obtained values

FIGURE 8 The relation between the estimated denudation rates and the years each site has been above sea level.

are probably fairly representative, indicating that the denudation rates here obtained reasonably well correspond to those obtained by Helldén (1974). This means that observations of differential weathering of this type might be used as an indirect tool for estimates of limestone denudation. The result also indicate that the denudation rates seem to have decreased during the 10 000 year period the processes have been acting in the area. Despite the fact that other factors to some extent are involved there are reasons to assume that this may reflect the warmer and wetter climate during the post glacial temperate period and a colder and drier period during the last 2 000-4 000 years.

ACKNOWLEDGEMENTS

LUG BEHAVIOR FOR MODEL STEEL PILES IN FROZEN SAND

O. B. Andersland and M. R. M. Alwahhab

Department of Civil Engineering, Michigan State University,
East Lansing, Michigan 48824 USA

The adfreeze bond strength for piles embedded in frozen sand includes ice adhesion to the pile, friction between the pile surface and sand particles, and mechanical interaction between frozen sand and the pile surface roughness. Experimental work has shown that the presence of lugs, small protrusions, increased the volume of ice matrix and soil particles involved in the initial rupture, thereby increasing bond due to ice adhesion. Additional pile movement and soil interaction with lugs mobilized sand dilatancy and particle reorientation effects along with soil bearing forces on the lugs. The model pile load was significantly increased. The net result was that creep displacement behavior will differ considerably depending on pile movement. Very small displacements characterize the start of tertiary creep (failure) for applied shaft stresses below those required for initial rupture of ice adhesion. Larger displacements and higher shaft stresses are associated with mobilization of mechanical interaction forces. Experimental relations presented include load displacement curves for constant displacement rate tests; constant load creep curves for a model pile with multiple lugs; and the dependence of creep displacement rates and/or adfreeze bond on lug size, temperature, and sand volume fractions (ice content).

INTRODUCTION

Pile installation in frozen ground often involves dry augered or bored holes with a mixture of sand and water used to fill the annulus around the pile. Load supporting capacity develops when the sand-water slurry is solidly frozen in place. Pile capacity is primarily dependent on the adfreeze bond strength of the frozen soil in the zone adjacent to the pile. This adfreeze strength is dependent on physical, thermal, and rheological properties of the frozen slurry and the pile surface roughness and type. Published load tests (Crory, 1963) have shown that adfreeze bond failure is sudden and abrupt and that strength can only be partially regained after motion stops. Increased pile surface roughness in the form of lugs or corrugations has been used to increase the load capacity. Lack of information on the influence of lug size and spacing, soil ice content, and temperature on increased long-term adfreeze bond strength has limited the use of lugs on field projects.

Load transfer at the pile/frozen soil interface includes ice adhesion, friction between the pile surface and soil particles, and mechanical interaction between frozen sand and pile surface roughness. The presence of a lug increases the volume of ice matrix and soil particles involved in rupture, thereby increasing the bond due to ice adhesion. Development of bearing forces is a function of lug size and requires larger displacements to mobilize the friction and dilatancy components of soil shear strength. Density of the soil particles relates to the soil friction and dilatancy and in turn mechanical interaction forces. Experimental relations are presented showing load-displacement curves for four lug sizes and a standard deformed No. 3 bar (about 9.52 mm, 3/8 in.); typical constant load creep curves; and the dependence of creep displacement rates and/or adfreeze

bond strengths on lug size, temperature, and sand volume fractions (dry density).

EXPERIMENTAL PROCEDURES

Model Pile Set-up

The frozen sand sample shown in Figure 1, with a plain steel 9.52 mm bar and one lug, served as a model steel pile section suitable for pull-out tests. Lug heights included h equal to 1.59, 3.17, and 4.76 mm with a length L of 12.7 mm. Plain bars were included to show the limiting condition as lug size goes to zero. The frozen sand sample shown in Figure 1 was representative of a slurry which might be used to fill the annulus around a pile in the field. All sand specimens were prepared in split molds 152 mm (6 in.) in diameter and frozen at close to -20°C for about 12 hours. Sample heights were limited to 152 mm or less so that pull-out loads would not exceed the equipment capacity. The sand consisted of subangular quartz particles with a uniform gradation (size range of 0.105 mm to 0.595 mm) and a coefficient of uniformity equal to 1.50. Relatively dense samples were formed by placement of sand in water and tamping until the desired density was obtained. Low sand volume fractions with reasonably uniform particle distribution were obtained by mixing precooled sand with snow and adding precooled water to increase the degree of saturation. Actual sand volume fractions were based on the sample height, dimensions, and weight of sand remaining after thawing at completion of the test.

After removal from the mold, rubber membranes (double thickness) were placed as shown in Figure 1 to protect the frozen sample during immersion in the refrigerated anti-freeze/water coolant mixture. A thermistor embedded in the frozen sample permitted

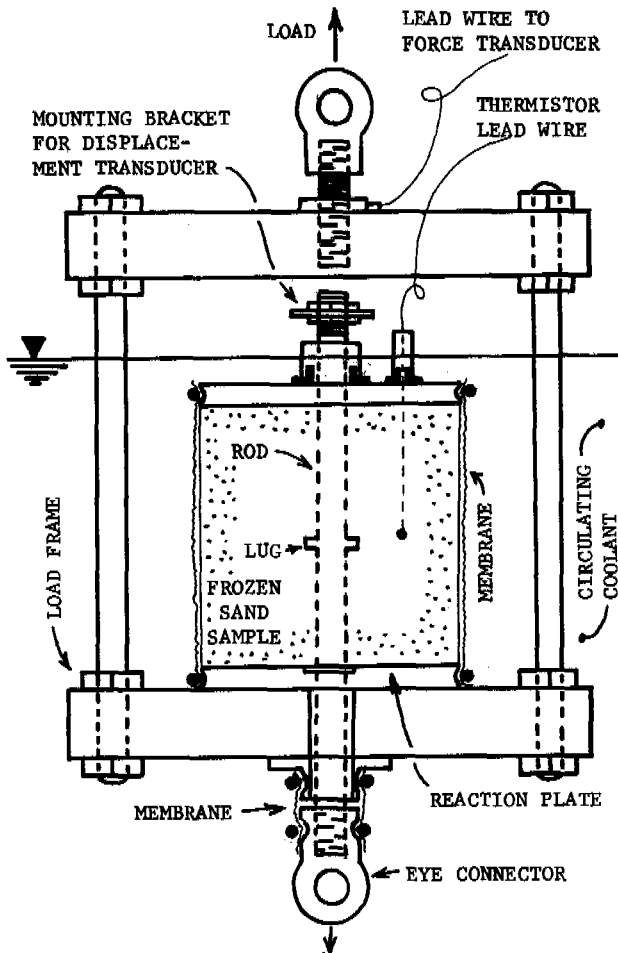

FIGURE 1 Equipment for pull-out tests including sample, steel bar with lug, and loading frame immersed in the circulating coolant.

temperature monitoring before and during the test. A threaded portion at both bar ends provided for easy hook-up to an eye connector and reaction hook at the bottom of the coolant tank and mounting of a displacement transducer at the upper bar end (Figure 1). Clearance between the bar and reaction plate was maintained at close to 1.6 mm for all bar diameters by use of a removable steel washer in the reaction plate.

Test Procedure

Both constant load (creep) and constant displacement rate pull-out tests were conducted using the loading frame shown in Figure 1. The initial bar stress prior to loading was limited to a very small value represented by the weight of the bar, lug, and eye connector. Constant loads were applied using a lever system and dead weights. Constant displacement rates were produced using a Graham variable speed gear box mounted on a 44.5 kN (10 kip) capacity Soiltest load frame. Movement of the bar relative to the lower reaction plate and soil sample was monitored using a displacement transducer mounted on the bar above the coolant liquid with the core supported by a rod extending down to the reaction plate. Loads were monitored by the

force transducer attached to the top of the loading frame shown in Figure 1. Sample temperatures were controlled by circulating an antifreeze/water coolant mixture from an external refrigerated bath around the protected sample and loading frame.

EXPERIMENTAL RESULTS

Constant Displacement Rate Tests

Load displacement curves for a plain steel bar with a single lug are given in Figure 2 for an average displacement rate of $15.2 \mu\text{m}/\text{min}$ and a temperature close to -10°C . Very little displacement (less than $50 \mu\text{m}$) was observed up to the first break in the displacement curves (initial rupture of the ice matrix). Transducer limitations prevented more accurate measurements for the small displacements. After rupture the load quickly dropped to a small residual value for the plain bar ($h = 0$). Introduction of a lug increased the ice matrix volume and soil particles involved in the initial rupture, thereby increasing the adfreeze bond due to adhesion. Additional bar displacement permitted bearing forces to develop in front of the lug as shear strength was mobilized in the sand. The drop in load after initial rupture decreased as lug size was increased. The ultimate load, which was mobilized at around 5 mm displacement, greatly exceeded the load for no lug and is a function of lug size.

A series of lugs on a standard deformed No. 3 bar in frozen sand at the same sand fraction (64%) and temperature (-10°C) gave the load displacement curves shown in Figure 3. The sample height H was reduced so that the equipment load capacity would

FIGURE 2 Load-displacement curves for a 9.52 mm steel bar and four lug sizes in frozen sand at -10°C and a sand volume fraction of 64% (data from Alwahhab, 1983).

not be exceeded. Initial rupture in the ice matrix appears to occur at larger displacements. The load continued to increase up to an ultimate value after which it decreased. This decrease in load, as compared to no decrease for a single lug, appears to be due to an overlap of pressure bulbs in front of the lugs and to formation of a void space behind the displaced lug. Preliminary work has used Boussinesq's equations to estimate pressure bulb overlap from consecutive lugs. Examination of the failure zone in front of single lugs after a test showed crushed sand particles extending forward a distance of 2 to 3 times the lug height.

Constant Load (Creep) Tests

Displacement-time curves for a plain 9.52 mm steel bar with multiple lugs ($h = 0.397$ mm) are given in Figure 4 for a temperature close to -10 °C. The sample height was limited to 76 mm (10 lugs) so as not to exceed equipment load capacity. Preliminary creep pull-out tests on plain bars showed that failure (tertiary creep) associated with ice adhesion was initiated at very small displacements, values close to 0.1 mm or less. For the standard No. 3 bar with multiple lugs the failure displacement of about 3 mm (Figure 4) may correspond to mechanical interaction forces. With a larger single lug experimental data indicated that secondary creep would continue with no failure for large displacements (80+ mm) as long as boundary conditions did not interfere. It appears that overlap of pressure bulbs and formation of a void space behind the lugs may be responsible for development of tertiary creep at close to 3 mm bar displacement. The conventional creep curves in Figure 4 show a small initial elastic displacement followed by a plastic (irreversible) creep up to steady-state creep, represented by the straight line portion of the curve. To reduce the number of samples required, a step loading procedure was used as shown by the

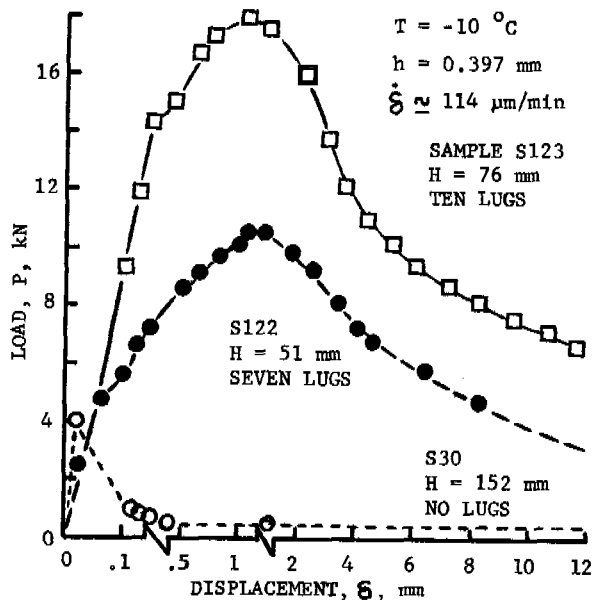

FIGURE 3 Load-displacement curves for a standard deformed No. 3 bar in frozen sand at -10 °C and a sand volume fraction of 64 % (data from Alwahhab, 1983).

FIGURE 4 Creep curves for step loading a standard No. 3 deformed bar with ten lugs in frozen sand at -10 °C and a sand volume fraction of 64 % (data from Alwahhab, 1983).

additional two curves in Figure 4. A small elastic and plastic displacement developed as each load increment was applied. Using duplicate samples and a single lug, it was shown that creep rates based on incremental loads were in agreement with creep rates for the first load. To insure development of secondary creep it was important that the load be greater than the long-term bond strength corresponding to the current displacement.

DISCUSSION

Adfreeze Bond Strength

Load transfer at the interface between the model pile and frozen sand involved three bond components: (1) ice adhesion to the pile, (2) friction between sand particles and the pile surface, and (3) mechanical interaction between frozen sand and the pile surface roughness. Different load transfer mechanisms are involved. Ice adhesion is the result of increased attraction between water molecules and the pile surface at freezing temperatures. Surface type (steel, concrete, etc.) and contaminants (salts, minerals, etc.) in the ice significantly influence adhesive forces at the interface and cohesive forces in the ice. Load displacement curves in Figure 2 showed that very little movement mobilized ice adhesion forces and that rupture occurred for displacements of 0.1 mm or less. During creep, ice adhesion may continue for larger displacements. The second component, friction, is dependent on the coefficient of friction (or friction angle) between the soil particles and pile surface and is proportional to the normal stress pushing particles against the pile. An upper limit would be the long-term strength, τ_{lt} , of frozen soil which is comprised of both cohesive, c_{lt} , and frictional, ϕ_{lt} , components and can be expressed by the Mohr-Coulomb relation,

$$\tau_{lt} = c_{lt} + \sigma \tan \phi_{lt} \quad (1)$$

where σ is the normal stress on the shear plane. Weaver and Morgenstern (1981) indicated that the

normal stress on a pile is typically less than 100 kPa so that the frictional component of adfreeze bond would generally be very small. Surface roughness of the pile introduces mechanical interaction forces when pile movement occurs relative to the sand particles. Roughness is dependent on surface geometry and actual heights of asperities on the pile surface. Lugs on the pile surface were used to increase surface roughness and to permit mobilization of bearing forces acting on the frozen sand. Bearing forces on the single lug in Figure 2 prevented the load from decreasing at larger displacements to the smaller residual load shown for the plain bar ($h = 0$). Use of multiple lugs (Figure 3) altered the load-displacement curves raising questions as to lug spacing for a given lug height.

Lug Size Effect

The use of lugs provided an increase in surface roughness of the model piles and increased both ice adhesion and mechanical interaction during movement in the frozen sand. The effect of increasing lug size on load displacement curves is shown in Figure 2. The lug increased surface area for ice adhesion but more importantly the lug increased the volume of ice matrix and soil particles involved in the initial bond rupture. This rupture involved both ice adhesion at the interface and cohesion in the ice matrix resulting in an increased adfreeze bond strength. After initial rupture the pull-out load decreased to a small residual value for plain bars. The presence of lugs and additional bar movement permitted mobilization of mechanical interaction forces. For a model pile with a single lug the ultimate load developed at from 2 mm to 5 mm displacement (Figure 2). The ultimate load for multiple lugs (Figure 3) developed at about 1.4 mm displacement and then decreased, probably due to pressure bulb overlap and formation of a void space behind the lug.

Data for constant load (creep) pull-out tests are summarized in Figure 5 with load and displacement (creep) rates both plotted on logarithmic scales. The data suggest a straight line relationship for each lug size for which the adfreeze load P can be expressed as

$$P = P_{c\theta} \left(\frac{\dot{\delta}}{\dot{\delta}_c} \right)^{1/n} \quad (2)$$

where $\dot{\delta}$ is the creep displacement rate, n is the creep parameter, and $P_{c\theta}$ is the adfreeze proof load for an arbitrarily selected displacement rate $\dot{\delta}_c$. The adfreeze strength can be readily calculated based on the 9.52 mm bar diameter and 152 mm embedment length. Some data points at the slower creep rates appear to fall to the left of their respective lines in Figure 5. It appeared that loads for these points were below the long-term strength for the corresponding bar displacement rate. Secondary creep would not have been reached for the time given to that load increment and the recorded creep rate would be larger than the true creep rate.

Temperature Effect

Temperature, thru its influence on cohesive forces in the ice matrix and adhesive forces at the pile/frozen sand interface, has a significant effect on adfreeze bond strength. This influence was

FIGURE 5 Lug height effect on load for creep of plain 9.52 mm bars in frozen sand at -10°C with a sand volume fraction of 64 % (data from Alwahhab, 1983).

shown by the pull-out load versus creep displacement rate data summarized in Figure 6 for tests on 9.52 mm diameter model piles with a single 3.17 mm lug. Temperatures of -2 , -6 , -10 , and -15°C are represented by the four lines. Again some observed creep rates are larger than their true values for the reason explained in the previous section. The slope and hence the creep parameter n are the same as in Figure 5. Selection of one creep displacement rate, plotting these loads, $P_{c\theta}$, against $(1 + \theta \theta_c^{-1})$, both on logarithmic scales, permits evaluation of the exponent ω (Figure 7) in the equation

$$P = P_{c\theta} \left(\frac{\dot{\delta}}{\dot{\delta}_c} \right)^{1/n} = P_{co} \left(1 + \frac{\theta}{\theta_c} \right)^{\omega} \left(\frac{\dot{\delta}}{\dot{\delta}_c} \right)^{1/n} \quad (3)$$

where θ is the absolute value of the negative temperature in degrees Celsius, θ_c is an arbitrary temperature, usually 1°C , and P_{co} is $P_{c\theta}$ for a freezing temperature close to 0°C . Other symbols are the same as in equation 2.

Bond Dependence on Ice Content

Adfreeze bond strength at the pile/frozen sand interface will vary with ice content. The one extreme will include only ice adhesion at the

FIGURE 6 Temperature effect on load for creep of plain 9.52 mm steel bars with a 3.175 mm lug in frozen sand with a sand volume fraction of 64 % (data from Alwahhab, 1983).

interface and cohesion within the ice. The other extreme, with very dense sand, will include large contributions from mechanical interaction between sand particles and the pile surface roughness. A series of constant load (creep) pull-out tests on frozen sand with different ice contents (or sand volume fractions) provided the load versus creep displacement rate data summarized in Figure 8. The 9.52 mm model steel pile included a single 3.17 mm lug. The line representing a 64 % sand volume fraction was also included in Figures 5 and 6 for $h = 3.175$ mm and $T = -10$ °C, respectively. It appears that the creep parameter n (based on slope of the lines) is independent of both temperature and ice content for the range of creep rates shown.

The influence of ice content on creep pull-out loads is shown in Figure 9 for two constant creep displacement rates. The zero sand volume fraction, represented by polycrystalline snow-ice, gave the

FIGURE 7 Temperature dependence of P_{co} for a creep displacement rate \dot{S} equal to 1 $\mu\text{m}/\text{min}$ (data from Figure 6).

smallest adfreeze strength. Most ice found in soil pores is of a polycrystalline type with random crystal orientation. The addition of dispersed sand particles to this ice increased the adfreeze strength, perhaps due to the greater stiffness of the particles which involves more ice volume at the pile/frozen sand interface in the failure process.

FIGURE 8 Effect of sand volume fraction on load for creep of plain 9.52 mm steel bars with a 3.175 mm lug in frozen sand at -10 °C (data from Alwahhab, 1983).

FIGURE 9 Load dependence on sand volume fraction during creep for plain steel 9.52 mm bars with a 3.175 mm lug at -10°C .

Beginning at a sand fraction close to 42 %, sand particle interaction with pile surface roughness rapidly increased the pull-out load and adfreeze strength. The curves in Figure 9 clearly show the benefits of using a high density sand slurry mixture during field placement of piles.

CONCLUSIONS

1. Ice adhesion was mobilized at very small displacements with rupture at less than 50 μm for constant displacement rate tests. The presence of sand particles and more surface roughness (lugs) increased the ice matrix volume involved in rupture and thereby significantly increased the adfreeze strength.

2. With an increase in surface roughness (addition of a single lug) load-displacement curves showed the initial rupture of ice adhesion followed by mobilization of mechanical interaction forces. Use of multiple lugs showed an increase in the ultimate pull-out load in a direct ratio to the number of lugs. Suitable lug spacing appears to be dependent on pressure bulb overlap for consecutive lugs and formation of a void space behind lugs.

3. Creep displacement behavior will differ considerably, depending on pile movement. Very small displacements characterize the start of tertiary creep for applied shaft stresses below those required for initial rupture of ice adhesion. Larger displacements and higher shaft stresses are associated with mobilization of mechanical interaction forces.

4. Sand volume fraction (or ice content) significantly influenced the adfreeze strength for a

given creep rate, bar and lug size. For ice-rich samples (sand volume fraction $< 42\%$) the adfreeze strength depends primarily on ice adhesion and behavior of the ice matrix. Mechanical interaction of pile surface roughness with sand particles was important primarily for ice-poor samples (sand volume fraction $> 42\%$).

5. Methods used to account for temperature effects on the adfreeze strength (or pull-out loads) agreed very well with the experimental data. The creep parameter n was independent of temperature and ice content over the range of creep rates observed.

INCREASE WITH DEPTH OF FREEZE-BACK PRESSURES ON THE SIDES OF
DRILLHOLES ASSOCIATED WITH FREEZING OF A FLUID IN A CAVITY

V. I. Antipov and V. B. Nagayev

Research Institute of Petrochemical and Gas Industry
Moscow, USSR

Recently, there has been a considerable growth of interest in the problem of secondary freezing of thawed materials around a drillhole. This is associated with the fact that the process of secondary freezing leads to the development of considerable freeze-back pressures on the walls of drillholes, which may lead to their collapse. Analysis of studies of secondary freezing has shown that no satisfactory theory has been advanced thus far which would permit reliable forecasting of a stressed condition in the freezing materials around a drillhole. The present paper suggests an approximate theory for calculating maximum freeze-back pressure σ_{\max} on the walls of a drillhole as the materials freeze around it and as drilling mud filtrates freeze in a cavity. Identification of the dependence of σ_{\max} on depth is based on the solution of the problem of the axially-symmetrical plane on the development of the freeze-back pressure $\sigma(t)$.

SOLUTION FOR FREEZE-BACK PRESSURE

In this paper an approximate theory is proposed on the basis of permafrost soil and ice equations derived from experiments. Following the work of Dubina (1977) it is easy to obtain the freeze-back pressure on well casings (Figure 1), if the equations of ice state are based on the Mellor and Smith (1966) isotherm and Royen (1922) hypothesis which considers dependence of ice properties upon temperature τ :

$$\sigma(t) = -n(Ksv)^{\frac{1}{n}} A^{\frac{1}{n}} \left[S(t)^{\frac{2}{n}} - S_0^{\frac{2}{n}} \right] - \frac{\xi K^m \text{Sin} [\pi(1-\lambda)]}{3 \frac{m+1}{2} \pi \lambda m S_0^{2m}} \times \int_0^t \frac{d}{d\tau} (S_0^2 - S(t)^2)^m (t-\tau)^{-\lambda} d\tau, \quad (1)$$

where t = time;
 d = radius of the casing;
 S_0 = radius of a cavity;
 $S(t)$ = inner radius of the ice-water interface in a cavern;
 v = velocity of the ice-water interface;
 n, A = the parameters of ice state equation;
 k = coefficient of volumetric expansion when ice forms from water;
 m, ξ, λ = the rheological parameters of permafrost soil.

To determine the maximum pressure on a casing σ_{\max} , which develops if there is complete freezing of mud filtrate in a cavity, it is necessary to assume $S(t) = a$, the radius of the casing and $t = t_a$ in equation 1, where t_a is time of complete freezing of fluid in a cavity.

$$\sigma_{\max} = -n(Kav)^{\frac{1}{n}} A^{\frac{1}{n}} \left(a^{\frac{2}{n}} - S_0^{\frac{2}{n}} \right) - \frac{\xi K^m \text{Sin} [\pi(1-\lambda)]}{3 \frac{m+1}{2} \pi \lambda m S_0^{2m}} \times \int_0^{t_a} \frac{d}{d\tau} (S_0^2 - a^2) (t - \tau)^{-\lambda} d\tau. \quad (2)$$

The calculation of σ_{\max} at various depths according to equation 2 gives the values which decrease with the depth, but do not agree with observations. In field experiments Ruedrich and Perkins (1974) observed that the value σ_{\max} increases as the depth Z increases. According to the plane axially symmetrical problem just solved, this is an unlikely result.

However, it is taken into account that during freezing of a fluid in a cavity a frozen girt (Figure 1) is formed in the top of the cavity, then a relationship $\sigma_{\max Z}$ which agrees with the field data may be obtained (Figure 1). This girt does not allow the fluid remaining to flow upwards under pressure and thus pressure builds up in the system. Eventually new and thicker ice layers form up to the well casing, thus increasing the volume of the frozen fluid. This results in continuous compression of the fluid remaining in a cavity, which accumulates stresses transformed to the well wall. So to determine value σ_{\max} at a depth Z it is necessary to add value σ_{\max} derived from the solution of the axial-symmetrical problem at the same depth to the pressure that has accumulated in the fluid adjacent to the casing in the frozen overlying layers.

Thus, to determine $\sigma_{\max Z}$ at a depth Z (Figure 2) the pressure $\Delta\sigma_{\max Z}$ adjacent to the well casing where an ice layer is built up and the hydrostatic pressure $\Delta\sigma_r$ corresponding to the difference in the elevation of Z and the elevation of the previous

calculation I, should be added to the value σ_{max1} :

$$\sigma_{maxZ} = \sigma_{max1} + \Delta\sigma_{maxZ} + \Delta\sigma_r \quad (3)$$

A computer-aided numerical solution of the first two quantities of this expression was developed according to the equations of Bulatov (1979) for cavities in the upper part of the profile of the well DS4-6 described by Ruedrich and Perkins (1974). Figure 3 illustrates the resulting theoretical relationship σ_{maxZ} , obtained with equation 3 and the experimental values obtained from transducers on the well casing.

CONCLUSION

In the framework of the model under consideration it is quite natural to expect freeze-back pressure build-up with depth. The comparison of computed freeze-back pressure values calculated with equation 3 with the field experimental data convinces us that the theoretical model chosen is appropriate.

When choosing the optimum technological production conditions of wells under permafrost one should consider build-up of freeze-back pressure according to equation 3 rather than equation 2, as the σ_{max} increases with depth.

THERMAL ABRASION OF COASTS

F. E. Are

Permafrost Institute, Siberian Branch
Academy of Sciences, Yakutsk, USSR

Thermal abrasion of the shores of any water body or stream is controlled by the same basic principles and is distinguished by peculiarities dictated by differing hydrological regimes. The main influence of the frozen state of the materials on the development of thermal abrasion is determined by their ice content and reveals itself when the materials slump on thawing. The greater the potential for settlement, the greater is the rate of thermal abrasion and the limiting value of shore retreat. The frozen condition of the materials does not prevent destruction of the shores. In the case of large water bodies the thermal abrasion rate is dictated by the removal of the thawed materials from the shore zone, while in small water bodies and in shores developed in massive ice bodies the limiting factors are the thermal processes. During recent decades climatic cooling has slowed the rate of thermal abrasion by the sea. One of the possible controls on the orientation of thaw lakes is the irregular development of thermal abrasion due to spatial variations in the distribution of sediments prone to thermal abrasion collapse in their shores. Rates of erosion in river banks developed in similar materials are identical whether or not permafrost is present.

Coastal thermal abrasion of water bodies (seas, lakes, storage reservoirs, rivers) is an integrated process of destruction of coasts, composed of frozen materials that follows the same general principles. Destruction is due to the combined hydromechanical and thermal impact of water masses on coasts. The hydromechanical effect is exerted by waves and currents which develop in various combinations on all water bodies. When considering the erosion of coasts of seas and other large water bodies, the destructive effect of waves has commonly been invoked. But choppiness is always accompanied by currents, the velocity of which is of the same order of magnitude as that of river currents. It is these currents that perform major work on wash-out of coasts and longshore drifts. On the other hand, large rivers commonly produce severe roughness which plays an important role in the destruction of their shores. For example, in the area near the mouth of the Lena River such strong gales occur that even lake-class vessels are compelled to take cover. Thus, there is no difference in the principles of erosion among coasts of seas, lakes, reservoirs and rivers. The same situation applies to the thermal effect of water masses on coasts. Just the same is the development of littoral benches, i.e. part of the littoral zone above the water on reservoirs and rivers. Processes of destruction of coasts of different types of water bodies differ only in some features produced by the different hydrological regime. This makes it possible to develop a unified theory of thermal erosion process for water bodies of all types.

Observations made by a number of researchers indicate that even under the most severe climatic conditions, in the spring thermal erosion starts at above-zero temperatures of water within water bodies. The published data on the depth and

character of seasonal thawing on the littoral shelf, measurements by this author on the coasts of the Lena, the Aldan, the Vilyui reservoir, and the Laptev Sea, as well as calculations of seasonal thawing depth on the littoral shelf lead us to conclude that from the earliest days of the ice-free period the underwater slopes of coasts attacked by thermal erosion are covered by a layer of unfrozen drift. Therefore, for a wide range of natural conditions thermal erosion results from the wash-out of an unfrozen surface layer. Direct wash-out of frozen ground is observable only in the upper part of the littoral shelf at the time of storms, high water and flash floods. Exceptions are coasts bordered by ice and those of some thermal-karst lakes in the tundra.

We should distinguish between the two kinds of thermal effect of water bodies on permafrost: a direct effect and an effect transmitted through a layer of unfrozen ground. The direct effect leads to a maximum impact. The theory of heat transfer lacks any solution for its calculation. To infer the order of magnitude, one can resort to the formula for computing convective heat transfer at longitudinal flow of a turbulent current along a plate. For the case of minor roughness (ripple 0.3 m high), these formulas give a value of the coefficient of convective heat transfer of the order of 1100 W/(m² °C). With such a coefficient of convective heat transfer and the temperature of water +1°C, a sheer ice precipice would recede about 30 m during three months of an ice-free period (Are 1979a).

O. N. Vinogradov and A. N. Krenke (1964) have determined the rate of ice coast retreat due to thermal erosion on Franz Josef Land (Sedov glacier) to be the difference in observed velocities of the glacier movement and the advance of a vertical ice cliff into the sea in the period between the

subsequent separations of icebergs. They have obtained a value of 20 m per year. In the area under consideration, the sea is predominantly ice-free from 2 to 4.5 months in the year, but throughout the summer it abounds in drift ice. The water temperature does not exceed 3°C. The Sedov glacier is descending into a relatively closed bay. Under these conditions strong chop-piness is seldom observed (Sukhodrovsky 1967).

Based on laboratory and in situ measurements, Pekhovich and Shatalina (1970), and Khodakov et al. (1978) have derived identical equations of convective heat transfer for the case of a water flow moving along ice plates. The coefficient of convective heat transfer, inferred from these equations for conditions of minor agitation, is 2000-3000 W/(m² °C).

The calculations of W. Morgan and W. Budd (Schwerdtfeger 1979), based on a generalization of ground-based and spacecraft observations of near-Antarctic water temperatures drift velocity and decrease of icebergs in size as these move away from the Antarctic coast, have shown that in the course of three months at a water temperature of +1°C, between 10 and 20 m of ice melt off the underwater surface of icebergs.

The above mentioned results of calculations, experiments and in situ observations indicate that the thawing rate of ice and primarily of exposed frozen ground in contact with water exceeds by a few or many times the observed rates of wash-out of coasts attacked by thermal erosion which in the Arctic seas normally do not exceed 10 m per year (Are 1980). Thus, the potential for ground thawing on a littoral shelf is very great, but because of the presence of a surface layer of unfrozen debris that slows down the thawing it is generally not fully implemented.

Under the severe climatic conditions of the Arctic coast at the subzero annual mean temperature of water, the bottom seasonal thawing near thermal abrasive coasts, composed of thaw-collapsible permafrost, causes the bottom surface to lower substantially. Every year this occurs until the permafrost surface accumulates a layer of thawed and settled sediments, whose thickness is equal to the depth of seasonal thawing. Mathematical simulation, on a computer, of the process in question has been carried out. In selecting the input data, it was assumed that thawing applies to a sea bottom composed of the ice complex (silty sediments of high ice content and a high content of polygonal ice wedges), whose properties are listed in Table 1. The surface temperature of the bottom is specified in two variants (Table 2). Variant A corresponds to warmer sea conditions in which the mean annual temperature of the bottom surface tends to be zero. Variant B roughly corresponds to more severe conditions near the coast of Kotelnny Island (Table 3). Under normal conditions, except for extreme variant 1-A, the process under consideration declines rapidly. For the first two years, more than a half of the possible subsidence was completed, and that frequently reached 2 m. The time required for it to reach an equilibrium state seldom exceeds 10 years.

The permafrost temperature effect in the development of thermal abrasion is small because, as soils are thawing, the amount of heat required

for their temperature to rise is generally much smaller than that required for ground ice to melt.

The main influence of a frozen state of soils upon the development of thermal erosion is determined by their ice content, and it manifests itself when ice content exceeds the porosity in an unfrozen state, that is, when soils involve thaw settlement. This effect implies two aspects.

On one hand, the volume of sediments coming into the water body when the coast composed by thaw collapsible ground is being destroyed, is smaller than that resulting from destruction. This diminishes the work of water bodies, required for them to wash out and transport soils, in comparison with coasts composed of similar thaw-uncollapsible ground.

On the other hand, thawing of collapsible soils forming the bottom is attended by a deepening of the water body and, therefore, by an increase of wave energy. In the absence of agitation, thermal settlement of the bottom itself may cause coastal recession.

For that reason, other conditions being equal, with increasingly excess ice content, there is an increase of the rate of thermal erosion and of the limiting value of coastline recession.

If ice content of soils composing the coast exceeds a critical value, the coast then recedes continuously. Critical ice content is that ice content in soils at which their complete thawing produces a settlement of the ground surface down to the water level in the water body (G_b). It is matched by the critical level of the water (G_k), which coincides with the surface level of soils constituting the coast, following their complete thawing and settlement. The possibility of

TABLE 3 Results of Calculations of Perennial Seasonal Thawing Below Sea Bottom (Limiting State)

III-A	1.1	0.7	0.4	9
II-B	1.5		1.0	4
III-B	0.75	0.5	0.25	4

unlimited destruction of the coast is determined by the relation $G_b \geq G_k$. If its left-hand side is less than the right-hand, coastal recession has a limit, and, if vice versa, recession becomes continuous, and one of the main principles of the theory of development of sea shores is violated, that at constant sea level erosion is restricted by the development of a limiting profile of equilibrium.

Perennially frozen unconsolidated deposits differ by having greater content of silt particles than their unfrozen counterparts. Particularly high silt content occurs in the ice complex of the Yana-Indigirka depression and the Kolyma-Alazeya shoreland where the predominant silt content amounts to 60-80%, and the maximum is around 95%. Silt content exerts the same influence upon development of thermal erosion as the ice content of thaw-collapsible soils because fine particles are easily suspended and transported by water (Are 1980). As for large shallow water bodies, the shores of which are formed by permafrost of high silt content, wash-out and transport of bottom sediments develop throughout the water area, and the concept of a shore slope below the water is virtually invalid here.

Perennially frozen unconsolidated deposits are able to withstand the destructing impact of water masses only in a frozen state. Once unfrozen, its wash-out capacity is equal to or greater than that of unfrozen soils of similar composition.

Calculations of the shore wash-out coefficient, according to Kachugin (1959) for several areas of sea and lake shores attacked by thermal erosion are formed of an ice complex, have shown that the values of the wash-out coefficient, inferred by neglecting thaw settlement, are in excess of $300 \cdot 10^{-9} \text{ m}^3/\text{yr}$. Thus, the ice complex, or permafrost with the highest ice content, is, according to Kachugin's classification, a soil readily yielding to wash-out. Its wash-out rate is equal to or larger than that of unfrozen soils of similar composition: fine and silty sands, loess-like sandy loam and loam (Are 1979a). Permafrost wash-out rate depends on its cryogenic texture. For instance, in the case of net-like texture it is one order of magnitude higher than for a massive one (Ershov et al. 1979).

The results of the investigations discussed so far indicate that, in the case of destruction of shores attacked by thermal erosion, ground thawing occurs before wash-out. Consequently, the

frozen state of soils, in all practicality, does not hinder shore destruction. For large water bodies, the rate of thermal erosion is limited by wash-out of unfrozen products of littoral zone destruction, rather than by thermal processes. Therefore, agitation on large water bodies plays the same role in the development of shores as outside the permafrost zone. Thermal-erosional shores of small bodies of water, with a water level exceeding a critical one, low energy of agitation, and weak currents recede mainly due to thermal destruction. This is the least intensive type of thermal abrasion.

The influence of the ice cover of water bodies upon thermal-erosional shores leads, in the main, to preventing their destruction. In this case, the most important role is played by the duration of the ice cover, and in seas also by the amount of drift ice in summer. The destructive effect of ice on shores is not great and does not substantially influence the shoreline position.

Thermal erosion is defined by its irregular discontinuous development. Its maximum rate is observed for extremely high water levels. In the seas, particularly strong storms, accompanied by a precipitously high level storm surge, produce shore destruction that would require many years to accomplish at normal rates of erosion.

The rate of retreat of thermal-erosional sea shores varies greatly in space and time. Even the values averaged over 20-25 years are most irregularly distributed along the littoral. There are no regular differences in retreat rate of thermal-erosional shores formed by yedoma and thaw-lake sediments.

The exceptionally rapid retreat of thermal-erosional sea shores, with a rate of 100 m or more per year, is generally recognized. In the last 150 years, the maximum rate of thermal abrasion was observed in 1944-1946 on Semenovskiy Island in the Laptev Sea to be at least 55 m per year. The average long-term rates are far lower. For shores formed by fine-grained soils of high ice content (ice complex, alas sediments, etc.) the maximum mean rate from many years of observations is roughly 10 m per year, while the predominant mean values for shores of mainlands and large islands vary from 2 to 6 m per year. The mean estimated thermal abrasion rates along the large lengths of the coast (tens of kilometers) usually do not exceed 2 m per year.

The rate of thermal erosion of sea shores formed

by ice-rich, fine-grained soils, under comparable conditions seems to exceed by 3-4 times that of shores formed by unfrozen ground of similar lithologic composition. But annual rates of shore retreat are close to each other because during most of the year the Arctic Seas are ice-covered.

The last decades have witnessed a tendency of the thermal erosion rate to decrease. A likely cause of this is the increase of drift ice amount in the Arctic Seas, as a consequence of the fall of temperature since 1940.

One of the main features of thermal erosion of lake shores is its dependence on dimensions of water area. This dependence is different for shores formed by soils of different ice content. If ice content is much lower than a critical one (thaw uncollapsible ground), shore wash-out can then develop for a geologically long time only for very large lakes, the hydrological regime of which is close to that of seas. Therefore, most of the lakes of this type have stable shores. If ice content of shore-forming soils exceeds a critical one, then thermal erosion proceeds irrespective of the water area dimensions. These factors have the implication that thermal erosion is presently observed mainly for thermokarst lakes. This has, in particular, been pointed out by Tomirdiano and Ryabchun (1973).

Thermal-erosion induced destruction of the shores of thermokarst lakes can develop irregularly due to the different force and duration of differently directed winds. This non-uniformity is believed to be one of the possible reasons for the formation of oriented lakes. But its influence depends on some other factors, discarded so far when considering the problem of oriented lakes. These include wash-out and thaw-collapsible rates of soils, the thickness of thaw-collapsible ground and its hypsometric position with respect to the water level. These factors can determine a given orientation of thermokarst lakes if they obey regular spatial variations and conversely, they can be responsible for the diversity in shape of lakes if their spatial variations have a random character.

The mean rates of many years of wash-out of the banks of the Lena River have been determined for the last 18-26 years (Are 1979). In the middle flow on a floodplain the total average rate of bank retreat is 6.5 m per year. The rate of retreat of steep banks of principal river branches amounts to 19-24 m per year. The front parts of islands are washed out with a rate of up to 40 m per year. The rate of wash-out of a sand terrace above floodplain, 25-30 m high, reaches 11 m per year in the area of the steep bank of one of the principal river branches.

In the Olenek channel of the Lena River delta the banks composed of muskegs up to 9 m thick, split by wedge ice and supported by a sand base, retreat at a mean rate of 1.7 m per year. In the sharpest curves the maximum rate is as high as 6 m per year.

Comparison of wash-out observations of the banks of the Ob River (Zemtsov and Burakov 1972, Trepetsov 1973) and the Lena River has shown that under quite similar hydrological conditions the floodplain and low terraces above the floodplain, formed of sand and sandy-loamy unfrozen and perennially

frozen thaw-uncollapsible soils, are washed out approximately with the same intensity.

Under comparable conditions, the annual values of retreat of river banks of the permafrost zone can be smaller than those outside it because of the short duration of active wash-out due to the peculiarities of the hydrogeological regime of rivers in the permafrost zone. These peculiarities are most pronounced in small plainland rivers, fed by atmospheric precipitation.

One of the possible reasons for the abnormally broad river valleys in the permafrost zone is the thaw-collapsibility of soils of the upper part of the geological cross-section. The influence of this effect decreases with the deepening of the valley because the ice content of soils drops off with depth.

PREDICTING FISH PASSAGE DESIGN DISCHARGES FOR ALASKA

William S. Ashton and Robert F. Carlson
Institute of Water Resources, University of Alaska,
Fairbanks, Alaska 99701 USA

Improper placement of highway culverts may selectively or totally block fish migration, thereby decreasing available spawning and rearing habitat. Blockage will occur with a combination of excessive culvert water velocities, lack of fish resting areas upstream and downstream of the culvert, and scour at the culvert outlet, creating perched conditions. Previous studies of fish passage culverts have determined fish swimming abilities and profiles of culvert water velocity. There are limited studies of the hydrologic relationship among frequency, duration, season, and magnitude of discharge for the design of fish passage through culverts in northern regions. We analyzed streamflow records from 14 gaging stations in south central, interior, and arctic Alaska (drainage area <260 km²) to determine the highest consecutive mean discharge with 1, 3, 7, and 15 day durations. Streamflow during three periods were analyzed: spring, April 1 to June 30; summer, July 1 to August 31; and fall, September 1 to November 30. The Lognormal distribution, using the Blom plotting position, predicted flood frequency values. Regionalization, with the index-flood method, of single station values provides a method for predicting discharges from ungaged drainage basins. Regressions developed to predict the 2-year return period discharge found that the significant basin characteristics were basin area and forest cover in the spring period, and basin area, forest cover, and mean annual precipitation in the summer and fall periods.

INTRODUCTION

Four criteria must be considered for effective and practical design of highway culverts to pass fish: the flow regime of the stream, the hydraulic properties of the culvert (i.e., shape, roughness, or length), the swimming abilities of the fish species and age classes present, and the time of year of fish movement and migration in the stream. Understanding the flow regime is important for determining the relationship among the frequency, duration, season, and magnitude of flow. The frequency is important to understanding the risk or probability that a given magnitude of flow will occur. The duration of time for which a given magnitude of flow is exceeded provides the time a fish species might be delayed in its normal migration. The season of the flow tells whether a given magnitude flow will occur during a critical period in the life cycle of a fish species. This three-dimensional representation provides a more detailed description of the flow regime than the highest annual instantaneous discharge.

Development of arctic oil and gas resources in the United States and Canada has provided an impetus to study the effects of highway culverts on fish passage in northern latitudes (Dryden and Jessop 1974, MacPhee and Watts 1976, Katopodis et al. 1978, and Elliott 1982). Prevention of extended delay of fish in their upstream migration is an important design criterion. Delay of spawnable fish can cause them to spawn at less suitable spawning sites, affecting spawning success and causing stress and physical damage. This makes them more vulnerable to disease and predation (Dryden and Stein 1975). Dryden and Stein estimate a maximum delay of 3 days during the mean annual flood may be tolerated by a

spawning run without serious biological consequences. During the design flood, with a return period of 50 years, they recommend a maximum delay period for spawners of 7 days. These maximum delay periods have been recommended in culvert designs for the MacKenzie Highway in the Northwest Territories (Dryden and Stein 1975). The State of Alaska Office of the Pipeline Coordinator (State Pipeline Coordinator's Office (SPCO) 1982) design requirements for the proposed Alaskan Northwest Natural Gas Transportation System specify use of the instantaneous mean annual flood. Allowable delay time is not mentioned. During 3 years of study on Popular Grove Creek, Alaska, spring upstream migration of arctic grayling (Thymallus arcticus), the primary design fish in interior Alaska, preceded the spring peak discharge in 1973, followed it in 1974, and occurred about the same time in 1975. Consideration must be given to spawning migrations of other species occurring during the summer and fall (Watts 1974). Morrow (1980) describes the periods of spawning migration generally as: arctic grayling in the spring, chinook and sockeye salmon during the summer, and Dolly Varden and coho salmon during the fall. To predict the effect of high flows on fish passage through culverts, knowledge of the flow regime during these fish passage periods is required.

Regionalization of single station discharge data is a technique for predicting discharge from ungaged drainage basins. Of the methods available, empirical approaches such as the index-flood method are practical in regions with few long-term stations (Benson 1962). One of the problems with the index-flood method is the effect of drainage basin size on the slope of

the frequency curve. To reduce this effect, only basins smaller than 260 km² are considered. To account for the differently timed spawning migrations of different species, three periods of analysis are used: spring, summer, and fall. Since most of the concern for fish passage is at low return period flows, only flows with return periods of 20 years or less are used.

METHODS

We used streamflow data from continuously recording U.S. Geological Survey gaging stations in the hydrologically similar area (Area II) defined by Lamke (1979; Figure 1). Stations

FIGURE 1 Areas of Alaska used in the flood-frequency analysis. Station numbers show approximate location of the gaging stations used in this paper (from Lamke, 1979).

within this region were deleted from further consideration if the basin area was greater than 260 km², 15% or more of the basin area was covered by glaciers, the streamflow was regulated, or there were less than 5 years of record as of November 1981. Aleutian Island stations, although within Lamke's region definition, were deleted from consideration. Outliers and stations with zero flow periods are treated as described in Kite (1977). Three periods of the year were selected for streamflow analysis: spring, April 1 to June 30; summer, July 1 to August 31; and fall, September 1 to November 30. The highest consecutive mean discharge with durations of 1, 3, 7, and 15 days were computed for each period. Predicted discharge values were computed using a Canadian flood frequency program (Condie et al. 1976). Four frequency distributions are available with this program: Gumbel (Extreme Value Type I), Lognormal, Three-Parameter Lognormal, and the Log-Pearson Type III. Each of the distributions uses the maximum likelihood method of fitting. In the event a true solution is not found by this method, a moment fit is used. Condie et al. revised the program in 1981 to replace the Weibull

plotting position formula with a generalized plotting position formula developed by Adamowski (1981). The Lognormal distribution was selected for further analysis of the streamflow data. The program was modified to provide the 95% confidence limits for each predicted value, and to use the Blom plotting position formula

$$F_i = (i - 0.375)/(N + 0.25), \quad (1)$$

where F is the plotting position of i th smallest as a probability value of the flow being less than the associated flow, i is the serial number of i th smallest in a sample size N , and N is the sample size (Cunnane 1978).

We regionalized the single station data using the index-flood method as modified for use with computers, the Lognormal distribution and computation of confidence limits (Coller 1963, as cited in Kite 1977). The mean annual flood was defined by the predicted flood with a probability of occurrence of 0.50. Only stations with 10 years or more of record were used. If a station had 10 years of record during at least two of the three periods, the station was included in the analysis, otherwise it was dropped from further consideration. Dimensionless flood ratios were computed by dividing predicted floods with return periods of 2, 5, 10, and 20 years by the predicted 2-year discharge. Floods with return periods higher than 20 years were not considered. Dimensionless ratios were computed for the four durations within the three periods, and median ratios were selected for dimensionless plots. Confidence limits for each ratio were determined by dividing the upper and lower 95% confidence flood value at each return period by the predicted 2-year return period discharge. Median values were selected from these ratios and plotted as confidence limits on the flood ratio plots. Multiple regression equations were developed using basin characteristics and climatic parameters to predict the 2-year discharge on ungaged drainage basins. Regression coefficients were computed using an HP 9845 stepwise regression program. Due to limited data, a maximum of three independent variables were considered for each equation. A variable was included in the model if it was significant at the 5% level and increased the R^2 by at least 5%. Variables considered in regression analysis were drainage area, mean annual precipitation, basin storage area, forest cover, glacier area, mean minimum January temperature, mean basin elevation, and mean annual snowfall.

RESULTS

Nineteen gaging stations met the criteria of basin size, percent of area as glaciers, and length of record. A base period of 1965-1981 was selected, reducing the number of stations to 14 (Table 1). Dimensionless flood ratios were computed and plotted with 95% confidence limits (Figure 2). The 2-year return period flood for ungaged basins is predicted using a regression

equation with the form

$$Q_{mn} = aA^bP^c(F+1)^d, \quad (2)$$

where

- Q_{mn} = dependent variable, the peak mean discharge for the mth period, where s is spring, su is summer, and f is fall, and the nth duration where l is 1 day, 7 is 7 days, and so forth, m³/s;
- a = regression constant;
- b, c, and d = regression coefficients for the independent variables (basin characteristics);
- A = drainage area, km²;
- P = mean annual precipitation, mm;
- (F + 1) = percent forest cover, expressed as a whole number.

The regression coefficients, with their associated percent standard error, are given in Table 2. Basin characteristics used in the analysis are from Lamke (1979) and SPCO (1981). Basin characteristics not included in these publications are taken from the sources cited by Lamke.

DISCUSSION

Regionalization of single station data illustrates the hydrologic complexity of small basins and regions with sparse data networks. Hydrologic similarity among drainage basins is required for regionalizations. In practice, however, the degree of dissimilarity permitted

within a homogenous region is not well defined (Molsey 1981). The regionalization by Lamke (1979) determined significant basin characteristics in the flood hydrology of Alaskan streams. Among these are the mean minimum January temperature and percent forest cover. These characteristics are believed to be indirect indicators of the presence or absence of permafrost. As more data become available, refinements are made of these initial assumptions. With five additional years of streamflow data, Janowicz and Kane (1983) and SPCO (1981) have determined, for instantaneous annual peak flows, that Lamke's Area II can be subdivided. Because of insufficient data and the generalized nature of the data we do have, we cannot determine the effect of permafrost on

arctic and subarctic statistical flood hydrology.

The regionalization presented in this paper predicts flood magnitudes for small drainage basins. These flood magnitudes can be predicted for the season of the year, flow duration, and frequency of occurrence of interest. This method provides reasonable estimates for watersheds with the following limitations: the basin area should be <260 km² and glacier cover should be <15% of basin area; predicted spring 1-day flows can exceed Lamke's predictions for some combinations of basin characteristics; and since spring flow predictions for streams in the Anchorage bowl are overestimated, multiply estimate by 0.4 (Lamke recommends 0.5 for instantaneous peak flows regardless of season).

For the design of culverts for fish passage, Watts (1974) recommends use of the probable discharge at the time of fish migration. Timings of fish migrations vary with species and geographic location. Of the fish passage culvert design methods (Watts 1974, and Dryden and Stein 1975) that recommend a fish passage discharge less than the instantaneous annual peak, none provide a method for predicting discharges on ungaged watersheds. The regionalization described in this paper provides culvert designers with a method for predicting the fish passage discharge on ungaged watersheds in Alaska.

ACKNOWLEDGMENTS

This paper presents results from research funded by the Federal Highway Administration and administered by the Alaska Department of Transportation and Public Facilities, project number F36202. The authors are grateful to D. Thomas for answering our statistics questions.

PERIGLACIAL GEOMORPHOLOGY IN THE KOKRINE-HODZANA HIGHLANDS OF ALASKA

Palmer K. Bailey

Department of Geography and Computer Science
United States Military Academy, West Point, New York 10996 USA

The portion of the Kokrine-Hodzana Highlands near the Arctic Circle and adjacent to the Dalton Highway is an easily accessible area containing a diverse assortment of periglacial features. The region is within the discontinuous permafrost zone and probably has never been glaciated. Bedrock is principally metamorphic with major intrusions of porphyritic granites and some mafic and ultramafic rock. The nature of the bedrock profoundly affects the type and character of the local landforms. Finely jointed and foliated bedrock tends to promote development of cryoplanation terraces. Terraces are most fully and distinctly developed on metamorphic bedrock, especially schist and phyllite, at elevations above 600 m. Terraces are usually obscure or absent on igneous bedrock. Widely jointed massive bedrock tends to form the best tors. Of the 128 tors physically inspected in the field, 88 are composed of highly weathered porphyritic granite distributed over a wide range of elevations. Both the diameter and the particle size of sorted polygons are likewise determined in part by bedrock type. Other periglacial landforms include felsenmeer, sorted circles, ice-wedge polygons, thermokarst depressions, open-system pingos, extensive gelifluction slopes, and anthropogenic mounds.

INTRODUCTION

The portion of the Kokrine-Hodzana Highlands adjacent to the Dalton Highway is an easily accessible area containing a diverse assortment of periglacial features. During the summer of 1982 an area approximately 6 km wide from a point 39 km north of the Yukon River extending 85 km northward along the highway to Gobbler's Knob was investigated (Figure 1). The area is astride of the Arctic Circle and is within the discontinuous permafrost zone. Permafrost, where present, is generally found between 0.5 and 3.0 m from the surface (Kachadoorian 1971). Drill holes associated with construction in the area often bottomed in permafrost at depths up to 20 m. The maximum depth of the permafrost is unknown. The area is beyond the maximum extent of the last major glaciation and has probably never been glaciated (Hamilton 1982). Bedrock of the region is principally Precambrian and lower Paleozoic metamorphic rocks with large intrusions of Cretaceous porphyritic granite. There are also smaller intrusions of Mesozoic mafic and ultramafic rocks (Kachadoorian 1971, Brosge and Patton 1982). The mean annual temperature at the tree line on Gobbler's Knob is approximately -3°C (Haugen 1982). Mean temperatures at lower sites in the region such as the Bonanza Creek, Fish Creek, and Kanuti River valleys are probably significantly colder because of persisting winter temperature inversions. The coldest official temperature in Alaska, -62°C, was recorded in 1971 at Prospect Creek, only 5 km north of Gobbler's Knob.

CRYOPLANATION LANDFORMS AND TORS

Cryoplanation has been an important process in the development of landforms in this region.

Excellent examples of ridgecrest, hillside, and summit cryoplanation terraces (Reger 1975) are visible from the Dalton Highway. Terraces are most fully and distinctly developed on metamorphic bedrock, especially schist and phyllite. Terraces are usually obscure or entirely absent on igneous bedrock. The majority of the residual rock tors, however, consist of igneous rocks. There is an average of 0.13 tors per km² in metamorphic bedrock and 0.46 tors per km² in granite. The distribution of tors shown in Table 1 tends to indicate that their occurrence is much more closely related to bedrock type than to elevation. The bimodal distribution of granite tors is simply a reflection of the mean elevation of two large outcrop areas, Finger Mountain and Bonanza Creek.

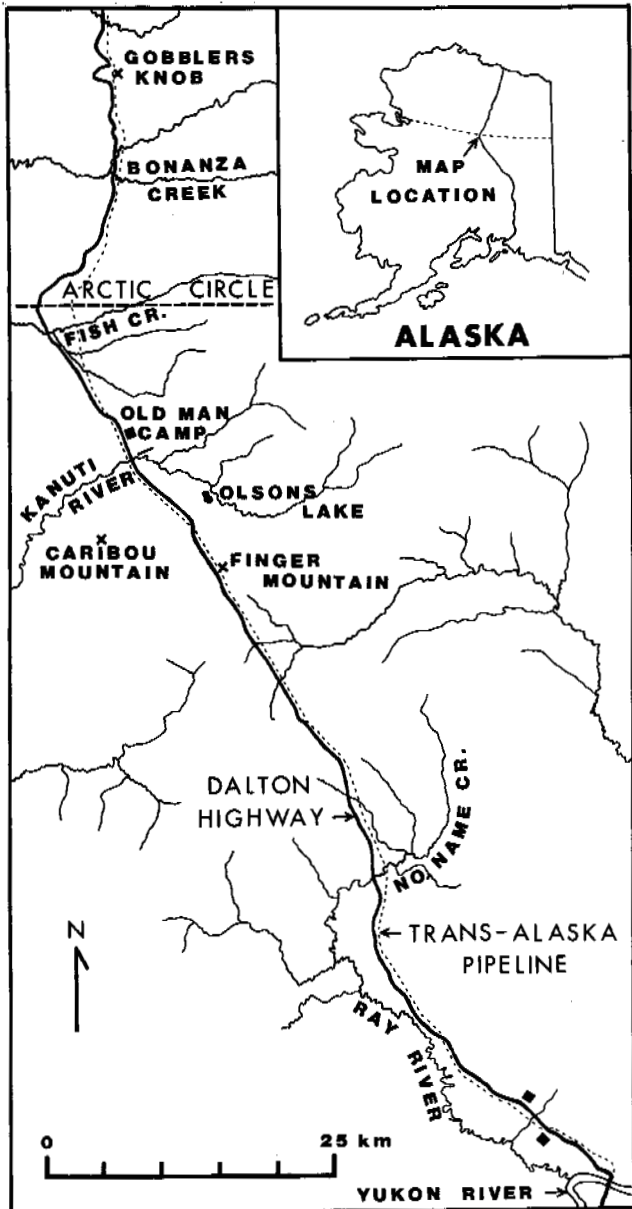

FIGURE 1 Location map.

Features on Igneous Bedrock

Of the 128 tors physically inspected in the field, 88 are composed of a highly weathered porphyritic granite containing large phenocrysts of feldspar (Cook and Bailey 1983). At many of the sites the weathering has been so intensive that rock specimens may be crushed in the hand. The deepest sample obtained during this study was from the base of a 7 m high quarry face near Bonanza Creek. This sample crumbled when tapped with a hammer. Drilling in the area has revealed weathered bedrock to a depth of up to 16 m. There is no apparent correlation between depth of weathered bedrock and permafrost conditions. The weathered rock and the abundant gus in the region

may be the products of either frost weathering or chemical disintegration by hydration of biotite (Reger, personal communication). Deep weathering must have occurred under conditions different than the present environment. The permafrost existing in most of the area inhibits both mechanical and chemical weathering below the active layer. Linton (1955) proposed a two-stage hypothesis of tor formation requiring deep chemical weathering during a warm climatic period followed by removal of weathered products by gelifluction under periglacial conditions. The great extent of weathering in the area supports this hypothesis but does not exclude other explanations.

Granite crops out at Finger Mountain, near Old Man Camp, and in the Bonanza Creek basin. At Finger Mountain, the bedrock is the least intensely weathered. Widely jointed resistant parts of the rock stand as large prominent tors (Figures 2 and 3). The tors occur at and above the local

FIGURE 2 Granite tor on the north side of Finger Mountain.

FIGURE 3 Finger Rock, a granite tor on Finger Mountain.

tree line. The area between tors is generally a coarse block field, often covered by low shrubs and tundra. The typical boulder diameter is nearly 1 m in places.

North of the Kanuti River near Old Man Camp the granite is more intensely weathered. The surface material is a thick residual mantle of weathered granite. Between Kanuti River and Old Man Camp there are no tors, but numerous small low mounds of disintegrating granite are apparent. These vegetation-free areas may be the residual products of tor weathering. If Linton's two-stage hypothesis applies here, the areas may, however, mark the site of future tor emergence. There are numerous tors north of Old Man Camp. These are much smaller, however, and lack the vertical development of tors at Finger Mountain. Block fields and sorted nets are rare and poorly developed.

In the Bonanza Creek basin the bedrock is similarly deeply weathered, but very large tors are present. They are generally massive hill-top outcrops displaying widely spaced vertical joints and surrounded by decomposed granite (Figure 4). Downslope from the tors the loose surface material is covered by a mat of *Cladonia* lichens with scattered spruce and birch trees. A dense mixed broadleaf and needle-leaf forest occupies most of the basin. The entire basin is at or below tree line and is predominantly free of permafrost.

FIGURE 4 Granite tor near Bonanza Creek.

Mafic igneous rocks underlie much of the area near the east end of Caribou Mountain and a narrow band on the south side of the South Fork of Fish Creek. Sorted stripes and polygons are excellently developed in both of those areas. Mafic tors were not found in the area studied. Just to the west, however, the summit of Caribou Mountain (Figure 5) displays a prominent ridgecrest of mafic igneous rock (Kachadoorian 1971).

Features on Metamorphic Bedrock

Nearly every hill or mountain of metamorphic rock in the area has several levels of cryopla-

FIGURE 5 Cryoplanation terraces and summit crest on Caribou Mountain.

FIGURE 6 Cryoplanation terraces on metamorphic bedrock near Fish Creek.

tion surface (Figure 6). In general, the most angular terrace profiles occur at the highest elevations. The more subdued rounded forms tend to occur at lower elevations. This agrees with observation at other Alaskan locations (Reger 1975, Reger and Péwé 1976). All terraces in the area are above 600 m elevation. The normal distribution of cryoplanation terraces with regard to elevation reported by Nelson (1982) was not observed. The limited maximum elevation in the area perhaps restricts the local distribution to the lower half of a normal curve, thus producing a simple increasing function.

Of the 40 tors of metamorphic rock, 11 consist of a dense greenstone. Some of the greenstone is probably metamorphosed basalt dikes, based on the mineralogy and structure of the band of greenstone east of the highway at the Arctic Circle. Foliated igneous rocks grade into greenstone in several

FIGURE 7 Both cryoplanation terraces and tors on metamorphic bedrock 55 km north of the Yukon River.

FIGURE 8 Cryoplanation scarp near the summit of the mountain shown in Figure 7.

tors. About 4 km south of Bonanza Creek several tors of metamorphic rock contain many small quartz veins that tend to increase their resistance to weathering. A few well-developed tors are composed entirely of schist and phyllite. In these tors the foliation is usually horizontal, the least favorable orientation for cryofraction, and joints are widely spaced. The most spectacular examples of these tors are found on a mountain 830 m high located east of the Dalton Highway about 55 km north of the Yukon River. On the summit are several well-developed cryoplanation surfaces with distinct scarps in association with several tors (Figures 7 - 10).

OTHER PERIGLACIAL FEATURES

The greatest variety of permafrost-related features is found on the flats of the Kanuti River

FIGURE 9 Large central tor on the mountain shown in Figure 7.

FIGURE 10 Large tors on the east end of the mountain shown in Figure 7.

near Olsons Lake. The many small lakes on the flats are probably thaw lakes of thermokarst origin. Ice-wedge polygons are present throughout the flats. Several low mounds on the south end of the flats have the form of low pingos (Kreig and Reger 1982). Shallow excavations in these mounds, however, revealed that they consist of clean, well-sorted sand. They are probably relict sand dunes stabilized by vegetation (Figure 11). The mounds have not yet been drilled to confirm the absence of an ice core.

Two large hills are located in a small basin 14 km south of Finger Mountain, 2 km west of the Dalton Highway. Those hills are composed of non-sorted sediment and are probably open-system pingos (Kreig and Reger 1982).

Seasonal frost mounds were observed near the north side of Old Man Camp airfield, near an access road crossing of the South Fork of Fish Creek, and adjacent to the Dalton Highway 1.3 km north of

The North Fork of Bonanza Creek. All three sites indicate an anthropogenic origin similar to those observed by Nelson and Outcalt (1982). Road and airfield construction has disrupted the local drainage, creating areas with excess water available for development of ice cores.

Sorted circles, nets, polygons, and stripes occur commonly in the region, usually above 550 m elevation. Sorted polygons often occur at the base of the concave slopes of cryoplanation scarps. Polygons were observed in all of the bedrock types of the study area. Both polygon size and particle size, however, are affected by lithology. The polygonal granite felsenmeer on Finger Mountain consists of coarse particles over 1 m in size with polygon diameters up to 10 m. Several kilometers south, the sorted polygons of metamorphic rock are

FIGURE 11 Flats of the Kanuti River near Olsons Lake. The mound in the center of the photo about 100 m long is probably a vegetation-stabilized sand dune.

FIGURE 12 Sorted nets of metamorphic rock 15 km south of Finger Mountain. Photo by Richard Cook.

no more than 5 m in diameter with a coarse particle size of 0.2 m (Figures 12 and 13).

Large gelifluction slopes are found throughout the region, especially on the north-facing sides of ridges. Some of these are long, uniform slopes covering many square kilometers. Many of the more gently sloping gelifluction surfaces show a remarkably regular spacing of alder shrubs (Figure 14), perhaps due to changes related to frost action (Everett 1981).

CONCLUSIONS

The geomorphic features in the Kokine-Hodzana Highlands have developed during long exposure to a cold, rigorous climate without interruption by glaciation. The type and character of features are determined in part by the nature of the bedrock. In general, widely jointed massive bedrock tends to produce the best tors. There are over three times more tors per unit area in granite bedrock than in metamorphic bedrock. Tors occur at all elevations in the area. Finely jointed foliated bedrock tends to promote cryoplanation. Cryoplanation terraces are most common and most distinct at higher elevations. None were identified below 600 m. Well-developed tors and distinct terraces seldom occur together. Sorted patterned ground occurs on all types of bedrock at elevations above 550 m. The sizes of individual features and their constituent particles, however, are strongly affected by rock type. A wide variety of other periglacial landforms indicates that a diversity of geomorphic processes have been or are active in the region.

ACKNOWLEDGMENT

This study was supported by a project of the U.S. Army Corps of Engineers through the U.S. Army Cold Regions Research and Engineering Laboratory.

UNCONFINED COMPRESSION TESTS ON ANISOTROPIC FROZEN SOILS FROM THOMPSON, MANITOBA

T. H. W. Baker and G. H. Johnston

Division of Building Research, National Research Council of Canada, Ottawa, Ontario, K1A 0R6

Laminated frozen soils, consisting of alternate horizontal layers of dark brown clay and light brown silt, with ice lenses between the layers, are found in the northern area of ancient glacial Lake Agassiz. Laboratory tests confirmed the results of in situ ground anchor, penetrometer, and pressuremeter tests performed at Thompson, Manitoba, which showed these soils to be stronger in the horizontal direction, parallel to the layers, than in the vertical direction. Undisturbed block samples of these laminated (varved) frozen soils were obtained and test specimens were prepared at various orientations to the direction of layering. Unconfined compression tests, using both naturally frozen and remolded frozen specimens, have shown the extent of strength anisotropy due to the natural anisotropic soil structure.

INTRODUCTION

A series of in situ creep loading tests was undertaken in the frozen varved clay soils at Thompson, Manitoba, between 1967 and 1974. These field tests included circular plate anchors (Ladanyi and Johnston 1974), power-installed screw anchors (Johnston and Ladanyi 1974), pressuremeter (Ladanyi and Johnston 1973) and electric penetrometer tests (Ladanyi 1976, 1982). Creep equations were developed using the theory of an expanding spherical cavity. It was found that the creep exponent deduced from the static penetration tests was much higher than that found in the pressuremeter tests. Still higher values were obtained from creep tests on the ground anchors, performed earlier at the same site. Since the anchor and penetrometer tests loaded the soil in a vertical direction and the pressuremeter loaded the soil in a horizontal direction, this indicated that the frozen varved clay was more resistant to deformation (i.e., stronger) in the horizontal direction than in the vertical direction. This was attributed to the natural anisotropic structure of the frozen varved soils (Ladanyi 1976). A systematic study was undertaken to determine the influence of the anisotropic structure of these soils on the response to the various loading conditions described above. This paper describes a series of unconfined compression laboratory tests on field samples of frozen varved clay from the Thompson area.

INVESTIGATING STRENGTH ANISOTROPY

The term strength anisotropy is used exclusively in this paper to describe the variation of stress-strain behavior in the soil with direction of loading. Most soils exhibit stress-strain anisotropy, due mainly to the nature of the depositional process. This anisotropy becomes marked in layered or laminated (varved) soils formed by cyclic sedimentation and subsequent one-dimensional consolidation. The testing of unfrozen varved soils to determine their strength and deformation properties has been reported by several

authors, including Tschebotarioff and Bayliss (1948), Eden (1955), and Metcalf and Townsend (1960). These investigators performed unconfined compression tests at various orientations to the varves and found a distinct anisotropy in shear strength. In testing Lake Agassiz varved clays from Steep Rock, Ontario, Eden (1955) found that when clay layers predominated, the shear strength was higher when the direction of loading was parallel to the layers. When silt layers predominated, the shear strength was higher when the direction of loading was perpendicular to the layers.

Frozen fine-grained soils often have an anisotropic structure, due to the existence of ice lenses formed perpendicular to the direction of freezing. Livingston (1956) studied the strength anisotropy by performing unconfined compression tests on frozen Keweenaw silt at various orientations to the ice lenses. There was a large scatter among the observed stress and strain values, due to specimen variability and to the extreme sensitivity of the soil-ice mixture to slight variations in temperature at the time of the test, particularly in the temperature range (-1 to -2°C) at which the tests were conducted. These tests indicated that the shear strength was generally higher for specimens with ice lenses parallel to the direction of loading.

The strength anisotropy of soils is usually expressed as the ratio of the shear strength with the major principal stress oriented at various angles to the vertical (S_{θ}) to the shear strength in the vertical direction (S_0). The obvious angles of significance for horizontally layered soils are $\theta = 45^\circ$, where the maximum shear stress is parallel to the layers, and $\theta = 90^\circ$, where the major stress is parallel to the layers.

The shear strength ratios for the Steep Rock varved clay and frozen Keweenaw silt are shown in Table 1. These ratios indicate a definite strength anisotropy which is dependent upon the properties of the individual layers. It was thought that the frozen varved clay from the Thompson area would show an even greater strength anisotropy than the soils mentioned above, due to the combined presence of horizontal varves and ice lenses.

TABLE 1 Strength Anisotropy of Some Soils From the Literature

Soil	$\frac{S_{90}}{S_0}$	$\frac{S_{45}}{S_0}$	Reference
Lake Agassiz varved clay (Steep Rock, Ontario)			Eden (1955)
predominantly clay layers	1.18	0.51	
predominantly silt layers	0.57	0.92	
Frozen Keweenaw silt	1.23	0.63	Livingston (1956)

SITE LOCATION AND DESCRIPTION

The city of Thompson (55°45'N, 97°50'W) is located in northern Manitoba about 640 km north of Winnipeg, within the discontinuous permafrost zone. Perennially frozen ground occurs in scattered small patches or islands varying in size from a few square metres to several hectares (Johnston et al 1963).

Thompson is also located within the northern extremity of ancient Lake Agassiz, which existed during the Wisconsin period of glaciation (Figure 1). Characteristic of the depositional processes associated with glacial Lake Agassiz was the formation of extensive deposits of laminated (varved) silt and clay. The varved soils are fully saturated and often contain ice lenses from hairline to 5-10 cm in thickness, normally oriented parallel to the predominantly horizontal laminations. The alternating horizontal layers of light brown silt and dark brown clay combine with the horizontal ice lenses to produce an anisotropic soil structure.

FIELD PROGRAM

Sampling

A backhoe was used to excavate a test pit to a depth of about 3 m at a site approximately 5.5 km north of the city of Thompson, near the southwest corner of the Thompson airstrip, in March 1978. The pit was located in a large spruce island close to a ground temperature cable installed by the Geological Survey of Canada (GSC) in 1973. The site (GSC 2A) is described in detail by Klassen (1976). The walls of the pit were visually logged, and samples were obtained for water content, organic content and grain size analyses. A log of the test pit is shown in Figure 2.

A layer of distinctly laminated (varved) frozen clay occurred between the depths of 1.25 and 2.25 m. Small (0.3 m³) blocks of the frozen varved material were wrapped in polyethylene sheeting, placed in insulated boxes packed with ice, and shipped to Ottawa by air. These samples were maintained at -6°C in a cold room until specimens were prepared for testing.

Ground Temperatures

Ground temperatures were measured weekly by NRC staff on the thermistor cable installed at the site by the Geological Survey of Canada. Figure 3 shows ground temperatures obtained in early March 1978 and the maximum, minimum, and mean temperatures for that year. The maximum and minimum temperatures for 1978 were near the extreme values observed for the years 1975-1978. The mean annual ground temperature, at the depth at which the block samples were obtained, was between -1 and -2°C. At the time of sampling, the ground temperature, in the sampling zone, was between -2 and -3°C.

LABORATORY TESTING

Test Specimen Preparation and Description

Cylindrical test specimens 76 mm in diameter and 152 mm in height were machined from the block samples using a band saw and lathe in a cold room. The procedures for sawing, machining and preparing the specimens are described by Baker (1976). Specimens were machined at various angles to the plane of the horizontal varves. "Vertical" specimens contained varves oriented perpendicular to the vertical axis of the specimen. "Horizontal" specimens contained varves oriented parallel to the vertical axis of the specimen. Another set of specimens was machined with varves oriented at 45° to the vertical axis of the specimen. Each specimen contained from 15 to 20 varves, consisting of dark brown clay layers from 8 to 12 mm in thickness and light brown silt layers from 2 to 5 mm in thickness. Ice lenses visible on the sides of the specimens ranged in thickness from hairline to a few millimetres.

Bulk densities were determined prior to testing by measuring the volume and weight of the test specimens. After testing they were weighed, oven dried, and weighed again to determine their total water contents. The densities and water contents are presented in Table 2.

Hydrometer tests on "combined" samples (containing both light and dark layers) indicated that the varved soil consisted of 80-90% clay size (<0.002 mm) material. Ignition-loss tests (ASTM D 2974) indicated an average organic content of 12%. Eight Atterberg Limits tests showed a liquid limit of 52.0%, a plastic limit of 32.7%, and a plasticity index of 19.3%. The average water content was 35.0%, about 2-3% lower than that determined at the field site (Figure 2).

Several remolded specimens were specially prepared in the laboratory to try and remove the anisotropic structure formed by the varves and ice lenses. Some specimens were completely thawed, and the soil was mixed and remolded to densities and water contents similar to the natural samples. These remolded cylindrical specimens were placed in the cold room at -6°C and allowed to freeze from all sides. They were removed from the molds, and their ends were machined prior to testing. Small hairline radial ice lenses could be seen at the ends of the frozen remolded specimens. These remolded specimens were tested for comparison with results obtained on the natural (undisturbed) frozen soils. Frozen bulk

densities and total water contents were determined before and after testing; these are presented in Table 2.

Unconfined Compression Tests

Unconfined compression tests were performed at a cold room temperature of -6°C, using a 250 kN capacity screw-driven universal testing machine. These tests were carried out at nominal strain rates of 0.01 and 1.0%/min. Some tests were performed at an intermediate strain rate of 0.1%/min, but were incomplete due to the limited amount of sample material available. Data from this incomplete test series will not be presented. An extensometer consisting of three displacement transducers located on the specimen, measured axial deformation and tilting (Baker et al 1982). Compliant platens (Baker 1978) were used to reduce end effects and to ensure a uniform normal application of pressure to the specimen ends.

Vertically oriented specimens had the maximum normal stress direction perpendicular to the plane of the varves to simulate the anchor and penetrometer tests performed in the field. Horizontally oriented specimens had the maximum normal stress direction parallel to the plane of the varves, in a manner similar to the field pressuremeter tests. Specimens oriented at 45° had the maximum shearing stress directed parallel to the plane of the varves.

Stress-strain curves for the two nominal strain rates are shown in Figures 4 and 5. The loading

direction relative to the plane of the varves for each specimen is indicated. Some tests were duplicated to show the variation in stress-strain behavior between specimens. The maximum axial strain imposed on specimens was between 10 and 15%, due to the limitations imposed by the 83 mm diameter extensometer ring. As a result, none of the tests reached peak stress.

DISCUSSION AND CONCLUSION

All of the specimens exhibited an initial yield at about 0.15% axial strain; the stress then continued to increase until the test was stopped. Although none of the specimens reached failure (peak stress), the value of the stresses at and beyond yield is an indicator of the relative strength of specimens and can be used to determine strength anisotropy. All specimens deformed as right cylinders without central bulging or expansion of individual layers. This indicated that the strains within the specimen were uniformly distributed.

In both ranges of strain rate the horizontally oriented specimens were consistently the strongest, followed by the specimens oriented at 45°. The vertically oriented specimens were the weakest. This relationship was also observed in the limited tests performed at the intermediate strain rate. Strength increase with strain rate seemed to be similar for all specimen orientations. Tests that were duplicated showed very similar stress-strain behavior. This probably reflects the narrow range in the natural physical properties (densities and total water content). The similarities in physical properties between specimens enhanced the reliability of comparing the test results. The remolded laboratory-frozen specimens were as much as 80% stronger than the naturally-frozen undisturbed specimens. Although there was some anisotropy in the structure of the remolded specimens, these results indicated that the natural anisotropic structure acts to reduce the shear strength.

The strength anisotropy is shown in Table 3 for the two strain rates and for axial strains corresponding to yield (0.15%) and 10%. The amount of anisotropy is not pronounced at yield or at small strain rates, but it becomes quite significant at 10% strain. High horizontal strengths are similar

TABLE 3 Strength Anisotropy

Axial strain (%)	Nominal strain rate (%/min)	$\frac{S_{90}}{S_0}$	$\frac{S_{45}}{S_0}$	$\frac{S_0}{S_R}$
0.15 (yield)	0.01	0.93	0.99	0.55
	1.0	1.14	1.18	0.67
10.0	0.01	1.13	1.03	0.72
	1.0	1.35	1.06	0.83

to those observed by Eden (1955) in unfrozen varved clays from Steep Rock when the clay layers predominated. Specimens in this study had a high clay content (80-90%). High shear strengths at 45° orientations have not been seen in any of the data on varved soils in the literature. Ice cementation may resist the shearing stresses acting between the layers. The higher strain rates used in this study are comparable to those used by Eden (1955) and Livingston (1956) in their test programs. Frozen Thompson varved clays appear to exhibit a greater strength anisotropy than either the unfrozen varved clay from Steep Rock (Eden 1955) or the frozen Keweenaw silt (Livingston 1956).

An estimate of the average unfrozen water content of the combined soil at the in situ temperature of -1°C, based on the liquid limits, is 15% (Tice et al. 1976). The unfrozen water content would probably be different in the individual clay and silt layers, due to the surface area of the soil grains, and would influence the relative stress-strain behavior of these layers. It is recognized that the change from the in situ temperature to the laboratory temperature of -6°C, coupled with sublimation of the samples during 2 years of cold storage, would lower the unfrozen water content. The strength anisotropy in these specimens is probably due to the combined effect of the varves and their different unfrozen water contents, and other physical properties, as well as to the ice lenses. No attempt was made to estimate the relative contribution of these various components.

The series of in situ tests performed by Johnston and Ladanyi in an attempt to determine the bearing capacity of the frozen varved soils at Thompson were analyzed using cavity expansion theory to estimate the stress-strain behavior of the soil. Cavity expansion theory assumes that the soil behaves as a homogeneous, isotropic, ideally plastic material (Ladanyi 1963). Horizontal varves and ice lenses make these soils heterogeneous. This laboratory study has shown that these soils are not isotropic but anisotropic in their stress-strain behavior. The stress-strain curves indicate that these soils do not deform in an ideally plastic manner. A modification could be made to the cavity expansion theory to take into consideration strength anisotropy. Davis and Christian (1971) have proposed a modification, taking into consideration strength anisotropy, to the yield criterion which Scott (1963) recommended for predicting the bearing capacity of undrained soils. They show strength anisotropy to be present in most cohesive soils.

A more detailed laboratory study similar to the one presented in this paper would be needed to determine the complete range and magnitude of strength anisotropy associated with a particular soil deposit. One would have to consider the influences of various components of the soil deposit (number and physical properties of the varves, ice lenses, etc.) that could contribute to the anisotropy. The results of field testing using the pressuremeter and penetrometer would provide a useful check on the strength relationships obtained and a qualitative appraisal of the influences of sampling and testing procedures.

ACKNOWLEDGMENTS

The authors wish to thank A. Chevrier and C. Hubbs for their help in preparing the specimens and carrying out the tests. This paper is a contribution from the Division of Building Research, National Research Council of Canada, and is published with the approval of the Director of the Division.

MECHANISM AND REGULARITIES OF CHANGES IN HEAT CONDUCTIVITY OF SOILS DURING THE FREEZING-THAWING PROCESS

Ye. N. Barkovskaya, E. D. Yerшов, I. A. Komarov, and V. G. Cheveriov

Geology Department,
Moscow State University, Moscow, USSR

The paper discusses the results of comprehensive experimental studies on the mechanism and regularities of heat conductive properties of a variety of soils of different genesis and age. These soils have different granulometric and chemical-mineralogical composition and are in various degrees of salinization and peating; they also have different cryogenic texture. The studies were carried out by the stationary regime method applied during the process of freezing and subsequent thawing in the temperature interval from +25° to -25°C, which encompassed the temperature interval of intensive phase transformation of water in soils.

INTRODUCTION

The study of heat conductivity of rocks and soils is important both scientifically and practically. Prediction and control of such cryogenic processes as freezing-thawing, heaving-settlement, thermokarst, and thermal erosion are impossible without the understanding of thermophysical properties.

During the last decades many researchers have studied thermophysical characteristics. Theoretical principles have been elaborated to describe heat transfer in porous soils, and a considerable amount of experimental material has been collected. The experimental data, however, was normally obtained for ground in the fully thawed or solidly frozen state. There is almost no data on heat conductivity of soils under large negative temperatures, i.e., in the range of intensive phase transition of water. The mechanism and regularities of heat conductivity of soils during the cyclic freezing-thawing process are still unknown. And, finally, a generalizing work has yet to be compiled on the mechanism and regularities of heat conductivity in cryogenic soils of various composition, structure, genesis, and age under different thermodynamic conditions of formation.

The staff of the Laboratory of Physics, Physical Chemistry, and Mechanics of Frozen Grounds, under the Chair of Geocryology of the Geological Faculty of the Moscow State University, has carried out comprehensive research to determine the mechanism and to establish the regularities in the changes of the thermal conductivity of frozen, thawed, and freezing and thawing soils, and further to analyze and generalize the available experimental material. This paper describes several basic results of these studies.

The materials studied were soils (derived from solid to fine-dispersion rock) of different genesis, age, granulometric composition, and chemical-mineral composition; these soils had various degrees of salinization and peating, humidity, density, and cryogenic texture. Samples of disaggregated soils with disturbed structure were specially prepared for the purpose of finding

regularities in the changes of their heat conductive properties. The method of comprehensive research was used because it combines the determination of heat conductivity in the temperature interval from +25° to -25°C with estimation of the macro- and microstructure of the solids and of the phase content of included water. This research was based on the method of stationary thermal regime, which permits the measurement of heat conductivity of rocks not only at high negative temperatures up to -0.5°C but also during the cycle of freezing and subsequent thawing; moreover, the method provides an estimation of the anisotropy of thermal properties.

The Mechanism of Changes in Heat-Conductive Properties of Rocks during the Freezing-Thawing Process

The temperature effect on heat conductive properties of rocks has various manifestations. As shown by both laboratory and published data, a decrease of temperature increases heat conductivity in crystalline rocks and reduces it in amorphous rocks. These effects are due to a difference in the mechanism of heat transfer; in crystalline rocks heat transfer occurs by elastic oscillations of the crystalline grid, whereas, in amorphous rocks it is the result of non-elastic dispersion of thermal energy.

Unlike solid rocks, moist soils have non-linear and extremal types of dependence of heat conductivity (λ) on temperature (Fig. 1). Typical parts of the curve may be selected for analysis. The change of λ coefficient in the region of positive temperatures ($t_1 \div 0^\circ\text{C}$ and $0^\circ\text{C} \div t_2$) is linear; this feature is related to the analogous dependence of heat conductivity of water on temperature. The parts from 0°C to the temperature of the beginning of freezing ($t_2 = t_{43}$) and from the temperature of the end of thawing (t_7) to 0°C correspond to relation $\lambda(t)$ in the region of positive temperatures, a fact attributed to the unchanging phase content of the system. The length of these parts depends on the composition of the soil.

In the course of further temperature decrease in

the interval (t_2 to t_3), corresponding to the region of intensive phase transformation, a considerable increase in λ value is observed. Starting with the temperature of the beginning of freezing (t_2), the value of heat conductivity coefficient at t_3 can be twice its value in the thawed state. This fact is a change in soil composition and to the first appearance of ice crystals, the heat conductivity of which is four times greater than that of water. A study of the microstructure of soils during freezing shows a complicated process of formation of ice-cementing structural ties. The particles and aggregates become larger, thus reducing the contact heat resistivity in soils.

The part of the curve corresponding to the temperature interval (t_3 to t_4), where the intensity of phase transition of water is reduced, the coefficient of heat conductivity somewhat increases to a certain constant value owing to the accretion of pore ice. Structural studies in this temperature range did not reveal any notable changes in the structure of frozen soils.

The decrease of temperature in the part of the curve (t_4 to t_5) causes a reduction of the heat conductive potential of the soil. The study of microstructural transformations in frozen ground has demonstrated that this effect is connected with the appearance of microcracks in ice and with its fragmentation; the near-contact ice-soil zones become more friable owing to thermo-mechanical stresses. The decrease of λ value in this interval of temperature can reach 25-30%. In soils the percentage increases from sands and sandy loams to clays and peats.

In the interval of negative temperatures (t_5 to t_7), the values of λ coefficient of soil during freezing do not coincide with the values for the same soil during thawing. This hysteresis in the $\lambda(t)$ dependence is observed in practically all studied grounds. It is attributed to the development of irreversible structural transformations and to peculiarities in the formation of the phase content of water. The area of the hysteresis loop depends on the content and structure of the solid particles and on the intensity of structural changes; it reduces from peats and clays to sandy loams and sands. The maximal difference in the values of heat conductivity of soils in the freezing-thawing cycle is not more than 30%.

Under conditions of phase transformation of water, the λ value of thawing ground in the range (t_6 to t_7) is more than that of freezing ground in the same temperature interval; this fact is related to a difference in phase content and structure under the same temperatures.

The expected hysteresis of heat conductivity of moist soils is practically absent in the range of positive temperatures, because, notwithstanding the changes in structure during thawing, heat transfer in the liquid phase is the determining factor of heat conductive properties in this temperature range.

Regularities in the Changes of Heat Conductivity during Freezing-Thawing of Soils with Different Composition and Structure

composition of soils on heat conductivity is associated with the peculiarity of crystalline-chemical structure of minerals, with the contents of the pores, and with organic admixtures and their quantitative ratios. Heat conductivity of solid rocks mainly depends on the heat conductive properties of minerals composing them; the most common mineral is quartz, whose heat conductivity is much higher than that of many pore-forming minerals. Thus, the increase of quartz content in magmatic rocks from basic to acid is responsible for the observed tendency of λ to increase in that series. Heat transfer in sedimentary-cemented rudaceous, sandy, and sandy loam rocks is also to a large extent determined by heat conductivity of rock-forming minerals. Their role, however, is reduced owing to micro- and macrocracks and porosity.

These effects are confirmed by the results of experiments carried out on sandy loams with different mineral content: quartz, and vermiculite (Fig. 2, curves 1 and 2). Heat conductivity of quartz sandy loam is higher than that of vermiculite sandy loam owing to the larger λ value of quartz. Vermiculite sandy loam is characterized by a stronger hysteresis of $\lambda(t)$, caused by microstructural transformations occurring with greater intensity as compared to quartz sandy loam.

The effect of the heat conductivity of minerals on the general heat conductivity of rocks is reduced with an increase in dispersion, because the role of contact heat conductivity is greater. Thus, the influence of mineral composition on the λ of clay soils is manifested not directly, but indirectly through hydrophilicity. Clays with sharply differentiated crystalline-chemical structures were chosen as the subjects of research: montmorillonite and kaolinite (with similar density values and pores almost completely filled with water) (Fig. 2, curves 3 and 4). In the region of positive temperatures the values for these clays are practically identical (0.5 to 0.65 W/m °C), and the shape of the $\lambda(t)$ dependence is close to linear. The slope of these straight lines is similar to the slope of the straight line depicting the temperature dependence of the λ coefficient of water. Consequently, heat conductivity of thawed clay soils does not depend strongly on the nature of the minerals, but is primarily determined by the heat resistivity of water molecules composing a single water layer. On the contrary, under negative temperatures the difference in the structure of minerals is fairly well manifested by affecting the proportions of ice and unfrozen water. The value of λ and the area of the hysteresis loop of $\lambda(t)$ for kaolinite clay are less than those for montmorillonite clay owing to larger irreversible transformations in the structure of the latter.

The presence of organic impurities in soils is an important factor influencing the development of their heat conductive properties. A special series of experiments on peats and peated grounds was performed to study the effect of the degree of peating and organic decomposition on the heat conductivity of ground. In the temperature range from +15 to -15°C the change in heat conductivity coefficient is in general the same for sands, peated sands, and peats (Fig. 3). When the pores are, for practical purposes, completely filled with water (or ice) the value of λ reduces with an

The effect of the chemical-mineralogical

increase of peating, which correlates with data obtained by A. A. Konovalov and L. T. Rotman (1970). Also the λ value in the region of negative temperatures close to 0°C decreases with the degree of peating. This effect is attributed to the difference in the quantitative water-ice ratio and to the nature of thermal contacts formed between ice, sand particles, organic inclusions, and water.

The reduction effect of the λ value for peat and peated sand, in a solidly frozen state, is associated with the development of microcracks in pore ice during cooling of the soil. Results obtained lead to the conclusion that the presence of organic impurities reduces heat conductivity in the +15 to -15°C range because of low heat conductivity of peat, a larger amount of liquid phase, and structural defects appearing as the result of cooling. The hysteresis in the $\lambda(\tau)$ dependence for peats under freezing-thawing conditions is caused by intensive physical-chemical and structural transformations. A tendency for an increase in the λ coefficient is noted in the frozen peat series from largely to slightly decomposed; heat conductivity of thawed peats is practically the same.

Salinization of rocks strongly influences heat conductive properties. The effect of NaCl salinization on heat conductive properties of fine quartz sand and medium loam was studied (salinization of frozen soils was $Z = 0.5, 1.0, 1.5\%$). The increase of Z to 1% reduces by half the heat conductivity of water-saturated sands. The obtained experimental data imply a complicated $\lambda(t)$ dependence (Fig. 4) including the presence of maximums, because under freezing the change in salinization affects not only the phase composition of water and the heat conductivity of porous solids, but causes structural transformations as well. For soils with different salinization the $\lambda(t)$ dependence is analogous, but the values of their heat conductivity differ by 50% and more. When the temperature decreases to -25°C the heat conductivity value of unsalinized sands (curve 1) monotonically decreases. For salinized sands the decrease of heat conductivity at temperatures below -15°C changes to a slow increase of λ values, owing to better thermal contacts resulting from the freezing-out of solution and the crystallization of salts.

The effect of grain size on heat conductivity was studied by many researchers, among them R. I. Gavriliev, V. T. Balobaev (1978), N. S. Ivanov (1962) and A. F. Chudnovsky (1962). These studies demonstrated a reduction of heat conductivity of soils with an increase of dispersion in the series (rudaceous-sandy-sandy loam-loamy-clay grounds) over the entire studied temperature range, which included the temperatures of the water phase transitions. The character of the λ dependence in the range from 0 to -5°C (Fig. 5) is associated with changes in the area of thermal contacts and in the amount of unfrozen water, both of which increase in the order shown for the dispersion series. In the course of study, data on heat conductivity of loess soils was obtained for the first time. The value of λ in loess soils at similar values of water saturation and density is intermediate between the heat conductivity of loamy sands and of clays. Among loess soils, the λ

coefficient increases with an increase in the size of their aggregates. Thus, all other conditions being equal, heat conductivity of coarse-dust loesses is 1.3 to 1.5 times greater than that of fully loesslike loams of the same genesis and age.

As shown by the results of experimental research, the nature of heat conductivity dependence on moisture of loess soils is the same as that of sands and sandy loams, but different from that of loams and clays, a result contrary to expectations based on the high content of dust and clay particles in loesses. This phenomenon can be explained by the model of loess soil structure; the model indicates that with an increase of water saturation up to values of 0.5 to 0.7 (water content reaching 20%) deformation of the surfaces of globules and extension of areas of thermal contacts occurs owing to the swelling of clay shrouds. Subsequent moistening up to 0.7 (water content >20%) does not cause notable changes in heat conductivity of the soil, because heat flow is then almost completely within the water system. The freezing of water-saturated loess soils is accompanied by a considerable growth of heat conductivity as the result of formation of ice-cementing bonds. Consequently, λ of frozen loesslike loam of natural composition at a water content of 30% is three times as large as λ at a water content of 3%.

The problem of the influence of cryogenic texture on soil heat-conductive properties is as yet hardly approached. The study of frozen sandy loam of natural composition shows that the value of λ for soils with massive cryogenic texture (1.8 to 2.2 W/m-degC) exceeds λ for soils with layered and subreticulate texture (1.4 to 1.6 W/m-degC). Numerous defects of ice structure (cracks, air bubbles, organic admixtures, etc.) have been noted in sandy loam soils of layered texture; these defects create additional resistivity to heat transfer.

Varying the conditions of freezing of clay has enabled us to obtain specimens of massive and of layered cryogenic texture with almost identical ice contents. Heat conductivity of clay with massive texture normally exceeds heat conductivity of clay with layered texture by about 25%.

In summary, results derived from experimental research have revealed a complicated mechanism of development of heat-conductive properties of soils and have indicated basic trends in the variations of heat conductivity, which depend on the composition and structure of soils and the temperature conditions.

PROPERTIES OF GEOTEXTILES IN COLD REGIONS APPLICATIONS

J.R. Bell, T. Allen and T.S. Vinson

Dept. of Civil Engineering, Oregon State University, Corvallis, OR 97331 USA

To investigate properties of geotextiles in cold regions applications, a laboratory program was conducted with five geotextiles. Freeze-thaw durability in fresh and saline water was considered. Geotextile strength before and after 300 freeze-thaw cycles showed no serious degradation. Geotextile load-deformation-time relationships were determined at +22°C and -12°C by wide-strip tensile and static creep tests. Temperature had little effect on strength, but creep was significantly affected. Lower temperatures resulted in reduced creep. Both geotextile structure and polymer type were significant to creep. Polypropylene geotextiles were affected to a greater degree by temperature than polyester geotextiles.

A preliminary investigation was performed to determine the potential of geotextiles as capillary breaks in a highly frost susceptible silt. Soil columns were frozen from the top at a constant rate. Free water was available at the bottom for two columns--one contained a geotextile layer and one did not. A third control column was frozen without free water or a geotextile. Heave and water content increases during freezing were determined for each soil column. The results indicate some geotextiles have the potential to significantly reduce frost heave. The effectiveness is different for different geotextiles.

INTRODUCTION

Geotextiles have been widely used in the more temperate areas of the world for the past two decades (Bell and Hicks 1980). More recently, engineers concerned with arctic and subarctic construction have incorporated geotextiles into their designs (Tart and Luscher 1981). To date, geotextiles have been used in their traditional roles to provide filtration, separation, and reinforcement in drains and roadways (Bell and Hicks 1980). They are also being used in erosion control structures in the Arctic (Leidersdorf et al. 1981).

While successful applications of geotextiles in cold regions have been made, questions remain unanswered relative to the influence of the cold environment on their performance. For example, the influence of cold temperatures on geotextile load-strain and creep relationships is largely unknown. Degradation due to freeze-thaw cycles also has had limited study.

In addition to the usual problems, engineering/construction practices for building foundations, roadways, and embankments in cold regions of the world are intimately associated with freezing related phenomena of initially unfrozen ground and thawing related phenomena of initially frozen ground. Freezing of initially unfrozen frost-susceptible soil can result in heave at the ground surface and disruptions of embankments or foundations placed on or wholly within the zone of freezing. Thawing of ice-rich soils results in settlement and loss of bearing strength (termed thaw instability).

The published information relative to geotextile uses in construction to limit or ameliorate problems associated with frost heaving and/or thaw weakening is limited. Kinney (1981) has suggested

that a geotextile layer could be used to bridge thermokarsts, but no installations are known. Creep is a very important consideration in this use. Brantman et al. (1977) reported the use of a geotextile as a capillary break in a roadway test section in the USSR but did not include an evaluation of the performance. Sale et al. (1973) and Bell and Yoder (1957) describe encapsulation of roadbed soils in waterproof membranes to limit frost effects.

Roth (1977) performed laboratory soil column freezing tests. He found a 10 cm (3.9 in.) thick layer of gravel sandwiched between two geotextile layers worked as a capillary cutoff and limited frost heave. He also concluded the cutoff layer should be above the free water but below the freezing front for maximum effectiveness. Hollingsworth (1976) and Hoover et al. (1981) performed laboratory capillary cutoff tests using only a fabric as the capillary break. They tested only one fabric (Mirafi 140). Both conclude the geotextile reduced water migration, and Hoover observed that two geotextile layers worked better than one layer. The geotextile properties which influence the performance of a geotextile layer as a capillary break are permeability, pore size, thickness, and wetting characteristics.

Hoover et al. (1981) installed Mirafi 140 as a combined reinforcement layer and capillary break in county roads in Linn County, Iowa, USA. The geotextile was placed on top of a frost-susceptible subgrade soil. They observed limited improvement in roadway stability.

The existing literature shows numerous individuals believe geotextiles to have great potential for use in arctic and subarctic regions. The results to date support this belief but are limited and often inconclusive.

In recognition of the need to determine geotex-

tile mechanical properties and the effectiveness of geotextiles to reduce frost action in cold regions, a research program was conducted at Oregon State University to investigate (1) the influence of freeze-thaw cycles in a freshwater and saline water environment on the load-strain-strength of geotextiles; (2) evaluate the load-strain-strength and creep characteristics of geotextiles at subfreezing temperatures; and (3) investigate the ability of geotextiles to act as capillary breaks and thereby limit frost heave. The results from the research program are summarized herein with emphasis on the frost heave tests. Additional results from the load-strain-strength and creep studies at subfreezing temperatures have been published elsewhere (Allen et al. 1982, Allen 1983).

GEOTEXTILES TESTED

Five geotextiles, each with different structure and/or material characteristics, were employed in the research program. These geotextiles are described in Table 1. The geotextile types were selected to ensure that the load-strain-strength characteristics associated with several geotextile structures and fiber polymer compositions could be compared in a meaningful way.

The geotextiles tested represented woven and nonwoven fabrics. For the nonwovens, needle-punched and bonded materials were tested. Both polyester and polypropylene fibers were included. The geotextiles represented a range of permeability, strength, modulus, and susceptibility to creep.

TEST PROCEDURES AND EQUIPMENT

Tensile Tests

A wide strip tensile test was used to characterize the load-strain-strength behavior of the geotextiles. A 200 mm (8.0 in.) specimen width and a 100 mm (4.0 in.) specimen length between test grips were employed to ensure the results obtained would simulate, to as great a degree as practical, the plane-strain loading conditions which exist in the field (Shrestha and Bell 1982). Five specimens of each geotextile type were tested. Both MTS and Instron test systems were employed in the program. The Instron was used for specimens which exhibited very large strains at failure.

Each geotextile type was tested under the following conditions:

- room temperature [22°C (71°F)] in a dry state
- subfreezing temperature [-12°C (10°F)] in a dry state
- room temperature in a saturated surface dry (wet) state
- room temperature [22°C (71°F)] in a saturated surface dry (wet) state following 300 freeze-thaw cycles in a dry state

TABLE 1 Geotextiles Tested.

Geotextile	Filament	Geotextile Construction	Nominal Weight, gm/m ²
Bidim C-34	Polyester Continuous	Nonwoven Needlepunched	272
Stabilenka T-100	Polyester Continuous	Nonwoven Resin Bonded	100
Typar 3401	Polypropylene Continuous	Nonwoven Heat Bonded	136
Fibretex 300	Polypropylene Continuous	Nonwoven Needlepunched	300
Propex 2002	Polypropylene Slit Film	Woven	150

- room temperature [22°C (71°F)] in a saturated surface dry (wet) state following 300 freeze-thaw cycles in distilled water
- room temperature [22°C (71°F)] in a saturated surface dry (wet) state following 300 freeze-thaw cycles in saline water.

The freezing temperature condition was achieved by placing the geotextiles in a walk-in cold room for 24 hours, and testing in the cold room. The saturated surface dry (wet) condition was obtained by soaking the geotextiles in water for 24 hours and blotting the specimens just prior to testing. Freeze-thaw cycling in either distilled or saline water was accomplished by placing a specimen in a sealed plastic bag filled with either distilled or saline water and placing the bag on a rack in a freeze-thaw chamber.

The tensile strength of each specimen was normalized to a nominal mass per unit area to account for specimen variability. The normalized strengths of five specimens of a given geotextile type for a given test condition were averaged. The significance of the average values when compared with the average normalized strength of other test cases was determined using a student's t-distribution for a 90% confidence level.

Creep Tests

The creep characteristics of the geotextiles were evaluated at room temperature [22°C (71°F)] and subfreezing temperature [-12°C (10°F)] when loaded to various percentages of ultimate wide strip tensile strength. Three test specimens of a given geotextile type for a given test condition were trimmed to a width of 152 mm (6.0 in.) and secured in grips with a spacing of 76 mm (3.0 in.). The three test specimens were connected in series for dead weight loading.

Average normalized strength was used to determine the load required for each set of creep specimens. Each geotextile type was tested at load levels of 20, 35, 50, and 65% of ultimate wide

strip tensile strength. The loads associated with a given test condition were applied as rapidly as possible without impact, and deformation readings were taken at 1, 2, 5, 10, 30, 60, 120, 240, 1,440, and 2,880 min. Thereafter, readings were taken every week up to approximately 15 weeks or until rupture occurred. A test was also terminated when no measurable deformation occurred during a period of one week. The subfreezing temperature condition was achieved by conducting the creep tests in a walk-in cold room.

Frost Heave Tests

Frost heave tests were performed in the frost heave chamber schematically in Figure 1. The chamber, operated in a walk-in cold room, contained three tapered lucite cups 171 mm (6.75 in.) high with 116 mm (4.17 in.) and 105 mm (4.13 in.) top and bottom diameters, respectively. The soil to be tested was contained in the cups. Two cups had small holes drilled through the bottom and a 6.5 mm (0.25 in.) thick porous stone on the bottom. The third cup had no holes, thereby excluding the entry of water. The three specimen cups were held in a 0.394 m (15.5 in.) diameter disk of high-density styrofoam (brand) insulation to assure uniaxial freezing. The base of the cups extended below the bottom of the styrofoam so water in the bath could be raised above the level of the porous stones. Thermistors were installed through the side of one of the cups with holes in the bottom. The thermistors were spaced vertically at 14 mm (0.56 in.) intervals. Thermistors were placed only at the top and bottom of the other two cups.

The water bath was insulated and the water temperature was maintained at 1°C (34°F). An environmental chamber was used to control the air temperature above the soil specimens at -5°C (23°F).

Three dial gauges were used to measure the heave for each specimen. Thin [0.3 mm (0.012 in.)] rubber membranes were placed around each soil specimen. The inside of each cup was coated with silicone grease to reduce friction. Plastic wrap was placed on the top of each specimen to reduce sublimation during freezing.

The test soil was a nonplastic silt from Fairbanks, Alaska, known to be highly frost susceptible. The test specimens were carefully compacted to 90% of standard maximum dry density (AASHTO T-99) at a water content 2% above optimum.

After the soil specimens were compacted in the cups and the cups were placed in the styrofoam insulation container, the soil was protected against evaporation and the assembly was precooled for 12 hours at 1°C (34°F). After chilling, the assembly was placed on the water bath, the dial gauges were mounted and zeroed, and the environmental chamber was placed over the assembly. The system was allowed to cool until the 0°C (32°F) isotherm had moved a maximum of 6 mm (0.25 in.) below the surface of the soil.

When the freezing front reached a depth of about 6 mm (0.25 in.), initial readings of all thermistors and dial gauges were taken. As freezing progressed, dial gauge and thermistor

FIGURE 1 Frost heave test cell.

readings were taken at 0.5, 1, 2, 3, 5, 8, 12, 18, and 24 hours. Readings were continued after 24 hours or until the freezing front reached the level of the geotextile layer, whichever was less. At the end of the test the specimens were removed from the cells and moisture content samples taken. Water content was determined immediately above and below the location of the freezing front at the end of the test and at approximately 19 mm (0.75 in.) intervals throughout the length of each specimen.

Three specimens were tested simultaneously with each test. The specimens were prepared as identically as possible except one had a geotextile layer 38 mm (1.5 in.) above the bottom of the specimen. The specimen with the geotextile and one other specimen were open to free water at the bottom. The third specimen was for control and had neither geotextile nor access to free water.

TEST RESULTS

Tensile Load-Strain-Strength

FIGURE 2 Axial load versus strain (dry condition).

Tensile axial load versus strain relationships for the geotextiles tested at temperatures of 22° and -12°C (71° and 10°F) are shown in Figure 2. The modulus and strength of the Typar increased with decreasing temperature. The strain at failure decreased significantly for all polypropylene geotextiles. No other statistically significant (90% probability) deviations in load-strain-strength characteristics were observed.

A summary of all the tensile load-strain characteristics of the geotextiles tested is given in Table 2. The strain at failure for the resin-bonded polyester geotextile increased upon wetting. Other results indicate that normalized strength, percent strain at peak strength, and normalized secant modulus at 10% strain do not change appreciably from the initial dry values when the geotextiles considered were tested in a wet condition at room temperature or following 300 freeze-thaw cycles in a dry, distilled water, or saline water environment. An exception was Propex 2002 which exhibited a significant decrease in strength (approximately 12%) after 300 freeze-thaw cycles in distilled and in saline water.

Creep

Typical creep strain versus time relationships for the geotextiles tested at 22° and -12°C (71° and 10°F) at a load level of 50% of the wide strip tensile strength are shown in Figure 3. A reduction in temperature to -12°C (10°F) resulted in a decrease in creep strains for geotextiles with polypropylene fibers. At this load level creep strains for geotextiles with polyester fibers were not significantly influenced by this temperature change.

This difference in the effect of temperature on creep for polypropylene and polyester geotextiles may be explained in terms of the glass transition temperatures of these two polymers. The glass transition temperature for polypropylene is about 0°C (32°F), whereas for polyester it is about

FIGURE 3 Creep strain versus time at 50% of tensile strength.

110°C. When the temperature of a polymeric material falls below its glass transition temperature, the ability of the material to deform is severely restricted. Since the glass transition temperature of the polyester is well above the range of temperatures tested in this investigation, and since for the polypropylene it is within this range, the deformation characteristics of polyester geotextiles change much less with temperature than those of the polypropylene geotextiles. At load levels of 20% ultimate strength, the decrease in creep strain with temperature was not statistically significant for any geotextile. The geotextile structure and polymer appear to dominate short-term creep strains, and the polymer and temperature control the long-term creep rates.

The polypropylene materials experienced tertiary creep and failed at load levels of 50% or 65% of wide strip tensile strength at 22°C (72°F). The geotextiles with polyester fibers did not fail at this temperature until the load level was 80% of wide strip tensile strength. Significantly, at -12°C (10°F) none of the polypropylene materials failed at a 50% load level, however, and only one geotextile (Typar) failed at a 65% load level.

Frost Heave

Frost heave rates for all tests are presented in Table 3, and water contents after freezing for two tests are shown in Figure 4. The data in Table 3 show all of the nonwoven geotextiles except the Stablenka caused a marked reduction in the heave rate. The only woven fabric, Propex, was intermediate in its effect.

Of the three most effective geotextiles, Fibretex and Bidim are both thick and have high permeabilities. Typar, in contrast, is thin and has a low permeability. Typar is also the most hydrophobic and requires a head of about 75 mm (3 in.) of water to initiate flow. Of the fabrics

tested, only the Stabilenka was hydrophilic and readily adsorbed water.

Figure 4 illustrates the water contents in the soil specimens for the poorest and one of the best results. It is clear that for the conditions of these tests, Stabilenka had virtually no influence on the water migration while Bidim essentially stopped heave completely. These tests are qualitative and cannot be directly related to field

FIGURE 4 Soil water contents after freezing.

conditions; however, it does appear that some geotextiles show potential as capillary breaks to limit frost heave. Different geotextiles have different effects and the factors affecting their effectiveness are not well defined. Additional research into this use of geotextiles is both needed and deserved.

CONCLUSIONS

Based upon the test results presented for the five geotextiles considered in this research program, the following conclusions have been reached: (1) the mechanical properties of geotextiles, in terms of load-strain-strength and creep characteristics, are not adversely affected by subfreezing temperatures in a temperature range associated with many cold regions engineering applications; (2) freeze-thaw cycling in dry, distilled water, or saline water environments has little influence on the load-strain-strength characteristics of most geotextiles; (3) geotextile structure and polymer tend to control short-term creep strains; (4) the fiber polymer and temperature control long-term creep rates; (5) for temperatures warmer than 0°C (32°F), polyester fabrics have much lower creep rates and higher thresholds of tertiary creep than polypropylene; however, for colder temperatures there is much less difference between the two polymers; (6) many geotextiles have considerable potential as capillary breaks to limit frost heave; (7) other factors equal, thick fabrics tend to be better capillary breaks than thin fabrics; (8) geotextiles which are hydrophobic are more effective capillary cutoffs than those which absorb water readily; and (9) geotextiles deserve further testing of their abilities as capillary breaks to limit frost action.

EFFECT OF COLOR AND TEXTURE ON THE SURFACE
TEMPERATURE OF ASPHALT CONCRETE PAVEMENTS

R. L. Berg¹ and D. C. Esch²

¹U.S. Army Cold Regions Research and Engineering Laboratory
Hanover, New Hampshire 03755 USA

²Alaska Department of Transportation and Public Facilities
Fairbanks, Alaska 99701 USA

During the fall of 1981 and the spring of 1982, eight test items were established on an asphalt pavement in Fairbanks, Alaska. The test items were: two sections of untreated pavement, yellow-painted pavement, white-painted pavement, "standard" chip seal, fine-grained "standard" chip seal, chip seal with dark brown aggregate, and chip seal with white marble aggregate. The test items were located on a main road. Surface temperatures were monitored hourly by thermocouples attached to an automatic data collection system. The ambient air temperature, wind speed and direction, amount of precipitation, and radiation balance were continuously recorded at an untrafficked pavement approximately 100 m from the test items. Incident and reflected shortwave radiation measurements were made nearly every weekday over each test item using a hand-held radiometer. N-factors, ratios of surface thawing indexes to air thawing indexes varied from about 1.2-1.3 for the white- and yellow-painted surfaces, respectively, to about 1.4-1.5 for the other surfaces. Daily and monthly n-factors for a particular surface varied depending on wind speed, the durability of the surface treatment, and the amount of incident solar radiation. Approximately 2200 vehicles per day crossed the test sections; turbulence induced by the traffic caused n-factors to be lower than reported by other authors. Abrasion by traffic reduced the effect of the surface treatments.

In the discontinuous permafrost regions of Alaska, extremely thick granular embankments (15-20 ft deep) may be necessary to completely contain seasonal thawing. Due to inadequate quantities of materials, costs of material acquisition and placement, or excessively elevated surfaces, the necessary thick embankments are seldom constructed, and considerable differential settlement frequently results beneath roads and airfields. Three passive methods have been used to minimize seasonal thaw depths and thereby minimize embankment thickness requirements: (1) thermal insulating layers (Berg 1976, Esch 1973); (2) high water content layers (Esch and Livingston 1978); and (3) materials that reduce the surface temperature of the embankment (Fulwider and Aitken 1963, Berg and Aitken 1973).

In this paper we discuss the effects of surface color and texture on the thawing season surface temperatures of an asphaltic concrete roadway pavement in Fairbanks, Alaska. The roadway carries a substantial volume of traffic each day, so this study differs from previous surface temperature studies of pavements that were not subjected to significant traffic-generated air movements and to the effects of tire wear on surface coatings.

SITE PREPARATION AND INSTRUMENTATION

The test sections are located on Peger Road between the entrances to the Interior District offices of the State of Alaska Department of Transportation and Public Facilities (DOT/PF) (Figure

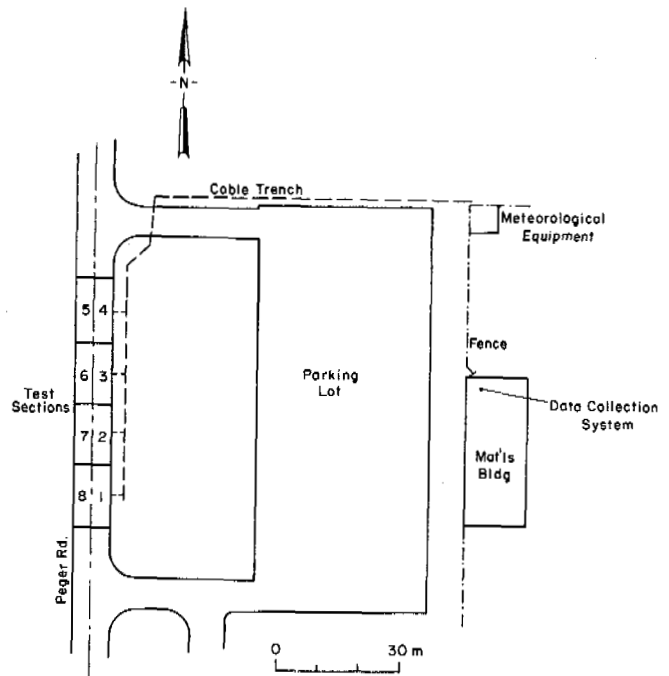

FIGURE 1 Layout of test sections and instrumentation at Peger Road test site.

1). Peger Road in Fairbanks, Alaska, was reconstructed in the summer of 1981, and in the fall of 1981 and spring of 1982 eight test sections were installed. The test items were: two sections of untreated pavement, yellow-painted pavement, white-painted pavement, "standard" chip seal, fine-grained "standard" chip seal, chip seal with a dark brown aggregate, and a chip seal with white marble aggregate. Prior to placing the 5-cm (2-in.) thick asphaltic concrete pavement, DOT/PF engineers installed four 2.5-cm (1-in.) diameter PVC pipes horizontally near the top of the base course. The pipes extended beyond the pavement on each side by about 0.6 m (2 ft). In the late summer, 15-cm (6-in.) diameter cores were removed from the pavement over the PVC pipes, and two 6-mm (1/4-in.) diameter holes were drilled through the cores from bottom to top. Two copper and two constantan thermocouple wires were fed through the PVC pipe from each core hole to the edge of the road. Two copper constantan thermocouples were then fabricated at each core hole and a thermocouple was epoxied into each hole, with leads extending from the bottom of the cores. The sensing tip of each thermocouple was approximately 3 mm (1/8 in.) from the top of the core. Warm liquid asphalt cement was poured on the exposed base course, and the core containing the two thermocouples was pushed into the asphalt cement. Additional liquid asphalt cement was poured into the annulus between the core and the undisturbed pavement.

Thermocouple wires were buried beneath the ground or laid on the ground surface from the edge of the pavement to the DOT/PF office building (Figure 1), where a data collection system was located. Meteorological equipment consisting of radiometers to measure incident and reflected shortwave radiation and incoming and emitted longwave radiation, equipment to measure wind speed and wind direction, and hardware to measure precipitation and air temperature were located within a fenced area to prevent vehicles from damaging the equipment. The meteorological equipment is located approximately 100 m (300 ft) from the test sections. Output from the meteorological equipment was transmitted to the

data collection system and other recorders through extension wires mounted on the fence. Measurements from all of the equipment commenced in March or April 1982 and will continue through early summer 1983. The data collection system recorded the surface temperatures and radiation totals hourly during summer 1982. Average wind speed and direction were also recorded hourly. Between 1100 and 1300 hr each day from April through September 1982, a hand-held radiometer was used to make instantaneous measurements of incident and reflected shortwave radiation over the test sections. The albedo of each surface was computed from these measurements.

The layout of the test sections is shown in Figure 1. Each test section was approximately 15.2 m (50 ft) long by 5.9 m (16 ft) wide. The average daily traffic on Peger Road during the 1982 summer was approximately 2200 vehicles per day in each direction. The speed limit on Peger Road is approximately 22 m/sec (50 mph). Gradations and asphalt application rates for each of the chip seals are shown in Table 1. Different liquid asphalt application rates were necessary to retain the various gradations of chips properly.

DATA ANALYSIS

The mean and design air freezing and thawing indexes from observations at the Fairbanks International Airport (period of record 1950 through 1979) are:

Mean air freezing index	3200°C-days (5760°F-days)
Design air freezing index	3724°C-days (6704°F-days)
Mean air thawing index	1844°C-days (3320°F-days)
Design air thawing index	2104°C-days (3787°F-days)

The design values were calculated as the average of the three extremes in the 30 years of record.

Thawing indexes from the Peger Road site and the Fairbanks International Airport for the 1982 thawing season are shown in Table 2. Summer 1982 was considerably warmer than normal and the air thawing index measured at the Peger Road site was

slightly warmer than at the airport, which is about 3 km (2 mi) west of the Peger Road test site.

Monthly and seasonal n-factors, determined from:

$$n = \text{surface thawing index} \div \text{air thawing index}$$

are also shown in Table 2.

The n-factor for the bare pavement was 1.53; for the chip seals, n-factors varied from 1.41 to 1.50. N-factors for the white-painted and yellow-painted pavements were 1.22 and 1.30, respectively. On the basis of data from airfield pavement studies in Fairbanks and at Thule, Greenland, the U.S. Departments of the Army and the Air Force (1966) relate summer n-factors to the pavement type and average summer wind speed. The average wind speed measured beyond the zone of traffic-induced turbulence near Peger Road was 0.7 m/sec (1.6 mph) for the 1982 summer. For an asphaltic concrete pavement, an n-factor of about 2.8 is obtained from the above reference.

Air and pavement surface temperatures have recently been measured at several arctic and sub-arctic locations. Table 3 contains n-factors that were determined from data gathered from asphaltic concrete pavements. In general, airfield pavements and test sections exhibit the highest n-factors and roadway pavements the lowest. The n-factors computed for Peger Road were significantly lower than those calculated for other roadway surfaces.

Airfields and test sections do not receive as much traffic to induce air turbulence as do roadway surfaces. At the location where surface temperatures were measured on the Richardson Highway, approximately 700 vehicles per day use the road. Approximately 4400 vehicles per day use Peger Road. It is unlikely that either the Kotzebue or Inuvik airports have more than 100 aircraft movements per day and probably fewer than 10 vehicles per day use the airfield or roadway test sections. These data imply that turbulence induced by vehicular traffic is an important influence on the n-factor of an asphaltic concrete pavement. In addition, vehicular

traffic may indirectly cause the pavement to absorb less solar radiation by wearing the black asphaltic concrete coating off a larger portion of the generally lighter-colored aggregate.

Berg and Aitken (1973) reported that the albedo of the asphaltic concrete test sections was 16%. At Peger Road the albedo averaged 13% (Table 4) on the bare pavement; therefore we conclude that the surface albedo did not cause the lower temperatures observed on Peger Road. Turbulence caused by passing vehicles seems to be the most logical explanation.

Since increased turbulence causes increased convective heat loss, lower surface temperatures result. Lunardini (1981) also indicates that increased average summer wind speeds cause reduced surface thawing indexes.

Surface temperatures on the white-painted test section on Peger Road resulted in an n-factor of 1.22 for the season. Berg and Aitken (1973) reported an n-factor of 0.98 and an albedo of 66% for the white-painted test section in their study. The albedo for the white-painted test section on Peger

Road averaged 38% for the entire thawing season and 45% after the test section was repainted on 8 June (Table 4). The most probable cause of the reduced albedo on Peger Road was degradation of the paint coating due to traffic.

The yellow-painted test section on Peger Road reflected nearly as much radiation as the white paint. The albedo averaged 35% for the entire summer and 41% after it was repainted on 8 June. The n-factor for the yellow-painted test section was 1.30, only slightly larger than that for the white-painted section.

None of the chip seals reduced the surface temperatures as much as the white or yellow paint. The Browns Hill B-chips were most effective. They were also the largest and were applied with the highest application rate of asphalt. The Fairbanks S&G and the white marble C-chips resulted in about the same n-factor. The white marble chips fractured due to traffic loadings. Had they remained intact they probably would have been more effective than the dark or colored chips. The Fairbanks S&G E-chips were the least effective chip seal. The application rate of asphalt in 1981 was inadequate to properly bond the Fairbanks S&G E-chips to the pavement; approximately one-half of the chips were lost, exposing the bonding layer of asphalt and lowering the albedo. White and yellow paints were applied twice to the roadway; each coat was approximately 0.2 mm (0.01 in.) thick. Annual repainting would be necessary to provide consistent coverage of roadways. Painting should be completed early in the thawing season to avoid damage by studded tires.

CONCLUSIONS

In this study, white or yellow paint applied to the pavement surface reduced surface temperatures and n-factors more than any of the chip seals.

Comparing these results with those reported by Berg and Aitken (1973) indicates that painted treatments may be more effective on airfield pavements where the volume of traffic is inadequate to cause rapid degradation of the paint. Airfield pavements may require repainting once every 5 years or more, but roadways will probably require repainting every year, due primarily to removal of paint by studded tires. Asphaltic concrete airfield pavements probably remain "blacker" due to less tire abrasion removing the asphalt coating from the aggregate.

The data obtained at Peger Road and at other arctic and subarctic sites indicate that traffic-induced air turbulence appears to reduce thawing season n-factors, i.e. the numerical value of the n-factor decreases with increased amount of traffic.

ACKNOWLEDGMENTS

This study was sponsored by the State of Alaska Department of Transportation and Public Facilities. The meteorological equipment and observers were furnished by the U.S. Army Atmospheric Science Laboratory detachment at Ft. Wainwright. Jerry Bower, DOT/FF, changed magnetic tapes and reported equipment malfunctions to the investigator from the

U.S. Army Cold Regions Research and Engineering Laboratory (USACRREL). Richard Guyer, USACRREL, programmed and installed the data collection system. Gregor Fellors, Gary DeCoff, and Linda Gee, USACRREL, prepared and executed the computer programs for converting, totaling, and averaging the data.

WEICHSELIAN PINGO REMNANTS (?) IN THE EASTERN PART OF THE NETHERLANDS

S. Bijlsma*

Soil Survey Institute and State Geological Survey,
P.O. Box 98, 6700 AB Wageningen, Netherlands

Three depressions with depths ranging from 4 to 19 m were investigated. It was determined that they are most probably pingo remnants. The pingos formed in fluvial sediments, perhaps between circa 29,000 and 23,000 years BP. Before circa 23,000 years BP, no surface expression of the pingos was present. It is assumed that a buried ice core remained and was covered by eolian and fluvial deposits. Circa 12,000 years BP the buried ice core melted and the overlying material subsided to form water-filled depressions, that subsequently filled with organic matter. The pingo remnants have no ramparts.

*Deceased

INTRODUCTION

Closed topographic depressions interpreted as pingo remnants are common in the till covered area of the northern part of the Netherlands (Figure 1) and were first described by Maarleveld and Van den Toorn (1955). A recent summary of the investigations of these pingo remnants is given by De Gans and Sohl (1981) and by De Gans (1982).

A few pingo remnants have been described from other parts of the Netherlands (Maarleveld 1976, Bisschops 1973).

The purpose of this paper is to describe depressions in the eastern part of the Netherlands that can be interpreted as pingo remnants.

These fine grained sands with thin layers of loam are called Older Coversand I.

Overlying the Older Coversand I is the Beuningen Complex. The basal part of the Beuningen Complex is an arctic soil developed in cryoturbated Older Coversand I (Van der Hammen et al. 1967). This soil is often overlain with a layer of coarser (fluvial ?) deposits with large ice-wedge casts (Maarleveld 1976, Kolstrup 1980). The uppermost part of the Beuningen Complex is a thin eolized pebble band called the Beuningen Gravel Bed.

TABLE 1 Stratigraphy of the Weichselian.

GEOLOGICAL FRAMEWORK

The eastern part of the Netherlands was covered by ice during the penultimate glacial, the Saalian. The ice left a landscape of ice-pushed ridges, basins, and almost level plains with till and glaciofluvial deposits. In the last glacial, the Weichselian (Table 1), the glaciers did not reach the Netherlands: this time periglacial conditions existed.

In the Early and Middle Pleniglacial (Table 1), small rivers laid down deposits of sand intercalated with loam and peat. Layers of fine sand and loam are particularly common in the upper part of the deposits. These fluvial deposits are called (niveo-)fluviatile by Van der Hammen et al. (1967), and fluvioperiglacial deposits (which include fluvial and lake deposits) by Zagwijn and Paepe (1968). Fluvioperiglacial deposits occur in the fieldwork area (Figure 1) in all the lower areas between the ice-pushed ridges. Palynological studies (Van der Hammen et al. 1967, Zagwijn 1974, De Gans and Cleveringa 1981) indicate a severe climate, with some warmer interstadial intervals (Table 1) during the deposition of the fluvioperiglacial deposits. It seems probable that during the Early and Middle Pleniglacial there was permafrost in areas not occupied by rivers.

In the Late Pleniglacial eolian sands were deposited over nearly the whole fieldwork area.

FIGURE 1 Generalized geological map of the Netherlands showing the location of the investigated pingo remnants and other pingo remnants described in the literature.

Overlying the Beuningen Complex, eolian deposits of Older Coversand II (with the same lithology as the Older Coversand I) are found.

In the Late Weichselian the so-called Younger Coversands were deposited. They are coarser than the Older Coversands and often contain some fine gravel. Loam layers are absent. In contrast to the Older Coversands, accumulation of the Younger Coversands often took place in the form of dunes.

Closed topographic depressions are indicated on the Geomorphological map of the Netherlands, scale 1:50,000. This map also gives information on their surface form and present depth. From this map depressions were selected for preliminary field study. As the purpose of the survey was to identify pingo remnants, depressions had to be circular or oval and more than 2 m deep (De Gans 1982). The accessibility of the depression and the thickness of the organic infill determined whether it was selected for a more detailed investigation.

The described depressions are in almost flat plains that were originally covered with Holocene peat. The peat was dug out for fuel in the last centuries and after it had been removed, organic sediments only remained in the lowest parts of the terrain, usually former lakes.

Detailed cross sections were made of the depressions and their surroundings. The lithostratigraphy was established by means of hand drilling equipment. Stratigraphic units were identified and correlated using lithological properties such as grain size, loam content and the presence or absence of gravel. The soil of the Beuningen Complex, an important marker horizon, is not identifiable but the overlying coarse sands and the gravel bed are usually recognizable in borings.

Depression A (Nieuwe Veen, $6^{\circ}40'00''\text{E}-52^{\circ}33'49''\text{N}$, see Figure 1) is nearly circular with a diameter of 350 m and an infill of organic material of 19 m thick (Figure 2). In all 45 borings were made to study the depression and the surrounding area. The depression formed in fluvio-periglacial deposits consisting of fine sands, alternating with layers of silt, probably lake deposits. These deposits are more than 4 m thick and the base was not reached by the borings. No rampart is present. Because of its depth the inorganic infill in the deeper parts could not be studied. An infill with Older Coversand I, deposits of the Beuningen Complex, and Older Coversand II were found on the sides of the depression. The lithology and thickness of these deposits seem to be the same as those in the surrounding area.

Some Younger Coversand is intercalated with the organic infill in the depression. Outside the depression the Younger Coversand is well developed. The beginning of organic sedimentation is dated as Earlier Dryas Stadial (pollen zone Ic, Table 1, Figure 5).

Depression B (Mokkelengoor, $6^{\circ}36'00''\text{E}-52^{\circ}19'20''\text{N}$, Figure 1) has an oval shape with a short axis of 320 m and a long axis of 430 m. Its depth, including the inorganic infill, is 4 m (Figure 3). 61 Borings were made to study this depression. The depression cuts through fluvio-periglacial deposits but not through the underlying till.

The fluvio-periglacial deposits are coarse grained at the base. The uppermost part of these deposits in the area surrounding the depression are very fine sands with thin silt layers that are sometimes peaty. They are interpreted as lake deposits.

No rampart was found. Older Coversand I is present in the depression as well as gravelly sands interpreted as a part of the Beuningen Complex. Older Coversand II is well developed in the surrounding area but is very thin in the depression. The beginning of organic sedimentation is dated as

FIGURE 2 Depression A. Upper part: shape of the depression, location of the borings and the cross section. Lower part: cross section.

Earlier Dryas Stadial (pollen zone Ic, Table 1, Figure 5).

Depression C (Mariënvelde, $6^{\circ}28'00''\text{E}-52^{\circ}01'00''\text{N}$, Figure 1) is nearly circular with a diameter of 275 m and a depth, including the inorganic infill, of 8 m (Figure 4). 39 Borings were made to study this depression and the surrounding area. The depression is formed in fluviperiglacial deposits consisting of fine grained sands. In most of the borings outside the depression, the uppermost layer is composed of very fine sand or silt, that can probably

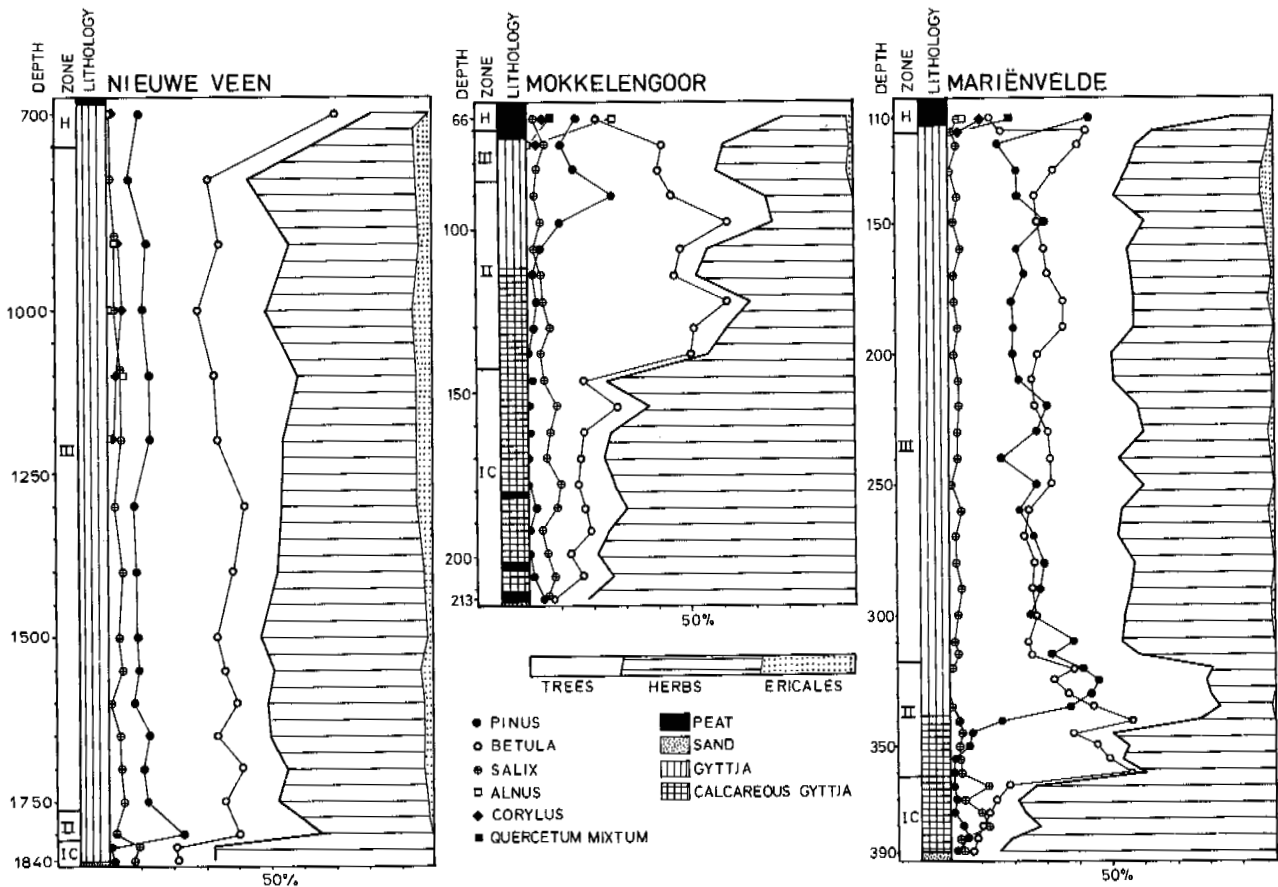

FIGURE 5 Pollen diagrams.

be interpreted as lake deposits. The depression has no rampart. In the depression, Older Coversand I, a thin gravel layer interpreted as a part of the Beuningen Complex, and Older Coversand II are found. The lithology and thickness of these layers do not differ from those of the corresponding layers in the surrounding area. The Younger Coversands are very thin in the depression but are well developed in the surrounding area. The beginning of the organic sedimentation can be dated as Earlier Dryas Stadial (pollen zone Ic, Table I, Figure 5).

DISCUSSION

Origin

The three depressions have so much in common that their origins do not need to be discussed separately. Although they differ in diameter and depth, they all formed as nearly circular depressions in fluvial deposits. Late Pleniglacial deposits are present in all the depressions but they do not fill them. The beginning of organic sedimentation is roughly synchronous and starts circa 12,000 years BP.

It is often very difficult to identify pingo remnants with certainty (Fleml 1976). According to

Fleml, pingo remnants are circular to oval ramparted or non-ramparted forms, with diameters ranging from a few tens to a few hundreds of meters. For areas without permafrost it must be proved that the depression formed in a period in which permafrost might have existed, i.e. in a glacial period.

Their circular form and the pollen data from the basal sections of the organic infill suggest that the depressions described above may be pingo remnants.

Fleml (1976) lists five possible mechanisms that can produce forms resembling pingo remnants: glacial, thermokarst, karst, eolian and anthropogenic processes.

Although the investigated area was covered by glacier ice in the Saalian, a glacial origin can be dismissed. Such depressions would have been filled with Eemian and Early Weichselian deposits, and not solely with Middle and Late Weichselian deposits.

As no soluble material underlies the depressions a karst origin is impossible. Anthropogenic processes are very unlikely, as pollen data from the organic infill indicate that deposition began during the Late Weichselian. Eolian processes can produce nearly circular ramparted or non-ramparted depressions that can reach the same dimensions as the described depressions, but are usually less than 2 m deep (De Gans and Sohl 1981). An eolian origin is therefore unlikely.

Thermokarst processes include the differential

melting of massive segregated ice (pingos, palsas, ice wedges or massive tabular sheet ice) or dispersed ice. It is difficult to envisage large bowl-shaped depressions being formed by differential melting of even large complex ice wedges, massive tabular ice sheets or dispersed ice, as for this the bodies of ice would have to have been nearly circular. Palsas are unlikely to have fossilized, as their structure is such that the former surface will be restored after melting (Lundqvist 1969). Although some other modes of origin cannot be ignored, the most likely explanation of the origin of the depressions is the presence of a large circular ice body that uplifted the overlying deposits. Part of these deposits was subsequently removed by erosion, and after the ice melted, a depression remained. This process very closely resembles the formation of pingos and pingo remnants as described by numerous authors (e.g. Mackay 1979), so an origin as a pingo remnant is assumed.

If the depressions are interpreted as being pingo remnants, the absence of ramparts must be explained. Ramparts are formed during pingo growth and the early stage of decay by creep, mass movement, and surface wash from the uplifted overburden (Mackay 1979). The overburden consisted of fine sands with some silt layers. Because it is elevated, the surface of a pingo is better drained than the surroundings and it seems quite plausible that part of the overburden could be removed by deflation. The remaining part of the overburden is probably present in and around the depression but because no lithological differences exist it cannot be identified in borings.

Age of Formation and Decay

As the supposed pingo remnants form depressions in fluvioperiglacial deposits it can be inferred that the pingos formed either in a late stage of, or after the deposition of these deposits. From the radiocarbon data available in the Netherlands and Belgium, Kolstrup (1980) indicates an age between 28,000 and 27,000 years BP for the uppermost fluvioperiglacial deposits. Most of the fluvial activity then ceased, probably because the climate changed to drier and colder conditions (Wijnstra and Van der Hammen 1971) after the Denekamp Interstadial, about 29,000 years BP. It may be imagined that after the fluvial activity ceased, permafrost developed in the alluvial plains (De Gans 1982). Pingos probably formed on the sites of residual ponds (French and Dutkiewicz 1976, Mackay 1979), or where ponds formed in thaw depressions (Czudek and Demek 1970). In the areas surrounding the pingo remnants lake deposits were found in the uppermost part of the fluvial deposits. Thus it is thought that the pingos formed after 29,000 years BP, but there is no good evidence that they did not form earlier.

Both the age of the organic fill and its intercalation with Younger Coversand show that the ice cores melted completely after the onset of the Late Weichselian, at circa 12,000 years BP. Water-filled depressions were formed. Over time these became infilled with organic matter.

As, especially in the depressions A and C, the development of the Older Coversand I and II and of the deposits of the Beuningen Complex found in the depressions is similar to that of the corresponding

deposits in the surrounding areas, it seems that neither a hill nor a depression was present during their deposition. A high hill would have prevented deposition, a depression would probably have been filled completely, resulting in the deposits being thicker than in the surrounding areas. If this interpretation is correct it would mean that during at least the later part of the sedimentation of Older Coversand I, the pingos had already been partly destroyed. The Older Coversand I was deposited between 27,000 and circa 23,000 years BP (Kolstrup 1980). Pingo formation may thus have occurred between circa 29,000 and 23,000 years BP. Partial melting of the ice core so that the pingo became almost level with the surface must then tentatively be assumed to explain the development of the inorganic fill.

Van der Hammen et al. (1967) assume that polar desert conditions existed in the Netherlands during the period from circa 27,000 to 13,000 years BP. Organic deposits are extremely scarce in sediments from this period. Together with the widespread occurrence of eolian deposits, this points to the absence of a closed vegetation cover. Under these conditions deflation would have been important in any dry, finegrained sediment. It can be expected that because of their elevation the pingo skins were well drained, so if they consisted of fine grained sand, deflation would have been easy.

Partial removal of the overburden e.g. by deflation of the upper part of the active layer, may cause the active layer to reach the ice core. The upper part of the ice core then melts. The meltwater can drain through the active layer or over the surface. The excess of moisture in the active layer may slow down or even stop deflation. This process may continue until an almost level surface is reached. Older Coversand I could then be deposited over the remaining overburden and the increasing thickness of the covering material could prevent the active layer from reaching the remaining ice core.

CONCLUSIONS

The depressions described may be pingo remnants, although they have no ramparts. They are all nearly circular crater-like depressions formed in fluvial deposits. They seem to have been formed in alluvial plains at a time of reduced discharge, when permafrost developed in the alluvial plains. It is not possible to date the pingo growth precisely: it occurred probably between 29,000 and circa 23,000 years BP. From the lithology and thickness of the inorganic fill, compared with those of the same sediments in the areas surrounding the pingo remnants it is tentatively concluded that before circa 23,000 years BP no surface expression of the pingos existed any more, but buried ice cores remained. These were covered with eolian and fluvial sediments. From the dating of the lowest parts of the organic fill the final melting of the ice core can be put at circa 12,000 years BP. Subsequently, the deposits covering the ice core subsided and water-filled depressions were formed. These depressions were filled with lake deposits and peat in the Late Weichselian and the Holocene.

THREE SUPERPOSED SYSTEMS OF ICE WEDGES AT MCLEOD POINT, NORTHERN ALASKA, MAY SPAN MOST OF THE WISCONSINAN STAGE AND HOLOCENE

Robert F. Black
 Department of Geology and Geophysics, University of
 Connecticut, Storrs, Connecticut 06268 USA

Actively growing, surface ice wedges up to 9-m wide in primary, secondary, and tertiary polygons began growing by about 12,000 years B.P. at McLeod Point, 120 km southeast of Barrow, northern Alaska. Below the surface wedges two superposed, buried systems of inactive ice wedges in primary, secondary, and tertiary polygons were both truncated by separate episodes of deep thaw. The younger episode clearly resulted from a thaw-lake cycle. The older is attributed to a thaw-lake cycle, but available evidence is less definitive. The two buried systems of truncated ice wedges are in deposits that are separated by an organic horizon that is >40,000 radiocarbon years B.P. By analogy and correlation with the major events in the Quaternary history of northern Alaska, it is inferred that the three systems of ice wedges and associated sediments may span most of the Wisconsinan Stage and Holocene.

INTRODUCTION

McLeod Point, 120 km southeast of Barrow, northern Alaska, is a 7.2-m bluff of fine-grained sediments and ground ice fronting on the Beaufort Sea. In 1981 the bluff revealed a system of actively-growing, massive, surface ice wedges (in unit III) overlying the truncated roots of two buried, superposed systems of inactive ice wedges in deposits of units I and II (Figure 1). An unconformity locally rich in finely comminuted organic matter separated units I and II.

At least one thaw-lake cycle (Britton 1967, Black 1969, Sellmann et al. 1975) of late Wisconsinan age has modified the sediments, ice content, and chemistry of the younger deposits and truncated the upper system of buried ice wedges. Another thaw-lake cycle, or less likely a marine transgression, truncated the ice wedges of the lowest unit.

Measurements on airphotos taken in 1948 show

that the bluff retreated 230 m on the west side and 420 m on the east side during the interval 1948/1981, or 10-18 m per year. Hence, the ice wedges studied in 1949/1950 (Black 1974) were destroyed. However, the small geomorphic entity--an old upland--in which the wedges were exposed is still represented today.

The main purpose of the field study in 1981 was to collect material for radiocarbon dating in order to determine when the large, surface ice wedges in unit III began to grow, and also, if possible, the ages of the older buried ice wedges. The radiocarbon dating indicates that the large, surface ice wedges of unit III began to grow about 12,000 B.P. The lower system of buried wedges is beyond the age of radiocarbon dating. By analogy and inference from the Quaternary history of northern Alaska the three systems of ice wedges may span most of the Wisconsinan Stage and Holocene.

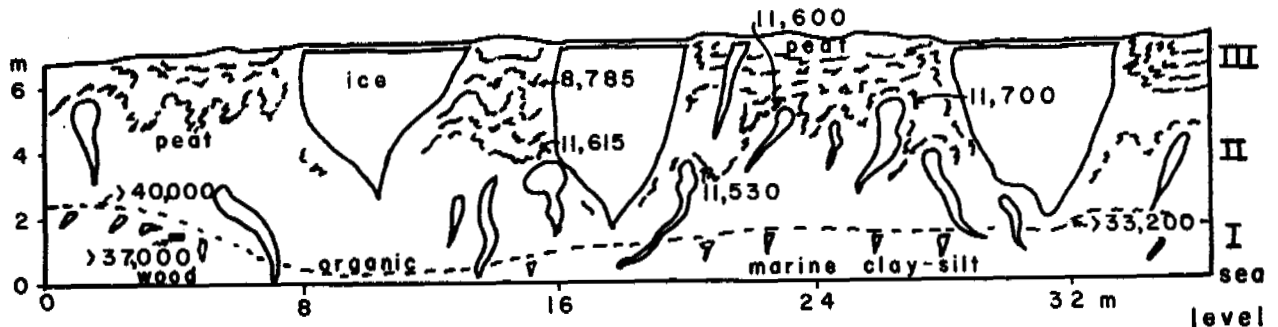

FIGURE 1 Composite diagrammatic sketch of part of the bluff at McLeod Point, showing the three units in which separate systems of ice wedges appear. The boundary between units I and II is a dashed line representing an unconformity with finely comminuted organic matter. The boundary between units II and III is the lowermost broken irregular line representing peat above the ice wedges in unit II.

STRATIGRAPHY

Black (1964, p. 68-69) characterized the lowermost sediments in the general area as marine silty clays and clayey silts with less than 10% very fine sand and correlated them with the Skull Cliff unit of the Gubik Formation of Pleistocene age. Organic matter makes up 6-8% of the total weight and increases in the upper part of the bank. The sediments are generally dark gray to black, greenish gray, or dark brown, but locally have dark yellow-brown, oxidized blotches, and irregular streaks. Ice in grains, granules, veins, dikes (including wedges), and small irregular bodies makes up 25-60% of the sediment by weight and increases upward. The marine sediments are cut into by thaw lakes, some of which extend to sea level. Most penetrate only 1-2 m. They leave characteristic deposits readily distinguishable from the underlying marine deposits by their color, bedding, and sorting. The lake sediments have much greater organic content and roots of water-loving plants in growth position in addition to large undecayed woody fragments and finely comminuted tissues.

The lower hiatus separating the two buried systems of ice wedges was considered in the field to be the bed of a former thaw lake rather than the result of a marine transgression on the basis of: 1. the lack of a lag of coarser sediments at the hiatus, 2. the presence of abundant finely comminuted organic matter, 3. the presence of local oxidized zones below the hiatus, as from groundwater movement, 4. the presence locally of truncated roots of ice wedges directly below the hiatus, and 5. differences in pH, specific conductance, and resistivity above and below the hiatus.

The measurements of pH, specific conductance, and resistivity of materials from the three units (Table 1) were made of the mineral zones rather than of the organic-rich zones. All are from the section at McLeod Point. Measurements from other nearby stratigraphic sections are not included, but showed similar results. Brown (1969) made more comprehensive studies of specific conductance of permafrost with marine and freshwater deposits at Barrow with similar results.

Arithmetic means and ranges of the small populations indicate good separation of values. The lowermost horizon (unit I) is considered to be marine on the basis of its uniform, thinly laminated stratification, greasy feel (typical of that unit), and widespread distribution. The uppermost unit (III) is quite clearly reworked

material deposited in a former thaw lake. The drop in specific conductance and rise in resistance from unit I to unit II suggest that electrolytes in the marine deposits were lost during the first presumed thaw-lake cycle.

No diatoms or other fossils of marine or fresh water were seen in samples of either units I or II. They were examined by both binocular and petrographic microscopes before and after treatment with hydrogen peroxide. However, the presence of fossils in similar sediments along the coast is not universal (David M. Hopkins, oral communication, 17 March 1983).

Preliminary laboratory examination of samples from the sediments above and below the hiatus reveals marked differences. Unit I is comprised mostly of well rounded, fine silt and clay with abundant fibrous plant tissues and coal fragments. Heavy minerals are sparse. Unit II is mostly well rounded, coarse silt and clay with a few percent of very angular, fine to medium sand, sparse fibrous plant tissues and coal fragments, and common heavy minerals of considerable variety. However, its fine silt is very similar in shape and composition to that in unit I. The bimodal textural distribution and distinctly different shape and composition of the sand compared with the fine silt preclude either a common origin or much distance of travel by water for the larger grains. A glacial deposit nearby is indicated. Thus, these findings support the interpretation of the local presence of glacial detritus of the Flaxman Formation of early Wisconsinan age (MacCarthy 1958, Hopkins 1979) in the stratigraphy. Presumably unit II with its glacial suite was the lowermost unit exposed in this area in 1949/1950 (Black 1964, p. 68).

A glacial origin for some fine-grained material in the bluff at McLeod Point is suggested also by the presence of occasional large erratics of igneous origin along the shore and in the bluffs. They are found from the Canadian border to Point Barrow and farther southwest (MacCarthy 1958). Leffingwell (1919) correlated them with the Flaxman Formation, a thin deposit of till on Flaxman Island, about 180 km southeast of McLeod Point. A granitic boulder, for example, just east of McLeod Point in 1950 rose above the shallow water about 1 m. It is possible, but not probable, that those erratics in shallow water were ice-rafted in modern times to their present position. However, this is not possible for those erratics occurring in the sediments of the bluffs. Even though none was seen in the bluff at McLeod Point, it is more logical to believe that they

TABLE 1 pH, specific conductance, and resistance of strata at McLeod Point.

UNIT	pH	SPECIFIC CONDUCTANCE	RESISTANCE(000)	NUMBER
III	(5.8) 4.5-7.1	(113) 70-176	(31) 24-40	8
II	(7.1) 6.8-7.7	(513) 255-720	(22.5) 18-26	7
I	(7.2) 7.1-7.4	(970) 800-1110	(19.5) 16.5-22	3

NOTE: Numbers in () are arithmetic means of the ranges. pH was measured on thawed sediment diluted 1:1 with distilled water. Specific conductance in parts per million was measured on thawed sediment diluted 5:1 with distilled water. Resistance in ohms was measured with an electrode spacing of 4 cm on thawed sediment, but with no added water.

were eroded from nearby bluffs, as at Drew Point or Cape Halkett (next west and east of McLeod Point, respectively) where they have been seen (Hopkins, written communication, 18 February 1983).

ICE WEDGES

Truncated remnants of ice wedges in the lowermost system (unit I, Figure 1) observed in 1981 were not recognized seaward in 1949/1950 (Figure 2). The ice wedges of unit I occurred only locally along the bluff in 1981. Where present they were less than 1-2 m above sea level and always with a discontinuous, finely comminuted organic zone directly above them. They were not seen where the organic zone approached sea level. The ice wedges were less than 1 m high and 1 dm wide (all widths cited herein are normal to the strike of the wedges). The wedges were spaced generally at intervals of 4-6 m, but only a few would be present in a particular spot. The ice-wedge remnants megascopically displayed vertical fabrics characteristic of other buried wedges (Black 1974). They were not exposed more than 1-2 dm into the bank, but their distribution and strike suggested that primary, secondary, and tertiary polygons were present (Black 1974).

The ice wedges in unit II above the lower organic layer were larger and better displayed than those in unit I, in the bluff as well as in a thermal niche carved by the sea beneath the face (Figures 1 and 2). (Black 1964, p. 68, and 1974, p. 250 reproduce other photographs of the bluff showing ice wedges in unit II). Some wedges were seen in three dimensions to join in polygons with diameters of 3-7 m. Primary, secondary, and tertiary wedges were present. Black (1974) described their fabrics. Many of these wedges penetrated the lower organic zone and upturned that stratum on both sides of the ice wedges (Figure 3). They clearly are younger than the organic zone they penetrated. Some wedges are as much as 1 m wide and several meters high. The larger wedges have flowed upward according to the exterior shape of the wedges, the disruption and distortion of foliation planes generated by inclusions in former contraction cracks, and the recrystallization and realignment of ice crystals. They have flowed upward 1-3 m, like diapirs, to elevate another unconformity with scattered bits of coarse fibrous peat in its upper part. These wedges also seem to have been truncated by deep thaw, according to their distribution, size, shape, and stratigraphic setting.

The upper organic zone, which is more disjunct and distorted than the lower, marks the inception of the low-centered polygon ponds associated with the uppermost, very large, surface wedges of unit III (Figure 1). The surface wedges were 5-7 m wide in the bank exposed in 1981 (Figure 1). One 9-m wide wedge was seen in 1949/1950 seaward of this locality. Open contraction cracks and megascopic fabrics within the ice wedges indicated current activity (Black 1974). Fibrous sedge peat, in part in growth position, is in sedimentary layers aggregating as much as 3.3 m in the former low-centered polygon ponds between the

surface wedges. The organic material increased in amount upward.

DATING

Four radiocarbon samples from the base of the upper peat (unit III, Figure 1) between the large surface wedges date the inception of vegetation in the low-centered polygon ponds. The dates range from 11,530 to 11,700 B.P. (Table 2). The vegetation is assumed to have begun growing within some centuries of the initiation of those wedges, when the double-raised rims adjacent to them generated low-centered polygon ponds. Hence, it can be assumed that the largest and oldest surface ice wedges of unit III began to grow about 12,000 radiocarbon years ago or somewhat earlier. Only a brief time would have been necessary to regelate the permafrost after draining of the thaw lake exposed the surface. The ice wedges of unit II were truncated by that thaw lake. How much time was involved in the thaw-lake cycle is not known.

Two dates of >33,200 and >40,000 B.P. (Table 2) on the lower organic zone that separates deposits of units I and II indicate the great antiquity of the oldest system of ice wedges. A spruce log (*Picea*) in the marine deposits below the ice wedges in unit I dated at >37,000 B.P. (Table 2). However, the same sample gave very low amino acid ratios as did a fragment of willow (*Salix*) from the same horizon (N. W. Rutter, written communication, 4 October 1982). This suggests a late Pleistocene age. All wood seen is erratic.

The pollen and spores in the two dated samples of the lower organic zone and in 13 other samples in the stratigraphic succession in the general area suggest the presence of herbaceous, wet tundra (Tom Ager and Effie Shaw, U. S. Geological Survey, written communication, 7 October 1982). "No clear evidence of dramatically different past vegetation types" was apparent between the older and younger materials. Preservation of pollen is generally poor. Many are recycled from Cretaceous, Tertiary, and older Quaternary deposits. Hence, none of the pollen provides much evidence of the age of the buried ice-wedge systems or of their host sediments.

The only previously dated, buried ice wedge in northern Alaska is 14,000 B.P. (Brown 1965, p. 39-41). It was at Barrow at a depth of 3 m in "a 'primary surface', or one that has not been recently reworked by the thaw-lake cycle". In central Alaska several buried ice wedges are dated 24,000-32,000 B.P. (Péwé 1975, p. 53).

At present the earlier ice wedges and strata at McLeod Point can only be dated by analogy with other events and sequences in the region. Previous studies have suggested that the lowermost sediments at McLeod Point range from mid-Wisconsinan to Illinoian. Black (1964, p. 67-68) noted that the lowermost sediments exposed in 1949/1950 in the vicinity of McLeod Point had a glacial component of sand and suggested (p. 89) that they might be Illinoian in age. The upper sediments (p. 69) were considered to be deposits in thaw-lake basins.

Sellmann and Brown (1973, p. 177-178) correlated the Skull Cliff unit of the Gubik

FIGURE 2 Photograph of the bluff at McLeod Point, showing the massive ice wedges of unit III at the surface and the much smaller diapiric wedges in unit II. No ice wedges of unit I are visible. 31 August 1950.

FIGURE 3 Root of a narrow ice wedge in unit II that cuts the organic layer with trowel between units I and II. Much of the surface is obscured by rapidly melting ice and clay-silt. The upturned organic layer is shown by inked dots. 2 August 1981.

Formation at Barrow with the Pelukian transgression (Sangamonian) and the lower marine phase of the Barrow unit of the Gubik Formation with the mid-Wisconsinan transgression. They considered the latter to be represented by the 7.5-8 m elevation attained by large ice-rafted boulders. This includes McLeod Point.

McLeod Point lies north of an extensive, elevated beach dated as more than 51,000 years B.P. (Carter and Robinson 1980). They suggested that the beach deposits and the marine mud to the north (including that at McLeod Point) may be synchronous and may constitute the youngest marine deposits on this part of the coastal plain.

David M. Hopkins (written communication, 18 February 1983) considered the beach deposits to be Pelukian (Sangamonian) in age and that the Flaxman Formation (early Wisconsinan) with its ice-rafted glacial component overlies those deposits at McLeod Point.

All these conclusions provide no clear-cut age assignment for the timing of growth of the ice wedges in units I and II. However, further constraints have materialized recently.

Carter (1981, 1982) describes a sand sea on the Arctic Coastal Plain immediately south of McLeod Point and associated, but older, fossil sand wedges immediately north and east of that sand sea (this volume). The primary sand wedges occur in sediments older than about 12,000 B.P. and have a maximum limiting age in sediments correlated with the Pelukian transgression. He concludes that arid conditions existed during late and middle Wisconsinan time and perhaps throughout the Wisconsinan Stage.

A frequency distribution of 78 radiocarbon dates from northern valleys of the central Brooks Range (roughly 300 km to the south) reveals no finite dates lie between 13,200-30,000 B.P. (Hamilton 1982). The suggestion is that conditions were unfavorable (too cold and dry) for growth of woody shrubs and peat-forming plants.

These interpretations place restrictions on the dating of the older buried ice wedges at McLeod Point as ice wedges require humid conditions and primary sand wedges require arid conditions for growth. It would seem that the sand sea is too close to McLeod Point to have had a distinctly different climate simultaneously. Moreover, the pollen from the interval between units I and II indicate herbaceous wet tundra (Tom Ager and Effie Shaw, written communication, 7 October 1982)--not the arid environment required for primary sand-wedge growth. Therefore, the logical conclusion is that the ice wedges of units I and II must be older than the sand wedges as they cannot be younger nor the same age. If the correlation of the sand wedges with late and middle Wisconsinan time is correct, the two older systems of ice wedges at McLeod Point must be early Wisconsinan or older.

The buried ice wedges are presumed to have grown as large as the present surface ice wedges. This seems necessary in order to provide sufficient ice in the ground to permit thaw lakes to incise to the roots of the wedges. Each system would require at least 12,000 years to grow to such size if the present surface wedges are a guide. The two thaw-lake cycles also require some

thousands of years. Thus, many tens of thousands of years are required for the development and destruction of the three systems of ice wedges.

CHRONOLOGY AT MCLEOD POINT

Two almost equally viable scenarios seem applicable to the chronology of the deposits and ice wedges at McLeod Point. If the lowermost sediments in the bank are Pelukian in age, then the ice wedges of unit I logically are early Wisconsinan. This correlation almost demands that the truncation of those wedges occurred during the Flaxman transgression which left the glacial sediments of Unit II. The ice wedges of unit II should have grown in the latter part of early Wisconsinan time in order to be older than the arid middle and late Wisconsinan interval of sand-wedge growth. The thaw lake that truncated the ice wedges of unit II could have started at any time during that long interval. It was drained sometime prior to 12,000 years B.P. to permit the growth of the wedges of unit III.

If, however, the lowermost sediments are Flaxman, then the ice wedges of unit I grew immediately thereafter in early Wisconsinan time. The hiatus that truncated them could be assigned to a thaw-lake cycle, which is preferred over a marine transgression. However, the ice wedges of unit II would still have to grow prior to middle Wisconsinan time in order to precede the growth of the primary sand wedges to the southeast. The record of middle and late Wisconsinan time is again presumed to be lost in the subsequent thaw-lake cycle that truncated the ice wedges of unit II. The growth of ice wedges in unit III followed about 12,000 years B.P. On the basis of knowledge to date the latter scenario is preferred, but the first cannot be ruled out with data in hand. At least it seems that most, if not all, the Wisconsinan Stage and Holocene are involved in the stratigraphy and ice wedges at McLeod Point and the time span may be longer.

ACKNOWLEDGEMENTS

Grateful acknowledgement is made to the National Science Foundation for funding my field studies in 1981. The logistic support provided by the U.S. Geological Survey in 1981 facilitated immensely the studies at McLeod Point and permitted other areas to be covered as well. Andrew M. Knowlton was a capable field assistant. The project would not have been possible without the background of knowledge I had gained while employed by the U.S. Geological Survey and without the former support of the Arctic Research Laboratory at Barrow and of the Office of Naval Research. Critical review of a draft of this paper by David M. Hopkins, Jerry Brown, and L. David Carter improved it considerably and is acknowledged gratefully.

THE SAGAVANIRKTOK AND ADJACENT RIVER SYSTEMS, EASTERN NORTH SLOPE, ALASKA:
AN ANALOG FOR ANCIENT FLUVIAL TERRAIN ON MARS

J.C. Boothroyd¹ and B.S. Timson²

¹Department of Geology, University of Rhode Island, Kingston,
Rhode Island 02881 USA

²Earth Surface Research, Inc., 114 State Street, Augusta, Maine 03240 USA

The large-scale geomorphic features of the Eastern North Slope, Alaska were formed by the Sagavanirktok and adjacent rivers during Quaternary time. The largest landforms are low hills, here called erosional remnants, situated between active and abandoned river courses. The erosional remnants are flanked by Pleistocene age terraces and abandoned floodplains lower than the remnant surfaces. Formation of remnants and terraces proceeded more rapidly during times of deglaciation when discharge was greatest, augmented by catastrophic drainage of moraine-dammed lakes. There has been extensive modification of valley floors and of remnant and terrace slopes by eolian, cryogenic, and debris-flow activity. Geomorphic processes on the Eastern North Slope have produced a suite of morphologic features characteristic of those seen, or inferred, on Viking Orbiter images of Mars in areas containing smaller outflow channels and depositional basins. The formation of these channels and basins--Ladon Valles (24°S, 29.5°W) is a good example--predates the development of most major outflow channels and may have occurred at a time when the Martian climate was "wetter" and thus more akin to present conditions on the North Slope. The similarity of the two suites of morphologic features suggests that similar processes, in type and magnitude to Quaternary processes that have shaped the Eastern North Slope, may have operated on Mars.

INTRODUCTION

The search for appropriate terrestrial analogs of the channels and valleys of Mars has resulted in the identification of several possible examples for the large outflow channels on Mars; specifically (1) the Channeled Scabland (Baker 1978, Baker and Nummedal 1978), (2) submarine canyons and valleys (Nummedal 1982), and (3) terrain modified by continental glaciation (Lucchitta 1982). It is also clear that the large outflow channels and the smaller channels and valleys have undergone extensive slope and floor modification by various mass-wasting and eolian processes after the original formative events (Mars Channel Working Group, in press). The purpose of this paper is to offer a terrestrial analog, the Sagavanirktok and associated drainage Systems of the Eastern North Slope, Alaska (Figure 1), for the smaller outflow channels and larger valleys on the Martian surface, and to illustrate some mass-wasting and eolian modifications to the fluvial valleys.

We examined LANDSAT images and U-2 color infrared photographs, particularly LANDSAT winter images obtained during times of snow cover and low sun angle (Figure 2). We then visited the Eastern North Slope in August 1979 and August 1981 and chose to work along the Sagavanirktok River because it is the most active river in the area that is easily accessible via the pipeline haul road. We did however, conduct a low-level aerial reconnaissance survey of the area shown in the large box on Figure 1.

GEOMORPHOLOGY OF THE CENTRAL ARCTIC SLOPE

General

The general study area, outlined in Figure 1, lies mostly in the Arctic Coastal Plain and Arctic Foothills physiographic provinces of northern Alaska (Wahrhaftig 1965). The coastal plain is underlain by semiconsolidated sandstone, siltstone, and claystone (continental and marine) of Tertiary age (Beikman 1980), which is in turn overlain by Quaternary age fluvial gravels and marine silt (Péwé 1975). The foothills are underlain by Cretaceous partially to totally consolidated terrigenous rocks that are moderately folded in contrast to the low northward dip of the Tertiary coastal plain sediments (Beikman 1980).

Rivers draining northward from the Brooks Range have created a complex fluvial drainage system on the Tertiary and Cretaceous rocks. The principal rivers, from west to east, are the Colville, Itkilik, Kuparuk, Toolik, Sagavanirktok, and Kadleroshilik (Figure 1). The Colville and Sagavanirktok have large tributaries associated with their stream systems. The present rivers, with the exception of the Colville and the Sagavanirktok, are underfit with respect to valley and floodplain width. Pleistocene-age, alpine glaciers of the Brooks Range advanced northward down the river valleys in the foothills to deposit prominent end moraines at the southern edge of the study area (Coulter et al. 1965, Hamilton 1978) (Figure 1).

Quaternary Landscape Development

The study area is underlain by up to 650 m of permafrost (Péwé 1975). Formation of ground ice has resulted in the development of ice-wedge polygons, other patterned-ground features, and pingos.

A summer active layer is present to a depth of 1-2 m (Pewe 1975).

The northward draining river systems have cut down into the underlying regolith and bedrock during Quaternary time to produce the following suite of landforms. The largest-scale geomorphic features are long, low hills, here called erosional remnants, situated between active and abandoned river courses. The erosional remnant hills are up to 100 km long and rise up to 200 m above presently active fluvial channels (Figure 2). The hills within the Coastal Plain physiographic province (Figure 1) have large, flat, relatively undissected upper surfaces that dip northward with an inclination slightly greater than the active river channels. Franklin Bluffs (Figure 2) is a good example.

The erosional remnants are flanked by Pleistocene-age fluvial terraces and abandoned floodplain segments that are lower in elevation than the remnant surfaces, but are 20-60 m higher than the present river beds. They are labeled (T) on Figure 2. The only structural control of remnant location appears to be a major southwest-northeast trending lineament that bounds the southeast or northwest side of each major remnant hill and is defined by the Colville River floodplain in the southwest (Albert 1978) (Figure 2). Contacts between the various Tertiary and Cretaceous units (Beikman 1980) cut across the remnants and play little role in remnant shape (Figure 2).

The southern older terraces exhibit etched topography on LANDSAT winter imagery and consist in part of drained thaw lakes that were active during late Pleistocene and early Holocene time (Gatto and Anderson 1975, Pewe 1975) (Figure 2). The etched terrain is bounded on the south by the foothills, folded belt of the Brooks Range. The folds trend generally east-northeast in this area. Tongues of morainal disintegration topography, labeled (H) on Figure 2, extended out of the valleys of the foothills and have been dissected by the active rivers.

The Colville and Sagavanirktok are robust braided rivers that are actively downcutting and laterally migrating to modify terrace and erosional remnant shape. However, most of the present rivers, with the exception of the Sagavanirktok and the Colville, are underfit with respect to valley and floodplain width, particularly the Itkillik and the Toolik. It is apparent that much of the remnant and terrace development took place during periods of deglaciation after Pleistocene ice advances. Hamilton (1978) indicates the past existence of glacial lakes dammed behind some of the moraines shown in the lower right on Figure 2. Increased runoff during deglaciation was augmented by catastrophic flooding during drainage of the moraine-dammed lakes.

THE SAGAVANIRK TOK DRAINAGE SYSTEM

Sedimentary Processes

The Sagavanirktok (Sag) is the second-largest river, after the Colville, on the North Slope of Alaska, with a length of 267 km. Maximum discharge is during spring breakup; flow declines to essentially zero during the winter freeze. The Sag is a coarse-gravel, braided river that is degradational

FIGURE 1 Location map of the Eastern North Slope, Alaska. General study area is outlined by large box centered on the Sagavanirktok (Sag) River; Figure 2 (LANDSAT image) is outlined by smaller inset. Rivers indicated by letters are (A) Anaktuvuk, (I) Itkillik, (K) Kuparuk, (T) Toolik, (Ka) Kadleroshilik.

through most of its length, becoming aggradational only on the last 20 km of delta plain.

Active bars are a combination of longitudinal bar complexes and large transverse bars. Many transverse bars are formed at the downstream end of chutes incised into low terraces of the inactive fluvial plain. Formation of chutes is due to blockage of the river by ice derived from icings (aufeis). Icings form by repeated overflows of water on river ice cover that is frozen to the river bed, due to intermittent thawing or, more importantly, a groundwater source (Hall and Roswell 1980, Sloan et al. 1976). Spring breakup results in ice drives that jam up and direct the river laterally to an unoccupied part of the fluvial plain. Thus icings play an important role in controlling downcutting and lateral migration of the active channel system.

Valley Modification

The Sag river is still actively downcutting adjacent to the Franklin Bluffs erosional remnant (Figure 2), but other portions of the Sag channel system together with the channel systems of adjacent rivers, have been abandoned and mass-wasting and eolian processes are modifying the older surface. Figure 3, a geomorphic map using U-2 imagery as a base, delineates some of the landforms that result from these modifying processes.

The Sag active bar and channel system is shown as (Fa). Other portions of the Sag channel system are inactive (Fi) or have been recently abandoned (Fb). The inactive channel segments exhibit fresh, unvegetated bar and bedform morphology but were not subject to flow during the latest meltwater seasons. The abandoned channel system is at the same elevation or slightly higher than the active bars and channels but is partially vegetated and modified by cryogenic processes.

Relict bar and channel systems exist as terraces elevated 10-30 m above the active river. Immediately adjacent to the terrace scarp is an eolian levee (E1) composed of silt and fine sand derived from the active and inactive bars and channels. Bar

FIGURE 2 LANDSAT band 5 image of Eastern North Slope, Alaska. Erosional remnants identified are: (IK) Itkillik-Kuparuk, (WH) White Hills, (SA) Sagwon, (FB) Franklin Bluffs. Other features are (T) terraces, (E) etched terrain, (F) foothills, (M) moraines. The dashed line on the (IK) remnant delineates a higher surface to the west from a lower surface to the east. Dash-dot line indicates the lineament of Albert 1978. Dotted lines delineate rock-unit boundaries of Beikman (1980); (1) Upper Tertiary marine rocks, (2) Lower Tertiary continental rocks, and (3) Cretaceous rocks. Box encloses map area of Figure 3. Scene E-1217-21235-5 01, February 25, 1973.

and channel topography is still identifiable in places (Er), but much of this terrain contains a lake/pond plain (Ep) of wind-aligned lakes developed in the active layer of the continuous permafrost. The eolian levee has longitudinal dunes oriented in an east-west direction, parallel to the dominant winds. The dunes are 20-30 m long and 1-4 m high. Similar dunes also are present on parts of the abandoned bar and channel system. In some locations,

the dunes have been eroded into streamlined, yardang-like landforms.

Still older surfaces, such as the upper surface of the Franklin Bluffs remnant, are low-relief, gently-sloping plains now being modified by solifluction (Cs1). Younger, moderate-relief slopes have been formed mainly by solifluction processes (Csm). The slopes of older remnants with greater relief are dominated by mass-wasting processes rang-

FIGURE 3 Geomorphic map of Franklin Bluffs area, Sag drainage system. Area is shown in Figure 2. Franklin Bluffs erosional remnant is shown by light-shaded pattern. Explanation: Fluvial Channels: (Fa) active (black), (Fi) inactive, (Fb) abandoned; Eolian/Cryogenic: (El) eolian levee, (Er) relict terrace, (Ep) lake/pond plain; Colluvial/Cryogenic: Solifluction Slopes: (Csl) low relief, (Csm) moderate relief. Thaw lakes and streams shown by dashed lines, pipeline haul road by solid straight line segments. Location of alluvial fans (Figure 4) shown by arrow.

ing from solifluction to debris flow that are fed by ground-ice melting and collapse, resulting in the development of thermocirques, debris lobes, and alluvial fans. Small alluvial fans are particularly well-displayed on the flanks of the Franklin Bluffs erosional remnant, where distal fan aprons are encroaching on the inactive fluvial plain of the Sag (Figure 4).

MARTIAN FLUVIAL TERRAIN

Introduction

The geomorphic processes operating in the Sagavanirktok River drainage system combine to produce a suite of morphologic features characteristic of those seen, or inferred, in Viking Orbiter images of Mars of areas containing smaller outflow channels and depositional basins. The Ladon Valles area of the Margaritifer Sinus Quadrangle (MC-19) (U.S. G.S. 1979) is a good example (Figure 5). The formation of these channels and basins predates the development of most of the major outflow channels and may have occurred at a time when the Martian climate was "wetter" (Carr 1980), and thus more akin

FIGURE 4 Small alluvial fans at the southwest corner of the Franklin Bluffs erosional remnant. The fans are growing by debris-flow deposition onto an inactive floodplain segment of the Sag River. Relief of the Bluffs is about 160 m, distance from fan apex to toe is about 300 m.

to present or Pleistocene conditions on the North Slope. The similarity of the two suites of morphologic features suggests that similar processes, in type and magnitude to Quaternary processes that have shaped the Eastern North Slope, may have operated in the Martian fluvial terrain.

Ladon Valles Drainage System

The Ladon Valles drainage system, centered on 24°S, 29.5°W, consists of (1) an array of small outflow channels separated by erosional remnants, (2) a late source area of chaotic terrain adjacent to and northeast of the crater Holden, and (3) a probable depositional basin to the northeast (Figure 5). The presumed depositional plain is inside an older, highly degraded, multiringed basin, the boundaries of which were mapped by Saunders (1979), discussed by Schultz and Glicken (1979) and named the Ladon Basin by Schultz et al. (1982).

The outflow channels and remnants, when viewed on stereo images (611A13, 32, 650A15, 16, 18) show several levels of channels and terraces (Figure 5), indicating a complex degradational history with presumed multiple flow events. The horizontal scale of features in Ladon Valles is comparable to channel and remnant features on LANDSAT imagery of the Sagavanirktok drainage system. The nature of the regolith on bedrock in the Ladon area is not known for certain, but because it is in the older cratered plains province of Mars (Saunders 1979), there could be a deep blanket of crater ejecta that, when combined with presumed permafrost and ground ice, is not unlike the semiconsolidated Tertiary rocks of the North Slope.

Water-release mechanisms are also unknown, but a past wetter climate, combined with the confined aquifer release mechanism of Carr (1979), could have resulted in multiple flows originating in the area northeast of Holden crater from water stored in presumed permafrost prior to the formation of chaotic terrain. This is a situation analogous to the release of water from the Brooks Range during deglaciations. The depositional basin to the north of the Ladon outflow channels functioned as a sedi-

FIGURE 5 Ladon Valles and adjacent area. Drainage flowed from late source area of chaotic terrain near crater Holden (H) to a depositional basin inside an ancient multiringed impact basin. Numbers indicate relative elevation and age of channel floors and terraces (1 is highest or oldest). (611A30, 650A18, 19).

ment sink much like the Sagavanirktok, Colville, and other delta plains and the Beaufort Sea have done on the North Slope.

Modification to Channels and Valleys

The Ladon Valles images are medium-scale resolu-

tion (190-220 m per pixel) and do not show fine details of secondary modification to valley walls such as mass-wasting and debris flow although chaotic terrain (Figure 5), on a scale consistent with the morainal disintegration topography (Figure 2) of the North Slope, can be mapped. Thus high-resolution images (30-50 m per pixel) of Martian channels

FIGURE 6 Debris fan in the northern channel of Kasei Vallis (27.2°N, 67°W) with source area on the canyon wall, and perhaps from the graben on the upper plateau. Note scale (665A24).

on a scale comparable to U-2 images on the Arctic Slope are used to illustrate valley modification.

Figure 6 shows an alluvial fan that appears to have formed by debris-flow processes in the northern channel of Kasei Vallis (27.2°N, 67°W). The fan extends about 5 km out onto the floor of the channel from a source on the valley wall.

The wall height of the Kasei channel is much greater than even those of the Brooks Range Valleys, but fan size is not inconsistent with the larger debris fans of the Sag drainage basin.

ACKNOWLEDGMENTS

The project was supported by the NASA Planetary Geology Program under grant NSG-7414. Access to study sites by Arco and Sohio oil companies and by the Alyeska Pipeline Service Company is gratefully acknowledged. This work has benefited greatly from discussions with members of the Mars Channel Working Group, particularly V. Baker, B. Lucchitta, H. Masursky, D. Nummedal, P. Patton and G. Pieri. L. Dunne assisted in the field; P. Ladd and J. Grant assisted in the laboratory; S. Ponte typed the manuscript.

PALEOTEMPERATURE ESTIMATES OF THE ALASKAN ARCTIC COASTAL PLAIN DURING THE LAST 125,000 YEARS

Julie K. Brigham and Gifford H. Miller

Institute of Arctic and Alpine Research and
Department of Geological Sciences
University of Colorado, Boulder, Colorado 80309, USA

Beach, nearshore, and shallow-marine deposits of the Gubik Formation in the western portion of the Alaskan Arctic Coastal Plain have been subdivided by stratigraphy, sedimentology, and amino acid geochronology into transgressive/regressive sequences representing six high stands of sea level of Pliocene and Pleistocene age. Combined with paleoclimatic proxy data and assumptions concerning permafrost conditions, amino acid results on mollusks from the last interglacial high sea stand, the Walakpa member (\approx 125 ka B.P.), provide a means of quantifying paleotemperatures in permafrost throughout Wisconsin time and places limits on the possible magnitude of temperature change throughout this period. The results indicate that glacial-age mean permafrost temperatures on the coastal plain averaged -18°C or lower and were more than 8°C colder than today. This implies that mean annual air temperatures probably averaged between -19°C and -24°C and arctic summers were probably cooler than at present. Areas such as Ellesmere Island, N.W.T., or the Dry Valleys of Antarctica may serve as partial modern analogs for the glacial climates of the North Slope.

INTRODUCTION

The Arctic Coastal Plain and adjacent continental shelves of northern Alaska (Figure 1) are mantled by a thin veneer of unconsolidated sediments known as the Gubik Formation (Black 1964). In addition to extensive fluvial, eolian and thaw lake constituent facies, beach, nearshore, and shallow-marine sediments that were deposited as a result of eustatic sea level changes during Pliocene and Pleistocene time compose a significant part of this complex stratigraphic sequence. This paper deals specifically with marine sediments of the last interglacial high sea stand (125 ka B.P.), now recognized as the Walakpa member of the Gubik Formation (Brigham 1983). From the extent of isoleucine epimerization in fossil *Mya truncata* and *Mya arenaria* in these sediments the data are used to constrain a series of possible paleotemperature models for the North Slope during the last 125,000 years that attempt to accommodate all of the presently known paleoclimatic proxy data.

METHODS

Amino acid geochronology is a technique that relates the extent of diagenetic changes of indigenous proteins in the carbonate matrix of fossil mollusks to variables of temperature (thermal history since deposition) and time (since death of the organism). Most amino acids may occur in one of two optically-active forms, or enantiomers, which are mirror images of each other. Those forms that rotate polarized light to

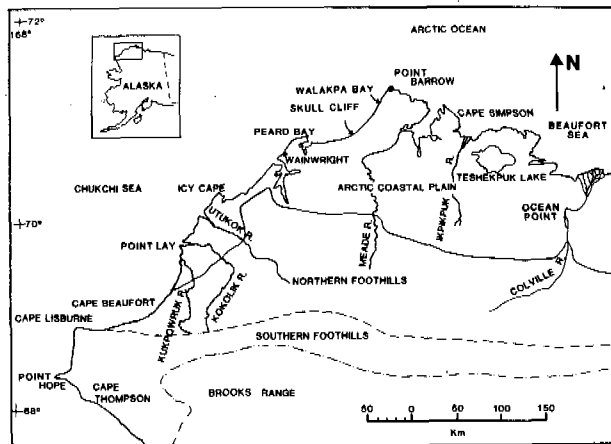

FIGURE 1 Arctic Coastal Plain of northern Alaska, showing the location of study area between Pt. Barrow and Cape Beaufort.

the right are D-amino acids (dextrorotatory) and to the left are L-amino acids (levorotatory). Constituent amino acids that comprise the protein within the carbonate matrix of living mollusks are exclusively of the L-stereoisomer configuration. After death of the organism the L-amino acids reversibly interconvert to the D-configuration until an equilibrium mixture is reached. Thus, fossil shells of increasing age contain a greater proportion of D-amino acids. In this study, the epimerization of L-isoleucine to D-alloisoleucine (hereafter alle/Ile) in the Total (Free plus peptide-bound) acid hydrolysate was measured in fossil mollusks to determine the relative are of

marine deposits exposed on the Arctic Coastal Plain, and to make Late Pleistocene paleotemperature estimates.

Temperature is the most critical rate-controlling factor governing protein diagenesis. In general, a 4°C temperature rise will approximately double the epimerization rate of L-isoleucine. However, for relatively young samples (e.g., 125 ka B.P.) at temperatures lower than about -10°C, the rate of epimerization is so slow that the change in the absolute value of the aIle/Ile ratio, created by fluctuations in temperature of a few degrees, is very small and often less than the resolving power of the technique. Hence, the method cannot detect temperature differences of $< \pm 2^\circ\text{C}$ in this time/temperature range.

Because rates of amino acid diagenesis vary between different genera, analyses were restricted to *Hiatella arctica* (Linné), *Mya arenaria* (Linné), and *Mya truncata* (Linné). When possible, at least three individuals of each genus were analyzed from each depositional facies in order to detect mixed populations of aIle/Ile ratios indicative of reworked fossils. Samples were prepared for analysis according to Miller (1982 p. 52). Analyses were completed using an ion-exchange liquid-chromatographic amino acid analyzer utilizing O-Phthalaldehyde fluorescence detection.

STRATIGRAPHY OF THE WALAKPA MEMBER

The absolute age and extent of amino acid diagenesis of fossil mollusks from the Walakpa member (Table 1) are of critical importance to the discussion of Late Quaternary paleotemperatures. This member, which represents one of the last transgressions on the western Coastal Plain, forms a prominent shoreline of gravel beach deposits up to 10-12 m a.s.l. that are continuously exposed above older transgressive marine units for almost 2.5 km on the southside of Walakpa Bay. Correlative gravel and sand facies on the north side of the bay grade northward into lagoonal sediments containing *Macoma balthica*. Near Barrow, the Walakpa member is composed of a barrier bar system that is exposed in the bluffs below the village and traceable in coastal bluffs for ~ 3 km southwest until it pinches out over the Karmuk member. Beach sediments of the Walakpa member also partition Wainwright Inlet from the Chukchi Sea. Due to the low thermal history of the region (current mean annual air temperature at Barrow, -12.8°C), isoleucine epimerization ratios in shells from the Walakpa member are only slightly above those in modern shells (modern sample = 0.011 ± .002). A radiocarbon analysis on drift wood from the Walakpa member near Walakpa Bay yielded an age of greater than 36,000 years B.P. (Beta-1766) and additional infinite dates on woody materials from this unit at Barrow have been reported by Sellman and Brown (1973, >39,900 years B.P., I-3628) and Coulter et al. (1960, >38,000 years B.P., W-380). A finite date on marine shells collected near Barrow (31,200 ± 810/900 years B.P., DIC-2569) is considered to be a minimum estimate. Correlative beach deposits of the barrier bar system extending from Barrow to

east of Teshekpuk Lake have been identified by Carter (Carter and Robinson 1981) and radiocarbon dated to >51,000 years B.P. (USGS-676). The Walakpa member is considered correlative with the Pelukian transgression of Hopking (1967) and to date from the last open-ocean δ¹⁸O minimum (5e) ~ 125,000 years B.P. (Shackleton and Opdyke 1973).

PALEOTEMPERATURE ESTIMATES

Equations which express the relationship between the extent of epimerization, absolute time, and diagenetic temperature are reviewed by Schroeder and Bada (1976) and may be expressed as:

$$\ln \left[\frac{1 + D/L}{1 - K' D/L} \right] = (1 + K') k_1 t + C \quad (1)$$

where D/L = aIle/Ile ratio of the sample; K' = inverse of the equilibrium constant (0.77); k₁ = forward rate constant of isoleucine epimerization; t = time since death of the organism; and C = analytical constant that represents the value of the left side of the equation at death of the organism and accounts for laboratory induced epimerization during preparation (C = 0.0195 in samples discussed here).

The relationship between k₁ and temperature is described by the Arrhenius equation

$$k_1 = Ae^{\left(\frac{-E_a}{RT}\right)} \quad (2)$$

where A = constant for each species; E_a = energy of activation; R = gas constant (1.987); and T = absolute temperature (°K). Radiocarbon dated control samples and pyrolysis data further define the relationship between the isoleucine epimerization rate constant (k₁) and temperature (T) for *Mya truncata* (Miller et al. 1983). The relationship between k₁ and T for *Mya truncata* is expressed as:

$$\log k_1 = 16.33 - 6131 / T \quad (3)$$

and the energy of activation is calculated to be 28.06 kcal mole⁻¹. By replacing equation (3) for k₁ in (1) and solving for T, the equation can be written with T, t, and D/L as the only variables.

$$T = \frac{6131}{16.33 - \log \left[\frac{\ln \left[\frac{1 + D/L}{1 - .77 D/L} \right] - 0.0195}{1.77t} \right]} \quad (4)$$

For a sample with a complex thermal history, T can be considered the effective diagenetic temperature (EDT) that is the temperature associated with an effective rate constant estimated by integration through a probable temperature history for a sample. Because of the exponential relationship between the rate constant (k_1) and temperature (T) this thermal integration is more sensitive to periods of high temperatures that accelerate the reactions more than the deceleration effected by an equivalent temperature decrease.

The effects of a variable thermal history on the EDT can be important on both an annual cycle and long-term climatic shifts. The arithmetic mean annual temperature of the ground will deviate from the effective diagenetic temperature in proportion to the amplitude of temperature about the mean. Although the mean annual air temperature at Barrow is currently -12.8°C , for example, integrating the monthly temperature cycle over the year calculates into an EDT of -3.6°C , reflecting the influence of warm summer temperatures. In permafrost, the value of the EDT is influenced by the amplitude of the annual temperature wave at a given depth and approximates the mean annual ground temperature at the depth of zero amplitude. Figure 2a shows the decrease in the EDT at discrete intervals calculated from the current mean monthly temperatures measured at depth in permafrost near Barrow (Lachenbruch et al. 1962). Near the ground surface, the EDT of the permafrost is quite high ($\approx -3.0^\circ\text{C}$ at -60 cm) reflecting the warm summer temperatures and large amplitude of the annual temperature wave. With depth, however, the amplitude of the annual temperature wave is increasingly attenuated to a point where the EDT in the permafrost (EDT -9.3°C at -18.5 m) is similar to the mean annual ground-surface temperature ($\approx -10.0^\circ\text{C}$).

We can evaluate the effect of the annual temperature wave and hence, the EDT, on the rates of isoleucine epimerization under the present climate and during colder glacial climates. The effect of the present climate (using the EDTs at depth in Figure 2a) on rates of epimerization is illustrated for a hypothetical case in Figure 2b in which the present climate is maintained for 100,000 years. Using equation (4) and solving for D/L in successively deeper samples, it can be shown that below a depth of approximately -3 m (dashed line in Figure 2b), the variation in the $aIle/Ile$ ratios created by changes in the EDT with depth is 11.5%; this is equivalent to the precision (expressed as coefficient of variation) attainable in isoleucine epimerization (compare with Table 1). For comparison, a series of Holocene samples subjected to the modern climate for 8,000 years would theoretically yield a depth related variation in $aIle/Ile$ ratios of only 2.5% (Figure 2b). From this exercise, we conclude that (1) over relatively short time intervals subtle changes at the EDT's below about -6°C effect only minor variations in the observed $aIle/Ile$ ratios, (2) consequently, paleotemperature estimates for

FIGURE 2 Effective diagenetic temperatures (EDT) and $aIle/Ile$ ratios in permafrost. (a) Calculated EDT versus depth in permafrost under the present climate. (b) Effects of the modern EDT profile on the $aIle/Ile$ ratio in samples 8.0 ka and 100 ka years B.P. The variation in ratios observed below -3 m (dashed line) is less than analytical variation in the amino acid method. For 100 ka, the mean $aIle/Ile$ below -3 m = $0.026 \pm .003$, c.v. = 11.5%; for 8 ka, the mean is $0.12 \pm .0003$, c.v. = 2.5%.

low-temperature sites are only precise to within -2° to -3°C , (3) that samples collected for amino acid studies in permafrost areas should come from a depth of at least 2.5 m to minimize the effect of the annual temperature wave, and most importantly (4) these data, in turn, allow us to conclude that the mean permafrost temperature at depth is a good first approximation for the long-term EDT experienced by buried shells during each climatic regime over the last 125,000 yrs. In this study, the EDT expressed in equation (4), represents the integration of the thermal history of the upper few tens of meters of permafrost over an entire time period (t), and places constraints on the magnitude of ground and air temperature changes that can have occurred.

PALEOTEMPERATURE RECONSTRUCTIONS

Paleoclimatic proxy data and geomorphic evidence demonstrate that Alaska has experienced a number of broad climatic oscillations during the last 125,000 years, including warm and moist interglacials similar to today, cold and dry glacials, and intermediate interstadial conditions (Hopkins et al. [1982] for reviews). Most of the paleoclimatic reconstructions for this time period are qualitative in approach due to the lack of a means to quantify directly temperature and precipitation parameters. Based upon amino acid paleothermometry, we present here a series of paleotemperature reconstructions for the Alaskan Arctic Coastal Plain during the last 125,000 years that attempt to accommodate all of available paleoclimatic proxy data from the region and to quantify and define limits for the magnitude of temperature change during this time period.

Paleotemperature estimates derived from equation (4) are most accurate when the absolute

age of a sample is known. Hence, the most important assumption in this reconstruction is that the Walakpa member is 125,000 years old; the rationale for its age outlined earlier. Younger age estimates can be tested by solving equation (4) for EDT's using younger assumed ages with the observed aIle/Ile ratios. Age estimates for the Walakpa member at 80 ka and 35 ka B.P. predict integrated diagenetic temperatures in the permafrost of -10.9°C and -6.8°C respectively, values similar to or significantly warmer than modern values. In light of paleoclimatic data that suggests the glacial periods in northern Alaska where colder and drier than modern interglacial conditions, we believe that such estimates are unrealistic and that an age of 125,000 is probably most reasonable for the Walakpa member.

AIle/Ile ratios in *Mya truncata* from last interglacial deposits (Walakpa member, $t = 125,000$ years B.P.) require an effective diagenetic temperature for the entire time period of $\sim -13.8^\circ\text{C}$. Using the paleoclimatic record as a guide for interglacial periods of "known" temperature, models can be developed that derive appropriate EDT's for periods lacking proxy data, especially full-glacial episodes. The models employ a computer program that allocates rate constants for intervals of specified climate, thus integrating an effective diagenetic temperature over each interval, and converts the computed rate constant back into a temperature (from equation 3) for an interval of unknown climate. The equation used for these reconstructions is modified from Miller et al. (1983) and written as:

$$k_x = \frac{\sum_{i=1}^n k_a t_a - (k_1 t_1 + k_2 t_2 + \dots + k_n t_n)}{t_2 - (t_1 + t_2 + \dots + t_n)} \quad (5)$$

(see Figure 3)

where, k_x = rate constant for a specific time interval of unknown temperature; k_a = rate constant for the entire assumed 125,000 year period; $k_1, k_2 \dots k_n$ = rate constant for intervals of known temperature; t_a = length of entire time period = assumed 125,000 years; $t_1, t_2 \dots t_n$ = length of each climatic interval. The effective diagenetic temperature for the unknown interval is calculated using the calculated k_x in place of k_1 in equation 3.

Paleoecological data from numerous Alaskan sources across Beringia suggest that (1) the last interglacial was slightly warmer than today, (2) an early Wisconsin glacial episode (Happy) occurred prior to 65 ka ago, (3) during the mid-Wisconsin (Boutellier Interval, about 65-30 ka B.P.) climate was intermediate between colder, drier glacial and warmer, more mesic interglacial conditions, (4) the late Wisconsin glacial stade (Duvanny Yar) occurred between 30 and 14 ka ago, and (5) during the late Pleistocene/early Holocene (Birch Interval, 14-8.5 ka years B.P.) summer temperatures, were somewhat warmer than the remainder of the Holocene (Hopkins 1982).

To model these climatic intervals, assumptions are necessary concerning the conditions in permafrost, as they may have effected propagation in the annual temperature wave. The most

FIGURE 3 Schematic diagram illustrating the parameters used in equation 5 for evaluating past temperature histories. The EDT for the unknown interval x is predicted using k_x in place of k_1 in equation 3. See text for the definition of terms shown here. Any number of known and unknown intervals can be included, but the calculated unknown DTS's will be the average of all the unknown time intervals.

important factors influencing the effective diagenetic temperatures in permafrost are (1) the thermal conductivity of the sediment (which has probably been continuously frozen since the mid-Pleistocene), (2) the depth and insulating value of snow cover, and (3) the amplitude of the annual surface temperature wave. The lack of winter snow cover during dry periods probably allowed greater winter ground cooling. Given the more continental situation of the coastal plain, summer temperatures might be thought to have been warmer, but this may not be true. Sparse vegetation and the high albedo of eolian sand would have inhibited the penetration of summer radiation. The dry soils however, may have had a lower heat capacity and warmed more quickly at given temperatures. It is clear that thaw lakes did not develop during the Duvanny Yar glacial period (30 ka to 14 ka B.P.). Because summer temperatures probably did rise above 0°C in the summer months, the lack of these features must indicate that the upper few meters of permafrost were severely desiccated.

Paleoclimatic models representing mean permafrost temperatures at depth (or EDT's) for known intervals and calculated for glacial intervals are depicted graphically in Figure 4. In each case, equation (5) is used to predict the temperature of the unknown (dashed) interval. In all cases, the temperatures assigned to the intervals are constrained by the fact that an integration of all intervals must yield an average EDT of -13.8°C for the last 125 ka, as calculated earlier.

FIGURE 4 Schematic diagram illustrating five possible temperature models calculated from equation 5. Solid lines represent intervals of "known" climate, while dashed lines represent temperatures calculated for intervals of "unknown" climate. All temperatures indicated represent EDT°C at depth in permafrost.

Case 1 is a simple model which partitions the last 125 ka years into only 6 broad climatic intervals. The modern permafrost temperature of -10°C is used to represent the last 8.5 ka years while a temperature of -9°C was chosen for the birch zone (8.5-14ka years) representing a slight warming of climate, accompanied by inferred thicker, more insulating snowcover. The Boutellier interval (30-65 ka years B.P.) is depicted as a period of intermediate climate, and assigned a temperature lower than at present yet above full glacial conditions. Finally, the last interglacial episode is assigned a above full glacial conditions. Finally, the last interglacial episode is assigned a temperature slightly warmer than today as indicated by the extralimital distribution of fossil marine mollusks in deposits of this age across the northern coast. The calculation for case 1 suggests that glacial-age permafrost temperatures

(for the Duvanny Yar and Happy (intervals) averaged roughly -18°C , or 8°C colder than today. Because the difference between mean annual ground temperature and mean annual air temperature can differ by as much as $1-6^{\circ}\text{C}$, depending on snow-cover (Gold and Lachenbruch 1973), this permafrost temperature suggests past mean annual air temperatures between -19 and -24°C . Because winter snowcover is interpreted to have been thin during the glacial times, the predicted permafrost temperature and mean annual air temperatures were probably similar.

Interpretations of global paleoclimates suggest that the period between 80 and 120 ka years B.P. was marked by oscillating, though not extreme, climatic conditions (Shackleton and Opdyke 1973); hence case 1 is probably oversimplified. In case 2, we have attempted to accommodate these fluctuations in climate with a more complex model by assigning intermediate warm and cold values for the oscillations of $\delta^{18}\text{O}$ stages 5a-d. This model effectively provides additional warmth to equation 5 and results in a predicted glacial permafrost temperature (for the Duvanny Yar and Happy glacial intervals) of -21°C . This value is colder than in case 1, and approaches some of the coldest values measured recently in permafrost from the Dry Valleys of Antarctica where the current mean annual air temperature ranges between -18°C and -25°C (Decker and Bucher 1982). The sensitivity of equation 5 to slight increases in temperature is illustrated in case 3, which is identical to case 2 except the EDT for the last interglacial interval (lasting 5,000 years) is increased by 1°C . This case results in a predicted temperature decrease during the Happy and Duvanny Yar periods (duration totaling 31 ka years) of almost 3°C , reducing permafrost temperatures to -23.8°C . An attempt to model $\delta^{18}\text{O}$ stages 5a and 5c with modern temperature values, generated more warmth than could be compensated by any temperature depression during glacial periods.

In case 4, we have attempted to predict an average integrated temperature for the entire time period of $\delta^{18}\text{O}$ stages 5a-d (80 ka-120 ka B.P.) assuming glacial permafrost temperatures similar to modern values measured at Alert, N.W.T. (-16.1°C at -15 to -18 m. This reconstruction predicts an average temperature of -14.6°C for this period, or almost as cold as glacial temperatures in that model. Finally, in Case 5 we've used the temperature predicted for $\delta^{18}\text{O}$ 5a-d in case 4, and assigned glacial temperatures of -18°C , lower than case 4, to predict temperatures for the Boutellier interval of -15°C . This case also illustrates the sensitivity of the equations and associated rate constants.

CONCLUSIONS

The temperature reconstructions outlined above are intended, as models, to be refined and tuned as additional paleoclimatic proxy data and information concerning permafrost temperatures under variable climates become available. The most important concept that arises from this exercise is that the climate of the North Slope

during the glacial episodes was at least 8°C colder than today. Very little warmth can be introduced into the calculations and still accommodate the available data. Any additional warmth (for example, a warmer birch zone) imposed on the illustrated models must be compensated by more intense or more numerous cold periods. Conditions during the latter portion of $\delta^{18}\text{O}$ stage 5(a-d) were definitely cooler than at present. Finally, we believe that models for glacial temperatures for the Duvanny Yar and Happy intervals lower than -25° to -28°C become unreasonable.

From these models we conclude that glacial permafrost temperatures on the North Slope probably averaged lower than about -18°C implying glacial mean annual air temperatures in the range of -19° to -24°C. Moreover, it is doubtful that summer temperatures were as warm as today.

The conditions depicted here for the Wisconsin glacial periods are reminiscent of the harsh polar desert climates of northern Ellesmere Island, N.W.T., northeast Greenland, or the Dry Valleys of Antarctica. Possibly these areas could serve as useful modern analogs for reconstructing the glacial age environment of the Alaskan Arctic Coastal Plain.

ACKNOWLEDGEMENTS

The research in this paper represents a portion of J. K. Brigham's dissertation completed at the University of Colorado, and was supported by the U. S. Geological Survey, the Outer Continental Shelf Environmental Assessment Program (BLM/NOAA) and an NSF Doctoral Dissertation grant DPP-81-02967 to Miller and Brigham. Additional support was provided by the Arctic Institute of North America, Geological Society of America, the Explorers' Club and Sigma Xi. Amino acid analyses were performed at the Amino Acid Geochronology Laboratory, INSTAAR, University of Colorado. Samples were prepared by J. Rohde and the manuscript typed by F. Al-Rahim and R. Chavez. We'd like to thank D. M. Hopkins, J. R. Williams, and L. D. Carter, U. S. Geological Survey, and Peter Lea, INSTAAR, for their thorough reviews and useful comments on early drafts of the manuscript.

HYDROLOGY OF THE NAHANNI, A HIGHLY KARSTED CARBONATE TERRAIN WITH DISCONTINUOUS PERMAFROST

George A. Brook

Department of Geography, University of Georgia, Athens, Georgia 30602 USA

Groundwater recharge rates are usually low where permafrost is present. However, in carbonate regions where a karst drainage system predates permafrost development, groundwater recharge and circulation may be vigorous. This is the case in the Nahanni north karst of northwestern Canada. Not only is the volume of groundwater flow in this permafrost region considerable-- $102 \times 10^6 \text{ m}^3$ of water flows annually to each of two springs which drain the area--but hydrologic activity is spectacular. Between July 19 and 31, 1972, an extreme summer storm deposited 224 mm of rain on the area. First, Second, and Third poljes flooded; maximum water depths were 8.5, 25, and 8 m, respectively; and Third Polje overflowed. The level of Raven Lake (0.25-0.50 km long) rose 49 m at an average 2.9 m/day. Field observations and evidence from LANDSAT images have provided a hydrologic record for the karst for the years 1972-1978. These data indicate that immediately prior to spring snowmelt depressions are dry, and that when snow and ice melts in May, several depressions may flood temporarily because their drainage routes are blocked by ice. The major surface and groundwater activity in Nahanni is not induced by snowmelt but results from unusually high rainfall in the months of June-August.

INTRODUCTION

The presence of permafrost usually retards infiltration into and percolation through soil to recharge groundwater flow systems because the hydraulic conductivity of soil is often several orders of magnitude lower when frozen. Therefore, under permafrost conditions, infiltration through joints in exposed bedrock accounts for a major proportion of groundwater recharge.

Large areas of northern Canada are underlain by limestones and dolomites in areas of both continuous and discontinuous permafrost. Bird (1966), for example, reports that limestone is the most common sedimentary rock in arctic Canada south of Parry Channel, where it covers about 300,000 km², or more than 12% of the land surface. Because limestones are soluble, any water penetrating joints will rapidly increase the secondary permeability of the rock, encouraging development of a subsurface drainage system. However, it appears that in some karst regions an efficient karst drainage system may have developed before the onset of the present conditions of permafrozen ground. In these areas, groundwater recharge and circulation is more vigorous than in other high-latitude regions of carbonate bedrock (Brook and Ford 1980, van Everdingen 1981). This is the case in the Nahanni karst of northern Canada, discovered in August 1971 (Figure 1).

THE NAHANNI KARST

In the Nahanni karst the predominant landforms are vertical-walled solution dolines, and remarkable networks of solution streets, plateaus, residual limestone towers, and poljes that are successive stages in the evolution of labyrinth karst (Brook and Ford 1978). The most spectacular

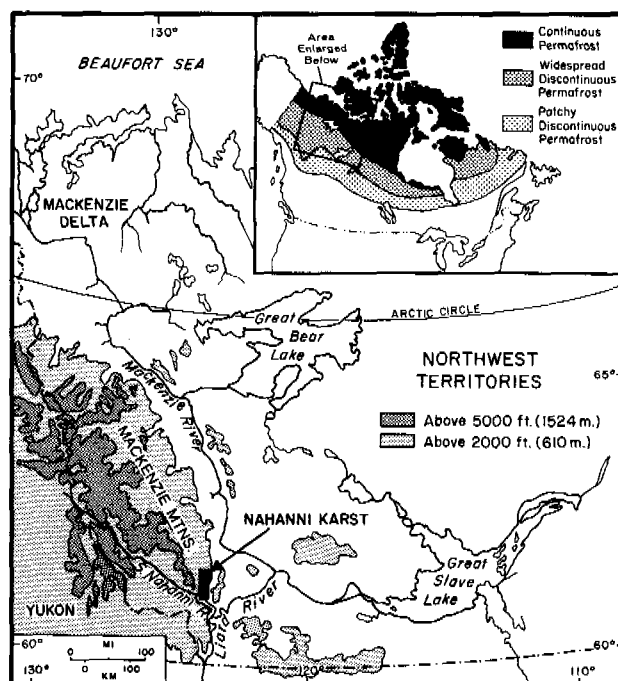

Figure 1 Topography and permafrost in the District of Mackenzie, N.W.T., Canada, and the location of the Nahanni karst. Permafrost boundaries are after Brown (1978).

labyrinths are located on a narrow structural col (the "north karst"), which connects the upwarded domes of Nahanni and Ram plateaus (Figure 2). With depths exceeding 200 m these are among the

most accentuated solutional labyrinths known. In addition, a number of closed fluvial canyon networks up to 1,000 m deep dissect the eastern flank of the south Nahanni Plateau and the southwest flank of the Ram Plateau. All of these canyon systems are blocked by glacial deposits, and today their drainage is through underground caves in limestone and/or dolomite.

Figure 2 The closed depressions and springs of the Nahanni north karst.

Karst in Nahanni is found at elevations of 840-1,400 m a.s.l.; the entire region falls within the zone of discontinuous permafrost. Calculated mean annual temperature is -4.5°C ; precipitation, 566 mm/yr. Vegetation below 1,200 m is northern boreal forest with tundra at higher elevations. Solutional landforms are developed in limestones of the Middle Devonian Nahanni Formation and in argillaceous limestones and calcareous shales of the underlying Headless Formation. Together these are 150-200 m thick. Beneath them are fine-grained dolomites up to 815 m thick, which transmit groundwater. Shales of the Fort Simpson Formation overlie Nahanni limestones in some areas and support surface streams at spring snowmelt or after rainfall. In many cases, water collecting on shales drains on to limestones, where it sinks underground.

Using the Turc (1954) equation, effective precipitation in Nahanni is estimated at 394 mm; evapotranspiration, 172 mm. Effective precipitation migrates underground as both diffuse and conduit recharge. Only two major springs appear to discharge water from the karst terrain. White

Spray in the north wall of First Canyon, South Nahanni River, emerges from dolomites, and Bubbling Spring, 30 km to the north, emerges close to the top of the Nahanni Formation limestones (Figure 3). The catchments of Bubbling Spring and White Spray have been delimited on the basis of dye traces, and on geological and topographical evidence. Each is about 260 km². The northern boundary of Canal Creek drainage is the approximate divide between the two recharge areas. Canal Canyon cuts through the crest of the Nahanni Plateau structural dome. To the north and south, groundwaters are believed to follow the stratal dip (Figure 3). Runoff into Canal Canyon, the mouth of which is blocked by a glacial end moraine, sinks at the base of the south wall. Water drains into dolomites at 823 m elevation and is thought to remain in cave systems until it reaches White Spray at 274 m a.s.l.

Figure 3 Topographic and geologic section through the Nahanni karst from Bubbling Spring to White Spray.

With 394 mm effective precipitation, approximately $102 \times 10^6 \text{ m}^3$ of water must drain to each spring annually at an average discharge of $3.2 \text{ m}^3/\text{s}$. Because both springs were discharging $>5.0 \text{ m}^3/\text{s}$ in summer 1973, discharge must vary seasonally. Assuming that flow averages $5.0 \text{ m}^3/\text{s}$ during the 6 months from April to September, mean discharge during the rest of the year must be $1.5 \text{ m}^3/\text{s}$. White Spray is known to flow in winter, and its discharge has been estimated at $1.0 \text{ m}^3/\text{s}$, confirming that when there is no recharge to the aquifer, discharge is much less than during the spring and summer months.

EVIDENCE OF PERMAFROST

The Nahanni karst falls close to the boundary between widespread and patchy discontinuous permafrost (Figure 1). There are various indications of permafrost conditions in the Nahanni. For example, short, relict cave conduits exposed in fluvial canyons and in street walls are often sealed by ice or permafrozen silt at, or close to, the limit of sunlight penetration. In addition, many of the large relict caves display a distinct

climatic zonation in the summer months, which gives some indication of temperature variations with depth in the carbonate bedrock. The entrance zone of Grotte Valerie, high in the north wall of First Canyon, South Nahanni River, is characterized by temperatures of 0°-2°C. Water can penetrate the rock above the cave, and small speleothems are being deposited. Further from the entrance is a second zone where rock temperatures are close to 0°C. This zone is characterized by a layer of warmer air near the ceiling, which overlies colder air at the floor. The boundary between the warm and cold air advances into the cave as the summer progresses. The warm air near the ceiling allows water to penetrate the overlying rock, but once it reaches the layer of cold air it freezes, forming ice sheets and ice stalagmites on the cave floor. The third climatic zone is found deeper in the cave where passages descend below the level of the cave entrance and temperatures are thought to remain constant all year. Air temperatures in this zone are -3°C. Passages are dry and dusty because no water can penetrate the roof of the cave (Ford and Brook 1976). Igloo and Ice Curtain caves in the walls of Death Canyon display a basically similar climatic zonation to Grotte Valerie. The coldest temperatures in Ice Curtain Cave were -1.5°C, and in Igloo Cave -4.0°C when measurements were made in July 1973.

The numerous vertical-walled dolines in Nahanni, some of which contain ponds up to 17 m deep, also suggest permafrozen conditions at depth. Ponds in these depressions do not reflect the upper level of a body of groundwater, for pond levels between closely spaced individuals may differ by as much as 33 m. The ponds are thought to be perched above subsurface ice bodies blocking the doline drainage routes. In late June, 1973 Surprise and Hidden dolines (later found to be connected by a short cave) on Cenote Col (Figure 2) contained ponds 17-20 m deep. In early August these dolines emptied abruptly presumably because the ice seal had melted. Perched Basin, another doline on Cenote Col, drained in mid-July 1972 after 3.5 cm of rain had caused melting of the subsurface ice barrier.

HYDROLOGY OF THE NORTH KARST FROM FIELD AND REMOTELY SENSED DATA

Not only is the volume of groundwater flow in the Nahanni Karst region considerable, amounting to 70% of the annual precipitation, but hydrologic activity is spectacular. This is particularly so in the north karst, which extends for 7 km south of Bubbling Spring. The area includes First, Second, and Third poljes, Ravirst Uvala, Raven Canyon, and North Col Canyon (Figure 2). These depressions are 1.4, 0.7, 1.4, 0.3, 0.5, and 1.0 km long, respectively. Between July 19 and 31, 1972, an extreme summer storm deposited 224 mm of rain on the area. First, Second, and Third poljes flooded; maximum water depths were 8.5, 25, and 8 m, respectively; and Third Polje overflowed. The level of Raven Lake (which varies from 0.25 to 0.50 km long), occupying the floor of Raven Canyon, a deep karst street, rose 49 m at an average 2.9 m/day (Figure 4).

Figure 4 Heavily flooded north karst depressions revealed on an August 22, 1972, LANDSAT image. All three poljes, Ravirst Uvala, Raven Canyon, and North Col Canyon were flooded on this date. Third Polje was overflowing, and there was considerable outflow from Bubbling Spring. See Figure 2 for comparison.

Field data on the hydrology of the Nahanni north karst collected in the summers of 1971-1974 were supplemented using data in LANDSAT 1972-1978 multispectral scanner (MSS) and return-beam Vidicon (RBV) images of the region. Near-infrared band-6 (700-800 nm) and band-7 (800-1,100 nm) images were used to monitor the presence or absence of floodwaters in north karst depressions. The low spectral reflectance of water to infrared radiation makes water bodies easy to identify, as these appear black (Figure 4).

Field observations and evidence from LANDSAT images have provided a reasonably detailed hydrologic record for the north karst for the years 1972-1978 (Table 1). These data indicate that immediately prior to spring snowmelt (surface water bodies become free of ice in May), karst depressions are dry. On April 23, 1977, for example, Raven Lake (70 m deep in July 1972) was a frozen pond 8 m in length. This suggests that surface flow into depressions is arrested as the winter freeze sets in (surface water bodies freeze over in October) and that any water remaining in depressions in October drains underground before the following spring.

LANDSAT images have also revealed that when snow and ice melts in May, several depressions, including First and Third poljes and Raven Canyon,

may flood because their drainage routes are blocked by ice. A May 27, 1975, image shows that lakes in the north karst were already free of ice by this

* ponds are present at the eastern end of Third Polje and in Brachiopod Basin, First Polje, even under very dry conditions

date and that ponds 250, 100, and 100 m long existed at the eastern end of Third Polje, in Ravirist Uvala, and in Raven Canyon, respectively. A May 12, 1976, image shows that many lakes were still frozen over and much of the north karst was mantled by snow at this time, ponds 500 m long, 150 x 300 m, and 150 m long were present at the eastern end of Third Polje, at the southern end of First Polje, and in Raven Canyon, respectively.

In the 7 years from 1972 to 1978, First Polje

is known to have flooded in the period June to September once in every 2-3 years, and Second and Third poljes flooded every year. It is apparent that in most years, north karst depressions are first inundated in June or July and less frequently in August. Flood waters in First Polje drain rapidly, so this depression is rarely flooded in the month of September. Second and Third poljes drain more slowly; once flooded, they almost always remain flooded through August and into September.

In many arctic and subarctic terrains, spring snowmelt is the major hydrologic event of the year. This is the case, for instance, in a karst area to the northwest of Smith Arm, Great Bear Lake, Canada. The northern part of this area lies within the zone of continuous permafrost. van Everdingen (1981) reports that in a given year the maximum flood level in a large depression in this karst is mainly a function of the amount of snow remaining on the ground at the start of snowmelt, and of the rate at which melting proceeds. The duration of flooding is a function of the maximum level reached during snowmelt and the amount and distribution of rainfall during the summer months.

Hydrologic data for the Nahanni indicate that the major surface and groundwater activity is not induced by snowmelt but results from heavy rainfall in the months June-August (Table 1). Unusually high monthly rainfall caused flooding in June 1973, August 1949, and August 1974, when rainfall at Fort Simpson was 307%, 171%, and 232% of normal, respectively; in May 1977, when rainfall at Little Doctor Lake was 245% of normal; in July 1972, when 267 mm of rainfall was measured in the Nahanni karst; and in August 1975 when rainfall at Fort Simpson and Little Doctor Lake was 190% and 168% of normal, respectively. In years with no unusually high monthly precipitation, depressions appear to remain dry or suffer minor flooding.

Flooding of the depressions in the Nahanni karst is believed to occur because of random perching of water above and below ground where drainage conduits are heavily alluviated or where flow is obstructed by subsurface ice bodies.

DISCUSSION

The flow of surface water into ponors in karst depressions in the Nahanni karst is clearly an effective means of recharging groundwater in an area of discontinuous permafrost. However, the recharge system may not have developed under the environmental conditions that exist in this region today.

Fossil caves in Nahanni contain speleothem deposits that have been uranium-series dated to >350,000 years B.P. (Harmon et al. 1977). These caves must, therefore, have been largely abandoned by the drainage water that produced them as much as 400,000 years ago. Furthermore, many speleothem deposits are located in dry cave passages where present temperatures are below freezing. For the speleothems to have been deposited, mean annual temperatures in Nahanni must have been much higher than today. The cave evidence indicates that there were at least four periods during which speleothem growth was enhanced by climatic conditions. These periods at 90-150, 185-235, 275-320, and >350 ka

were almost certainly interglacial phases (Brook 1976; Harmon et al. 1977). It is extremely likely that the present karst drainage system of Nahanni was developed during one or more of these warm phases.

According to Lachenbruch (1968), heat flow from the earth's interior normally results in a temperature increase of approximately 1°C per 30-60 m increase in depth. The mean annual temperature in Nahanni is -4.5°C, suggesting that the base of permafrost could lie between 270 and 135 m--the lower of the two figures being the most likely, based on cave temperature evidence. This suggests that the karst conduits which funnel water to Bubbling Spring and White Spray are largely located within the subpermafrost zone where rock temperatures may be one or more degrees above freezing.

A second important process which helps to keep the karst groundwater system operative is the warming of the surface rocks by recharge waters. In summer 1973 the temperatures of water at White Spray and Bubbling Spring were 4.8° and 4.6°C, respectively. These groundwater temperatures are believed to reflect a mixing in the karst aquifer of snowmelt waters (at, or close to, 0°C), with water derived from summer rainfall. The average temperature of surface waters in the Nahanni in the summers of 1972 and 1973 was 9.5°C. As snowfall accounts for 40% of annual precipitation, groundwater temperatures somewhat below 6°C might be expected. Temperatures of 4.5°C indicate that groundwaters lose heat to the bedrock, thus helping to keep the karst drainage system open.

Several hundred mounds occur on the lower slope of Sukakpak Mountain. The mean mound height is approximately 1 m and most are elliptical or circular in plan. Clear, massive ice can be found within, below, and adjacent to some mounds. Within and adjacent to one mound, free water under low pressure was observed in late winter. Frozen sediments were found below the water lens. Trees with smooth trunk curvature on top of the mounds suggest long period of stability. Most mounds are found in active drainage channels that develop thick surface icings each winter. As a tentative hypothesis, we suggest that the mounds form by closed-system freezing at sites with higher moisture contents than their surroundings. The causes and frequency of occurrence and annual magnitude of this upheaving are under investigation.

Palsas and ice-cored mounds have been observed in many permafrost regions of the world (Washburn 1983). Only a few have been reported in Alaska, such as those described by Péwé (1975) in the McLaren River valley and by Nelson and Outcalt (1982) on the eastern Arctic Slope, but the dearth of reported Alaskan occurrences of palsas may only reflect a lack of opportunities to make appropriate ground observations. Most palsas reported in the international literature are in regions with terrain and environmental conditions comparable to central Alaska, including discontinuous permafrost, abundance of wet terrain in bogs and on slopes, and slightly negative mean annual air temperatures.

Mackay (1978) suggested that palsas may be distinguished from pingos with the term palsa applying to mounds in which the top of the ice core lies at the base of the active layer. Most published reports suggest that segregation ice, often observed as thin lenticular ice inclusions, is responsible for palsa formation (for example, Ahman 1977, Friedman et al. 1971). Palsas have also been reported that have massive ice (> 50 cm) in their centers (Brown 1973, Sollid and Sorbel 1974). Van Everdingen (1982) reported on seasonal frost blisters, which form when outlets of springs are blocked by freezing of the active layer and formation of surface icings. Progressive freezing of injected water in the active layer causes the overlying surface ice and frozen soil to dome. These mounds usually collapse in summer as the surface icings melt and the ground thaws. The Sukakpak mounds have some of the characteristics of both palsas and frost blisters.

SETTING

The study site is at approximately mile 205 on the Dalton Highway (67°37'N, 149°42'W), some 300 km

north of Fairbanks (Figure 1). The mounds occur on the mid- and lower west-facing slopes of Sukakpak Mountain at a mean elevation of 400 m; they were noted earlier by Hamilton (1979) and Brown and Berg (1980). The trans-Alaska pipeline and the Middle Fork Koyukuk River form the western boundary of the site (Figure 2b). The site lies within the northernmost zone of discontinuous permafrost (Kreig and Reger 1982). Open-system pingos are found in the south central Brooks Range (Hamilton and Obi 1982).

Sukakpak Mountain is composed of marble and dolomite overlying graphitic and calcareous quartz schist and intruded metabasite dikes (Dillon 1982). Coarse rubble forms large talus aprons at the break in slope between the exposed bedrock and the more gentle lower colluvial slopes (2° to 6°). The lower slopes are composed of water-saturated, medium to coarse gravel and calcareous sand and silt. Boreholes indicate that the depth to bedrock ranges between 5 and 15 m near the road.

The mean annual air temperature is estimated to be -7°C, with a total of 1275 thawing degree-days (C) and 3800 freezing degree-days (C). Annual precipitation averages 400 mm (Haugen 1982 and unpublished data). Ground temperature near the road is approximately -0.5°C at a depth of 12 m (Brown and Berg 1980, and authors' unpublished data). The active layer can exceed 3 m; thaw zones 3 to 5 m thick are found beneath the frozen active layer.

Although the mounds occur throughout much of the site, a large number are confined to surface drainage lines or channels in two areas above the road (Figure 2b, A and B) and below the road (C). These wetter areas generally lack the black spruce (*Picea mariana*) tree cover of the surrounding areas, and are instead composed of calcareous fens that support a rich flora distinct from those on the mounds and the adjacent spruce-covered upper slopes. Spruce of widely varying ages and sizes are found on most mounds, although some have only a cover of medium-height birch and willow shrubs.

The spruce growing on the mounds display degrees of tilting and bending at various heights along their trunks. On some, the J-shaped curvature begins at the base of the trunk (Figure 2e), while others are curved at the top. Presumably these differences reflect different periods of upheaval and readjustment of growth. The larger trees may be more than 100 years old, which implies considerable stability for the mounds. Some mounds, particularly near the road on the upslope side, have ruptured and are in various stages of collapse (Figure 2f). Such ruptures are probably due to renewed growth induced by the wetter conditions associated with impeded drainage near the road.

MORPHOLOGY AND STRATIGRAPHY

Based on a sample of 102 mounds, heights of the mounds range from 0.35 m to 2.3 m, with a mean of 0.95 m and a standard deviation of 0.4 m (Figure 3). Axial (width/length) ratios indicate that most of the mounds approximate the classic elliptical to circular domed shape (Figure 3). Widths range from 1.8 to 15.1 m, and lengths from 2.6 to 40.2 m. Median width and length are 4.6 and 7.4 m, respectively. Elongated mounds are typically found oriented parallel to the slope in the drainage

FIGURE 3 Frequency distributions of heights (upper) and ratio of axial lengths (lower) of 102 measured mounds.

FIGURE 4 Stratigraphy of three mounds and adjacent areas based on April 1982 augering and coring.

channels on the upper slope and oriented perpendicular to the slope below the road.

In April 1982, three mounds and adjacent areas were augered and cored. Two of the mounds, situated about 30 m from the road, were approximately 1 m high. The third mound, about 60 m upslope from the road, was 2.5 m high and represented one of the largest mounds found on this site. All three mounds were surrounded by 30 cm of surface icing beneath the snow pack. Figure 4 shows the idealized stratigraphy of these mounds.

One of the two smaller mounds (M-1), had a 50-cm thick ice core underlain by 50 cm of water under pressure. Water rose to within 50 cm of the surface in the hole. A hole cored adjacent to this mound through 30 cm of surface icing encountered artesian water, which rose 15 cm above the ice-covered ground surface. Massive ground ice was encountered above the subsurface water layer. Although some thawed sediments were encountered beneath the water, the deeper underlying sediments were frozen. A second hole 6 m upslope revealed 1.5 m of frozen peat, sand, and gravel over 20 cm of buried clear ice that contained vertically oriented, clean plant roots. There was no water or thawed zone.

A second mound (M-2) contained 20 cm of clear ice at a depth close to the surrounding ground surface. Drilling adjacent to this mound indicated no buried ice or thawed ground. The third mound (M-3) was completely frozen and was composed of relatively dry organic material, sand, silt, and fine calcareous gravel. Massive ice, more than 2 m thick, was encountered below ground level in the mound. This ice changed in character downward from dense to bubbly and porous ice near the bottom of the hole. The lower limit of the ice was not determined. The surface of this mound consisted of large irregular blocks of broken sod and soil and appeared to have undergone forceful growth or subsequent degradation. A hole adjacent to the mound yielded a thawed slurry of fine black sand that extended to a depth of at least 3 m. There was 1.6 m of frozen ground over this thawed zone.

Several additional mounds were sampled in October and the grain size was determined (Table 1).

SLOPE HYDROLOGY

During late spring, summer, and early fall, surface water flows down the slopes along fen-covered drainage lines or channels. Some ponded areas also exist well up to the base of the mountain. These waters are presumably derived from

surface runoff provided by melting snow and ground-water emerging from the porous talus slopes and fractured bedrock. Sloan et al. (1976) reported that icings occurred at the base of Sukakpak Mountain before the road was built.

During early fall a thin snow cover develops, but water continues to flow in all drainage channels even as air temperatures drop to -10 and even -20°C. As the active layer refreezes, water was observed seeping from the base of some mounds. Low negative temperatures, overflows, and freezing are observed mainly in the evening. The drainage channels become progressively covered with surface icings; this process continues into the winter and spring. Water was also observed flowing beneath the road in October, apparently between the gravel subbase and the buried peat layer. The area surrounding the mounds in locality C was also covered by a shallow icing. The culverts, which are steamed open in the spring, had already frozen closed in mid-October.

By early spring, icings exceeding 30 cm surround most mounds under a snow cover of 70 cm or more. At that time, free water observed at the base of the snow pack was apparently still flowing from unfrozen zones or from contraction cracks, which criss-cross the slope.

The specific conductance of the surface water during October ranged from 970 to 1400 microsiemens. Melted ice from the newly formed icings ranged from 150 to 460 microsiemens. Water obtained from under the ice layer in M-1 (Figure 4) in April 1982 had a value of 870 microsiemens. The cation composition of that sample in mg/L was Ca = 174, Mg = 72, and Na = 2.7. The overlying ground ice, as expected, is very pure with values of Ca = 0.0022, Mg = 0.0022, and a relatively high value of Na = 0.0078 mg/L. Krothe (1981) analyzed spring water from a location just north of Snowden Creek in the Dietrich River valley. The chemical composition was very similar to M-1 with a conductance of 1399 microsiemens (Ca = 198, Mg = 88, Na = 3; sample S70). This similarity in cation concentrations suggests that the water feeding the mounds may be of deep origin.

DISCUSSION

Most hypotheses on the formation of palsas and ice-cored mounds are quite vague. An explanation representative of much of the earlier literature was given by Brown (1968), who suggested that palsas form where shallow (< 1 m) pools of water freeze to the bottom and underlying water-saturated peat is domed up at "random" locations by "intensive frost action and ice lens growth." Most published reports suggest that ice segregation is responsible for palsa formation, possibly because many palsas display numerous, thin lenticular ice inclusions that may be interpreted as annual growth increments.

A recent experiment performed by Seppälä (1982) in Finland clearly showed the importance of thin snow cover for palsa initiation. After keeping a 5-m² area free of snow over a winter, a frozen layer persisted throughout the following summer. After two years, a 0.35-m high palsa had grown, which Seppälä attributed to increased frost penetration depth and segregation-ice formation. From Seppälä's description, it seems likely that soil water is

drawn from unfrozen soil toward the freezing region, adding an annual increment of segregation ice to the base of the newly formed permafrost. This palsa clearly gained height in annual increments, supporting the intuitive remarks of many earlier investigators. This type of palsa may be the most common in classic peat-bog palsa sites.

Palsas or mounds with massive ice cores, such as the Sukakpak mounds, have also been reported. The possibility seems not to have been widely considered that such features represent single-year growth with subsequent stability. Under such a hypothesis, the mode of origin of both types might be similar, except that the latter would not necessarily be characterized by repeated growth episodes.

Unlike van Everdingen's (1982) seasonal frost mounds at Bear Rock, N.W.T., the Sukakpak mounds appear to be quasi-stable perennial features, although a few ruptured and collapsed ones were observed on the upslope side of the road. On the stable forms, some trees have a smooth J shape that begins at the base of the trunk, suggesting a single uplift event and subsequent stability (Shroder 1980). The Sukakpak mounds are much smaller than those at Bear Rock, which have axial dimensions ranging from 20 to 65 m and heights that often exceed several meters. The small size of the Sukakpak mounds suggests that a limited water supply is available to individual mounds.

A closed-system freezing situation can be envisioned in fine-grained soils when backfreezing of the active layer is retarded in a super-saturated pocket of soil above an impervious substrate — in this case ice-bonded permafrost. Heaving occurs in response to formation of segregation ice near the base of the active layer and at the bottom of the descending freezing plane. These lenses are fed from the saturated sediments within the confined unfrozen pocket. Such a growth history would be confirmed by observing a desiccated layer of mineral soil separating two layers of nearly pure ice.

In the case of coarser soils, backfreezing of the active layer would again be slowed at the site of pools or supersaturated sediments. Pore water would be expelled from the freezing planes, resulting in an enclosed reservoir under increasing pressure. Complete freezing of the reservoir would result in a massive ice core; in some features, rupture of the overlying frozen soil would release still-unfrozen water. Examples of both these phenomena have been observed at Sukakpak Mountain.

If the water-bearing pocket is completely frozen in a single winter, no further vertical growth is experienced, and the mound may be preserved over a long period of time. Conversely, if some water within the pocket remains unfrozen, vertical growth can be reinitiated in subsequent years. This is particularly likely to occur if the unfrozen pocket is reconnected with surrounding thawed zones in summer. This could also result in the voids or "vaulted chambers" sometimes found in summer beneath the massive ice cores of some frost mounds, including a few observed at Sukakpak Mountain.

CONCLUSIONS

Despite the lack of detailed subsurface and process data, certain tentative conclusions can be drawn.

1. The apparent stability of many of the mounds at Sukakpak is evidenced by smoothly J-shaped trees, which may indicate a single upheaval event followed by a long period of stability. Other mounds at the site may experience multiple-year growth.

2. Mound initiation at this site appears to be heavily dependent on local variations in soil moisture. Subsurface ice-rich strata are present both within and adjacent to the mounds themselves; the mounds probably grow only where especially water-rich sediments are trapped between the seasonal freezing layer and ice-bonded permafrost. Limited prethaw drilling has demonstrated the presence of unfrozen water under pressure within one mound; in concert with the frozen sediments found beneath this feature, this fact is indicative of closed-system freezing.

3. The mounds are concentrated into separate fields occupying two unconnected drainage areas on the lower reaches of Sukakpak Mountain. This, of course, reflects the wetter conditions found at these sites. The chemical composition of the ice cores in the mounds is different from the surface water that forms icings at these sites. Ice within the mounds may be derived from groundwater, or the strong mineralization could reflect a concentration of impurities that accompanies freezing. The presence of surface icings may also be responsible for deeper frost penetration than in surrounding areas that are free of ice cover, since icings have a much higher thermal conductivity than does low-density snow cover (van Everdingen 1982). However, latent-heat effects in the water-rich substrate may offset such effects.

4. The Sukakpak mounds have some characteristics similar to classic peat bog palsas, such as their perennial character, size, and external morphology. However, some are associated with massive ice, occur in different topographic position, and apparently result from closed-system freezing.

ACKNOWLEDGMENT

This study has received partial support from the Department of Energy, The National Science Foundation, and the Cold Regions Research and Engineering Laboratory. Mr. Louis DeGoes provided valuable assistance during the initial spring 1982 observations.

TESTING PIPELINING TECHNIQUES IN WARM PERMAFROST

L. E. Carlson and D. E. Butterwick

Foothills Pipe Lines (Yukon) Ltd.

1600, 205 - 5th Avenue S.W., Calgary, Alberta, Canada T2P 2V7

A thaw settlement research facility was built by Foothills Pipe Lines (Yukon) Ltd. as part of the permafrost engineering design for the Alaska Highway Gas Pipeline Project. The main purposes of the test facility were (1) to study construction methods for the installation of large diameter pipelines in permafrost, (2) to observe the effectiveness of mitigative designs in minimizing thaw settlement of the pipe and right-of-way surface, (3) to study the behavior of cuts in ice rich hills, and (4) to provide data on the thermal behavior of design modes for comparison with thermal model predictions. This paper discusses the observations of the pipeline design performance and the comparison of that performance with initial predictions.

INTRODUCTION

As a part of the Alaska Highway Gas Pipeline Project, Foothills Pipe Lines (Yukon) Ltd. constructed the Quill Creek Test Facility. The test site is located in the Yukon territory of Canada on the alignment of the proposed gas pipeline approximately 165 km southeast of the Alaska border (Figure 1). The test facility encompassed various programs to study construction techniques and their effects on permafrost terrain and also to test some pipeline design concepts for operating warm gas pipelines across permafrost terrain.

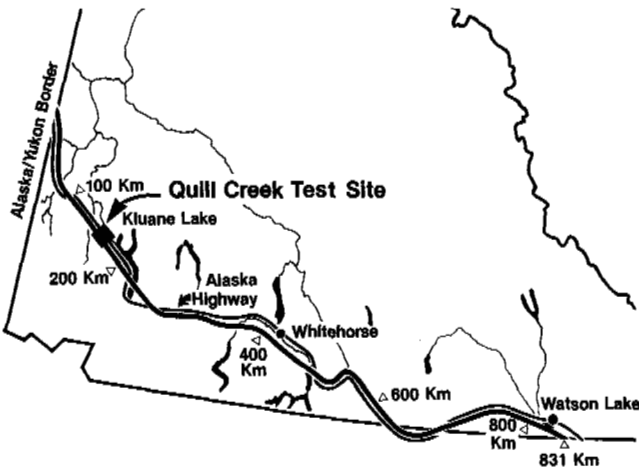

FIGURE 1 Quill Creek test site.

Overall, the test site is approximately 5 km in length and includes a number of separate areas where specific test programs were performed. The site layout as shown on Figure 2 includes (1) the sidehill grading area where various methods of protecting and stabilizing cuts in ice rich hills are studied, (2) the disposal area where the ice rich spoil from the sidehill cuts was stored, (3)

the buoyancy control area where select granular fill was tested for its adequacy as a pipeline buoyancy control technique and also excavation procedures could be tested in permafrost terrain, (4) the permafrost mitigative design construction area where problems associated with construction and maintenance of a reasonable length of pipeline with special designs could be evaluated, (5) the mitigative design operational area where shorter test sections are heated to operational temperatures and their performance monitored, and finally, (6) the site power generation, control and data gathering facilities area.

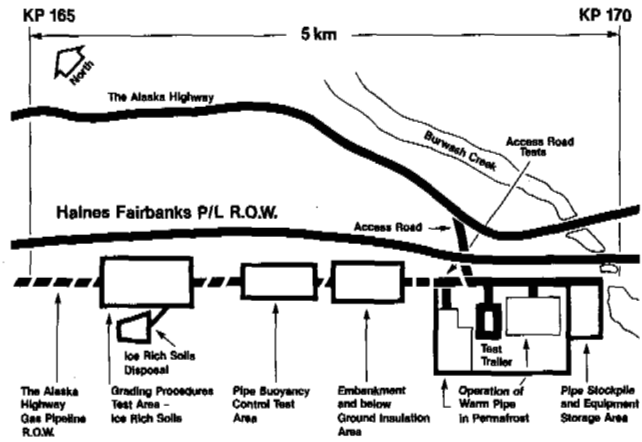

FIGURE 2 General layout, Quill Creek test site.

This paper will deal specifically with observations of the operating design area and the sidehill cut area.

The soil in the operating design area is typically an interbedded sequence of peat, silt, and clay overlaying a thaw stable gravel or gravelly till at a depth of about 5 m. Visual ice content in the top 5 m is 30-50%. The soil in the

sidehill cut area consists of a surface blanket of organics of 20-50% ice content, varying in thickness from 1 to 3 m. Beneath this is a clayey till layer with a high percentage of gravel sizes to depths of 4-7 m below ground surface. This material is very rich in ice, having from 30 to 60% visible excess ice. The mean ground temperature across the site is -1.5°C . The freeze index is 2900°C days and the thaw index is 1300°C days.

PIPELINE DESIGNS IN PERMAFROST

Foothills Pipe Lines is proposing to use either a chilled or warm gas operating mode (gas temperature below or above 0°C , respectively) depending on the relative occurrence of frozen and thawed terrain in the discontinuous permafrost region through which the pipeline alignment passes. If the presence of permafrost is relatively infrequent, as occurs along the southernmost three quarters of the alignment in the Yukon, the pipeline will operate warm. Regions of unstable permafrost are still encountered, however, and pipeline design measures are required to mitigate potential thaw settlement of the pipeline foundation soils. To study the behavior of such a mitigative design is one of the purposes of the Quill Creek Test Facility.

The basis of the thaw settlement design is to minimize thawing of the permafrost soils and thus maintain their strength and support capability. Geothermal analysis indicated that no reasonable amount of pipeline insulation could prevent significant thaw of soil supporting a buried pipeline and therefore the choice for this test is an abovegrade design. Geothermal analysis indicated that a gravel pad of an adequate thickness and width can cause the permafrost table to rise up into the granular material, thus stabilizing the subgrade. The amount of gravel, however, can be excessive depending on permafrost temperatures and ambient temperature conditions. The design problem, therefore, was to develop a design which utilized a reasonable amount of granular material and still provided adequate foundation support for the pipeline.

The gravel pad used in this test is nominally 1 m thick with 100 mm (or 50 mm) of polystyrene insulation board. The plastic foam insulation can significantly reduce the quantity of gravel necessary to meet the above thermal performance (Berg 1980). The insulation was laid on a graded gravel pad approximately 300 mm thick and covered with about 600 mm of gravel. The pipeline was then laid on this gravel pad and covered to protect the pipe from environmental and other externally caused damage and from low ambient temperature and to restrain the pipeline from movements due to pressure and temperature loads. Two methods of covering the pipe are used at the test site, one a gravel berm covering the pipe and the other a segmented concrete type of cover. Three test sections are covered with the gravel berm. The test sections differ in the amount of pipeline

insulation applied. One section has no insulation, another section has 100 mm of urethane insulation and the other section has 200 mm of urethane insulation. Two additional test sections are covered with the segmented concrete design. These have no pipe insulation as such but the pipe lies on a "saddle" of urethane insulation and the inside of the concrete weights is also insulated prior to placement over the pipe. This latter method of insulating the pipeline was studied as an alternative to continuously insulated pipe. The layout of these five test sections is illustrated in Figure 3.

FIGURE 3 Layout of aboveground test sections.

The design variations constructed and monitored in this section of the test site are used to provide verification of the thermal modeling of the designs as well as experimental observation of the design performance. The pipe sections are maintained at a constant temperature of 15°C by an air heating system. Verification of the thermal modeling is the purpose of the varying amounts of insulation on the test sections. The differences in thaw below the test sections will also provide an opportunity to observe the relationship between depth of thaw and amount of settlement and compare it with predicted thaw strains.

Construction of these test sections was performed during two different seasons of the year. The three gravel berm designs were constructed during the winter (Feb.-Mar.), while the concrete covered test sections were constructed during the late summer (Sept.). This affords the opportunity to verify the thermal model with a different set of initial conditions as well as to observe the thaw settlement behavior during construction and operation of gravel pads built on different soil thermal states.

Figures 4, 5, and 6 illustrate the thermal history of the designs through one year of operation. The thermal state of the soil is determined from a matrix of thermistors located below and within the gravel pad. The gravel embankment design without insulation around the pipe (Figure 4) shows a growth of the thaw bulb directly under the pipe. The presence of the warm pipe prevents the seasonal freezing of the material in and under the gravel pad. Our thermal calculations indicate that the thaw bulb will continue to grow with time. The gravel embankment designs with either 100 mm or 200 mm thick insulation around the pipe behaved almost identically. Figure 5 shows complete thawing of the gravel and slight thawing of the peat surface layer below the edge of the embankment during the summer months, but complete freezeback during the winter, for these insulated pipe sections. The insulation around the pipeline effectively negates the thermal influence of the warm pipeline, and the thermal effect is similar to an insulated gravel pad. The concrete covered design (Figure 6) was constructed in the late summer over a thawed active layer. The construction activity and warm gravel placement deepened the thaw under the gravel pad. Before construction the active layer was approximately 1/2 m thick and this was increased to approximately 2 m due to the construction. In the first year of operation the thaw depth has remained relatively constant with seasonal cold ambient temperatures not completely freezing back the active layer.

FIGURE 4 Thermal History. Uninsulated pipe in insulated embankment.

FIGURE 5 Thermal History - Insulated pipe in insulated embankment.

FIGURE 6 Thermal History. Concrete covered pipe on insulated gravel pad.

Computed predictions of the thermal behavior of the various designs have been in good agreement with the measured results. A comparison of these predicted and measured values is illustrated on Figure 7 and 8. These figures show a comparison of the calculated 0°C isotherm with interpolations of measured thermistor temperature readings. The thermal calculations are performed with a finite element thermal program that considers soil/water latent heat effects and takes into account changing meteorological conditions (Hwang 1976). Thermal parameters used in these simulations are given in Table 1.

TABLE 1 Soil stratigraphy and thermal properties, Quill Creek test site.

The pipe settlement history for the first 18 months of test site operation is shown on Figure 9. The two variations of the gravel embankment design (insulated pipe and uninsulated pipe) have both settled similar amounts with the uninsulated pipe settling slightly more. The presence of the warm (15°C) pipeline has yet to exhibit a significant influence on the settling or the effectiveness of the concept as a thaw settlement mitigative design. A longer embankment section in the construction procedures area of the test facility has settled a similar amount. That test section has the same design cross section as the heated insulated pipe sections but this longer pipeline was not heated. The majority of the settlement of the embankment design to-date can therefore be attributed to consolidation of the surface material under the embankment following the small amounts of thawing occurring seasonally under the embankment due to ambient temperatures.

This is not to say that the design variations will not perform differently in the future. The observation is that the uninsulated pipe causes thaw bulb growth which is sustained through the winter. Increases in thaw depth would likely cause an acceleration of pipe settlement relative to the insulated pipe design.

The concrete covered test sections exhibited significantly less settlement to date than the gravel embankment. This is attributed more to the season of construction than differences in pipe covering. Consolidation of the underlying material occurs more rapidly during construction when the material is thawed and reaches a measure of stability more quickly after the test site is put into operation.

FIGURE 9 Pipe settlement.

SLOPE STABILIZATION

The northernmost area of the Quill Creek Test Facility is dedicated to the evaluation of cut slope stabilization techniques for ice rich permafrost. A side cut facing northeast was made in a hill for approximately 400 m with the cut height varying up to 8 m. As described previously, the soil on this hill has a 20-60% visible ice content.

This test area is divided into six test section where different stabilization methods are used. The first section consists of a vertical cut face approximately 2 m high. The north half of the section was left unprotected and the south half has a wire mesh pegged to the organic cover above the top of the cut. Significant sloughing in the area of the slope face was observed. The organic cover on top of the cut face became undercut during the summer and fell onto the slope along the entire section. No appreciable movement occurred during the winter and little additional sloughing or movement occurred during the subsequent summer. The second test section consists of a 1:1 cut slope varying from approximately 2 to 4 m in height. The north half is protected by wire mesh pegged to the organic cover above the cut and the south half is unprotected. The organic cover developed a small undercut near the top of the cut face and fell onto the slope in late summer of the first year. No significant change occurred during the winter. The next summer showed greatly reduced thawing and effective stabilization of the slope face. The third test section consists of a 2:1 slope approximately 8 m high covered by a gravel blanket nominally 2 m thick. There is no visible change to this test section, although approximately 20 cm of settlement has been measured. The fourth test section consists of a 2:1 cut slope approximately 8 m high covered by an organic blanket reinforced by a jute

netting. The organic material is nominally 1.5 m thick. There is no visible change to this test section, although settlement in the order of 10 cm has been measured in the cleared area on top of the slope and 15 cm on the peat covered slope area. The fifth test section consists of a 1/2:1 cut slope approximately 4 m high protected by a gravel buttress with an outside slope of 2:1. The general shape of the buttress remains unchanged but settlements ranging up to 30 cm have occurred at the top of the buttress where the gravel abuts the cut face. The sixth test section consists of an unprotected vertical cut approximately 6 m high. Significant changes have occurred all along this section. The organic mat atop the cut face was significantly undercut during the first summer, and this overhang collapsed onto the cut face during September. No changes occurred during the winter months, and minimal changes were recorded to the slope profile during the second summer, however, the organic mat was torn off in some places along the slope. The changing cross-section profile of this test section is illustrated in Figure 10.

FIGURE 10 Six meter cut profile at Quill Creek test site.

SUMMARY

Two years of operation of the Quill Creek Test Facility has provided valuable data and observations regarding the construction and operation of pipelines in permafrost. The operating test sections have confirmed the pipeline design concepts for permafrost and have confirmed the application of computer thermal modeling in permafrost design work. The observation of the sidehill cuts in ice rich material have confirmed that adequate stabilization can be achieved.

THE GEOLOGY OF MARS

Michael H. Carr

U.S. Geological Survey, Menlo Park, California 94025 USA

Mars has had a long and varied geologic history. Large sparsely cratered volcanoes and vast lava plains attest to sustained volcanism. An extensive system of fractures appears caused by a bulge of continental dimensions in the Tharsis region. Well-integrated valley networks imply slow erosion by running water, while large channels appear formed by catastrophic floods. Collapsed ground, moraine-like ridges, and pitted terrains suggest the effects of ice, landslides and rock glaciers indicate large-scale mass wasting, and dunes and yardangs are evidence of wind action. Despite the similarity in the range of processes that have affected Mars and Earth, differences between the two planets remain large. Under present climatic conditions liquid water is unstable everywhere on the surface and ice is unstable at latitudes below 40°. A permafrost zone is 1 km thick at the equator and 4 to 5 km thick at the poles. Climate changes caused by perturbations in the orbital and rotational motions are small although they may cause alternating cycles of erosion and deposition at high latitudes. Climatic variations during the current epoch appear representative of climates throughout most of Mars' history. Branching valley networks in old terrain suggest different conditions over 3.5 billion years ago. Persistence of climatic conditions that hinder flow of water has prevented cycling of surface materials by erosion, sedimentation, burial, and metamorphism.

INTRODUCTION

The last two decades have witnessed an explosive growth in our knowledge of the Solar System. Spacecraft have made observations on all the planets as far out as Saturn, returning an enormous amount of data. Mars is of special interest to the geologist since most of the geologic processes that operate on Earth have occurred there also, although under quite different environmental conditions. We also know more about Mars than any planetary body other than the Earth and the Moon. Most of its surface was photographed by the Viking orbiters at a resolution of 200 m and large fractions at much better resolutions, ranging down to 8 m. Ground temperatures, atmospheric temperatures and the water content of the atmosphere were monitored planet-wide for over two martian years. In addition, the Viking landers analyzed materials at the surface and recorded meteorological conditions at two locations for several years. This paper examines current climatic conditions, then contrasts them with those that might be inferred with the geologic record in order to determine the extent to which present conditions are representative of those that have occurred in the past. Emphasis is on processes at the surface that involve water or affect its stability. The intent is to provide a context within which the potential for development of permafrost features on Mars can be assessed. For comprehensive summaries of martian geology, see Carr (1981) and Mutch et al. (1976).

PHYSIOGRAPHY AND TOPOGRAPHY

Mars, the fourth planet from the sun, has a

diameter of 6788 km, intermediate between that of the Earth (12,756 km) and the Moon (3,476 km). The planet is markedly asymmetrical. Most of the southern hemisphere is heavily cratered like the lunar highlands, whereas much of the northern hemisphere is only sparsely cratered. The heavily cratered terrain stands 1 to 3 km above the reference elevation datum. As on the Moon, several large impact basins are present, the largest being Hellas (1,800 km in diameter) and Argyre (800 km in diameter). Between many of the large craters are what appear to be volcanic plains. Both the craters and the intervening plains are dissected by branching valley networks that superficially resemble terrestrial river valleys and suggest slow erosion by running water. In contrast, much of the northern hemisphere is covered by plains at elevation mostly 1 km below the reference level. The plains have far fewer superposed craters than the southern highlands, and almost no branching valleys. Most of the plains at low latitudes are clearly volcanic, having flows visible on their surface, but in many places, especially at high latitudes, the plains have been considerably modified by the action of wind to produce yardangs and dunes, by water to carve valleys and possibly by ice to form collapse pits, patterned ground and moraine-like features.

The general north-south asymmetry is broken by anomalously high elevations in the Tharsis region, where a broad dome, 5,000 to 6,000 km across and 10 km high, is centered at 115°W on the equator. Arrayed around the bulge and affecting about a third of the surface area of the planet are numerous radial fractures. At the summit and on the northwest flank of the bulge are several huge volcanoes. Olympus Mons, on the northwest edge, is over 600 km across and 27 km

high, and Alba Patera just to the north of Tharsis is 1,600 km across but only a few kilometers high. A smaller bulge 2,500 km across and 5 km high, centered in Elysium at 25°N, 210°W, also has superimposed volcanoes.

To the east of Tharsis is a vast system of interconnected canyons. They extend from close to the summit of the Tharsis dome, eastward for almost 4,000 km. Most of the canyons are over 3 km deep and over 100 km across. In the central section, three parallel canyons merge to form a depression over 7 km deep and 600 km wide. The canyons are mostly flat floored with steep gullied walls. Many contain thick, partly eroded, layered sequences of sediments.

The canyons merge eastward with "chaotic terrain," in which the ground has seemingly collapsed over thousands of square kilometers to form a jumbled array of blocks at a lower elevation than the surroundings. Several large channels emerge from the chaotic terrain east of the canyons and extend northward down the regional slope for over 2,000 km, causing extensive erosion of the volcanic plains of Chryse Planitia. Other channels start north of the canyons and they also converge on, and ultimately die out in, Chryse Planitia. The channels are enormous by terrestrial standards. Many are several tens of kilometers wide; Kasei Vallis, the largest, has eroded a broad swath of terrain in places over 200 km across. All start full-size and have few if any tributaries. These channels have been widely attributed to floods of enormous magnitude although erosion by wind and ice have also been suggested.

The physiography of the poles is distinctively different from the rest of the planet. Extending outward from both poles for a little over 10° in latitude are layered deposits. The layers range in thickness from several tens of meters down to the limiting resolution of the available photographs. Incised into the deposit are numerous valleys and low escarpments that curl outward from the pole in a counterclockwise (eastward) direction in the north and in a predominantly clockwise (westward) direction in the south. Preferential removal of frost from the sunward facing slopes of these valleys gives the poles a characteristic swirl texture in summer. The polar layering and the incised valleys are of considerable interest because they may result from periodic climate change.

CURRENT SURFACE CONDITIONS

Mars currently has a thin atmosphere composed mostly of carbon dioxide. The composition at the surface is 95.3 % CO₂, 2.7 % N₂, 1.6 % Ar, and only small amounts of other constituents (Owen et al., 1977). The average pressure is around 8 mbars, but ranges widely because of the large surface relief. At the summit of Olympus Mons the pressure is only 0.3 mbars; in the deeper parts of the canyons the pressure is around 15 mbars. Surface pressure also varies with season, since about one-third of the atmosphere condenses out to form the winter CO₂ caps. Pressure at the Viking 1 landing site, for example, ranged from 6.9 mbars

in late southern winter to 9 mbars in southern summer.

Because the atmosphere is thin it has a low heat capacity. It cools and heats rapidly and has less effect on ground temperatures than on Earth. Ground temperatures have a large diurnal range. Those in southern summer range from around 200°K just before dawn to 280-290°K at midday. Peak northern summer temperatures are 20-30° lower. Assuming a heat flow of 35 erg cm⁻²sec⁻¹ (Toksoz and Hsui, 1978), mean annual temperatures are such that the 273°C isotherm is at a depth of 1 km at the equator and 4-5 km at the poles (Rossbacher and Judson, 1981), so that the planet everywhere has a thick permafrost zone. The temperature profile within the atmosphere is sensitive to the amount of dust it contains. When the atmosphere is clear, heating is largely from the ground below, and diurnal temperature fluctuations are restricted to a thin near surface layer. However, when dusty, absorption and emission of radiation by the atmosphere is enhanced and temperature fluctuations occur throughout the vertical profile (Pollack et al., 1979). One result is increased tidal winds, which blow from the cold nightside to the warm sunlit side of the planet.

A meteorological phenomenon of considerable geologic interest is the annual recurrence of near global dust storms. During spring and summer in the southern hemisphere, local dust storms are common, particularly around the edge of the retreating seasonal cap and in areas with high slopes. In most years storm activity grows to engulf almost the entire planet, obscuring the surface from view. After the storms cease the dust slowly settles out and the atmospheric opacity returns to its pre-storm level in 3-4 months. A number of theories have been proposed to explain the storms. The most plausible is that a feedback mechanism develops between the dust storm and tidal winds (Leovy and Zurek, 1979). The local dust storms raise dust that increases the contrast between the day and night atmospheric temperatures. This in turn increases the tidal winds that raise more dust, thereby causing a runaway effect. The storms subside when the atmosphere is so opaque that the near surface temperature fluctuations and hence the winds are so reduced that dust can no longer be raised. The storms now occur only during southern summer. At this time diurnal temperature variations are enhanced because Mars is close to perihelion.

The atmosphere contains only minute amounts of water. For most of the year the distribution is fairly even with latitude and the atmosphere typically contains 5-10 precipitable micrometers (Farmer and Doms, 1979). However, the atmosphere is always close to saturation for night temperatures so it holds almost all it can. The only major deviation from the generally uniform latitudinal distribution is during northern summer. At this time the atmosphere at high northern latitudes may contain up to 100 precipitable micrometers, a result of loss of water from a residual northern water-ice cap and a constant illumination that enhances the carrying capacity of the atmosphere.

Pressure and temperature conditions are such that liquid water and ice are unstable almost

everywhere on the surface. Liquid water will rapidly freeze or evaporate, depending on local conditions. Ice is stable at the surface all year round within 10° of the poles and for parts of the year down to latitudes as low as 30° . It is never stable at lower latitudes. At latitudes greater than 30° , ground ice is stable all year round at depths of 1 m to 1 km, depending on the specific latitude (Figure 1); at latitudes less than 30° ground ice is unstable with respect to the present atmosphere at all depths (Farmer and Doms, 1979). If ice were introduced into the ground in these equatorial latitudes it would slowly sublime, the rate being controlled by the ability of the water vapor to diffuse to the surface. Despite this disequilibrium, Smoluchowski (1968) suggested that ground ice could survive in the equatorial regions for billions of years if effectively isolated from the atmosphere, such as by a thick, impermeable, fine-grained regolith.

The surface conditions just outlined could alter as a result of changes in the orbital and rotational motions. Mars currently has an orbital eccentricity of 0.093, as compared with 0.017 for the earth. The rotation axis is inclined 25° to the pole of the orbit plane with the southern hemisphere tilted toward the sun near perihelion, thereby causing southern summers to be shorter and hotter than those in the north. However, precession of the rotation axis and the orbit plane causes climatic conditions to alternate between the two hemispheres on a 51,000 year cycle (Leighton and Murray, 1966). In 25,000 years it will be the northern hemisphere that has short, hot summers that trigger global dust storms.

Eccentricity and obliquity also undergo periodic changes. The eccentricity oscillates between 0.01 and 0.4 with characteristic periods of 95,000 and 2×10^6 years (Murray et al., 1973). Clearly, when the eccentricity is at a minimum, climatic differences between the two hemispheres are suppressed; when eccentricity is at its maximum, climatic differences are accentuated. Currently, with an eccentricity of 0.093, Mars is in the middle of its eccentricity range. The obliquity (the angle between the equatorial plane and the orbit plane) varies between 11° and 38° with characteristic periods of 1.2×10^5 and 1.2×10^6 years (Ward, 1973). As obliquity increases polar temperatures rise and equatorial temperatures fall. Because large amounts of volatiles are stored at high latitudes either as ice or adsorbed in the regolith, obliquity variations can significantly affect the volatile inventory of the atmosphere. Mars is at present also in the middle of its obliquity cycle.

These perturbations can affect climatic and geologic processes in a variety of ways. Currently, the north pole may be a region of dust deposition since its seasonal cap forms when the atmosphere is dusty from the southern summer dust storms. In contrast, when the southern cap forms the atmosphere is clear. Thus the northern cap is dirty and dissipates under a clear atmosphere, whereas the southern cap is clean and dissipates under a dusty atmosphere (Kieffer et al., 1976; Pollack et al., 1979). One consequence is that the northern seasonal CO_2 cap dissipates completely in summer to leave a remnant water-ice cap

(Farmer et al., 1976), whereas the CO_2 cap in the south does not completely dissipate.

Accumulation of dust scavenged from the atmosphere by formation of the seasonal cap may be the cause of the polar layered deposits (Pollack et al., 1979). Deposition is now taking place in the north but the site of deposition will alternate with the precessional cycle, so the layering may be due in part to precession. The coupling of depositional rates with astronomical perturbations are likely, however, to be complicated and depend in part on the threshold conditions for initiating dust storms (Cutts et al., 1982). At present such conditions are achieved only during southern summer. If eccentricity decreases, the triggering thresholds may not be achieved in either hemisphere and little deposition would occur at the poles. Furthermore, retention of the dust storm debris may depend on the stability of water-ice, which probably acts as a cement. Under conditions of high obliquity ice will be unstable during summer, thereby allowing the dust to dissipate. Thus, while changes in the stability of water and in the rate of dust deposition induced by perturbations of the planet's motions are likely causes of the polar layered deposits, precise correlation of the layers with specific periodic changes is not possible.

Astronomical perturbations may also affect the atmospheric pressure. Carbon dioxide resides in three major sinks: the atmosphere, the polar caps, and the regolith. Several lines of evidence indicate that the present atmosphere represents only a fraction of that outgassed from the planet (McElroy et al., 1977; Pollack and Black, 1979). Particularly significant is the lack of fractionation of oxygen isotopes in the atmosphere despite substantial enrichment in ^{15}N and several mechanisms for exospheric loss of oxygen, which should cause enrichment in ^{18}O . The simplest explanation is that substantial amounts of CO_2 and H_2O exist in the ground close to the surface where they can exchange with the atmosphere and so dilute any fractionation effects. The regolith has a substantial storage capacity for CO_2 , most being adsorbed on mineral grains (Fanale and Cannon, 1974, 1979; Fanale et al., 1982). Increase in regolith temperatures will tend to drive off the gas and so increase atmospheric pressures; a decrease in regolith temperature will have the reverse effect. The penetration depth of the annual and diurnal temperature changes is small so that they have little effect on atmospheric pressure. However, temperature changes caused by perturbations of the orbital and rotational motions, which have periods of 10^5 to 10^6 years, penetrate to depths of a kilometer and could significantly affect the atmosphere. Of special importance are obliquity changes that cause large variations in temperatures at high latitudes. According to the modeling of Fanale et al. (1982), during periods of low obliquity the atmospheric pressure may fall as low as 0.1 mbar mainly as a result of growth of a large permanent CO_2 cap; at high obliquities the pressure may rise to 15 mbars. This range is small despite substantial exchange between regolith and atmosphere because of buffering by the polar cap.

The current epoch is thus characterized by a permafrost zone 1 km thick at the equator and thickening to 4-5 km at the poles, instability of liquid water planet-wide, instability of ground-ice at low latitudes, deposition of layered deposits at the poles, intermittent recurrence of global dust storms, and low atmospheric pressures that vary by about a factor of 100. In the next section we will consider the extent to which these conditions are typical of the planet's geologic history.

CHANNELS AND VALLEYS

Lingenfelter et al. (1968) showed that water could flow for considerable distances even on the Moon if discharge rates were high enough. Estimates of the discharge rates of the postulated floods that cut the large martian channels range from 10^6 to 10^9 m³ sec⁻¹ (Masursky et al., 1977; Carr, 1979). Loss by evaporation and freezing under any possible Mars climatic conditions would be negligible in comparison with these discharges. The flood features are thus poor indicators of past climates and could form under present conditions. The branching valley networks are however quite different. They lack bedforms common in the large channels, have a regular hierarchy of tributaries, and start small and increase in size downstream. The networks are thus not channels like the flood features but more akin to terrestrial river valleys. Their presence suggests that streams of modest discharge have at times flowed across the surface.

Over 99 % of the valley networks occur in the densely cratered terrain, which dates from over 3.5 billion years ago (Carr and Clow, 1981). In contrast, the large flood features are found on surfaces of a wide range of ages. The simplest explanation for the restriction of valley networks to old terrains is that conditions required for valley formation existed only very early in the planet's history. Alternative explanations are that the old terrain is more erodible or that water is more available (by seepage) in the old older terrains as compared to the younger. The drainage pattern of the valleys is very open. The old terrain is partly dissected everywhere, but wide undissected interfluvies occur between branches in any one network and the drainage basins themselves are widely spaced. Most drainage basins are also small, the distance from the end of the most distal tributary to the mouth of the main valley being generally less than 300 km. These characteristics suggest an immature drainage system in which erosion has not been sufficiently sustained to achieve efficient coverage of the entire landscape or for single drainage basins to dominate large areas at the expense of neighboring networks. Many characteristics of the networks also suggest that groundwater sapping is a prominent process in their development (Pieri, 1980).

A plausible explanation of the valley networks is that early in its history Mars had a thicker atmosphere than at present, and as a consequence, higher surface temperatures. The conditions were such as to occasionally permit

flow of water at small discharges. At this time impact rates were high and competed with erosion by wind and water in reshaping of the landscape. Around 3.8 billion years ago the impact rates declined, the landscape stabilized and many of the valleys we now see were formed. However, the rate of valley formation appears to have declined rapidly thereafter for valleys are rarely found on younger terrain and mature drainage systems did not develop even on the oldest terrain. Carbon dioxide may have been lost irreversibly from the atmosphere by formation of carbonates and other minerals. Conditions then approached those that presently prevail with a thick permafrost over all of the planet's surface. The large floods that occurred subsequently were possibly the result of break-out of water confined under high pressures beneath the thick permafrost (Carr, 1979). Alternatively, the floods were caused by geothermal melting of ice (Masursky et al., 1977), liquefaction of near surface materials (Nummedal and Prior, 1981) or geothermally induced decomposition of hydrated minerals (Clark, 1978).

Several other surface features support the sequence of events just outlined. An ancient cratered terrain, remarkably little affected by eolian erosion, has survived from over 3.5 billion years ago; the floors of many large craters are almost indistinguishable from those of lunar craters being almost saturated with small (< 1 km in diameter) craters; fine primary depositional features are preserved on impact ejecta and volcanic flows that are billions of years old. Erosion rates have thus been low throughout most of the planet's history. Arvidson et al. (1979) estimated from the preservation of craters in Chryse Planitia that erosion rates can have been no more than 10^{-9} m year⁻¹ over the last 3.5 billion years. For comparison, Menard (1961) estimated that erosion rates in North America are 3×10^{-5} m year⁻¹. While not conclusive, such low erosion rates suggest that the martian atmosphere has been thin, and hence the surface temperatures low, throughout most of Mars' history.

Indirect evidence also suggests that the stability of ice on the surface has not changed greatly throughout Mars' history. If true, then climatic conditions since termination of the very early era of active valley formation have been fairly stable and subject only to the relatively mild changes caused by the perturbations in the orbital and rotational motions. We have seen that at latitudes less than 30-40° ice is currently unstable with respect to the atmosphere for the entire year, whereas at higher latitudes ice is stable for parts of the year. The 30-40° latitude band is also one of transition in erosional style. In the low latitudes primary volcanic and impact features are well preserved. At high latitudes such features are poorly preserved; most of the landscape is modified as if blankets of debris had been repeatedly deposited and removed (Soderblom et al., 1973). Parallel moraine-like features suggest that rates of removal of the debris blankets changed cyclically, possibly indicating again the effects of variations in the orbital and rotational motions (Carr, 1980). The transition in erosional style along the stability boundary of ice is unlikely to be coincidental. Freezing and

sublimation of ice may have played a significant role in the stabilization and destabilization of the debris blankets.

The location of the "fretted terrain" appears similarly related to the ice stability boundary. In these terrains most high standing massifs are surrounded by extensive debris aprons, which suggests that rates of mass wasting are unusually high. The terrain is also characterized by large, flat-floored, steep-walled valleys in which debris flows from opposing walls converge on the valley center. Debris flows appear to be particularly mobile in these areas, resulting in enhanced erosion along steep scarps and widening of river valleys into broad flat-floored features. Squyres (1979) showed that the fretted terrain occurs mainly in two latitude belts 25° wide centered on 40°N and 45°S. He noted that these are regions where the maximum amount of water-ice is expected to be precipitated out of the atmosphere in winter. The amounts are small (< 1mm); nevertheless, he suggested that mass wasting is enhanced in these regions because ice mixes with talus debris. The flat-floored valleys appear to have a wide range of ages. If current stability relations of ice are responsible for their formation then their scarcity outside the two belts identified indicates that the stability conditions of ice have not changed dramatically during much of the planet's history, a conclusion which is also consistent with the contrast in erosional styles between high and low latitude. By implication, surface pressures and temperatures are unlikely to have been significantly greater than at present for extended periods after the early period when the valley networks formed, and liquid water is unlikely to have played a major role in the subsequent evolution of the surface.

GLOBAL IMPLICATIONS

A major cause of the differences between Mars and Earth is their contrasting tectonics. The Mars surface is fixed and all those features, such as linear mountain chains, ocean deeps, transcurrent fault zones, and spreading centers that characterize plate junctions are absent. Crustal stability also results in preservation of an ancient geologic record in almost all areas of the planet. The Earth's surface is thus a complicated system in which material is being recycled both through the mantle by subduction and ocean floor spreading, and within the lithosphere and hydrosphere by weathering, metamorphism, erosion and deposition. A second major cause of differences between the Earth and Mars are the climatic conditions which on Mars hinder flow of water across the surface. On earth, water plays an essential role in two major processes: weathering, the chemical breakdown of rock forming minerals into assemblages more in equilibrium with conditions at the surface, and gradation, the steady reduction of surface relief by erosion and transport of materials from high to low areas. Both processes are complemented by opposing processes such as metamorphism and tectonic activity.

The dynamics of the martian crust are totally different. Although the planet has been volcani-

cally and tectonically active throughout much of its history, the lithosphere appears not to have been recycled through the underlying lithosphere. Huge volcanoes have formed, as well as vast fracture systems, but the activity is not concentrated in linear zones as on earth, but rather affects areas of broad regional extent. Furthermore, although water has probably flowed across the surface at times in the past, erosion has been trivial. Where channels are present, they mostly wind between the craters or down the crater rims; rarely has erosion been sufficiently sustained to wear away the craters themselves. Erosion of young features such as the large volcanoes is imperceptible.

The lack of significant sediment transport implies that weathering products are not recycled. Chemical analyses of the surface materials indicate that weathered products, such as clays, are present. How they formed is not known, but liquid water may be abundant below the permafrost. Such water, being highly charged with CO₂, is likely to be an efficient weathering agent. However, without erosion most of the weathered products must remain where they form so are not actively recycled as on Earth. Thus recycling of surface materials and their interaction with the hydrosphere and atmosphere are hindered by climatic conditions that prevent flow of water. The result is that despite sustained internal activity, the planet's surface is relatively stable and features with considerable relief and a wide range of ages are almost perfectly preserved.

FIGURE 1. Stability relation of ice near the martian surface as a function of latitude. In the equatorial regions that are shaded on the diagram ice is always unstable with respect to the atmosphere under present climatic conditions. In the polar regions that are shaded ice is always stable. In the unshaded areas ice is stable for parts of the year. L_s is the areocentric longitude of the Sun and is a measure of the time of year (adapted from Farmer and Doms, 1979).

FOSSIL SAND WEDGES ON THE ALASKAN ARCTIC COASTAL PLAIN AND THEIR
PALEOENVIRONMENTAL SIGNIFICANCE

L. David Carter

U.S. Geological Survey, 4200 University Drive, Anchorage, Alaska 99508-4667 USA

Fossil sand wedges occur over a broad area of the Arctic Coastal Plain of Alaska upwind of a large field of stabilized linear dunes. The sand wedges are as much as 3 m wide and 7 m deep and form polygonal systems. They developed when wind-driven sand moving across the coastal plain toward the dunes dropped into open thermal-contraction cracks. Radiocarbon dating of organic remains from deposits overlying the sand wedges and from eolian sand in the dune field, together with the age of the deposits in which the sand wedges developed, show that the sand wedges and dunes are Wisconsinan. Growth of the sand wedges could have occurred continuously or episodically throughout the time the dunes were active, but probably was most rapid during the coldest periods, and particularly during late Wisconsinan time. The sand wedges and associated dunes record desert conditions over a significant part of the Arctic Coastal Plain during middle and late Wisconsinan time and perhaps throughout the Wisconsinan Stage.

INTRODUCTION

Sand wedges are wedge-shaped bodies of sand oriented with their apexes pointed downward, that underlie the borders of unvegetated, nonsorted polygons in the drier parts of Victoria Land, Antarctica (Péwé 1959, Black and Berg 1963, Berg and Black 1966) and in some parts of the Sverdrup Islands of arctic Canada (Hodgson 1982). They form in a manner analogous to ice wedges, which commonly underlie the borders of nonsorted polygons in tundra-covered arctic areas and in the more humid parts of Victoria Land. Both sand and ice wedges grow as a result of repeated formation and filling of thermal-contraction cracks in permafrost; ice wedges form when the cracks fill with snow, hoar frost, or meltwater (Leffingwell 1915, Lachenbruch 1962), whereas sand wedges form when the cracks fill with sand that trickles down from the surface (Péwé 1959, Black and Berg 1963, Berg and Black 1966).

Fossil features similar to modern sand wedges have been reported in Pleistocene deposits at several localities in North America (Berg 1969, Foscolos et al. 1977, Mears 1981), and northern Europe and Asia (Jahn 1975), and in Precambrian deposits in Africa (Deynoux 1982). Recently, fossil sand wedges have been identified in Pleistocene deposits over a broad area of the Arctic Coastal Plain of Alaska (Figures 1 and 2). The Alaskan sand wedges and associated stabilized eolian dunes suggest a dry, barren, and windswept environ-

FIGURE 1 Location of Arctic Coastal Plain. Rectangle outlines area discussed in report.

FIGURE 2 Distribution of sand wedges and dunes and location of sites mentioned in text and in Table 1.

onment that is in sharp contrast to the modern tundra-covered, lake-dotted surface beneath which ice wedges are forming.

DISTRIBUTION AND DESCRIPTION

The fossil sand wedges in northern Alaska occur in sandy Pleistocene marine and alluvial deposits north and east of a large area of stabilized eolian dunes (Figure 2). The eastward limit of the sand wedges is undetermined, but they have been observed in the Prudhoe Bay area about 40 km east of Figure 2 (S. E. Rawlinson, personal communication, 1982) and on the north side of Barter Island about 180 km east of Prudhoe Bay (D. M. Hopkins, personal communication, 1983).

Individual sand wedges range up to 3 m wide and 7 m deep (Figure 3), and the distance between the largest wedges ranges up to 15 m. Small secondary sand wedges are locally present between larger wedges, and some large sand wedges are cross-cut by smaller wedges. Wherever exposures are sufficiently extensive, the wedges can be seen to form polygonal systems. Bedding in the host material is invariably upturned at wedge edges.

The wedges possess a distinctive foliated fabric (Figure 4) of near-vertical to vertical laminae in wedge centers grading outward to inclinations that parallel the wedge edges. In many places the laminae are mutually cross-cutting. Wedge apophyses penetrate the host material, and pieces of the host material have been incorporated into the wedges and are cut by laminae that most likely represent individual thermal-contraction cracks (Figure 4). The maximum width of individual laminae is about 5 mm and most are about 1 or 2 mm wide. The fabric of these sand wedges is thus similar to that described for modern Antarctic sand wedges (Berg and Black 1966) and for the fabrics of ice wedges (Black 1974) and serves to distinguish them from ice wedge casts (Black 1976).

Microfossils or plant fragments have not been found in sand of the wedges although they are common in the host materials and in deposits overlying the wedges. The wedge sand is not cemented by ice, and deformed laminae that could be attributed

FIGURE 4 Sand wedge fabric (A) and host materials (B) at site 1. Pieces of the host material (C) occur within the sand wedge and are cut by laminae of the sand wedge.

to slumping due to melting of snow or ice have not been observed.

Sand composing the wedges is always texturally distinct from the host materials. This textural difference is illustrated for site 1 (Figure 2) by size analyses for five samples of the host material and samples from five individual wedges (Figure 5). The wedge sand is fine to very fine sand with mean grain sizes ranging from 2.74 to 3.09 phi. The host material, which at this site is predominantly fluvial sand, is distinctly coarser than the wedge sand and has mean grain sizes that range from 1.48 to 2.41 phi.

Although the sand wedges have formed in materials that range from gravelly fluvial sand to silty marine sand, the texture of the wedge sand is remarkably uniform over the broad area of their occurrence. Mean grain sizes for samples from 11 wedges at sites 1 through 4 (Figure 2) range from 2.60 to 3.10 phi (Figure 6). Significantly, the textural analyses for the sand wedges are essentially encompassed by the field of cumulative curves for 20 samples of sand from the dune field (Galloway 1982). Wedge sand is thus texturally distinct from the host materials but similar to sand composing the dunes.

FIGURE 3 Large sand wedges (A and B) at site 1. Man is about 1.7 m tall.

LIMITING AGES

Radiocarbon dating of remains of herbaceous plants at sites 1 and 2 (Figure 2) provides minimum limiting ages for cessation of sand wedge development. At site 1, involutions of peat that intrude sand wedges and thus postdate wedge formation are $9,300 \pm 90$ and $9,600 \pm 100$ years old (Table 1). At site 2, two samples of herbaceous plants collected in growth position just above the base of silty sand that overlies sand wedges are $9,689 \pm 110$ and $10,200 \pm 110$ years old. Sand wedges have not been observed within Holocene deposits and are always overlain by Holocene thaw lake or eolian deposits. Furthermore, some sand wedges are cut by large Holocene ice wedges and by Holocene ice wedge casts. The sand wedges are evidently pre-Holocene.

FIGURE 5 Grain-size analyses for five sand wedges and five samples of the host sand at site 1. Stippled pattern indicates the field occupied by cumulative curves for the sand wedge samples, and the diagonal lines indicate the field occupied by cumulative curves for samples of the host sand.

FIGURE 6 Grain-size analyses for 11 sand wedges at sites 1 through 4 and 20 samples of eolian sand from the dune field. Stippled pattern indicates the field occupied by cumulative curves for the sand wedge samples, and the horizontal lines indicate the field occupied by cumulative curves for the dune sand samples.

Stratigraphic relations at site 2 suggest a maximum limiting age for the sand wedges there. At this site, the sand wedges are developed in fossiliferous marine beach deposits composed of pebbly sand. Marine ostracodes in the beach deposits include *Cythere lutea* O.F. Muller, 1785 and *Hemicythere borealis* of Hazel, 1967 which occur today in temperate to subpolar waters of the North Atlantic but not in the Beaufort Sea (E. L. Brouwers, written communication, 1980). The mollusk fauna includes *Natica janthostoma* which today is limited to waters adjoining Japan, Kamchatka, and the Commander Islands (D. M. Hopkins, written communication, 1980). Spruce (*Picea*) driftwood is locally common in the beach deposits. These facts indicate more open water and warmer climatic conditions than presently prevail, and the deposits are interpreted to represent an interglacial marine transgression. These are the youngest interglacial beach deposits on the Arctic Coastal Plain, and although they are more than 51,000 years old (Carter and Robinson 1981), they are young enough that amino acid ratios (Ala/Ile) determined on valves of *Hiatella arctica* collected from these deposits are barely distinguishable from those determined on modern specimens of *Hiatella arctica* (J. K. Brigham, written communication, 1983). This transgression is therefore correlated with the Pelukian (last interglacial) transgression of Hopkins' (1967) Alaskan sequence. If this is correct, then the sand wedges at site 2 developed entirely during the Wisconsinan Stage.

Maximum limiting ages for sand wedges at other sites cannot be determined with current data. However, their relation to the dune field suggests that all the sand wedges reported here are Wisconsinan, although multiple episodes of formation during Wisconsinan time cannot be ruled out.

RELATION TO DUNES

Bedding attitudes in eolian sand and the orientation of dune ridges indicate that the dominant winds during formation of the dune field were easterly to northeasterly (Figure 2), similar to the modern prevailing winds (Carter 1981). The sand wedges thus formed upwind of the dunes. This fact, together with the similarity in grain size between the wedge fillings and the dune sand, suggest that the loose sand that entered the thermal-contraction cracks to form the sand wedges was derived from wind-driven sand moving across the coastal plain toward the dunes.

The dune field consists of large, linear dunes as much as 20 km long, 1 km wide, and 30 m high that are overlain by a sheet of eolian sand a few meters thick (Carter 1981). Small parabolic and longitudinal dunes a meter or so thick and up to 1 km long (Black 1951) formed in the sand sheet sometime after it was stabilized by soil development. Radiocarbon dates of *Salix* (willow) in growth position within the eolian sand sheet range from $9,640 \pm 150$ to $11,400 \pm 160$ years B.P. (Carter 1981), and a paleosol dating from 11,000 to 12,000 years B.P. is locally present at its base (Table 1). Because the sand wedges are overlain and intruded by deposits

TABLE 1 Radiocarbon dates relating to the time of sand wedge development and the activity of linear dunes.

Site	Latitude N & Longitude W	Material	Occurrence	Age and Laboratory Number	Significance
1	70° 04.35' 151° 22.9'	Peat	Involution intruding sand wedge	9,330 + 90 (Beta-5384)	Minimum limiting age of cessation of sand wedge development

the same age as the sand sheet, they are older than the sand sheet. Furthermore, the period from 11,000 to 12,000 years B.P. was a time of dune stabilization, soil development, and ice wedge growth; conditions which are generally unfavorable for the growth of sand wedges. Therefore, the most probable time of development of the sand wedges was while the large linear dunes were active.

Organic remains are extremely scarce within sand of the linear dunes, but radiocarbon dating of the few herbaceous plants that have been found shows that the dunes were active during middle and late Wisconsinan time and perhaps earlier (Table 1). Deposits of an interdunal lake at site 11 that are underlain by eolian sand contain herbaceous plants that yield a radiocarbon age of $35,900 \pm 1,200$ years B.P. Wood collected from alluvial deposits that underlie the linear dunes at site 13 has been radiocarbon dated as about 49,400 years old, but this may be merely a minimum limiting age for the alluvial deposits. Formation of the dunes thus either began between 36,000 and 50,000 years B.P. or perhaps beyond the range of radiocarbon dating. However, deposits such as peat beds that would indicate relatively warm, mesic intervals are absent within the dune sand, suggesting that the linear dunes formed entirely since the last interglacial episode, and are Wisconsinan.

TIME REQUIRED FOR GROWTH

Rates of sand and ice wedge growth have been measured in Antarctica (Black 1973, 1982) and rates of ice wedge growth have been measured in Alaska (Black 1974). The measurements from Antarctica seem most appropriate for use here because they include sand wedges. The measurements were made during two intervals that cover a total of about 20 years and they indicate that growth rates are highly variable and are affected by short-term variations in climate and ground conditions (Black 1982). During the first interval, net growth rates averaged 0.79 mm per year, and during the second interval average net growth was only 0.04 mm per year. Black proposed that the reduction in growth rates was due to climatic warming.

Assuming the most rapid growth rate above, the largest of the northern Alaskan sand wedges could have grown in only 3,800 years, whereas the second growth rate would require about 75,000 years. The first growth rate corresponds to the addition of a 2-mm-wide sand lamina every other year. On the basis of observations that the probability of cracking in any one year is less for large wedges than for small ones (Berg and Black 1966), and the assumption that the rate of growth of sand wedges should slow with increasing age (Berg and Black, 1966), this is probably a reasonable short-term upper limit for the growth rate of the Alaskan sand wedges during the coldest periods of their development. The second growth rate corresponds to the addition of a 2-mm-wide sand lamina once every 50 years. Such slow growth rates are unlikely over the long term but, as in Antarctica, could have occurred in response to episodes of climatic warming during the period of wedge development. The system of sand wedges on the Arctic

Coastal Plain therefore probably took more than 4,000 years to develop and may have grown continuously or episodically throughout the period that the linear dunes were active.

PALEOENVIRONMENTAL SIGNIFICANCE

Sand wedges indicate dry conditions in which locally there may be a net transfer of moisture from permafrost to the air (Black and Berg 1963), and thus progressive desiccation of the ground. Furthermore, they document an absence of surface water from the time the thermal-contraction cracks form in middle and late winter until they fill with eolian sand (Foscolos et al. 1977); otherwise, ice or composite wedges would form. Therefore, snow cover must have been extremely patchy or absent during middle and late winter or was removed prior to spring thaw. Modern snow cover on the coastal plain is essentially continuous throughout the winter, and represents about half of the 195-252 mm (water equivalent) that falls (Benson 1982). The other half is removed by the wind and deposited in drifts, with an unknown part of this lost by sublimation during transportation (Benson 1982). The area containing the sand wedges could have been kept bare of snow by intense and relatively constant winds, but if this were a primary factor, then snowdrifts should have formed within the dune field and subsequently would have been buried by wind-blown sand, as is common in cold climate dunes (Ahlbrandt and Andrews 1978). However, neither buried snow nor deformational structures indicative of melted snow or ice have been observed in sand of the linear dunes. Lighter snowfall than now occurs coupled with sublimation induced by desiccating winds seem required to produce the necessary bare ground.

Vegetation must have been extremely sparse or absent in the area containing the sand wedges, because significant plant cover would have inhibited the movement of eolian sand and prevented sand wedge development. The most favorable sites for plant growth would have been in the relatively protected troughs above the wedges. However, had plants grown there, one would expect plant fragments to be incorporated with eolian sand in the wedges. The absence of plant fragments in the sand wedges suggests that the area was completely devoid of vegetation, as in Antarctica where sand wedges are forming today. Vegetation within the dunes downwind of the sand wedges was extremely sparse at best and consisted of scattered clumps of herbaceous plants on the dunes and aquatic bryophytes in interdunal ponds. Scanty snow cover may have been an important factor limiting plant growth both in the dunes and in the area of the sand wedges.

The sand wedges and associated linear dunes thus record dry, barren, and windswept conditions across a significant part of the Arctic Coastal Plain during middle and late Wisconsinan time and perhaps throughout the Wisconsinan Stage. Even so, radiocarbon dating of fossil bones indicates that south of the barren belt defined by the sand wedges and dunes, vegetation was sufficient to support large herbivores such as mammoth, horse

and bison (Carter 1982). None of the dates of these mammals, however, is less than 28,000 years B.P. Furthermore, few organic remains have been found in coastal plain deposits between 14,500 and 28,000 years old compared to older and younger deposits, and pollen spectra of this age from the northern Yukon indicate sparse, discontinuous vegetation in the arctic foothills (Cwynar and Ritchie 1980). Desert conditions evidently expanded south of the barren belt during late Wisconsinan time coincident with the expansion of glaciers in the Brooks Range (Hamilton 1982). This arid Wisconsinan cold phase may have coincided with the period of most rapid growth of the sand wedges.

ACKNOWLEDGMENTS

Discussions in the field with R. F. Black and D. M. Hopkins contributed significantly to this study. The manuscript benefited from reviews by O. J. Ferrians, Jr., and D. M. Hopkins. Assistance in the field was provided by J. P. Galloway, who also performed the grain size analyses.

RUNOFF FROM A SMALL SUBARCTIC WATERSHED, ALASKA

E. F. Chacho, Jr.¹ and S. Bredthauer²

¹U.S. Army Cold Regions Research and Engineering Laboratory
Fairbanks, Alaska 99703 USA

²R&M Consultants, Anchorage, Alaska 99503 USA

Precipitation-runoff ratios were measured on Glenn Creek, a small, second-order, subarctic stream located near Fairbanks, Alaska, in the Yukon Tanana Upland physiographic province. Glenn Creek drains a watershed of 2.25 km², of which 70% is underlain by permafrost. A Parshall flume was used to measure streamflow, and a pair of 1.22 m by 2.44 m lysimeters were used to measure precipitation and runoff from the moss-covered permafrost slope. The data from one summer season (1979) and one snowmelt season (1980) indicate the sloping surfaces of the watershed have a very fast response time, long recession, and subsurface runoff prior to complete saturation of the overlying organic material. Glenn Creek streamflow is comparable to the lysimeter runoff with regard to response time and runoff recession, however the watershed precipitation-runoff ratio is much lower. This is attributed to longer travel distances in the watershed, which result in greater evapotranspiration losses, little contribution from the non-permafrost areas, and only partial areas of the watershed contributing to the streamflow.

Watershed studies in the discontinuous permafrost zone of the North American taiga have a relatively short history. The first detailed studies of hydrologic processes in subarctic Alaska were performed by Dingman (1966a,b; 1971; 1973) in the Glenn Creek watershed near Fairbanks, Alaska. Further studies of permafrost-dominated watersheds were initiated in 1969 with the establishment of the Caribou-Poker Creeks Research Watershed 48 km north of Fairbanks, Alaska (Slaughter 1971). Analyses of streamflow from permafrost and nonpermafrost-dominated watersheds of interior Alaska have shown that the presence of permafrost and its associated soil and vegetation types greatly influences runoff generation (Dingman 1971, Ford 1973, Slaughter and Kane 1979, Kane et al. 1981, Haugen et al. 1982). Examination of precipitation and streamflow data by Dingman (1971) for Glenn Creek and Ford (1973) and Haugen et al. (1982) for Caribou Creek resulted in similar observations of (1) prolonged streamflow recessions in permafrost basins, attributable to delayed flow through organic soils associated with permafrost, (2) rapid streamflow response to precipitation, within two hours on the average, and (3) streamflow response time not related to antecedent moisture conditions. Dingman (1971) had reported that the ratio of runoff to precipitation was related to antecedent moisture conditions. This relationship was not found in the Caribou Creek data, but may be due to a lack of precision in the data (i.e. use of mean daily flows) rather than the absence of any relationship (Ford 1973, Haugen et al. 1982).

Previous studies have addressed the infiltration characteristics of both the permafrost and non-permafrost soils typical of Alaska's taiga (Kane et al. 1978, Slaughter and Kane 1979, Kane 1980). In general, it was found that the thermal and hydraulic conditions in the nonpermafrost soils result in

infiltration rates high enough to accept all incident moisture (snowmelt or precipitation). No surface or near-surface flows were observed in the field. In the permafrost areas, however, the soils beneath the active layer (depth of seasonal thaw) are essentially impermeable, due to high moisture contents in the frozen soils. The result is saturated conditions in the overlying organic soils and observations of large quantities of water moving downslope through these soils. Dingman (1971) had formed the same conclusions following observations of storm runoff on Glenn Creek. Santeford (1979) studied the moisture-retention properties of the permafrost-associated organic soils by measuring vertical percolation in lysimeters. He concluded that the water-holding capacity of the organic soil had to be exceeded before any drainage occurred.

This paper addresses the processes of runoff production on moss-covered slopes underlain by permafrost through the use of lysimeters installed on a slope in the Glenn Creek watershed. Comparison of the lysimeter data to Glenn Creek streamflow indicates that the overall watershed response to precipitation is lower than that of the lysimeter.

WATERSHED DESCRIPTION

The Glenn Creek watershed is located 14 km north of Fairbanks, Alaska, at latitude 64°57'N, longitude 147°35'W, at the southern edge of the Yukon-Tanana Uplands (Wahrhaftig 1965). The watershed was selected by Dingman (1971) in 1964 for detailed hydrologic studies based on its size, accessibility, lack of human disturbance, and apparent representativeness of the area. The original study basin had an area of 1.8 km² (Figure 1). When hydrologic studies were reactivated on Glenn Creek in 1978, the streamflow gauging site was

relocated downstream, increasing the study basin area to 2.25 km². The drainage area is uniformly distributed between the peak elevation of 493 m at the eastern perimeter and 250 m at the basin outlet. Slope tangents (Figure 2) range from 0 to 0.6, but 80% of the basin ranges between 0.05 to 0.25, with an average basin slope of 0.184. Glenn Creek is a second-order stream for 88% of its total length; the head waters extend up to nearly 400 m. The channel gradient is fairly uniform throughout the lower 1300 m of its course, averaging 0.049 (Dingman 1971). A complete description of the geologic setting of the Glenn Creek watershed is given by Dingman (1971).

The distribution of vegetation types is closely associated with the distribution of permafrost (Figure 1, Table 1). Birch-aspen-white spruce stands, primarily on south-facing slopes, cover 30% of the basin. This vegetation type generally occurs on moderately well-drained silt loams covered with up to 15 cm of thin organic soil. Permafrost is not normally present. The remainder of the

watershed (70%) consists of black spruce stands on the north-facing slopes and valley floors underlain by permafrost. These areas generally consist of poorly drained mineral soils overlain by a thick (30-45 cm) organic mat composed of three primary sublayers, each 10-15 cm thick. The living surface layer is predominately sphagnum moss intertwined with various surface plants such as blueberries, cranberries, labrador tea, sedges, and lichens. The middle layer is denser than the surface layer and is composed primarily of dead sphagnum moss. The bottom layer is much denser and is composed of peat and decomposing vegetation (Santeford 1979). The location of the permafrost table occurs at depths from the organic mat/mineral soil interface (Santeford 1979) to 1 m below the surface (Dingman 1971).

The climate of the area is continental, characterized by large diurnal and annual temperature variations, low annual precipitation, low cloudiness, and low humidity. The Fairbanks records show January as the coldest month with a mean temperature

FIGURE 3 Precipitation at lysimeter (top), moss-filled lysimeter runoff (middle), and Glenn Creek discharge for summer 1979. The precipitation and lysimeter plots are of accumulated volumes for individual events. Runoff for Glenn Creek is shown as discharge computed over the entire 2.25 km² watershed area. A break in the continuous line indicates periods of missing data where timing of runoff is unavailable; dashed lines show total volumes over the indicated time interval.

of -24.4°C, and July as the warmest month with a mean of 17.1°C. The annual precipitation at Fairbanks averages 285 mm, half of which occurs during the months of June, July, and August (U.S. Department of Commerce 1980). The 1979 summer (May-September) precipitation at Fairbanks was slightly below the mean summer precipitation of 175.5 mm (Haugen et al. 1982).

MEASUREMENTS

Beginning in 1978, stream flow has been measured at the outlet of the basin with a 22.9 cm Parshall flume and F-1-type water level recorder. In the summer of 1979, two lysimeters, each 1.22 m by 2.44 m, bounded on both the bottom and sides, were monitored in the permafrost area with a slope tangent of 0.22, slightly higher than the average ground slope of the basin (Figures 1 and 2). The lysimeters were constructed in September 1978, near the end of the thaw season when the thaw zone was approximately at the organic mat/mineral soil interface. One lysimeter was filled with the in-situ organic soil (moss). The adjacent lysimeter was left empty and functioned as a precipitation gauge. A drain system ran from each lysimeter to a barrel equipped with an F-1-type water-level recorder that measured runoff as a volume.

The available data for the 1979 summer season are plotted in Figure 3. The runoff from the empty lysimeter (precipitation) and the moss-filled lysimeter are shown as accumulated runoff for each event. Runoff at Glenn Creek is shown as discharge in mm/day computed over the entire 2.25 km² watershed. The results of selected moss-filled lysimeter measurements and the Glenn Creek data are shown by event in Table 2. The hydrologic response (HR)

ratio was computed as the ratio of total runoff volume to total precipitation. The moisture deficit (MD) on the moss-filled lysimeter was computed indirectly as the difference between precipitation received and runoff measured. The runoff volumes of Glenn Creek for individual storm events were separated by plotting the recession discharges vs. time on semi-logarithmic paper and extending the recession curve to an assumed base flow by straight-line extrapolation (i.e. recessions were assumed to follow a simple exponential decay [Dingman 1971]). The beginning of a runoff event was measured from the initial apparent streamflow response; that is, the time at which the water level first began to rise. The two largest events recorded on the lysimeters are replotted in Figures 4 and 5 as total accumulation of runoff over the time periods indicated.

DISCUSSION OF LYSIMETER DATA

The summer 1979 measurements indicate that the response time of the moss-filled lysimeter was very fast, as shown in Table 2 and Figures 4 and 5. Runoff from the moss-filled lysimeter began within one hour of the start of the precipitation in all measured events. It appears that, based on timing of runoff alone, water percolates through the organic mat and moves downslope well before the total moisture deficit of the mat is satisfied. This is also confirmed by inspection of the HR ratios and MD values shown in Table 2. In storm events 1 and 2 (Figure 4), 9.6 mm of precipitation produced 2.4 mm of runoff, resulting in an HR ratio of 0.25 and indicating 7.2 mm of water was retained to satisfy the moisture deficit. In addition, little drainage occurred after the precipitation ended. Event 2 occurred 6 hours later, and had an HR ratio of 0.47 and an MD of 7.4 mm. Since the second event resulted in an additional moisture retention of 7.4 mm, it is apparent the first event did not fully saturate the moss layer, although the higher HR ratio does indicate that the antecedent moisture conditions resulted in less retention of the percolating water.

Events 3a through 3c (Table 2, Figure 5) had greater intensities, larger precipitation volumes, and occurred in such close succession (14 hrs) that the moss-filled lysimeter did not completely drain between storms. The runoff volumes of events 3a, 3b, and 3c have been separated based solely on the timing of precipitation, as shown in Table 2.

FIGURE 5 Precipitation and runoff from moss-filled lysimeters between July 4 and July 16, 1979 (precipitation and runoff read on same scale).

Separation of runoff events in this way neglects the long-term drainage that did occur, but further separation was impossible without using subjective techniques of hydrograph separation. As a result, the HR ratios are slightly lower and MD values slightly higher than would be computed using the total runoff, and should be considered limits to these values.

Event 3a followed a pattern similar to Event 1 with a high percentage of moisture retained by the moss, a response time of one hour, and runoff apparently occurring before complete saturation of the moss layer. Event 3b was a long intense rain-storm resulting in more than 59% of the precipitation running off and moisture retention approaching 22 mm. Exceedance of the water-holding capacity of the moss-filled lysimeter is indicated, since the rate of runoff equals the rate of precipitation on July 6, as shown by the nearly equal slopes of the runoff accumulation curve and the precipitation accumulation curve (Figure 5). Event 3c, occurring 14 hours later, also resulted in a high HR ratio (>0.57) and a low MD value (<5 mm). Drainage of the moss-filled lysimeter continued for nearly 6 days with an additional runoff of 3.6 mm. Event 3d added 0.8 mm precipitation about midway through this drainage period, but little detectable change in the runoff accumulation curve was observed (Figure 5). Parameters for the overall period, event 3 in Table 2, are shown as limiting values due to an incomplete precipitation record after July 11. Since more precipitation occurred than was recorded, the HR ratio of 0.55 is a maximum and the MD value of 36.2 is a minimum for the total period shown for event 3.

Since the moisture deficit (MD) is computed as the difference between precipitation input and drainage from the moss-filled lysimeter, losses to evapotranspiration would also be included in the moisture deficit value. During long periods of drainage the moisture deficit may, therefore, be overestimated. Pan evaporation at the University of Alaska (14 km south) was 22.1 mm for 4-11 July 1979 (U.S. Department of Commerce 1979). The actual rate of evaporation from the moss is unknown.

Event 7 was of low volume, 1.1 mm, following a dry period in excess of 10 days, and produced no runoff from the moss-filled lysimeter. Event 8 was also of low volume (2.5 mm) but produced 0.4 mm of runoff for an HR ratio of 0.16 and an MD of 2.1 mm. Drainage continued for nearly 7 hrs after the end of the precipitation event. For Event 9, only the beginning time and the precipitation and runoff volumes from the lysimeters were recorded. The HR

ratio of 0.61 was the highest recorded for the summer.

The same lysimeters were monitored during the 1980 snowmelt runoff season, as has been previously reported by Kane et al. (1981). The results from that study indicated that of an initial snowpack of 69.9 mm, 21.1 mm were lost to sublimation and evaporation, 24.9 mm were measured as runoff from the moss, and 23.9 mm were retained by the moss. Snowmelt runoff of 5.9 mm had occurred on the empty lysimeter over a 4-day period before runoff first appeared on the moss-filled lysimeter. Assuming that the rate of snowmelt was equal on both lysimeters, the delay in runoff from the moss-filled lysimeter can be attributed to several factors. A portion of the initial snowpack meltwater supplied heat to the organic mat, raising the temperature to the melting point, somewhat analogous to satisfying the cold content of the snowpack. No quantitative data are available for the amount of heat required from the meltwater. The time delay can also be attributed to dessication of the organic mat over the long, cold winter. Santeford (1978, 1979) has reported a redistribution of moisture from the organic mat to the overlying snowpack ranging from 19 to 23 mm over the winter season. Examination of the data from Kane et al. (1981) indicates that only a portion (5.9 mm) of the initial snowmelt was reabsorbed before percolation through the moss layer resulted in measurable runoff. The noteworthy point is that runoff from the moss-filled lysimeter began after only one-fourth of the total moisture deficit of the organic mat had been satisfied.

In previous lysimeter studies on permafrost areas, reported by Santeford (1979), a similar installation was used, but the lysimeters were installed without any slope. Santeford's data show a delayed response in runoff from the moss-filled lysimeter. A model was proposed based on the assumption that no drainage would occur until the water-holding capacity of the moss had been satisfied, at which point all incoming precipitation would percolate through the moss. The data reported here do not support such a model for the sloping portions of the watershed. In fact, the data indicate that the organic mat has a high unsaturated hydraulic conductivity, which results in rapid percolation of precipitation even when a large moisture deficit exists. The concept of a threshold water-holding capacity does not seem to apply. The data suggests that the moisture retention of the moss is a function of precipitation intensity and duration, but the limited data set prohibits any quantitative analysis.

Comparison with Glenn Creek

The HR ratios for Glenn Creek are also shown in Table 2 for the available record. These values fall on the low side of the range reported by Dingman (1971) for Glenn Creek for the summers of 1964-1967 and Haugen et al. (1982) for Caribou and Poker Creeks for the summer of 1977-1979. The fast response times agree with observations made in previous studies (Dingman 1971, Haugen et al. 1982).

The apparent discrepancy of the HR ratios between the lysimeter data and the watershed data can be attributed in part to the short travel distances in the lysimeter compared to travel

distances in the watershed. The low HR ratios for the watershed can also be partially explained by the findings of Kane et al. (1978, 1981) and Slaughter and Kane (1979) that nonpermafrost areas contribute virtually no near-surface runoff during the snowmelt or summer seasons because the rate of infiltration exceeds the rate of moisture input. Luthin and Guymon (1974) indicated that the potential evapotranspiration from the birch-aspen forests of interior Alaska (nonpermafrost areas) exceeds the normal summer rainfall and that contribution to baseflow from these areas should be negligible. In the case of Glenn Creek, where 30% of the watershed is nonpermafrost, the runoff-contributing area can be reduced from 2.25 km² to 1.6 km², which raises the computed HR ratios slightly (Table 2). The bounded moss-filled lysimeter, which allows no subsurface inflow, may be considered representative of the driest parts of the watershed; that is, those parts of the watershed that are fully drained. Assuming uniform precipitation (Dingman 1971) and evapotranspiration throughout the watershed, the lysimeter should, therefore, be representative of the areas with the highest moisture deficit and the lowest hydrologic response ratio. The measurements at Glenn Creek show that the overall watershed hydrologic response is much lower than that in the moss-filled lysimeter. This lends support to the suggestions by Dingman (1971) and Kane et al. (1981) that only portions of the watershed area contribute to overland flow (shallow subsurface flow in the organic mat) and that the partial- and variable-source-area concepts of streamflow generation are applicable to interior Alaska.

SUMMARY AND CONCLUSIONS

An analysis of data on lysimeter runoff from permafrost-associated organic soils indicates that response time is short, drainage of saturated soils is prolonged, and runoff from slopes occurs before the total moisture deficit of the soil is satisfied. Although the slope of the lysimeters was near the average slope of the basin and they were isolated from subsurface inflow, the hydrologic response to storm events was much higher than that computed from the total watershed or from the permafrost areas only. The indication is that large portions of the watershed, including permafrost areas, do not contribute to streamflow.

The implications that runoff is produced from moisture-deficit soils and that partial watershed areas contribute to streamflow are critical in watershed modeling. Clearly, further studies are required to understand the relationship between the flow of water through organic soils and the moisture content of the soil. Lysimeter studies combined with observations of where in the soil profile down-slope movement of water takes place may provide some insight to the processes of streamflow generation in permafrost areas.

FROST HEAVE OF SALINE SOILS

E. J. Chamberlain

U.S. Army Cold Regions Research and Engineering Laboratory
Hanover, New Hampshire 03755 USA

Theories of ice segregation and frost heave processes in saline soils are briefly examined and modified to explain observations made on clay and sand soils frozen under laboratory conditions. Seawater was observed to reduce the rate of frost heave by more than 50% for both soil types and to dramatically reduce the size of ice lenses. The effect of seawater is to cause the formation of a thick active freezing zone with many ice lens growth sites, each with its own brine concentration. Unbounded brine-rich soil zones between ice lenses are identified as potential zones of low shear strength.

An understanding of the frost-heave and ice-segregation behavior of soils that contain saline pore water is important to the development of off-shore petroleum resources in the Beaufort Sea. Understanding the freezing behavior of saline soils is also important to the artificial ground freezing industry. Unfortunately, little is known of ice segregation processes in saline soils that would allow design for frost heave and for changes in physical and mechanical properties.

Mahar et al. (1982) reported a modified form of the Berggren equation to predict frost penetration in saline soils where little or no frost heave occurs. This is important for determining where potential failure planes may occur in artificial islands. If significant amounts of ice segregation and frost heave occur, however, this method may overpredict the depth of freezing. In addition, the potential failure plane may not be forced below the region of freezing as commonly assumed. Partially frozen brine-rich zones within frozen layers may occur and they must also be considered as potential failure zones. A good example of this type of problem was recently observed at a ground freezing site (Maishman, personal communication) where, after excavation, a brine-rich clay layer was observed to slough back to the freezing pipes. Inspection of the site showed that the soil between ice lenses had little ice bonding and thus provided little strength for supporting the excavation.

Inspection of borehole logs obtained by Osterkamp and Harrison (1979) on Reindeer Island in the Beaufort Sea reveals that the occurrence of ice and ice bonding is sporadic and unpredictable, even though temperatures were below the freezing point of seawater.

This paper presents the results of a series of laboratory freezing tests on two soil types saturated with seawater. The freezing behavior is compared with freezing tests on the same soil types saturated with distilled water. Finally, an explanation for the unique freezing behavior of saline soils is offered.

FREEZING PROCESSES IN SALINE SOILS

The freezing of soils that contain saline pore water solutions is a complex process, due to the

soluble salts in the pore water fluid. The effects of salts on freezing behavior extend well beyond simply lowering the freezing point. Salts are excluded from growing ice crystals and are concentrated in the adjacent pore fluids, so that ice segregation temperatures are lowered and additional sites for ice nucleation form at or near the original ice segregation temperature.

Hallet (1978) suggested that ice tentacles reach out from a morphologically complicated interface. Domains of solute-rich solutions can become isolated from the unfrozen pore-water solutions and eventually become trapped in solidly ice-bonded material. He suggested that significant solute partitioning will accompany frost penetration in frozen ground, with lower bulk concentrations occurring in ice-bonded layers, and increased concentrations of salt occurring in unfrozen soils beneath a growing ice lens. He further stated that constitutional supercooling in soils will lead to a situation where ice will nucleate and grow in a zone ahead of and separate from the freezing front.

Sheeran and Yong (1975) suggested that ice growth in pores that contain salt solutions requires progressively reduced temperatures because the increased salt concentration due to brine exclusion lowers the freezing temperature of the remaining adjacent pore water. Only partial freezing occurs at the freezing front. Substantial phase change may occur up to a meter behind the frost front as cooling continues, depending on the magnitude of the thermal gradient.

Mahar et al. (1982) concluded that the freezing front progressing through saline saturated soil is characterized by a transition zone of partially frozen soil grading from isolated ice crystals to ice-bonded soil. Continued ice growth requires progressively reduced temperatures. Because of the irregular shape of soil grain boundaries and the complex heat transfer pattern in a pore space, isolated brine pockets develop that may not freeze.

The situation in freezing saline soils is somewhat analogous to the frozen fringe concepts of Miller (1978) and Konrad and Morgenstern (1981). The hydraulic conductivity of the frozen fringe controls the availability of water to growing ice lenses. In the case of saline soils, however, the frozen fringe can be very thick, and ice accumulation probably occurs throughout the zone.

EXPERIMENTAL STUDIES

Two frost-susceptible soils, Dartmouth sand and Morin clay, were selected for this study. Dartmouth sand is a well-graded granular material containing numerous fines. The Morin clay material is classified as a clay of low plasticity. The properties of each of these materials are given in Table 1.

Replicate specimens of both of these materials were prepared using distilled water and seawater solutions. The samples were compacted in layers in 150-mm-diameter multiring Plexiglas cylinders, 150 mm high, lined with rubber membranes. The specimen properties are shown in Table 2. After compaction, the test specimens were saturated with the appropriate water solution under vacuum.

Calibrated thermocouples were inserted at 25-mm intervals through the sides of the rings to monitor the progress of freezing. The appropriate distilled water or seawater solution was made freely available through a porous stone at the base of the sample. Cooling plates connected to refrigerated circulating baths were placed at the top and bottom of each sample, and the entire assembly was placed in an insulated box in a cold room with a 0°C ambient temperature. A small surcharge of 24 kPa was placed on top of each sample.

Freezing was accomplished in three stages: (I) constantly decreasing boundary temperatures; (II) fixed boundary temperatures; and (III) rapidly decreasing boundary temperatures.

During Stage I, a temperature gradient of approximately 0.025°C/mm was propagated downward through the test specimens at a frost penetration rate of approximately 1.5 mm/hr until the zone of freezing was within the middle 50 mm of the test specimen. During Stage II, the boundary temperatures were held fixed, imposing the same temperature gradient for at least 100 hr. Finally, in Stage III, the samples were frozen rapidly to the bottom. The purpose of this freezing procedure was to establish frost heave and brine exclusion characteristics under a constant rate of frost penetration, then to

force the growth of ice lenses and the exclusion of salts, and finally to trap the excluded brine for further analysis.

PRESENTATION AND DISCUSSION OF RESULTS

Four freezing tests were conducted on each of the clay and sand materials, two each for the distilled water and seawater solutions. Typical results for each of the soils and pore water solutions are illustrated in Figures 1 through 4. Individual test results are discussed below.

Morin Clay

The Morin clay samples saturated with distilled water heaved rapidly at nearly 12.5 mm/day during Stage I (Figure 1). The frost-heave rate during Stage II of freezing gradually slowed to approximately 2 mm/day. Many small ice lenses developed during Stage I (Figure 1), and a very large ice lens, nearly 50 mm thick, developed during Stage II. The growth of the ice lens during Stage II was shut off by the depletion of the water content in the unfrozen zone below to the plastic limit w_p .

The frost-heave rate for the Morin clay saturated with seawater was 60% lower than that for the distilled water (Figure 2). During Stage I of freezing, the heave rate for the seawater was approximately 4.5 mm/day; it fell below 1 mm/day during Stage II. No large ice lenses were observed to form during either of these stages. Water contents were limited to 50% in the ice-lensed zone (vs. nearly 400% for the distilled water case), and to 35% in the zone frozen rapidly during Stage III. Salinities were considerably partitioned by the freezing process, being reduced to as little as two-thirds of the original value (34.6%) in the ice-lensed zone and increased by nearly 25% in the zone beneath the active ice lens growth. It should be noted that the salinities were determined for 15-mm-thick slices and represent bulk salinities of the soil, ice, and unfrozen water system. Salinity partitioning within smaller elements of each slice was not determined.

Dartmouth Sand

The Dartmouth sand froze with a 50-mm zone of fine- to medium-size ice lenses (Figure 3), most of which formed during Stage I of freezing. The fixed boundary conditions of Stage II could not induce the growth of large ice lenses. The frost-heave rate during Stage I was approximately 8 mm/day, but it fell to nearly 2 mm/day during Stage II.

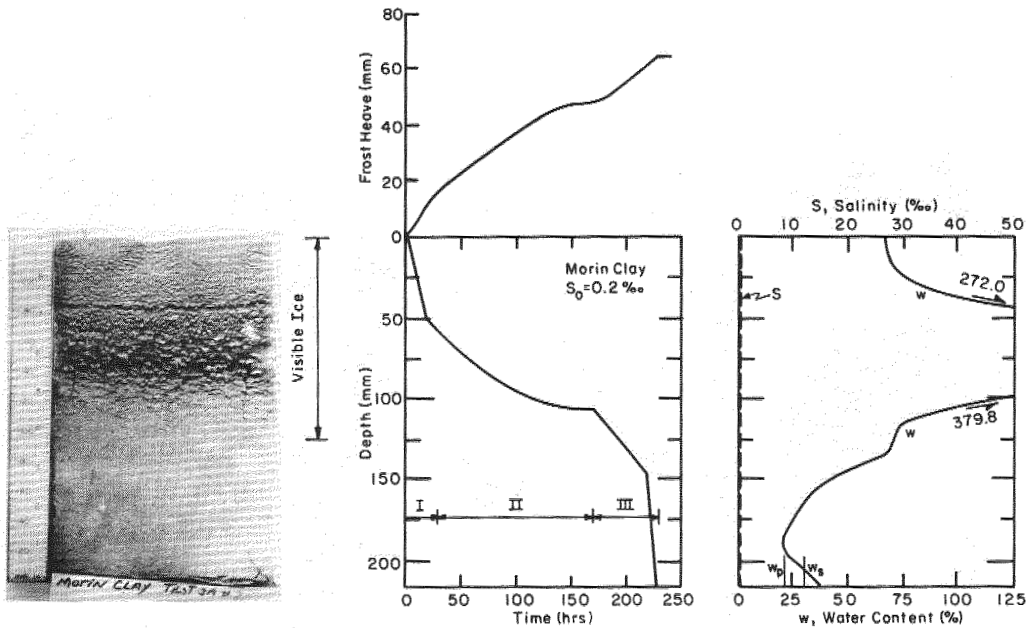

FIGURE 1 Freezing test results for Morin clay saturated with distilled water. Natural salinity S_0 is 0.2%. Plastic limit water content w_p and saturation water content w_s are shown for comparison.

FIGURE 2 Freezing test results for Morin clay saturated with seawater. Initial salinity S_0 is 34.6%.

Water contents in the visible ice region were as much as 60%, whereas in the zone rapidly frozen during Stage III they were reduced to less than the original saturated water content of 21%.

Addition of the seawater solution to the Dartmouth sand markedly reduced the frost-heave rate and changed the ice segregation characteristics as it did with the Morin clay. The heave rate during Stage I was less than 3.5 mm/day and it fell to less than 0.5 mm/day during Stage I (Figure 4). Little visible ice was evident. The maximum water content

was 30%, which indicates that some ice segregation occurred (the initial saturation water content was 21%). The water content in the rapidly frozen zone formed during Stage III was only slightly above the initial water content, which indicates that little ice segregation occurred there.

The salinity profile (Figure 4) is partitioned to approximately 85% of the original salinity ($S_0 = 35.7\%$) in the upper portions frozen during Stage I and the early part of Stage II, and increases to 120% of S_0 in the region frozen during Stage III.

FIGURE 3 Freezing test results for Dartmouth sand prepared with distilled water. Natural salinity S_0 is 1.2%.

FIGURE 4 Freezing test results for Dartmouth sand prepared with seawater. Initial salinity S_0 is 35.7%.

CONCEPTUAL CHARACTERIZATION OF THE EFFECTS OF SALTS ON FROST HEAVE

A few explanations for the effects of salts on frost heave in soil materials were briefly reviewed earlier in this paper. A refinement of these explanations is suggested to account for the reduced ice segregation potential of saline soils and to explain the apparent simultaneous formation of several ice lenses witnessed by Mahar et al. (1982) and shown in the recent freezing tests.

As Hallet (1978) suggested, the solute concentration in saline soils is partitioned by freezing, with solutes being rejected to the surface of the growing ice lens. A schematic diagram of the freezing process is shown in Figure 5. Ice first nucleates when the temperature of the saline pore water T_w falls below the initial equilibrium freezing temperature T_{eq}^0 (Figure 5a). As T_w

is lowered with time, the ice lens grows, excluding salt into the unfrozen zone below while trapping some brine within the ice.

A second ice lens formation site develops (Figure 5b) when T_w falls below the equilibrium freezing temperature beneath the brine concentration. Ice will continue to grow at the first site at progressively reduced temperatures, concentrating salts in the unfrozen soil layer between the two ice growth sites until the hydraulic conductivity of this layer is insufficient to meet the demand. As T_w continues to be lowered, a second brine concentration forms and a third ice growth site develops below it (Figure 5c). Continuation of this process will result in the growth of many ice lenses concurrently. Growth of the uppermost active ice lens will stop when water is no longer available.

The average equilibrium freezing temperature for all the equivalent moisture within the frozen

FIGURE 5 Schematic diagram of ice segregation process in saline soils. (a) At time zero (t_0), the pore water temperature profile is T_w and a thin soil layer has frozen; (b) at time t_1 , an ice lens is growing and a freezing point depression bulb has formed beneath it due to the exclusion of salts. The segregation freezing temperature at the first ice lens growth site decreases because of the brine concentration, and a second ice nucleation site forms; (c) at time t_2 , a third ice nucleation site has formed below the freezing point depression bulb formed by the second ice lens; (d) the process continues at time t_3 , with many ice lens growth sites. Ice lens growth at the original nucleation site is shut off by reduced hydraulic conductivity.

zone is higher than the initial condition T_{eq}^0 because of the net exclusion of brine. The equilibrium freezing temperature within the soil elements is lower than T_{eq}^0 because of brine concentrations in the unfrozen water.

The growth of large ice lenses is restricted by this process because the many small ice lenses and entrapped soil layers lower the hydraulic conductivity within the active freezing zone. Furthermore, the increasing concentration of salts near each ice lens growth site requires progressively lower temperatures to continue growth, whereas progressively lower temperatures reduce the hydraulic conductivity. The flow of water to the uppermost growing ice lens is thus shut off before the lens can develop significant thickness.

FURTHER DISCUSSION OF RESULTS

The water content profiles in Figures 1 through 4 give some evidence of the reduced hydraulic conductivity of the freezing zone in saline soils. For Morin clay prepared with distilled water (Figure 1), the water content in the soil below the zone of high ice segregation has been reduced to the plastic limit water content, which is the practical limit to which a soil can be desiccated by the freezing process (Chamberlain 1981). For the case of the saline Morin clay (Figure 2), the water content in

the soil beneath the active ice segregation zone actually increased over the initial saturated (w_s) value during the passing of the freezing front. This indicates that there is a tendency to desiccate the soil elements within the high suction zone of freezing in saline clay soils and to reduce the hydraulic conductivity there, whereas in the clay soil prepared with distilled water the highly desiccated zone lies below the active freezing front.

IMPLICATIONS

Under natural freezing conditions with very small temperature changes with depth, such as within islands in the Beaufort Sea, thick zones of active freezing can occur with alternating zones of ice-bonded and salt-enriched unbonded soils.

From an engineering design point of view, the reduced frost-heave susceptibility of saline soils is a positive factor. However, if the design of an artificial island is predicated on the development of the ice-bonded strength of the fill material, unfrozen zones with brine concentrations may cause weak zones to form above the freezing front.

Under artificial freezing conditions for construction purposes, unfrozen zones of brine-enriched soil can also occur, particularly in clay soils. These unfrozen zones can cause failure of a freeze-wall, even if they are only a few millimeters thick.

CONCLUSIONS

The frost-heave susceptibility of sand and clay soils is significantly reduced by saline pore water. Salts also dramatically reduce the ice lens size and decrease the segregation water content.

The effect of saline seawater on frost heave and ice segregation can be explained in terms of a thick active freezing zone with many ice lens growth sites, each with its own brine concentration. The thick active freezing zone reduces the hydraulic conductivity, and thus the rate of frost heave.

The brine concentrations can cause zones of unbonded soil to occur within an ice-bonded material. These zones of brine concentration can cause planes of low shear strength to occur in frozen structures. These potential failure planes must be considered by engineers designing artificial islands to resist ice forces or ground-freezing projects to stabilize excavation sites.

HOLOCENE TEMPERATURES IN THE UPPER MACKENZIE VALLEY DETERMINED BY
OXYGEN ISOTOPE ANALYSIS OF PEAT CELLULOSE

Stephen C. Chatwin

Agriculture Canada, Tanzania-Canada Wheat Project,
P.O. Box 6160, Arusha, Tanzania.

Oxygen isotope ratios in nonexchangeable plant cellulose extracted from samples of Sphagnum are positively correlated with the Mean Annual Temperature at their respective growth sites. Furthermore, the isotope ratio of aquatic plant cellulose is independent of the plant species. These results were used to extract a paleotemperature record, spanning the last 10,300 years from an Upper Mackenzie Valley peat core. Temperature does not appear to have been an impediment to permafrost aggradation in this area for the period of record. A comparatively cool climate between 10,000 and 7,000 years B.P. was followed by a warming trend between 6,000 and 5,000 years B.P. Cooling followed, reaching minimum Holocene temperatures approximately 3,500 years B.P. Preliminary results suggest this temperature was 3°-4° cooler than present day Mean Annual Temperatures. Steady warming since that date has resulted in widespread permafrost degradation. Present day temperatures are the warmest that have occurred during the Holocene for the area.

INTRODUCTION

Paleoclimatic information is vital in deciphering the history of permafrost aggradation and degradation in Sub-Arctic peat lands. Recent studies suggest paleotemperature data may be inferred from isotope analysis of plant cellulose. The natural deuterium and heavy oxygen contained in plant cellulose reflects the isotopic ratio of the water incorporated by the plant during synthesis of cellulose (Epstein et al 1976, Thompson and Gray 1977). Furthermore, variation in the ratios of heavy to light isotopes in meteoric water is largely a response to temperature changes at the site of precipitation, decreasing with mean annual temperature (Dansgaard 1964). It follows that the isotopic variations in plant cellulose may reflect the temperature of precipitation at the growth site.

The climatic significance of D/H ratios (Epstein and Yapp 1976) and $^{18}\text{O}/^{16}\text{O}$ ratios (Gray and Thompson 1976) have subsequently been demonstrated for tree rings grown in different climates. The technique was further applied to buried wood samples in an effort to examine late Wisconsin climates (Yapp and Epstein 1977).

This paper examines the isotopic relationship between climate and peat forming plants and then uses the technique, through analysis of a palsa core, to estimate paleotemperatures in the Upper Mackenzie Valley over the past 10,000 years.

METHODS OF ANALYSIS

Oxygen isotope analysis was conducted on 15 samples taken from a 3.5 m core of frozen peat that was collected from a palsa complex near Ft. Simpson, N.W.T. (latitude 61°28'N, longitude 120°55'E). The upper 1.5 m of the core was slightly decomposed, the lower 1.3 m was moderately decomposed, and the bottom 0.2 m was well decomposed. Seven isotopic analyses were conducted on the aquatic plant species presently

growing at the palsa site. Additional Sphagnum samples from various North and South American localities were supplied by D. Vitt, University of Alberta, and were also subjected to isotopic analysis.

Cellulose was extracted from the plant samples using a modification of a method described by Theander (1954). The method yields a greyish-white to light grey substance. An X-ray diffraction pattern of the substance reveals strong peaks in the range characteristic of alpha-cellulose. Following extraction, approximately 25 mg of vacuum dried sample is weighed into a nickel boat, placed under vacuum, then combusted in a reaction vessel at 1150°C for 1 hour (see Thompson and Grey 1977). The reaction produces a mixture of CO, CO₂, and H₂ gases. The H₂ gas diffuses through the walls of the reaction vessels, forcing the reaction to completion. After combustion, the gases are trapped in a silica gel maintained at liquid nitrogen temperature. The CO fraction is converted to CO₂ and C by sparking between platinum electrodes. The CO₂ fractions are combined and the yields measured manometrically. The yields averaged 90-95% of the theoretical predictions, indicating trace amounts of contaminant. All peat samples were run as replicates; if replicate results did not agree, a third sample was run. The precision of the replicate analysis was better than ± 0.4%. Isotope measurements were made on a 90° sector, 25 cm double collecting isotope ratio mass spectrometer. All isotope measurements are expressed as a value (‰) with respect to Standard Mean Ocean Water (SMOW).

Radiocarbon determinations were made by the isotope laboratory of Waterloo University. The samples received standard treatment, including washing with distilled water, removal of organic acids with NaOH, and removal of carbonates with HCl. The ages are corrected and given as years B.P.

RESULTS

Effect of Different Plant Species

Peat is usually composed of a variety of plant species. To compare the oxygen isotope ratios of individual peat forming species, cellulose from samples of all the major aquatic species growing at the palsa site was analyzed. The results (Table 1) show that within the limits of analytical error, all the species have very similar oxygen isotope values. This is a very convenient result, as it means cellulose from bulk peat samples can be analysed irrespective of species composition.

TABLE 1 Isotopic Composition of Modern Peat Forming Plants

Plant Species	^{18}O SMOW	$\pm 0.2\text{‰}$
<u>Sphagnum fuscum</u>	18.65%	
<u>Sphagnum recurvum</u>	18.51%	
<u>Drepanocladus</u>	18.37%	
<u>Carex aquatilis</u>	18.40%	
Carex (various spp.)	18.47%	
Duckweed	18.39%	
Mixture	18.48%	

Analysis of the Palsa Core

Results from replicate analysis of 15 samples from various depths along the frozen peat core are listed in Table 2. The isotopic results are plotted with respect to depth, together with a radiocarbon age-depth profile and an illustration of the peat stratigraphy (Figure 1).

TABLE 2 Peat Oxygen Isotope Results

Sample	Depth (m)	Replicates	^{18}O SMOW	Standard deviation
E 3-1	.05	3	16.80	.40
E 3-2	.20	2	17.02	.14

E 3-15	3.45	3	15.50	.41

The forest peat is a mixture of Ledum groenlandica leaves, Picea mariana needles,

Vaccinium spp. and Cladonia spp. Forest peat is presently forming subaerially on the frozen palsa surfaces. No isotopic measurements were made of the upper forest peat layer. The Sphagnum layer is very homogenous with only occasional twigs of Ledum. Present day Sphagnum bogs are only found in "thaw bogs" entirely surrounded by the palsa complex. Brown moss and sedge peat are typically found in the unfrozen fens and string fens surrounding the palsa. Aquatic peat includes well decomposed aquatic mosses, duckweed and algae as is found in open shallow ponds within both the palsa complex and the fens.

FIGURE 1 Change in oxygen isotope ratios of peat cellulose with depth of sample in the palsa. Five C-14 measurements provide time-depth control. Peat stratigraphic names are explained in the text.

In constructing the age-depth profile, rates of peat accumulation were assumed linear between dated samples. Peat accumulation began 10,380 years B.P., terminating approximately 400 years B.P. Results from analysis of the aquatic plants growing at the palsa site were used to extrapolate the isotope curve to the present day.

The oxygen isotope curve is characterized by relatively little variation throughout the profile. Isotopic values were approximately 3 ‰ lower between 10,000 and 7,000 years B.P. This was followed by a warming trend culminating between 6,000 and 5,000 years B.P. Minimum isotopic values are recorded between approximately 4,000 and 3,000 years B.P. Interestingly, this corresponds with a change in peat type that suggests temporary freezing of the bog. A gradual increase in the oxygen isotope ratios has occurred in the upper 1.5 m of the core, suggesting steady climatic warming. Plants growing at the palsa site have higher isotope ratios than any of the peat samples.

Calibration of the Isotope Curve

Before paleo-temperature interpretations can be made of the oxygen isotope fluctuations in the peat column, a temperature coefficient, linking temperature change to isotope change, must be found for peat cellulose. A temperature coefficient of $1.30/00$ $^{18}O/0C$ for Edmonton spruce (Gray and Thompson 1976) was found by comparing isotopic results from individual tree rings with modern temperature records. Unfortunately, peat cannot be calibrated in the same way, as it is impossible to separate yearly accumulations.

A method of deriving a temperature coefficient is to plot the $^{18}O/^{16}O$ ratio of plants from various locations versus the mean annual temperature at those sites.

FIGURE 2 The oxygen isotope ratio of *Sphagnum* and tree rings as functions of the mean annual temperature of their growth sites.

Sphagnum samples from a wide variety of climatic zones were analysed; the results are plotted against Mean Annual Temperature (average of last 5 years) in Figure 2. For some locations, *Sphagnum* samples were available from more than one bog; the range of results at these locations is plotted as a bar. On the same graph, oxygen isotope values of modern tree ring cellulose from various sites are plotted (P. Thompson, unpublished results). This data set includes the previously mentioned Edmonton spruce analyzed by Gray and Thompson (1976). The isotopic values from northern continental North America (Edmonton, Alberta; North Bay, Ontario; Fort Simpson, N.W.T.; Old Crow,

Yukon; and Coppermine, N.W.T.) are reasonably defined by the linear relationship

$$\delta^{18}O = 0.5T + 19.90 \quad (1)$$

The values for subtropical and tropical localities (Houston, Texas; Campinas, Brazil) fall significantly below this line, while values from a Pacific maritime area (Queen Charlotte Islands, B.C.) fall above the line.

DISCUSSION

The results summarized in Figure 2 establish that oxygen isotope ratios for peat cellulose increase as Mean Annual Temperatures increase. That is, the temperature coefficient is positive. The regression equation (1) cannot be used to directly infer paleo-temperatures, however. While Mean Annual Temperature is the prime determinant of the isotopic ratios of precipitation at a particular site, other factors such as thermal history of the air mass (Dansgaard 1964) the seasonality of the annual precipitation, and the evaporation and evapotranspiration rates (Epstein et al 1976) will locally alter the general temperature coefficient. This becomes evident with a comparison of Gray and Thompson's (1976) site specific temperature coefficient of $1.30/00/0C$ for Edmonton tree rings and the regression line of $0.50/00/0C$ connecting the various sites (Figure 2).

The parallel regression lines for tree rings and *Sphagnum* suggest that their temperature coefficients may also be similar. If $1.30/00/0C$ is a roughly valid coefficient for peat forming plants, then a minimum Holocene temperature of approximately 3-4°C colder than present day is indicated by the paleo-isotope curve (Figure 1) for the Ft. Simpson area. Considerably more work in controlled environment growth chambers is required before reliable temperature coefficients can be established.

Any large change in the humidity or evapotranspiration rate at the Ft. Simpson bog during the Holocene will also affect the paleo-isotope curve. In peatlands the humidity is always high, however, and calculated changes in evapotranspiration over a 3°-4°C temperature range are also very small. These effects therefore should not markedly change the shape of the curve (Figure 1). If enrichment due to increased evapotranspiration rates has occurred, the effect will be to overestimate Mean Annual Temperature.

Climate changes during the Holocene may have included changes in the seasonality of the annual precipitation. Such changes will alter the δ values in peat cellulose, which may or may not be related to the Mean Annual Temperature.

There is also a possibility that oxygen exchange occurred between the C=O bonds in the peat cellulose and percolating bog waters or with bacteria during decomposition. If such exchange did occur, the result would be to homogenize the isotope values in the peat. Experimental evidence (Gray and Thompson 1976, Epstein et al 1976,

Chatwin 1981) suggests that such exchange is very unlikely, as the C=O molecular bond is covalent and very strong. Furthermore, Yapp and Epstein (1977) found no evidence for isotope exchange having occurred in wood that was buried in wet soils for 11,800 years.

Holocene temperature trends indicated by the oxygen isotope curve are somewhat at variance with some paleoclimatic studies completed in the Mackenzie Delta area, approximately 1,500 km to the north. Here, there is reasonably strong evidence for mean summer temperatures having been higher than present day (Ritchie and Hare 1971, Mackay 1978). Others (Delorme et al 1977) have suggested very warm conditions in the early Holocene. This study indicates climatic warming beginning in the early Holocene, up to 5,500 years B.P.; however, the predicted mean annual temperatures are less than present day values. Part of this discrepancy may be due to previous investigators having examined changes in mean summer temperatures, whereas this study is concerned with mean annual temperatures.

Another possibility for this discrepancy is that in the early Holocene glacial meltwaters may still be contributing to the hydrology of the peatland. This reservoir of light δ value water would result in peat isotope ratios lower than expected from the mean annual temperature.

CONCLUDING STATEMENTS

Oxygen isotope analysis of peat cellulose may be a powerful tool in deciphering the history of permafrost aggradation and degradation. Analysis of a peat core from Ft. Simpson in the Upper Mackenzie Valley suggests that temperature has not been an impediment to permafrost formation during most of the Holocene. There is no evidence for Mean Annual Temperatures warmer than present day during the past 10,000 years. Other factors, in particular the local hydrology or vegetative cover, may be responsible for the limited evidence for permafrost in this area in the early Holocene. Maximum permafrost development probably occurred approximately 3,500 years B.P. when minimum Holocene temperatures were experienced in this area. Preliminary estimates are that Mean Annual Temperatures were approximately 3°-4°C colder than present day. The recent widespread degradation of permafrost is the result of steady climatic warming, in particular over the past 400 years.

ACKNOWLEDGMENTS

This project was funded by the Boreal Institute for Northern Studies and the Geological Survey of Canada. John Gray and Peter Thompson, University of Alberta, provided laboratory facilities and valuable discussion.

INFLUENCE OF PENETRATION RATE, SURCHARGE STRESS,
AND GROUND WATER TABLE ON FROST HEAVE

Chen Xiaobai, Wang Yaqing, and Jiang Ping

Lanzhou Institute of Glaciology and Cryopedology, Academia Sinica
People's Republic of China

To protect structures in permafrost and seasonal frost regions from damage, the authors studied the factors that influence the frost-heave process by conducting experiments on various types of soils, such as loess, clayey loam, loam, sandy loam, and sand, both in the laboratory and in situ. The results showed that the frost penetration rate, surcharge stress, and groundwater table are important factors, in addition to soil particle size. Two critical penetration rates divide the extent of the frost-heave ratio into intensive, slow, and no changing stages, and indicate whether ice will be segregated in the soil. Under surcharge stress, because the freezing point of the soil water is lowered and the specific suction water ratio in the soil at the freezing front decreases, the heave ratio descends, as shown by Equation 7. The influence of the ground water table on frost heave of soils is obvious and must be considered in practice.

Protecting structures from frost damage is one of the important problems in cold regions, promoting the study of the factors influencing frost heave processes, such as particle size, frost penetration rate, surcharge stress and groundwater depth. Many investigators are engaged in these subjects (see references). In this paper all of the above factors, except particle size, are discussed.

TEST CONDITIONS

The experiments were conducted both in laboratory and in situ, including permafrost and seasonal frost regions.

In the laboratory, the samples were made of loess (Lanzhou), red clayey loam (Qingzang Plateau), loam (Zhangyi) listed in Table 1, and medium (for building) sand. The sample cell for the frost susceptibility test is made of plexiglass with a height of 13.0 cm, a top diameter of 11.6 cm and a bottom diameter of 11.0 cm. A permeable plate was put under each sample for water supply in open system. The cell was surrounded with a plastic foam insulator to ensure one-dimensional freezing. Under surcharge stress, besides above condition, the samples were tested in consolidation apparatus using a plexiglass cell with a height of 8.9 cm, a top diameter of 8.5 cm and a bottom diameter of 8.3

TABLE 1 Physical Properties of the Soil Samples

No	Soil Type	Location	Percent by weight for the following particle sizes (mm)						Liquid limit	Plastic limit

Figure 1. Frost heave ratio vs frost penetration rate.

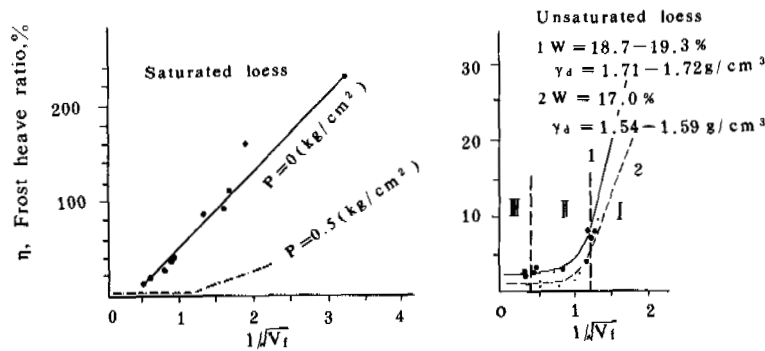

Figure 2. The relationship between frost heave ratio and frost penetration rate.

cm. A plexiglass tube with a diameter of 11 cm and a height of 120 cm was used to measure the redistribution of moisture along depth under various water tables during freezing.

The field work was conducted mainly in the Qilian Mts. (a permafrost region), and in the Zhangyi district (a seasonal frost region) with humus clayey loam, clay, clay loam, loam, sandy loam and fine sand etc. (some of which are listed in Table 1). The process of frost penetration, air and ground temperature, frost heave (by layer), ground water table, and moisture content along depth, etc were observed.

RESULTS AND ANALYSES

Frost Heave Ratio η and Frost Penetration Rate Vf

The results of our experimental research show that whether for saturated or un-saturated soil, and in laboratory or in situ including permafrost and seasonal frost regions, there is a good relationship between the frost heave ratio η and frost penetration rate Vf (see Fig. 1, where curve I is for saturated loess in an open system). The frost heave ratio decreases with the increase of the penetra-

tion rate, which can be expressed as follows,

$$\eta = K / V_f \quad (1)$$

where K=const. For unsaturated soil in the laboratory or in situ, because of water migration when frost penetrates, the moisture condition along the depth will vary slightly. So even though the curve shapes are similar, there are still some differences from that of the saturated case (see Fig. 1, curves I to IV).

If the relation between η and Vf is as shown in Figure 2, we may divide the development of frost heave ratio into three stages:

I. when $V_f \leq V_{f1}$, i.e. $(1/\sqrt{V_f}) \geq (1/\sqrt{V_{f1}})$, then $\eta = \eta_0 + \Delta\eta + c [1/\sqrt{V_f} - 1/\sqrt{V_{f1}}]$ (2)

II. when $V_{f2} \leq V_f \leq V_{f1}$, i.e. $(1/\sqrt{V_{f1}}) \geq (1/\sqrt{V_f}) \geq (1/\sqrt{V_{f2}})$, then $\eta = \eta' = \eta_0 + \Delta\eta [(1/\sqrt{V_f} - 1/\sqrt{V_{f2}}) / (1/\sqrt{V_{f1}} - 1/\sqrt{V_{f2}})]^3$ (3)

III. when $V_f \geq V_{f2}$, i.e. $(1/\sqrt{V_f}) \leq (1/\sqrt{V_{f2}})$, then $\eta = \eta_0$ (4)

For Lanzhou loess and red clayey loam, the relation between their frost heave rate

Figure 3. Frost heave rate vs frost penetration rate.

R and penetration rate V_f is shown in Figure 3. Comparing Figure 3 with Figure 2, we see that: Firstly, when $V_f < V_{f1}$, R consists of two parts, one is produced by freezing of pore water, another is produced by ice segregation. It rises rapidly with the increase of V_f . Secondly, when $V_{f2} \geq V_f \geq V_{f1}$, R also includes above two parts, but it decreases with the increase of V_f . Thirdly, when $V_f > V_{f2}$, R is only produced by freezing of pore water in situ and is proportional to V_f . Thus, there is no water migration in this section.

Frost Heave Ratio η and Effective Surcharge Stress P

It is known that according to the thermodynamic equilibrium principle the freezing point of soil water will be depressed when external pressure P and water potential P_w are raised, which is expressed by

$$\Delta T = T_0 (V_w P_w - V_i \Delta P_i) / L \quad (5)$$

where ΔT =the freezing point depression, °C
 T_0 =freezing point of pure water, °K
 V_w =specific volume of water
 ΔP_i =ice stress
 V_i =specific volume of ice

L =latent heat of fusion for water
 In an open system, $\Delta P_w = 0$ and ΔP_i equals the effective surcharge stress P. Based on the above equation, the relationship between ΔT and P for saturated loess was measured and can be expressed approximately by a linear equation,

$$\Delta T \approx 0.07P \quad (6)$$

In addition, when the effective surcharge stress rises, the density of soil will increase and the permeability will decrease. As a result, the specific volumetric suction of water ξ_w during freezing decreases (Figure 4). For saturated loess ξ_w can be expressed as follows,

$$\xi_w = \xi_{w0} \exp(-aP) \quad (7)$$

where ξ_{w0} is specific volumetric suction water when $P=0$, a =const.
 Because of mentioned above, the higher the surcharge stress in soil, the lower the water migration rate to the frost front will be. As a result, the heave will be lower. When the surcharge stress

Figure 4. ξ_w vs P of Lanzhou loess.

Figure 5. Frost heave ratio of saturated loess vs its surcharge.

reaches the shut-off pressure P_0 , there will be no water flow to the frost front, and thus no frost heave will be measured. When the stress P is greater than P_0 , the pore water at the front will be expelled during freezing. As shown in Figure 5, the shut-off pressure for saturated loess frozen in an open system is about 4.6 kg/cm² (for $V_f \approx 1$ mm/hr).

The semi-exponential relation between the frost heave ratio η or heave rate R and the penetration rate V_f is shown in Figure 6.

Figure 6. Frost heave ratio and rate vs surcharge.

It is obvious that the relationship for not only a saturated loess in the laboratory but also for a clayey loam in situ can be described as follows,

$$\eta = \eta_0 \exp(-bP) \quad (8)$$

$$R = R_0 \exp(-DP) \quad (9)$$

Above equations show that the frost heave of a foundation soil may be controlled by surcharge. Conversely, the normal frost heaving force acting on foundation can also be calculated if the given frost heave is known.

Frost Heave and Ground Water Table H_w

In addition to the water content of soil, the groundwater table is an important factor for evaluating the relative frost susceptibility of soil in open system. Some observations obtained at Zhangyi Station on the effect of ground water table are presented in Figure 7. It is shown that the heave ratio for a clayey soil increases rapidly as the groundwater table rises. With a rather deep water table, because the capillary rise in clayey loam is higher than that of sandy

Figure 7. Frost heave ratio η vs distance from ground water table to frost front H_w (Gansu).

Figure 8. Variation of water content and suction during freezing of a clayey loam (soil no. 3, Table 1). AF = after freezing. BF = before freezing.

loam, its heave ratio is larger. However, when the water table is rather shallow, the heave ratio of sandy loam will be larger because of its higher permeability. Zhu Qiang (1981) derived the following linear equation for evaluating the frost heave ratio of a silty loam with varying groundwater table H_w at a test canal in the Zhangyi district as follows,

$$\eta = 64.4 - 29.6 H_w \quad (10)$$

The redistribution of moisture with depth under various water tables during freezing was obtained in the laboratory and in situ. Figure 8 gives two examples for clayey loam (see Table 1, No.3) tested in the laboratory. It is shown that there is an intensive water migration zone beneath the frost front with a range of about 30 cm. Before freezing, the soil water suction at the same depth for different water table depths is quite different. However, after freezing, their suction forces near the frost front are nearly the same. As a result, the suction gradient for a shallow water table is much greater than for a deeper water table. This results in more water migration to the frost front and greater ice segregation for the shallow water table condition.

In addition, for the deeper water table, because the water can not be sufficiently supplied to the freezing front, the moisture content at the base of the frozen portion is almost always less than before freezing (see Figure 8).

CONCLUSIONS

1. Two critical frost penetration rates divide the development of the frost heave ratio into intensive, slow, and un-changing stages, and determine whether ice segregation occurs.
2. Under surcharge stress, the freezing point is depressed and specific volumetric suction water during freezing decreases. As a result, the frost heave ratio decreases exponentially with an increase of the surcharge stress.
3. Before freezing, the soil water tension at a given depth is much larger for a shallow water table than for a deeper water table. However, after freezing, the moisture tensions near the frost front are almost the same, thus causing much more water migrate to the freezing front under shallow water table condition.
4. Therefore, besides the particle size, the effect of frost penetration rate, surcharge stress, and groundwater table should be considered for evaluating the frost susceptibility of soil during freezing.

VERTICAL AND HORIZONTAL ZONATION OF HIGH-ALTITUDE PERMAFROST

Cheng Guodong

Lanzhou Institute of Glaciology and Cryopedology, Academia Sinica
People's Republic of China

Alpine permafrost cannot be classified into continuous, discontinuous, and island types, since no alpine permafrost is actually continuous. According to its stability, indicated by its thickness and the mean annual ground temperature, the permafrost on the Qinghai-Xizang Plateau should be divided into three zones: upper zone (extremely stable), middle zone (stable, substable, and transitional), and the lower zone (unstable and extremely unstable). The distribution of alpine permafrost shows latitudinal variation. The lower limit rises northwards to its extreme value at latitude 25°22'N, then descends as the latitude continues to increase. Data show that the elevation of the permafrost lower limit is related to the aridity of the area. A region with higher precipitation usually has more cloud cover, which reflects both outgoing and incoming radiation. North of about 40°N, the incoming radiation is less than the outgoing so that the main effect of the cloud cover is to heat the air, raising the alpine permafrost's lower limit; south of 40°N, however, the incoming radiation is greater than the outgoing, so the main effect of the cloud cover is to cool the air, lowering the permafrost's lower limit.

The permafrost above a certain elevation to the south of the permafrost southern boundary is called high-altitude permafrost, but the permafrost to the north of permafrost southern boundary is called high-latitude permafrost. There are many mountains and plateaus in China. The area of high-altitude permafrost in China is up to 1,732,000 km² which occupies 80.6% of the total permafrost area of China, and 74.5% of the total permafrost area of Northern Hemisphere.

Summarizing the recent data of high-altitude permafrost distribution reported from the whole world with special reference to the data of China, it has been found that there is an obvious three-dimensional zonation in permafrost distribution, i.e. vertical zonation, aridity or longitude zonation, and latitude zonation.

VERTICAL ZONATION

High-altitude and high-latitude permafrost are quite different in distributional pattern. There is an obvious vertical zonation in the distribution of high-altitude permafrost, therefore the projection of so-called "continuous permafrost" on plane is usually not continuous but isolated. Thus, according to the projections on plane, there are islands of "continuous permafrost," "discontinuous permafrost," and isolated permafrost (Figure 1). The ground temperatures and thicknesses of these permafrost islands are quite different. Under these circumstances, the division of permafrost into zones by using continuous coefficient and the names such as continuous, discontinuous, and isolated

are not convenient to high-altitude permafrost. On the other hand, the high-altitude and the high-latitude permafrost have common characteristics in origin. They all are the products of heat and mass exchange between the earth's crust and the atmosphere, and exist in a zone with a lower level of energy. Based on these features, and with special reference to the data of Qinghai-Xizang Plateau, a scheme for classifying high-altitude permafrost into zones has been suggested by using mean annual ground temperature as the main index as shown in Table 1.

The vertical permafrost spectra in various climatic regions are different. In continental regions where the mean annual air temperature near snow line is about -12°C (Daxue Shan, Qilian Shan), there are three zones. In subcontinental regions where the mean annual air temperature near snow line is about -8.5°C (Lenglong Ling, Qilian Shan), there are two zones, and in the maritime regions, the mean annual air temperature near the snow line is about -4°C (Guxiang, Tibet), as a result there is only one zone (Figure 2). On the other hand, where the base zone is the upper zone we have only one zone; where the base zone is the middle zone we have two zones; and where the base is the lower zone, we shall have three zones. Therefore, various combinations of elevation, latitude, and distance from ocean render different permafrost vertical spectra, so that the regional distribution of high-altitude permafrost could be better described than before by using the concept of permafrost vertical spectra.

TABLE 1 Classification of Permafrost of Qinghai-Xizang Plateau.

Name of the zones		Mean annual ground temperature (°C)	Thickness of permafrost (m)	Relationship between elevation of zone boundary (Y) and latitude (x)	Mean annual air temperature at lower limit (°C)
Upper zone	Extremely stable	-5.0	>170		
	Stable	-3.0 ~ -5.0	110 ~ 170	$Y_5 = 111.1 - 1.72x$	-8.5
Middle zone	Substable	-1.5 ~ -3.0	60 ~ 110	$Y_4 = 108.6 - 1.72x$	-6.5
	Transition	-0.5 ~ -1.5	30 ~ 60	$Y_3 = 106.2 - 1.72x$	-5.0
	Unstable	+0.5 ~ -0.5	0 ~ 30	$Y_2 = 104.2 - 1.72x$	-4.0
Lower zone	Extremely unstable			$Y_1 = 101 - 1.72x$	-2.0 ~ -3.0

LATITUDINAL ZONATION

The changes of timberline, snowline, boundary of mountain cold desert soil, and permafrost lower limit with latitude are quite similar (Niu Wenquan 1980; Cheng Guodong and Wang Shaoling 1982; Jiang Zhongxin 1982). By fitting the Gauss curve to the data of high-altitude permafrost lower limit in Northern Hemisphere (Table 2), the empirical correlation between lower limit of high-altitude permafrost (H) and latitude (ϕ) has been obtained as follows:

$$H = 3650 \exp[-0.003 (\phi - 25.37)^2] + 1428 \quad (1)$$

Tentative application gives satisfactory results (Figure 3). Different from those linear mathematical models obtained before, this function has an extreme value and a point of inflection. As indicated by it, starting from the equator, the permafrost lower limit rises with increasing latitude, and reaches its extreme value of 5078 m at the latitude of 25°22'N. Then it descends with increasing latitude. At the initial stage, the descending slope is steeper, and reaches its maximum at latitude 38°N, then becomes gentle with increasing latitude. These features of the function are closely related to the features of mean latitudinal distribution of earth's radiation budget. Starting from the equator, the incoming radiation also intensifies with increasing latitude, and reaches its maximum at about 25°N of latitude, then reduces with increasing latitude. The difference between incoming and outgoing

FIGURE 3 Comparison of permafrost lower lower limit in Northern Hemisphere between observed and calculated value.

radiation also reaches its maximum at about 25°N (Critchfield 1974) (Figure 4). The mean annual ground temperature of permafrost measured on Qinghai-Xizang Plateau has been divided into four groups with reference to the practical conditions on the plateau. Then these four groups of value have been correlated with elevation and latitude, which gives a fairly good result (Figure 5). Applying the linear

FIGURE 4 Mean latitudinal distribution of earth's radiation budget. (after Houghton)

 3. -1.5~-3.0; 4. -3.0~-5.0.

equations of Y_1 to Y_5 in Figure 5, we can roughly divide the high-altitude permafrost into zones by using elevation and latitude (Table 1). Making a comparison between the practical permafrost zones on Qinghai-Xizang Plateau and tentatively divided zones by using five equations of Y_1 to Y_5 , the results are satisfactory (Cheng Guodong and Wang Shaoling 1982).

ARIDITY ZONATION

Former research works have determined that the permafrost lower limit descends with increasing aridity (Haerberli 1978; Harris and Brown 1978; Qiu Guoqing et al. 1983). But the works on Qinghai-Xizang Plateau have arrived at a contrary conclusion: the permafrost lower limit descends with increasing precipitation. As an example, the following binary regression equation has been obtained for Qilian Shan Mountains.

$$H = 7789.5 - 121.3x + 8.3\omega \quad (2)$$

where: H is the elevation of permafrost lower limit (m);
 x is the latitude (degree);
 ω is the angle of precipitation continentality (degree),

$$\text{ctg}\omega = \frac{\text{annual precipitation (mm)} \times 10}{\text{elevation (m)}} = \alpha$$

$$\omega = \text{arcctg}\alpha$$

The correlation coefficient of equation 2 is $R=0.95$, and residual standard error $s=53.7$ (m). The results of checking computations are in Table 3, its accuracy is enough for use.

Equation 2 also indicates that the permafrost lower limit descends with increasing precipitation, which is contrary to the former conclusion. To this contrast, we try to explain as follows.

Based on the statistical analysis of meteorological data in Western China, the correlation between mean annual air temperature (T) and elevation (X_1), latitude (X_2), as well as precipitation (X_3) has been obtained.

$$T = b_0 + b_1X_1 + b_2X_2 + b_3X_3 \quad (3)$$

where: b — coefficient

The values of coefficient b in different latitude sections and corresponding correlation coefficients R and residual standard errors S are listed in Table 4.

Table 4 shows that the values of coefficient b_3 related to precipitation are positive to the north from 40°N , but negative to the south from 40°N . It means that to the north from 40°N the increase of precipitation makes the mean annual air temperature rise, but quite the contrary to the south from 40°N . The reason for this phenomenon is as follows. The region with more precipitation usually has more cloud cover which can reflect both incom-

TABLE 4 Values of Coefficient b in Different Latitude Sections

Latitude	Number of station	b_0	b_1	b_2	b_3	R	S
$\geq 44^\circ$	20	58.41	-0.42	-63.13	3.25	0.82	1.53
$\geq 42^\circ$	38	66.70	-0.58	-71.46	1.41	0.91	1.55
$\geq 40^\circ$	54	65.88	-0.57	-70.44	1.20	0.92	1.52
$40^\circ \sim 32^\circ$	55	59.60	-0.57	-62.02	-3.84	0.98	1.03
$38^\circ \sim 32^\circ$	39	67.32	-0.58	-73.87	-4.15	0.99	0.81
$36^\circ \sim 32^\circ$	19	70.04	-0.59	-84.75	-4.22	0.97	0.80
$34^\circ \sim 32^\circ$	11	82.88	-0.66	-94.23	-5.36	0.96	0.88

ing radiation to cool the air and outgoing radiation to heat the air. As shown in Figure 4, to the north from about 40°N , the incoming radiation is less than the outgoing, so that the main effect of the cloud cover is to heat the air, therefore the mean annual air temperature rises with increasing cloud cover or precipitation, correspondingly the permafrost lower limit rises. But south of 40°N , the incoming radiation is greater than the outgoing one, so that the main effect of cloud cover is to cool the air, thereby the mean annual air temperature descends with increasing cloud cover, correspondingly the permafrost lower limit descends.

Because the Qinghai-Xizang Plateau is situated south of 40°N , the permafrost

lower limit rises with increasing aridity. But the majority of other high-altitude permafrost are situated to the north of 40°N , therefore in these regions the permafrost lower limit descends with increasing aridity.

As mentioned above, the permafrost lower limit does not simply monotonously rise from continental to maritime regions, but changes as shown in Figure 6. South of 40°N , both the snow line and permafrost lower limit descend from continental to subcontinental climate, but the descending magnitude of the lower limit is less than that of the snow line; the snow line continuously descends from subcontinental to maritime climate, but the lower limit turns to rise with the increasing effect

FIGURE 6 Change of permafrost lower limit with aridity

a. to the south of 40°N ;

b. to the north of 40°N .

1. snow line; 2. permafrost lower limit.

of snow cover. North of 40°N , the lower limit rises from continental to subcontinental climate, which is against the changing trend of snow line; and the rising magnitude of lower limit increases with the increasing effect of snow cover from subcontinental to maritime climate.

DISTRIBUTIVE REGULARITIES OF HIGH ICE-CONTENT PERMAFROST ALONG QINGHAI-XIZANG HIGHWAY

Cheng Guodong and Wang Shaoling

(Lanzhou Institute of Glaciology and Cryopedology, Academia Sinica)

Investigations along the Qinghai-Xizang Highway show that in similar geomorphologic units, the lower the mean annual ground temperature, the better the development of high ice-content permafrost. In the same permafrost-temperature zone, the development of high ice-content permafrost has such an order in degree: the most in low mountain and hill regions, second in middle and high mountain regions, and the least in valley and plain regions. In the first region, the development of high ice-content permafrost on north-facing, gentle slopes and low parts of slopes is better than on south-facing, steep slopes and middle and upper parts of slopes; In the valley and plain regions, except the high plain with widespread lacustrine deposits, commonly the high ice-content permafrost does not usually develop well and only exists in swampy sections consisting of fine-grained soil and the backside of high terraces that have an adequate content of fine-grained soil and supply of suprapermafrost water. In the depression between fens, there is commonly high ice-content permafrost.

INTRODUCTION

High ice-content permafrost is a group term including rich-ice permafrost, saturated-ice permafrost and ice layer containing soils (Wu Ziwang 1982). Discussion in this article is restricted to depths of 0 to 1 m under the permafrost table.

The ice content of the permafrost relates to two groups of factors: first, geological-hydrogeological factors which mainly include grain size and suprapermafrost water, and second, thermophysical factors which may be expressed by mean annual ground temperature approximately (Vtyurin 1975). Generally speaking, when other conditions are equal, the lower the mean annual ground temperature, the more favorable the formation of high ice-content permafrost (Cheng Guodong 1982). Because the mean annual ground temperature obeys certain zonation laws, therefore the distribution of high ice-content permafrost also follows certain zonation laws. The high ice-content permafrost may exist in fine-grained soil having appropriate water content within the continuous permafrost zone, but it is only encountered in swampy fine-grained soil having humus within the sporadic permafrost zone.

The first group of factors is not zonal, but the second is. The combination of these two groups of factors in concrete geographical environments controls the regional distribution of high ice-content permafrost. This distribution is reflected in regular change of ice content of permafrost in various geomorphologic units and topographic positions.

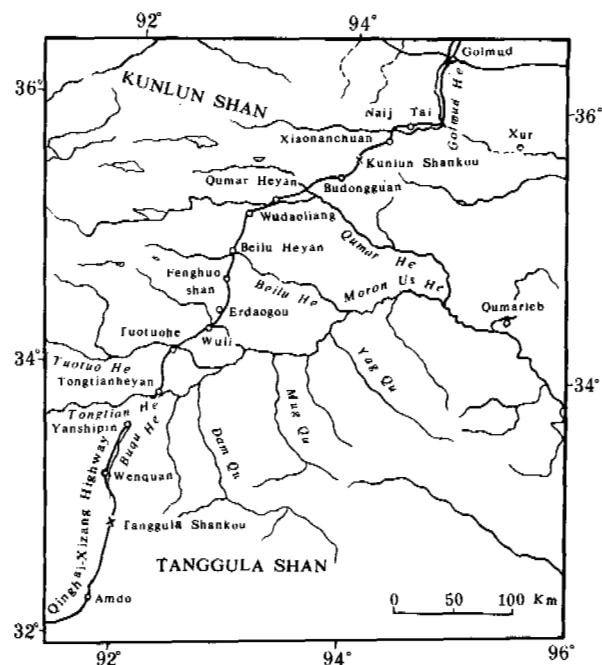

FIGURE 1 Location of the study area

DISTRIBUTION IN SIMILAR GEOMORPHOLOGIC UNITS BUT DIFFERENT PERMAFROST-TEMPERATURE ZONES

In the permafrost region along the Qinghai-Xizang Highway, three kinds of macro-geomorphologic units can be discerned, i.e. middle and high mountain regions, low mountain and hill regions, and valley

TABLE 1 Development of Ground Ice in Different Mean Annual Ground Temperature Zones*

Regions		Mean annual ground temperature (°C)	Thickness of permafrost (m)	Relative development of ground ice
I Middle and high mountain permafrost regions	I ₁ Near southern boundary of continuous permafrost	0 ~ -0.3	< 20	A little granular ice
	I ₂ Between 114 and 115 maintenance squads	-0.7 ~ -1.0	40 - 50	A little granular ice on south-facing slope; layered ground ice on north-facing slope
	I ₃ In Taorjiu mountain	-1.0 ~ -1.2	50 - 60	Thickness of ground ice up to 10 cm near permafrost table
II Low mountain and hill permafrost regions	II ₁ Near southern boundary of continuous permafrost	0 ~ -0.3	< 20	A small amount of ice
	II ₂ Around 114 maintenance squad	-0.6 ~ -1.0	30 - 50	Layered ground ice just below permafrost table, ice content 30-50%
	II ₃ Between 112 and 113 maintenance squads	-1.0 ~ -1.2	50 - 60	Layered ground ice

* After Wang Jiacheng et al., 1979.

and plain regions. When these three kinds of geomorphologic units belong to different permafrost-temperature zones, the development of ground ice in each zone is different in degree.

The development of ground ice in valley and plain regions can be illustrated by examples of Beilu He and Tuotuo He. The first terraces of Beilu He and Tuotuo He consist mainly of mudstone, marle, and siltstone of the Tertiary System. The first terrace of Beilu He lies in the zone with mean annual ground temperature at -0.5°C to -1.5°C , while the first terrace of Tuotuo He lies in the zone above -0.5°C . Drill hole CK 5 in the first terrace of Beilu He reveals that the thickness of ground ice layers below the permafrost table is 3-4 cm, and the ice content is 70-80%. Drill hole No. 6 in the first

terrace of Tuotuo He (mean annual ground temperature at -0.2°C) reveals that the permafrost is of net cryogenic structure at 2.5 to 3.4 m below permafrost table, and the volumetric ice content is only 10-20%. Obviously, when other conditions are equal, the ground ice in the valley and plain regions lying in the lower mean annual ground temperature zones forms better than in the higher mean annual ground temperature zones.

In both the middle and high mountains, and the low mountain and hill regions, this can be illustrated by the example of the continuous permafrost zone on the southern slope of Tanggula Shan (Table 1).

As shown in Table 1, the mean annual ground temperature decreases northwards, and the ice content of permafrost correspondingly increases.

* The kind of permafrost is determined by the total water content of 1 m permafrost just below the permafrost table.

DISTRIBUTION IN SIMILAR ZONES BUT DIFFERENT GEOMORPHOLOGIC UNITS

The ice content just below the permafrost table in the continuous permafrost zone is higher than in the sporadic permafrost zone. The distribution of various

kinds of permafrost in different geomorphological units from K139+00 to K693+00 along the Qinghai-Xizang Highway listed in Table 2.

From Table 2 we can see that, in the continuous permafrost region, the development of high ice-content permafrost is

highest in the low mountain and hill regions, second in the middle and high mountain regions, and lowest in the valley and plain regions. This is because there is an obvious vertical zonation of permafrost distribution on the Qinghai-Xizang Plateau and precipitation increases with rising elevation. This makes the mean annual ground temperature lower and precipitation greater in the low mountain and hill regions. Moreover the solifluction deposits are well developed in this region and provide suitable fine-grained soil, and moisture conditions for syngenetic ice. Therefore, the low mountain and hill regions have high proportions of high ice-content permafrost. Although middle and high mountain regions offer the lowest mean annual ground temperature, which is favorable to the growth of ground ice, and more precipitation, the proportion of high ice-content permafrost is less than in the low mountain and hill region because of thinner surficial deposits and coarser soils, which are unfavorable for the growth of ground ice. The valley and plain regions possess the lowest proportions of high ice-content permafrost due to lower elevation, higher mean annual ground temperature, the thermal effect of rivers, and wide-spread coarse-grained surficial deposits. All are unfavorable for the growth of ground ice. Only in the high plains and in some basins consisting of lacustrine deposits, which possess thick deposits with much fine-grained soil, less thermal effect of rivers, and lower ground temperature, is the proportion of high ice-content permafrost high.

DISTRIBUTION IN SIMILAR GEOMORPHOLOGIC UNITS BUT DIFFERENT TOPOGRAPHICAL POSITIONS

Low Mountain and Hill Region

Orientation of slope. In the same low mountain and hill region, where other conditions are equal, the south-facing slope has more radiation, higher ground temperature and evaporation. Thus the ground ice on the north-facing slopes forms better than that on the south-facing slopes. E.g. the ground ice on the north-facing slopes of Dongdagon in Fenghuo Shan possesses larger thickness and extent than on the south-facing slopes. But in margins of the continuous permafrost and the sporadic permafrost zones, it usually shows a difference in quantity and distribution of ground ice, i.e. there is high ice-content permafrost on the north-facing slopes but not on the south-facing slopes. For example, drill holes CK 116-5 and CK 116-6, situated to the north of Amdo, have the same elevation and reveal similar types of soils. CK 116-6, situated on a north-facing slope with more moisture and vegetation, reveals a soil profile as follows:

2.6 m, permafrost table; 2.6-2.8 m permafrost of net cryogenic structure; 2.8-4.4 m, permafrost of moderate to thick layered cryogenic structure with thickness of ice layer up to 15-20 cm. But CK 116-5, on a south-facing slope with rare moisture and vegetation, only reveals permafrost of massive cryogenic structure with no high ice content. Thus, because of different slope orientation, there is a difference in the quantity of ground ice.

Slope. Steep slopes, with thin soil cover and poor drainage are unfavorable to the growth of ground ice. Gentle slopes, with adequate moisture and good vegetation cover are favorable for the growth of ground ice. According to data along the Qinghai-Xizang Highway on slopes of gradients less than 10° , ground ice is usually formed. Slope gradients of 40° - 80° are especially favorable to the growth of ground ice. On slopes with gradients of 10° - 16° the conditions for growth of ground ice become bad. On slopes with gradients over 16° usually no thick layered ground ice is found. When slope gradients are over 25° , denudation is dominant and there is only cracking ice.

Position. In different positions on slopes with similar orientations, the distribution of ground ice shows a regular change. On the top where bare bedrock or thin soil cover exists, because of coarse soils and good drainage, there is only permafrost of massive and crack cryogenic structure, mostly rare-ice and some-ice permafrost. From the upper to lower positions on slopes, the loose deposits become thicker and water accumulates easily. Thus, the ground ice becomes thicker or the types of permafrost change downslope from rare-ice permafrost to ice layers containing soil.

Basins with fine-grained soils and adequate moisture are favorable for the growth of ground ice, e.g. in the broad area of alluvial-pluvial plain and pluvial fen edges between Maintenance Squads 121 and 122 with smooth terrain, many bogs and 1 m thick humus, the development of ground ice is fairly good, although the mean annual ground temperature is higher. In basins consisting of lacustrine deposits, ground ice amounts are high, e.g. to the south of Maintenance Squad 113, a surface layer 1-2 m thick is composed of contemporary alluvial-pluvial deposits. Below is clay and silty clay containing gravel of lacustrine origin of Early Quaternary age. Near the permafrost table there is thicker layered ground ice with ice thickness of 4-10 cm and volumetric ice-contents of more than 70-80%.

The Valley and Plain Region

The taliks are through-going under large river beds, but not under moderate and small river beds. Owing to relative lower elevation, the thermal effects of

river water, higher mean annual ground temperatures and coarse-grained soils, usually sand and gravel, there is only rare-ice and some-ice permafrost in these places. In the high flood plains and first terraces there are also only rare-ice and some-ice permafrost. Even in sections consisting of fine-grained soils, only rare-ice and some-ice permafrost develop. Only in swampy sections with well developed vegetation and humus, is there high ice-content permafrost. For example, drill hole CK 114-3 situated on the high flood plain on the eastern bank of Jicbu Qu as far as 1.5 km south of Maintenance Squad 114 reveals mainly rare-ice permafrost, because of sparse vegetation and thin permafrost in spite of fine grained material. But drill hole CK 114-6 situated on the eastern bank with 50% vegetation cover and swampy conditions, reveals the following profile: 3.0 m, permafrost table; 3.0-3.4 m, layered ice with ice thicknesses of 4-5 cm and volumetric ice-content of 50%; 3.4-6.6 m, layered ice with lower volumetric ice content than upper part. On the second and third terraces there are rare-ice and some-ice permafrost. Sometimes, one can find high ice-content permafrost at the back of high terraces on the gentle slope of pediments, if there is supply of supra-permafrost water and fine-grained soils are present. For example, drill hole D-14 on the third terrace on southern bank of Tuotuo He reveals that the permafrost table lies at a depth of 2.3 m and the volumetric ice-content is 50-70% from a depth of 2.3-3.5 m.

In the middle and upper parts of tilted plains consisting of pluvial and outwash fens, there is mainly rare-ice and some-

ice permafrost due to coarse sediments, e.g. in the broad outwash-pluvial fen between Maintenance Squads 104-107 with gravel sediments and sparse vegetation, there is permafrost of massive cryogenic structure, with occasional thin, layered cryogenic structure. The ice content is usually less than 10-15%. But high ice-content permafrost may occur, if fine-grained soils and swampy conditions exist, e.g. in the tilted plains of the outwash fen in Nanshan of Xidatan, there is high ice-content permafrost. In the low part of pluvial and outwash fens and depressions between fens, ground ice amounts are higher than in the middle and upper parts, because it lies in the overflow zone of ground water and has adequate water and a high percentage of fine-grained soils. For example, in the depression in front of the outwash-pluvial fen between Maintenance Squads, 101-104, there is permafrost of thin layered cryogenic structure with 1 cm thick ice lenses in clay silt and silty clay.

The use of tritium analysis made it possible to establish the existence of considerable amounts of water in permafrost rocks and in ground ice in the zone of annual temperature fluctuations. The moisture was found to migrate from the active layer into the permafrost, resulting in the formation of ice lenses. High tritium concentrations caused by the inflow of meteoric water under 30 years of age are inherent in the growth of wedge ice and golets ice. However, tritium is absent from buried wedge ice and in lenses of primary ice. Tritium analysis offers new possibilities for studying laws governing the formation and age of ground ice in permafrost.

INTRODUCTION

Being a component of a water molecule, tritium is a splendid natural indicator of moisture transportation processes. Its radioactivity makes it possible to determine the age of natural waters. Because of that, tritium analysis has found wide application in meteorology, hydrology and hydrogeology. Since 1976 we have been studying the content of tritium in permafrost and ground ice in Southern Yakutia and the north-western part of the Amur region of the Aldan, Olekma and Giliui river basins. In total, over fifty analyses have been performed. Estimates of tritium concentrations in the samples of permafrost materials from two wells in the Mackenzie river-valley were made in Canada (Michel & Fritz, 1978). As a result, new information was obtained about the insufficiently known processes of water-transportation in the permafrost ground water system, about the formation of the cryogenic structure of the upper horizons of permafrost sediments and the age of ice inclusions.

TESTING PROCEDURE

Selection of samples for tritium analysis was performed as part of a study of complex permafrost and hydrogeological conditions. Samples of frozen material and ice from bore holes, excavations and exposures were thawed out on site, and the water was collected in polyethylene jars. The volume of samples was no less than 0.5 l. All the samples were collected from permafrost of contemporary and Late Quaternary deposits. The maximum sampling depth was 10 to 11 m. In addition, samples of atmospheric precipitation, surface and underground water, and of icings were collected. General chemical analysis of the water and the ice was also carried out.

Concentrations of tritium were determined in the isotope research department at the Institute of Water Problems of the USSR Academy of Sciences (IWP) by using a liquid-scintillation spectrometer after preliminary electrolytic enrichment of water samples. The measurement error in most cases did not exceed $\pm 10\%$. Where this was not the case, the value of the error is indicated. Results of

measurements are presented in tritium units (one tritium unit—T.U. equals a concentration of one atom of tritium per 10^{18} atoms of protium).

RESULTS AND DISCUSSION

The results of the analyses revealed that the concentration of tritium in frozen materials and underground ice of various genesis ranges from 0 to 350 T.U. In liquid atmospheric precipitation in the area it amounted to 170-390 T.U., in snow 80-320 T.U., in surface and suprapermafrost water 150-290 T.U., and in icings 250-400 T.U. Concentration of tritium in subpermafrost water ranges from 426-402 to 8 T.U., depending on its age (Afanasenko et al., 1981). The lowest values are inherent in the sources of deep mineralized water and subpermafrost water in the zone of restricted water exchange. The intake of tritium into the permafrost hydrological system is performed through atmospheric precipitation. Data on average annual tritium concentration in the atmospheric precipitation of the area are presented by I. K. Morkovkina, V. V. Romanov, A. I. Tiurin, and A. B. Chizhov (1981). The considerable increase in tritium concentration in the atmospheric precipitation, which started in 1953, reached its maximum (5200 T.U.) in 1963, then declined to a level of 180-150 T.U.

When interpreting the results it is necessary to take into account the relatively short half-life of tritium (about 12.5 years). Therefore, the absence of tritium points to the isolation of the tested object from access to atmospheric moisture at least for the past 50 years. Concentrations of tritium in excess of 5 T.U. point to the presence of moisture younger than 1953-54 when thermonuclear tritium started to accumulate. And by relating the tritium concentration in the samples to its average concentration in precipitation over the period from 1953 to the date of testing it is possible in some cases to consider in the samples the approximate content of the contemporary water enriched by thermonuclear tritium. The average concentration of tritium in the total amount of precipitation by the time our research began (with due regard for radioactive disintegration) was about 320 T.U.

By 1982 this amount decreased to 270 T.U. Below we shall consider the data obtained on the concentration of tritium in various types of frozen materials and underground ice.

Frozen Unconsolidated Deposits and Ice in the Layer of Seasonal Thawing and Freezing

The uppermost part of the permafrost is bounded by the layer of seasonal thawing. The thickness of this layer at the time of maximum thawing (early October) changes from 0.5-0.7 m in peat, to 2.5-3.0 m in sand. It is to the layer of seasonal thawing above permafrost that the supra-permafrost water is timed. In winter the layer usually freezes completely. There with schlieren of segregation ice as thick as 5 cm are formed in dispersion rocks. Congelation ices are abundant in the layer of seasonal thawing in block deposits of rock glaciers. Tritium concentrations in frozen dispersion deposits and peat varied from 64 to 350 T.U. (10 samples). This is connected both with perennial and annual variability of tritium content in atmospheric precipitation. The lowest values (64 T.U.) were in schlieren ice samples in sandy loam from a depth of 0.55-0.8 m on August 9, 1982 (the depth of thawing at the moment of research was 0.5). These values are consistent with the precipitation in June, 1981. But in the summer of 1981 and 1980 tritium concentrations at the same depths reached 258 and 326 T.U. Tritium in rock glaciers in 1977-78 was between the limits of 80-167 T.U., which approximately corresponded to its content in snow. This is well in accord with the current notion about formation of this type of ice as a result of refreezing of snow melt water.

Strata and lenses of injection and injection-segregation types of ice are widespread in the layer of seasonal freezing above floodplain taliks. Tritium concentrations in the taliks correspond to its content in river water or are somewhat higher. The higher values are caused by the influx of sub-permafrost water into alluvium.

Permafrost and Enclosed Ground Ice

Permafrost in the studied area is predominantly discontinuously distributed. Its annual mean temperature varies from 0°C to -4°C; the thickness reaches 200-300 m. The stratigraphic column of perennially frozen deposits is composed of an upper unit of ice-bearing Quaternary deposits underlain by Mesozoic and older bedrock. The thickness of the Quaternary deposits rarely exceeds 20-30 m. They include deposits of bedded and recurrent wedge ice.

High tritium concentrations (80 T.U. and over) are found at depths of 0.2-0.3 m and below the upper boundary of permafrost. Tritium concentrations are related to the existence of an upper transitional layer of permafrost which melted over the last 25-30 years only in the warmest seasons. An idea about the character of tritium distribution at great depths is given by core samples from bore-hole 9 drilled in a 7.5 m high frost mound in the Gorbyliakh river-valley (Fig. 1A). From the surface it is composed of peat which is frozen at a

depth of 0.3 m. At a depth of 2.9 m the boring penetrated a meter-thick layer of ice which had a dissolved solids content of 150 mg/l. The ice was underlain by sandy loam with ataxitic cryogenic texture (volumetric moisture content equals 40-70%). The revealed distribution of tritium concentrations may be explained by moisture migration (diffusion) from the layer of seasonal thawing into perennially frozen material in the direction of lower temperatures. To test the hypothesis about the existence of moisture migration from the base of the seasonally thawed layer deep into the permafrost zone, calculations of changing tritium concentrations with depth were made on the basis of solving the equation of diffusional transportation

$$C(z) = C_{(z=0)} \exp - \sqrt{\frac{\lambda}{k}} z \quad (1)$$

in which $C(z)$ is tritium concentration at a depth of z , k is a coefficient of diffusion, λ is a constant representing radioactive disintegration of tritium (0.056 year^{-1}).

The theoretical curve of the diffusional distribution of tritium concentrations coincided with the actual one, on which tritium concentrations were placed in the middle of the tested intervals using $k = 6.10^{-4} \text{ cm}^2/\text{s}$ (Morkovkina et al., 1982). This quantity does not exceed the limits of certain well-known values of k in dispersion rocks by laboratory estimates. Approximate estimate of the rate of migrational flow gives a value of 10^{-2} kg/m^2 per day. Time of its existence is determined by the period from the beginning of seasonal thawing to the refreezing of seasonally thawed layer.

Perhaps only by the moisture migration from the layer of seasonal thawing of high tritium concentration in the strata of underground ice in the peatland of the Niukzhi river valley can be explained (bore hole 63, Fig. 1A). In the nearby bore hole 65, tritium concentration in sandy loam with ataxitic cryogenic texture at a depth of 3.2-4.2 m was 21 ± 3 T.U. Essentially the same value (20 ± 3 T.U.) was obtained for a sample of frozen sandy loam, underlying peat bogs at a distance of 0.5 km from bore hole 65 (exploratory shaft 73, Fig. 1B). Attention should be drawn to the fact that the results of the analyses of the samples from exploratory shaft 73 do not reveal regular depth variations of tritium concentrations. Similar findings are also observed for peat bogs in the Derput brook-valley (exploratory shaft 1, Fig. 1B). Low tritium concentrations in its exposed section are evidently conditioned by the character of the temperature regime. The layer of winter freezing does not extend to the upper surface of the perennial frozen peat. This results in its very insignificant temperature gradients and the thawed material at the contact with perennial frozen ones is dehydrated. All this deteriorates the conditions for moisture migration.

Both the areas of bore hole 65 and shaft 73 are composed of slightly to moderately decayed peat with rare interlayers of ice as thick as 5-7 cm. Volumetric moisture capacity of the peat is 70-90%. The age of the lower peat horizon in the area of the Derput brook is estimated by the radiocarbon

method at 9,500 years; the age of the upper horizon is 1,800 years. The freezing of peat occurred 2,000 to 1,500 years ago.

Tritium was not discovered in the layers of segregational ice 15-16 cm thick, deposited at a depth of from 2 to 3.5 m in powder-fine sands (Upper Pleistocene alluvium). These are primary types of ice which were formed simultaneously with enclosing perennial frozen sediments, which include extensive wedge ice. Ice wedges of this type are characterized by a concentration of dissolved solids that is usually less than 50 mg/l.

The obtained data and the results of investigations in the Mackenzie river-valley (Mickel & Fritz, 1978) are indicative of intensive penetration of contemporary atmospheric moisture from the layer of seasonal thawing into upper horizons of permafrost. Data on tritium concentration make it possible to approximately determine that in the ground ice there is about 20-30% of moisture content younger than 25-30 years of age and up to 7-10% in perennially frozen unconsolidated deposits. The conclusion about the existence of moisture migration from a seasonally thawing layer into the permafrost zone with formation of icy schlieren agrees well with the results of laboratory experiments (Ershov et al., 1976). This process is hindered by the existence of primary strata of slightly mineralized ice in perennially frozen unconsolidated deposits which have practically no liquid phase. The latter proposition is confirmed by the results of the tritium analysis of ancient recurrent wedge ice.

Recurrent wedge ice (RWI). Underground wedge ice is widespread in alluvium, peat bogs, and proluvium deposits in the north of the Amur region and more seldom in Southern Yakutia. One distinguishes contemporary growing RWI and ancient buried RWI, which are deposited at a depth of more than 0.5-1 m below the layer of seasonal thawing. The depth of penetration of contemporary RWI commonly does not exceed 2-2.5 m, although the depth of the ancient ones is up to 5-7 m.

In contemporary growing ice wedges, tritium concentrations vary within the limits of 20-230 T.U. (9 samples). High tritium concentrations (over 70-80 T.U.), to all appearances, indicate the formation of the great bulk of ice in the last 25-30 years. Lower values are typical of wedges which began forming long before the outset of the thermonuclear tritium intake. The greater part of the ice in this case contains tritium in concentrations less than 5 T.U., which is within the limits of error of the analysis. This is confirmed by the change of the tritium concentrations in one of the veins from 98 T.U. in the middle part to 21 ± 3 T.U. at the lateral boundary. Decrease in tritium concentrations in ice veins from the upper part to the lower one should also be noted. The distribution of tritium inside the veins is evidently determined by conditions of their formation.

In contrast to the contemporary growing ice wedges, tritium in the ancient buried wedges is actually non-existent (the error of observation in most cases did not exceed ± 5 T.U.). This is the case even at the upper boundary of the buried ice wedge at a depth of 1-1.5 m. In August, 1982 studies were made of a section of an ice wedge

complex in the Lake Tchikun depression, where a modern wedge 10 cm wide at a depth of 1.1 m penetrates into buried wedge ice and is distinctly traced within it to a depth of 2.3 m. Tritium concentration in the younger ice wedge at its point of entrance into the buried one is 64 T.U. In the same contemporary wedge, within the body of the buried one at a depth of 1.5-1.6 m, the tritium concentration equals 20 ± 9 T.U. No tritium has been found in the sample selected at this depth from a buried vein at its point of contact with a contemporary one. It confirms that there is no moisture transportation in the ground ice, in which dissolved solids do not exceed 50-70 mg/l.

Golets ice. This type of ice extends under the layer of seasonal thawing in rock glaciers. It is mainly formed in the process of freezing snow melt water. Fig. 1C shows the changes in tritium concentrations in a golets ice cross-section through one of the rock glaciers in Southern Yakutia (Morkovkina et al., 1981). Ice to a depth of 2.4 m with tritium concentrations of 140-167 T.U. forms a part of the seasonal thawing layer. The presence of tritium further down is connected with the moisture inflow during the period 1953-77. This might be brought about by the movement of rock fragments and ice under the influence of gravity force and of ground heaving. Calculation performed from the data on tritium content in atmospheric precipitation in the layer of perennial golets ice gave the amount of its feeding about 6 mm/year. About 20% of ice was formed during the last 25 years.

CONCLUSIONS

1. Comparatively high tritium concentrations were established in frozen dispersion deposits in the zone of annual temperature fluctuations. Tritium content in frozen rocks of the layer of seasonal thawing and in the transitional layer is near the concentration of atmospheric precipitation. Downward, as a rule, the concentration is less where connected with presence of moisture older than 25-30 years of age.

2. Data obtained from tritium analysis show the existence of a considerable amount of moisture migration from the layer of seasonal thawing into permafrost. This process to a great extent influences the formation of the cryogenic structure and ice content in dispersion permafrost within the zone of annual temperature fluctuations. As a result, the age of segregation ice may be considerably less than the time that has passed since formation of permafrost. The intensive growth of ice layers and formation of cryogenic textures may also be modern.

3. Tritium is an indispensable component of contemporary growing ice wedges. Yet, it does not exist in ancient buried wedge ice and in primary ice strata, which are not influenced by the process of moisture migration.

4. About 20% of golets ice was formed in the process of freezing contemporary atmospheric water enriched by thermonuclear tritium. It is indicative of intensive water exchange in rock glaciers and of comparatively young age of golets ice.

5. Employment of tritium analysis in permafrost studies opens new possibilities in the study of moisture transfer processes in the system perma-

frost-natural water, for determining the nature of moisture exchange in permafrost rocks and for age assessment of ice inclusions.

THE RECOGNITION AND INTERPRETATION OF *IN SITU* AND REMOULDED TILL DEPOSITS,
WESTERN JYLLAND, DENMARK

Leif Christensen

Department of Geology, Aarhus University, DK-8000 Aarhus C, Denmark

Major engineering projects in western Jylland, Denmark are greatly influenced by the extent and thickness of remoulded till deposits. A remoulded till study was carried out on the southern slopes of the Saalian landscape of Skovbjerg Bakke north of Skjern using airphoto interpretation and test hole drilling. Remoulded deposits can be recognized on airphotos revealing deformed large-scale crop-polygonal patterns. Apparent shear strength parameters determined by vane-tests for clayey and silty deposits indicate lower strengths in remoulded deposits and higher strengths in *in situ* deposits. Thickness of remoulded deposits varies between 0,5 to 4 meters in the study area. Approximately 40% of the study area is underlain by remoulded deposits.

INTRODUCTION

Intensification of engineering activities in Denmark during the 1970's has resulted in increasing concern about the distribution of remoulded and *in situ* Saalian till deposits in western Jylland. The presence of compressible layers in remoulded deposits and of compressible organic Eemian deposits below remoulded deposits influence major engineering projects such as heating plants and sewage plants. Since such construction projects encounter numerous transitions from compressible to incompressible deposits it is essential that the distribution of remoulded deposits can be mapped as accurately as possible. This concern has prompted an investigation to accurately determine the extent of *in situ* Saalian till deposits and remoulded deposits of till origin in a selected area built up of clayey till deposits north of Skjern, western Jylland, Denmark (Figure 1).

Preliminary terrain studies including the interpretation of airphotos and test hole drillings indicated, that remoulded deposits were extremely widespread and variable and that more detailed investigations were necessary. These studies included detailed large-scale airphoto interpretation of crop-marks and test hole drillings.

DESCRIPTION OF STUDY AREA

The study area is located on the southern slopes of Skovbjerg Bakke. It is commonly accepted that "Bakkeerne" - the landscape of Saalian till and meltwater deposits in western Jylland - have experienced active periglacial modifications throughout the Weichselian Glaciation, when the inland ice reached central Jylland (Figure 1). Solifluction has reduced the lower slopes in angle and extended the slopes in length, while the upper parts of "Bakkeerne" suffered erosion and retreat and near stable slopes were ultimately attained.

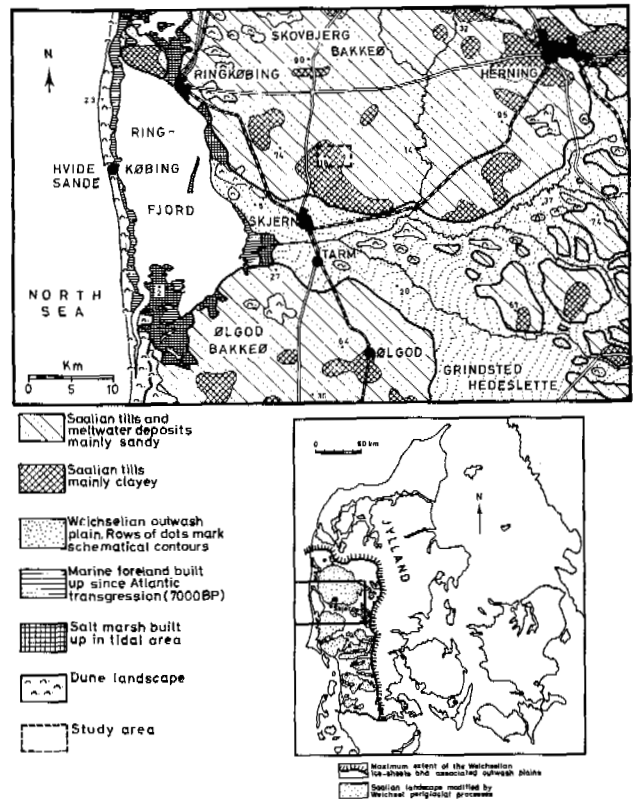

FIGURE 1 Location of the study area.

DELINEATION OF REMOULDED AREAS USING AIRPHOTO MAPPING

Airphoto mapping and interpretation of crop-marks is aided by dry spells. During these periods water-stress conditions reveal differences in plant growth and development which appear as crop-marks in northwest European fields (Shotton 1960, Williams 1964, Morgan 1971, Svensson 1964a, 1964b,

FIGURE 2 Random orthogonal polygonal crop-patterns in a field of spring barley south of Saedding. Photo 9.7.1975.

FIGURE 3 Stripes and elongated orthogonal crop-patterns oriented downslope in a field of rape east of Saedding. Photo 9.7.1975.

FIGURE 4 Pseudomorph of ice-wedge fractured after transition into a fossil state. Central part on Figure 3.

FIGURE 5a. Pseudomorph of ice-wedge deformed after transition into a fossil state.

FIGURE 5b Sketch of Figure 5a.

1972, 1973 and 1976, Christensen 1974 and 1978, Jakob & Lamp 1980). In spring and early summer when evaporation exceeds precipitation, positive and negative crop-marks are especially well developed in cereals such as spring barley, wheat and oats (Christensen 1978). Crop-marks can be observed too in root crops and maize during dry spells in late summer and early autumn. Continuous mapping of an area therefore demands crop rotation and airphotos from several different years with different periods of water deficiency during the season of growth. The increased use of irrigation by Danish farmers since the mid 1970's has reduced the value of more recent airphotos.

Crop-marks are better primary indicators of *in situ* and remoulded deposits than terrain features because remoulded fossil solifluction deposits of till origin have lost their topographic forms (Christensen 1982).

Three categories of polygonal crop-patterns are commonly found. Random orthogonal and hexagonal patterns are found on flat ground (Figures 2 and 6). On gradients of 1° the patterns change to orthogonal, elongated and are oriented downslope. On gradients of 2° or more only stripes are found (Fig-

FIGURE 6 Vertical airphoto showing different categories of polygonal crop-patterns around Saedding. Photo 11.5.1954. Copyright Tactical Air Command, Karup. (Figures 3 and 6).

In situ deposits are commonly found in areas revealing hexagonal and random orthogonal patterns, while remoulded deposits are commonly found in areas revealing elongated patterns and stripes.

The soil structures revealed in excavations through these crop-marks have been interpreted as pseudomorphs of ice-wedge polygonal patterns (Christensen 1974, 1978 and 1982, Svensson 1973 and 1978).

In areas with elongated patterns and stripes excavations have revealed fractured, deformed and overturned pseudomorphs of ice-wedges below crop-marks (Figures 4 and 5).

DELINEATION OF REMOULDED DEPOSITS USING DRILLINGS

In delineating clayey remoulded deposits apparent shear-strength parameters as measured by vane tests in drillings can be used (Christensen 1982). The apparent shear-strength values - c_v intact and c'_v remoulded - are markedly lower in remoulded clayey deposits. Figure 7 illustrates that the apparent shear-strength values - c_v and c'_v - as measured by vane responds to changes in the thickness of the remoulded deposits and changes in soil type.

FIGURE 7 Some typical relationships of *in situ* and remoulded deposits to terrain and crop-marks with the corresponding apparent shear-strength values for each drill hole except drill hole 19. Vertical exaggeration x 30.

Downslope the remoulded deposits of till origin become more sandy than the *in situ* deposits. The resultant sandy deposit can often appear quite different than that from which it has derived.

LABORATORY STUDIES

Undisturbed samples from drillings have been investigated for unit weight of soil γ , water content w , grain size composition and consolidation tests.

The unit weight of soil γ is higher and water content w lower in *in situ* tills than in the remoulded deposits of till origin (Table 1).

TABLE 1

Unit weight of soil γ and water content w of *in situ* till deposits and remoulded deposits of till origin in the Saedding area.

	γ t/m ²	w weight %
<i>in situ</i> till deposits	2,07-2,24	11,5-19,5
remoulded deposits of till origin	1,89-2,12	14,8-24,7

Grain-size distributions of *in situ* tills and remoulded deposits of till origin, show that the latter material is more silty and sandy, the clay content being lower (Figure 8).

FIGURE 8 Grain-size distribution ranges for *in situ* till deposits (38 samples) and remoulded deposits of till origin (83 samples) in the Saedding area.

Consolidation test-curves have been made on selected samples. A marked difference between *in situ* clayey till materials and clay materials from remoulded deposits is found (Figures 9 and 10). The clays of the example test curve in Figure 9 is considered to be preconsolidated, while the clays of the example test curve in Figure 10 are probably normally consolidated.

It is generally considered that glacial conditions favour consolidation of sediments.

FIGURE 9 Working curve from consolidation test of preconsolidated *in situ* till.

FIGURE 10 Working curve from consolidation test of clay layer in remoulded deposit of till origin.

DISTRIBUTION OF REMOULDED DEPOSITS

Remoulded deposits were present over 40% of the study area and ranged from a low of approximately 5% areal extent in flat areas with gradients less than 1° to around 60%-70% on sloping terrain.

An example of a survey map (Figure 11) shows the distribution of *in situ* and remoulded deposits in a section of the study area east of Saedding.

CONCLUSIONS

Remoulded deposits of till origin in the study area are confined to areas with a slope of 1° or more. These areas occupy approximately 40% of the study area. Remoulded and *in situ* till deposits can be recognized on airphotos revealing deformed large-scale crop-patterns. Only drillings can estimate the thickness of remoulded deposits. Drillings therefore are useful for providing data to confirm

airphoto interpretations.

ICE-SOIL MIXTURES: VISUAL AND NEAR-INFRARED REMOTE SENSING TECHNIQUES

Roger N. Clark

Planetary Geosciences Division, Hawaii Institute of Geophysics,
University of Hawaii, Honolulu, Hawaii 96822 USA

The spectral properties of ice-soil mixtures are reviewed. Spectra of intimate mixtures of soil and ice are highly complex, nonlinear functions of the optical properties of ice and soil. Water ice has an absorption coefficient that varies by several orders of magnitude in the visual and near infrared (0.4-3 μ m) and has several prominent overtone absorptions (at 2.0, 1.5, 1.25, and 1.04 μ m). Thus, different wavelengths can be used to probe to different depths in the surface as well as for different mineral impurity concentrations. Empirical and/or theoretical models might be used for deriving characteristic grain size of ice or impurity minerals and for deriving abundance of the ice and rock or soil components. Quantitative analysis of remotely obtained reflectance spectra can only be performed by using the absorption features in the spectra of ice and soil and not by broadband response. This might be done by special selection of several narrow band filters in the near infrared that will adequately define the ice absorptions.

INTRODUCTION

Understanding the optical properties of water ice and mixtures of ice and soil are essential for remote sensing studies. The amount of sunlight reflected from a surface composed of ice and soil depends on the abundances and grain sizes of each mineral component, the absorption coefficients of the minerals and the physical state of the ice-soil association. The spectral properties of an ice-soil intimate mixture (e.g., like frozen mud) are a highly complex (nonlinear) combination of the end member spectral properties. Intimate mixtures are one end of the range of possibilities that may be encountered. The other end of the range is called an areal mixture, where the materials are optically isolated patches of the pure end members located on the surface. The spectrum of the latter is a simple linear addition of the spectra of the optically isolated patches of minerals weighted by the fractional areal coverage of each patch in the field of view of the detector. There is a continuous range of mixture possibilities in between the intimate and areal mixtures, as well as vertically stratified cases such as a frost layer on a soil. Inversion of a remotely obtained spectrum of a surface to determine mineral abundance is a formidable problem, if a quantitative and unique answer is desired. Fortunately, water ice has optical properties that are very different from those of other derived from remotely obtained spectra. This paper reviews the current understanding of the spectral properties of ice and mixtures of ice and soil for the purpose of remote sensing.

ICE

H₂O ice contains absorptions in the infrared owing to O-H stretches (3 μ m), H-O-H bend (6 μ m), and many translation and rotational modes at longer wavelengths. In the spectral region of reflected

solar radiation, ~0.4 to ~2.5 μ m, ice displays overtones of the above modes at 2.02, 1.52, 1.25, 1.04, 0.90, and 0.81 μ m. In reflectance, scattering controls the light returned from the surface to the detector, and scattering can occur from ice-air interfaces (grain boundaries or crystal imperfections) or from impurities mixed in the surface such as a soil. Thus, even in a pure ice or snow, the effective grain size greatly controls the appearance of the reflectance spectrum (Figure 1). The words frost and snow are used interchangeably in this paper since there are no distinguishable spectral differences.

The mean path length that photons travel in a mineral is determined by scattering and by the absorption coefficient of the material. For instance, at 3.075 μ m the absorption coefficient of ice is 14008 cm⁻¹ (Irvine and Pollack, 1968), and a path length of 1 μ m results in absorption of 25% of the light, whereas at the center of the 1.04- μ m ice absorption, the absorption coefficient is 0.34 cm⁻¹ and a path length of 4.1 cm is required for the same 25% absorption. Thus, different wavelengths probe to different depths in an icy surface. This large variation in optical path length is an advantage for remote sensing studies since each absorption is sensitive to different amounts of impurities and to scattering due to different grain sizes.

SPECTRAL PROPERTIES OF ICE-SOIL MIXTURES

There has been considerable advancement in the understanding of the optical properties of ice and snow and the spectral properties of ice-soil mixtures over the last several years. Warren (1982) reviewed the optical properties of snow, concentrating on how the visual reflectance is affected by small amounts of impurities. Clark (1982) discussed the implications of using both visual and near infrared broadband detectors for remote sensing studies. The visual reflectance of a pure

frozen water can vary from 1.0 for a fine grained frost to ~0.4 for an ice with little internal scattering that is characteristic of some terrestrial ice in the arctic and antarctic. With small fractions of a weight percent soot or dust, the visual reflectance can vary from unity to less than 0.1 (Warren, 1982; Clark, 1982). Thus the visual reflectance of ice varies so much with scattering conditions due to grain size and small amounts of impurities that it is unreliable to use the visual albedo alone for any quantitative remote sensing study.

Clark (1981a, b) studied the spectral properties of ice blocks, frosts of various grain sizes, and ice-mineral mixtures. Impurities in an ice or frost layer can radically change the appearance of the reflectance spectrum in the near infrared, as well as in the visual part of the spectrum. The addition of mineral grains dusted on the surface of a frost layer decreases the 1.5- and 2.0- μm absorptions roughly proportional to the fractional areal coverage. However, since the surface of the frost is not a flat layer but a "fairy castle" structure, the mineral grains are somewhat mixed in the uppermost part of the surface, which results in a higher probability of a photon encountering a soil grain. This results in reduced scattering and path length in ice. Also, the albedo of the surface may be drastically reduced many times more than expected for a fractional areal coverage by using an additive model for areal mixtures. Thus, mineral grains on a frost layer are detectable in very small quantities. For example, a fractional areal coverage <0.005 is detectable if the mineral has suitable absorptions outside the major water ice features and the data are of sufficiently high quality, 0.5% precision (Clark, 1981a).

In the case of a frost layer on a soil, a thick frost layer (>1 mm) is required to mask the soil at wavelengths shortward of 1.4 μm owing to the low absorption coefficient of ice but also depends on the mineral reflectance features and the frost grain size. Frost on a very dark surface (e.g., reflectance 6%) is easily seen even when only a few micrometer layer of frost is present.

Spectral studies of minerals with adsorbed water show that the physically and chemically bound water absorptions, which occur at 1.4, 1.9, and 2.2 μm , are distinguishable from the broader water ice absorptions at 1.5 and 2.0 μm and do not shift appreciably in wavelength (<0.01 μm) over the temperature range from 273K to 150K (Clark, 1981b).

In the case of intimate mixtures, a dark material intimately mixed with water ice can completely mask the water absorptions shortward of 2.5 μm (Clark, 1981a). The higher overtones (0.8 μm to 1.25 μm) are more readily masked than the stronger 1.5- and 2.0- μm absorptions; in fact, these weaker absorptions become suppressed with minerals dusted on frost. Even relatively high reflectivity (e.g., 0.8) grains, intimately mixed in a frost layer, can greatly reduce the scattering, thus limiting the path length and suppressing the higher overtone absorptions. These effects cause a decrease in the ratio of higher to lower overtone absorption band depths (e.g., the depth of the 1.25- μm band/1.5- μm band or 0.8- μm band/1.5- μm band). This is in contrast to a thin frost layer on an ice surface whose spectra show an increase in the corresponding apparent band depth ratios (Clark, 1981b).

More recently, Clark and Lucey (1983) have studied the spectral properties of mineral particulates intimately mixed in ice blocks in more detail, and one of their series of spectra are shown in Figure 2. Note how the ice bands at 2.0, 1.5, 1.25, 1.04, and 0.9 μm change with the particulate content. The relative depth of an absorption is defined with respect to a continuum (a smooth line such as a cubic spline polynomial) fit to the reflectance peaks between absorption bands (Clark, 1981b; Clark and Roush, 1983). If R_b is the reflectance at the absorption band center and R_c is the reflectance of the fitted continuum at the same wavelength as R_b , then the band depth D is (Clark and Roush, 1983)

$$D = (R_c - R_b) / R_c \quad (1)$$

The band depths for the ice absorptions increase as the mean optical path length increases until significant absorption occurs in the wings of the absorption bands, then the bands become saturated and the depth decreases. A saturated band may almost completely disappear as seen with the 1.5- and 2.0- μm bands in the pure ice spectrum in Figure 2.

In order to help provide a calibration of ice purity from reflectance spectra, Clark and Lucey (1983) derived the curves of growth for several ice bands as a function of the photon mean optical path length in ice by using the methods of Clark and Roush (1983). A curve of growth is the relationship between an absorption band depth and increasing optical path length through the material. This is shown in Figure 3 and is similar to curves of growth produced from laboratory spectra in Figure 2. The albedo of the particulate impurity greatly affects the spectrum and the curves of growth. The darker the particulate, the less scattering takes place in the surface, which results in a lower optical path length in ice and a smaller band depth. Clark and Lucey (1983) found that the band depth D , divided by the continuum reflectance R_c , removed the effects of particulate albedo (Figure 4). Polynomials fit to such data for the 1.04-, 1.25-, 1.52-, and 2.02- μm bands provide calibration curves to abundance.

REMOTELY SENSED SPECTRA

The previous discussion implies that some quantitative information can be obtained from remotely sensed spectra of an icy surface, given adequate spectral coverage and data precision. In remote sensing studies of the earth's surface, the atmosphere provides an additional difficulty, owing to many absorptions, mainly from water vapor, oxygen, and carbon dioxide (the latter two are relatively weak). Nevertheless, McCord and Clark (1979) have shown that the extinction due to atmospheric absorptions in this region can be removed in at least some cases. To do this, the same physical area must be measured for different path lengths through the atmosphere at each wavelength. From a satellite or airplane this might be accomplished by changing the look direction while flying over the spot. However, this adds another complication in that the viewing geometry with respect to the surface normal and the solar phase angle will also

change. Thus, the scattering within the surface will also change and the spectral properties will change slightly. This is a second order effect, however, and will not significantly affect the crude abundance calculations outlined in the last section.

Recently, Hapke (1981) presented a theory for computing bidirectional reflectance of intimately-mixed, multiminerale surfaces from the complex indices of refraction, grain sizes, weight fractions, and densities of the mineral components. Most presentations of reflectance theories are in terms of deriving the absorption coefficient from laboratory spectra of a powdered sample, given the grain size of the material. However, Clark and Roush (1983) presented a method for deriving abundance from reflectance spectra. In a remote sensing study, if the materials present can be identified from absorption features in the reflectance spectrum, then the absorption coefficients of the materials are known (or can be measured). The reflectance theories can be used to derive the average particle single scattering albedo from observations of the surface at many phase angles. Using the equations to compute the single scattering albedo, when the absorption coefficient is unknown can only determine the product of grain size and absorption coefficient. If the absorption coefficients are known, however, then a non-linear least squares algorithm can be employed to solve for the grain size and the weight fraction of each component.

The ice absorptions may be adequately defined with as few as 9 wavelengths centered near 0.95, 1.04, 1.12, 1.25, 1.40, 1.52, 1.83, 2.02, and 2.24 μm . With these wavelengths, either the previously discussed theoretical or empirical methods might be used to derive abundance from a reflectance spectrum. If a detector system were to obtain images of a planetary surface at wavelengths such as those listed above, in principle it is possible to map the abundance of ice and other minerals.

In practice, for a terrestrial remote sensing project of this sort, an ideal data set would involve ~5 parameters: intensity at many wavelengths (~100 spectral channels from 0.5 to 2.5 μm), position (2 spatial), equivalent atmospheric thickness (air mass), and solar phase angle. The air mass data are required to correct for absorptions in the atmosphere, and solar phase angle data are required to determine the scattering properties (and thus microstructure) within the optical surface. Many spectral channels are required for mineral identification from observed absorption bands. Current technology is adequate for obtaining such a data set. A NASA project will acquire such a data set on a planetary scale beginning in 1989/90 with the Galileo mission to Jupiter where three satellites (ranging in size from Mercury to our moon), whose surfaces contain abundant ice, will be mapped at 204 wavelengths and at a spatial resolution as high as 1 km.

CONCLUSIONS

Reflectance spectra of ice-soil mixtures are very complex, nonlinear functions of the optical and physical properties of the components compris-

ing the surface. Fortunately, these spectra can be understood, and it appears that some quantitative information regarding mineral abundance can be derived. The mineral abundance from remotely obtained spectra can be crudely determined from empirically derived relationships of the optical properties of ice-soil mixtures. A potentially more powerful technique involves a nonlinear least squares analysis of spectra obtained at several different viewing geometrics.

FIGURE 1 The near-infrared spectral reflectance of (a) a fine grained ($\sim 50 \mu\text{m}$) water frost, (b) medium grained ($\sim 200 \mu\text{m}$) frost, (c) coarse grained ($400\text{--}2000 \mu\text{m}$) frost and (d) a ice block containing abundant microbubbles are shown. The larger the effective grain size, the greater the mean path that photons travel in the ice, and the deeper the absorptions become. Frost data from Clark (1981b). Ice data from Clark and Lucey (1983).

FIGURE 2 The reflectance spectra of ice blocks containing Mauna Kea soil of $15 \mu\text{m}$ mean grain size are shown (from Clark and Lucey, 1983). Note how the water ice band depths at $2.0, 1.5, 1.25, 1.04,$ and $0.90 \mu\text{m}$ change as a function of the weight fraction of the particulates in the ice. The particulate soil limits the photons from penetrating into the ice, thus a greater particulate weight fraction results in less photon path length in the ice and smaller absorption bands. The particulate reflectance also limits the photon path with darker grains reducing the multiple scattering and also the absorption band depths.

FIGURE 3 Theoretically, derived curves of growth (from Clark and Lucey, 1983) for five ice absorptions are shown. The optical path is the photon mean path length in ice at the absorption band center. Since ice is less absorbing at wavelengths outside the absorption bands, the mean optical path lengths are as much as an order of magnitude greater than at the band centers.

FIGURE 4 The data from Figure 2 (crosses) plus reflectance data for ice-charcoal mixtures (solid boxes) and ice-kaolinite mixtures (open boxes) were used to derive the 1.04- μm ice absorption band depth divided by the continuum reflectance (from Clark and Lucey, 1983) as a function of the log weight fraction of particulates in the ice. Although there is a factor of about 20 between the reflectance of the bright kaolinite grains and the dark charcoal grains, division of the band depth by the continuum reflectance removes the effects of particulate contaminant reflectance. Thus the curve can be used for crude abundance determinations from remotely obtained reflectance data. Other ice absorption bands are sensitive to different amounts of impurities. Some scatter in the charcoal data is due to near zero band depths and very low continuum reflectance, thus approaching zero divided by zero.

GROUND ICE IN THE EQUATORIAL REGION OF MARS: A FOSSIL REMNANT OF AN
ANCIENT CLIMATE OR A REPLENISHED STEADY-STATE INVENTORY?

Stephen M. Clifford

Department of Physics and Astronomy, University of Massachusetts,
Amherst, Massachusetts 01003 USA

Various lines of morphologic evidence suggest that substantial quantities of ground ice have existed in the equatorial regolith of Mars throughout its geologic history. However recent calculations on the stability of ground ice in this region suggest that any ground ice, emplaced earlier than 3.5 billion years ago, may have long since been lost by sublimation to the atmosphere. It is proposed that one possible explanation for the continued existence of ground ice in the equatorial regolith is that it may be replenished by subsurface sources of H₂O. The existence of a geothermal gradient in the Martian crust could provide the means necessary to thermally cycle H₂O between a deeply buried reservoir of ground-water, similar to those found in cold regions on Earth, and the base of a near surface layer of ground ice. Calculations indicate that a geothermal gradient of 25 K/km would be sufficient to replenish a layer of ground ice 1 km thick over the course of Martian geologic history.

INTRODUCTION

Consideration of the partial pressure of H₂O in the Martian atmosphere and the range of mean annual temperatures at the Martian surface suggests that the occurrence of ground ice in equilibrium with the water vapor content of the atmosphere is restricted to the colder latitudes poleward of $\pm 40^\circ$ (Fanale 1976, Farmer and Doms 1979). However, photographs taken during recent spacecraft missions to Mars have provided considerable geomorphologic evidence that the distribution of ground ice on Mars may be global. Much of this evidence is based on the identification of Martian analogs to cold-climate features found on Earth, such as patterned ground, debris flows, and thermokarst (e.g., Carr and Schaber 1977, Rossbacher and Judson 1981, Luchitta 1981). Additional evidence for the presence of regolith H₂O is based on the occurrence of an unusual type of crater morphology called "rampart" craters which is peculiar to Mars (Figure 1). The distinctive lobate nature of the ejecta blankets which surround these craters is thought to originate from the fluidization of ejecta material during an impact into a water or ice-rich regolith (Carr et al. 1977, Johansen 1978).

The existence of substantial quantities of ground ice in the equatorial region of Mars presents a major problem, for it is difficult to reconcile both the initial origin and the continued survival of ground ice in an area where present mean annual surface temperatures exceed the 198 K frost point temperature of the atmosphere by more than 20 K. The problem is further compounded by a recent study of the climatic history of Mars (Toon et al. 1980) which indicates that, throughout most of its history, conditions on the planet have closely resembled those we observe today. These conditions imply that equatorial ground ice should experience a net annual depletion, as H₂O is transferred from the "hot" equatorial regolith to the colder poles (Flasar and Goody 1976).

How, then, is it possible to account for the existence of ground ice within the equatorial regolith? Currently, the most widely accepted explanation is that it was emplaced very early in Martian geologic history and under substantially different climatic conditions. Evidence for such a period comes from the Martian valley networks (Figure 2)—features which bear a close resemblance to terrestrial runoff channels and which are found almost exclusively in the ancient (~4 billion year old), heavily cratered terrain of Mars (Pieri 1980, Carr and Clow 1981). This evidence suggests that conditions on early Mars were suitable for the global distribution of water within the near-surface regolith; therefore, significant reservoirs of ground ice may have formed as the climate gradually cooled.

If equatorial ground ice on Mars is a relic of some ancient climate, then we must assume it has survived in disequilibrium with the Martian atmosphere for nearly 4 billion years. But is such an assumption reasonable? Those who have addressed this question often suggest that the sublimation of a fossil ground ice layer could be substantially retarded by the diffusion-limiting properties of a relatively shallow layer of fine-grained regolith (Soderblom and Wenner 1978, Arvidson et al. 1980, Luchitta 1981, Rossbacher and Judson 1981). This explanation is based on the work of Smoluchowski (1968), who showed that under certain limited conditions of porosity, pore size, temperature, and depth of burial, a 10 m thick layer of ground ice in disequilibrium with the Martian atmosphere might survive for as long as a billion years. However, based on data obtained from recent spacecraft missions, a new study suggests that the physical properties of the Martian regolith may be inadequate to preserve equatorial ground ice for the required period of time (Clifford and Hillel 1983). In the following discussion the results of this study, and its implications for the existence of equatorial ground ice on Mars, will be reviewed.

FIGURE 1 A Martian rampart crater.

FIGURE 2 The Martian valley networks.

THE STABILITY OF EQUATORIAL GROUND ICE

The stability of ground ice in the equatorial region of Mars is governed by the rate at which H_2O molecules can diffuse through the soil and into the Martian atmosphere. On Mars this process is complicated by the fact that the atmospheric mean free path of an H_2O molecule is approximately 8 microns (Farmer 1976). Therefore, when molecular transport occurs in very small pores ($r/\lambda < 0.1$), collisions between the diffusing H_2O molecules and the pore walls will far outnumber the collisions which occur with other gas molecules; this is the region of Knudsen diffusion. Only in soil pores where the ratio of the pore radius, r , to the mean free path, λ , is large ($r/\lambda > 10$), will ordinary molecular diffusion will be the dominant mode of transport. Since the boundary between ordinary molecular diffusion and Knudsen diffusion is not distinct, the contributions of both processes must be considered when molecular transport occurs in pores of intermediate size ($0.1 < r/\lambda < 10$) (Youngquist, 1970).

To illustrate this dependency more clearly, the effective diffusion coefficient of H_2O on Mars has been plotted as a function of pore size in Figure 3. For pore radii less than about 10 microns, the effective diffusion coefficient of H_2O falls rapidly with pore size--this is the region of Knudsen diffusion. For radii greater than 100 microns, the domain of ordinary molecular diffusion, the effective diffusion coefficient is independent of pore size. Since very small soil pores can significantly retard the diffusive transport of H_2O on Mars, gaseous transport will occur preferentially within the larger pores of any given soil (Smoluchowski 1968, Clifford and Hillel 1983). This effect is clearly seen in Figure 4, where the diffusive flux of H_2O has been plotted

as a function of pore size for three different pore size distributions.

To investigate the stability of ground ice in the equatorial region of Mars it was necessary to make certain assumptions regarding the physical properties of the regolith as well as the quantity and vertical distribution of ice within it (Clifford and Hillel 1983). Observations made by orbiting Mariner and Viking spacecraft and the results of the limited physical investigations of the Martian surface carried out by the Viking Landers have given us at least a rudimentary understanding of the structure and physical properties of the Martian regolith. By comparing these properties with soils on Earth that possess similar characteristics, a probable range of pore size distributions for Martian soil was inferred. Based on this type of analysis, high-porosity terrestrial silt and clay-type soils appear to provide the best match to the known Martian surface properties. Theoretical arguments (Pollack and Black 1979) suggest that the global inventory of H_2O on Mars is equivalent to a 100 m layer of ice averaged over the surface of the planet. In our analysis, it was assumed that this ice occupied the available soil pore space in a single massive layer which initially extended from a depth of 100-300 m. To maximize the lifetime of this buried ice layer, the top 300 m of the Martian regolith were considered isothermal. Finally, the temperature range which was considered in our analysis (215-220 K) corresponds to the range of mean annual surface temperatures for the latitudes lying between $\pm 30^\circ$.

Fine-grained soils, such as those thought to exist on Mars, typically exhibit broad pore size distributions. For this reason, the evaporative loss of ground ice was calculated by means of the parallel-pore model of gaseous diffusion (Youngquist 1970), where a porous solid is viewed as a collec-

FIGURE 3 The effective diffusion coefficient of H_2O on Mars as a function of soil pore size (Clifford and Hillel 1983).

tion of parallel cylindrical pores of constant radii. The recession of the evaporating upper surface of the ground ice from an initial depth of 100 m to a final depth of 300 m was taken into account by recalculating the flux of H_2O at 1 m intervals. The total lifetime of the buried ice layer was then determined from the sum of these individual contributions.

Calculations based on the above model suggest that, on a global scale, it is unlikely that an unreplenished layer of ground ice could have survived in disequilibrium with the Martian atmosphere for as long as 3.5 billion years. However, it should also be noted that in view of the likely range of geologic environments which may be found on Mars, the necessary conditions for the long-term survival of equatorial ground ice may exist in isolated regions.

Therefore, the fundamental problem that originally motivated this study still remains: how does one account for the seemingly abundant morphologic evidence that substantial quantities of ground ice

presently exist within the equatorial regolith? The possible answers appear to be: (1) the actual physical characteristics of the Martian regolith, and/or the quantity of H_2O stored in the regolith as ground ice, may differ substantially from the model parameters chosen for this study; (2) the accepted interpretation of certain Martian surface features as morphologic indicators of ground ice may be in error; or, (3) equatorial ground ice may have been replenished by subsurface sources of H_2O . While none of these three alternatives can be safely ruled out, the possible subsurface replenishment of equatorial ground ice appears to have some important points in its favor, for it is consistent with our present understanding of Martian geomorphology, surface properties, and climatic history.

POSSIBLE EVIDENCE OF GROUND ICE REPLENISHMENT

As noted earlier, under present climatic conditions, the atmospheric loss of ground ice from the equatorial regolith appears irreversible—once ice has evaporated, or been removed by some other process, it is difficult to see how that ice could be replenished by any atmospheric means. Yet, within the equatorial region of Mars there appears to be morphologic evidence that, at least in some areas, ground ice has in fact been replenished.

First, consider the results of a major impact in the near equatorial regolith. The estimated thickness of permafrost in the equatorial region of Mars is on the order of 1 km (e.g., see Fanale 1976, Rossbacher and Judson 1981); therefore, as first noted by Allen (1979), the production of a crater many tens of kilometers in diameter should result in the excavation of any ground ice which existed, in the region interior to the crater walls, prior to the impact (Figure 5a). While backfilling and melting of nearby ground ice may partially replenish some of the lost H_2O near the crater periphery, it appears unlikely that its lifetime would be very long given the high temperatures and porosity of the postimpact environment. Therefore, it is interesting to note that within a number of large impact craters in the equatorial region of Mars there appear clearly defined rampart craters (Allen 1979). As discussed earlier, the distinctive morphology of this type of crater is thought to result from an impact into a water or ice-rich regolith (Johansen 1978). If one accepts this interpretation, then the presence of rampart craters within the interiors of numerous older craters in the equatorial region of Mars appears to present a problem in that it is difficult to conceive of a scenario by which any ground ice that existed prior to the original cratering event could have managed to survive to produce the distinctive fluidized ejecta pattern often seen as the result of a second and sometimes third (Figure 5b) consecutive impact.

As before, several explanations are possible: (1) contrary to popular belief, rampart craters may not be specific indicators of ground ice (Schultz and Gault 1981), (2) the original emplacement of ground ice in the near-equatorial region may have occurred sometime after many of the earlier impacts but prior to a subsequent period of rampart cratering (although such an explanation runs counter to the findings of both Johansen (1978) and Allen

FIGURE 4 Figures 4a, 4b, and 4c, represent three hypothetical pore size distributions whose differential porosity is given by the solid line and whose cumulative porosity is given by the dashed line. Figures 4a', 4b', and 4c' depict the corresponding flux curves of H_2O through these distributions.

FIGURE 5 (a) The probable ground ice distribution resulting from a major impact in the equatorial region of Mars. (b) A rampart crater within two earlier and concentric impact features (20°S , 203°W) (Clifford and Johansen 1982).

(1979)), or (3) ground ice which was removed by the early impacts was thereafter replenished by some nonatmospheric means (Clifford 1980, 1982, Clifford and Johansen 1982).

PROCESSES OF REPLENISHMENT

It has been proposed that one possible explanation for the continued existence of ground ice in the equatorial regolith is that it may be replenished by subsurface sources of H_2O . Based on current estimates of the inventory of H_2O on Mars (Pollack and Black 1979, J. S. Lewis, personal communication, 1980), it has been suggested that Mars may possess an extensive network of deeply buried aquifers similar to those found in Siberia, the Antarctic, and other cold regions on Earth (Carr 1979, Clifford and Huguenin 1980, Clifford, 1980). Alternatively, the occurrence of large amounts of subsurface water may be restricted solely to regions of past major volcanic activity such as Tharsis (10°N , 120°W) (Carr 1979, Fanale, personal communication, 1983). In either case, the vertical transport of H_2O , from such subsurface reservoirs, appears to be a viable mechanism for the replenishment of equatorial ground ice on Mars, even when the vertical distances separating the groundwater from the base of the ground ice layer are measured in kilometers.

Of the various mechanisms which may result in the vertical transport of H_2O on Mars, perhaps the most important has been the process of thermal moisture movement (Clifford 1980, 1982). Like Earth, Mars is thought to be radiating internal heat which will give rise to a geothermal gradient within the planet's crust (Fanale 1976). Clearly, when a temperature gradient is present in a moist porous medium, it will give rise to a corresponding vapor pressure gradient. As a result of this pressure difference, water vapor will diffuse in the Martian crust from the higher temperature (high vapor pressure) depths to the colder (lower vapor pressure) near-surface regolith.

Philip and deVries (1957) and Cary (1963) have formulated two different but widely accepted models for calculating the magnitude of this type of

thermally driven moisture transfer. The Philip and deVries approach is based on a mechanistic description of the transport process. They suggest that the exchange of water vapor in an unsaturated soil occurs between numerous small "islands" of liquid which exist at the contact points of neighboring soil particles. The existence of a temperature gradient in the soil causes water from the warmer liquid islands to evaporate, diffuse across the intervening pore space, and condense on the cooler liquid islands at the opposite ends of the pore. In this fashion both moisture and latent heat are transferred through the soil (Figure 6a).

It should be noted that the microscopic temperature gradient across an individual pore is not the same as the measured macroscopic temperature gradient. The macroscopic gradient is an average of the individual gradients which exist across the volumes of air, water, and solids, present in the soil. Of these gradients, the gradient through the air in the pores will be the largest. Since it is the air temperature gradient which governs the magnitude of vapor diffusion, the total amount of H_2O transport through the soil can be several times greater than that predicted on the basis of the macroscopic temperature gradient alone (Philip and deVries 1957).

The Cary model of moisture transport differs from the Philip and deVries approach in that it makes no assumptions regarding the actual mechanism of vapor transport but merely attempts to provide a phenomenological description of the process based on the thermodynamics of irreversible process (Cary, 1963). Despite the differences in approach, it has been shown that the final form of the flux equations for both models are identical (Taylor and Cary 1964, Jury and Letey 1979). After Cary (1966), we can describe the thermally driven vapor flux by the equation

$$J_v = - \frac{\beta D_{AB} P_s H}{R^2 T^3} \frac{dT}{dz} \quad (1)$$

where D_{AB} is the binary diffusion coefficient of H_2O in CO_2 , P_s is the saturated vapor pressure of H_2O at a temperature T , H is latent heat of vaporization, R is the universal gas constant, and β is a dimensionless factor whose value (typi-

FIGURE 6 (a) The process of thermal moisture transfer proposed by Philip and deVries (1957). (b) The thermally driven transport of H_2O in the Martian regolith may provide the mechanism whereby the interiors of equatorial craters are recharged with ground ice, thus explaining the occurrence of features such as depicted in Figure 5b (Clifford 1980, Clifford and Johansen 1982).

cally around 1.83 (Jury and Letey 1979)) depends on regolith temperature, porosity, and water content. Making use of this equation, we find that for a Martian geothermal gradient of 25 K/km, the calculated flux of H_2O to the freezing front at the base of the ground ice layer is approximately 4×10^{-3} g/cm² per Martian year. At this rate, over the course of Martian geologic history, the geothermal gradient could supply enough H_2O from a subpermafrost groundwater system to replenish a layer of ground ice over 1 km thick. It should be noted that this transport will occur on a continuous and global basis for as long as there exists a geothermal gradient and subsurface reservoir of H_2O .

Inspection of equation 1 reveals that for the higher temperatures expected at depth the flux of H_2O leaving the groundwater surface greatly exceeds that which finally reaches the freezing front at the base of the ground ice layer. This difference is due to the decrease in saturated vapor pressure which occurs with decreasing temperature. As shown by Jackson et al. (1965), once a closed system has been established (i.e., the ground ice capacity of the near-surface regolith has been saturated under conditions where the ice exists in stable equilibrium with the atmosphere), a dynamic balance of opposing fluxes is achieved. As water vapor rises from the warmer depths to the colder regolith above, it will condense, creating a circulation system of rising vapor and descending liquid condensate (Figure 7).

CONCLUSION

Identifying the processes responsible for the existence of equatorial ground ice on Mars may be a

key factor in understanding the nature of the Martian hydrological balance. Theoretical calculations on the stability of equatorial ground ice seem to indicate that, with the possible exception of isolated regions possessing unusual conditions of low porosity and small pore size, any ground ice present in the equatorial regolith should have long since been lost by sublimation to the atmosphere. Yet various lines of morphologic evidence suggest that substantial quantities of ground ice may still reside in the equatorial regolith. One possible explanation for this evidence is that equatorial ground ice has been replenished from sources within

FIGURE 7 The presence of a geothermal gradient in the Martian crust may give rise to a convective cycling of H_2O between a subsurface reservoir of groundwater and near-surface ground ice.

the planet's crust. The proposed thermal migration of H₂O from these subsurface reservoirs is consistent with both our current knowledge of the physical and thermal properties of the Martian crust and with our understanding of the physics of soil water movement in the presence of a temperature gradient.

DETECTION AND EVALUATION OF NATURAL GAS HYDRATES FROM WELL LOGS,
PRUDHOE BAY, ALASKA

Timothy S. Collett

Department of Geology/Geophysics, University of Alaska, Fairbanks, Alaska 99701 USA

The purpose of this study is to develop techniques for the detection and evaluation of in-situ gas hydrates from well log data and to determine possible geologic controls on the occurrence of hydrates in the North Slope region of Alaska. Several new methods of evaluation for subsurface gas hydrate were developed and incorporated with existing techniques. For each of 125 wells examined as part of this study the geothermal gradient was determined and the theoretical stability zone for methane hydrate was calculated. Among these, there was 102 apparent hydrate occurrences in 32 wells. A subsurface structural-stratigraphic framework was established to a depth of 1,000 meters. This sediment package is characterized by three deltaic depositional sequences. The high frequency of hydrate occurrences in the structurally up-dip region of the Kuparuk Oil Field suggests that upward migration of free gas preceded hydrate development in the zone of hydrate stability.

INTRODUCTION

Significant quantities of gas hydrates have been detected in many permafrost regions of the world; in western Siberia, in the Mackenzie Delta of Canada, and on the North Slope of Alaska (Kvenvolden et al. 1980). In 1970 Makogon reported that the Messoyakha field in western Siberia had reserves in the billions of cubic meters of methane gas frozen as gas hydrates (Figure 1). Although gas hydrates have been identified in many regions, their significance and geographical extent have seldom been studied. Work done in the Messoyakha field showed that injections of methanol into the hydrate zones could increase gas reserves by 54% above what would be expected in an equal volume of reservoir rocks filled with free gas (Makogon 1981).

In-situ hydrates can occur in permafrost and can also occur below the base of the permafrost at temperatures above the freezing point of water (Figure 2). Various schemes for hydrate development have been postulated. One theory suggests that a gas hydrate could be part of a preexisting gas reservoir, which was frozen in place. It has been suggested that a hydrate body could form by a flux of free gas into a zone of methane hydrate stability and be frozen in place. Another theory states the possibility that free gas could be trapped at the base of the permafrost and be frozen into hydrate. Hydrates can also be found in association with decaying biomatter, such as coal, which would serve as a source for the methane needed for hydrate development (Pratt 1979).

The overall study of in-situ gas hydrates has been limited, with only several preliminary studies completed (Pratt 1971, Bily and Dick 1974, Kvenvolden et al. 1980). The work of Bily and Dick (1974) provided the most conclusive study to date on the occurrence and detection of in-situ natural gas hydrates. Bily and Dick incorporated well logs including dual induction, sonic, and mud logs as potential hydrate detection devices.

Published research to date into the gas hydrates of the Prudhoe Bay region is limited to the work of Osterkamp and Payne (1981), and also Pratt (1979).

CONSIDERATIONS FOR HYDRATE OCCURRENCE

The depth and thickness of the zone of potential hydrate stability can be calculated if the mean annual temperature, geothermal gradient, lithostatic pressure gradient, and gas density are known. The past mean surface temperature at Prudhoe Bay was -10.9°C and the lithostatic pressure gradient is 9.84 kPa/m (Lachenbruch et al. 1982). The mean value of -10.9°C can be viewed as the average surface temperature with which the deep permafrost is presently in equilibrium.

The high number of methane gas shows on the mud logs and several sets of detailed gas analysis from drill stem tests suggest that the dominant gas type in the upper units in Prudhoe Bay is methane.

The geothermal gradients needed to predict the thickness of the hydrate are not generally available. Lachenbruch et al. (1982) observed three geothermal gradients from different bore holes along the Alaskan arctic coast. The lowest geothermal gradient was calculated at Cape Thompson, which was $2.0^{\circ}\text{C}/100\text{ m}$, at Pt. Barrow the gradient was $2.3^{\circ}\text{C}/100\text{ m}$ and the geothermal gradient at Cape Simpson was $3.3^{\circ}\text{C}/100\text{ m}$ (Lachenbruch et al. 1982). The variance in the geothermal gradient is due to differences in thermal conductivity.

The variance in the geothermal gradient indicates that no one regional gradient should be used to calculate the thickness of the zone of potential hydrate occurrence. The geothermal gradient was calculated separately for each well, the base of the permafrost was assumed to be at -1°C (Lachenbruch et al. 1982), and a temperature gradient was calculated to the base of the permafrost.

Formerly, the base of the permafrost was assumed to be in equilibrium at 0°C, but due to freezing point depression the interface is now believed to be at equilibrium at -1°C with an error of ±.5°C (Lachenbruch et al. 1982). Freezing point depression is related to several factors that may affect the thermal stability of the phase boundary. These factors include the presence of salt ions in solution, the existence of freeze-back pressure, and variations in the types of solids and fluid saturation levels.

Obviously it is impossible to make a reliable temperature estimate at the base of the permafrost in a well bore. However, the error in a regional geothermal gradient would be more significant than using a calculated gradient for each well bore, in which the base of the permafrost is assumed to be at -1°C. The values for the depth to the base of the permafrost were taken directly from the work of Osterkamp on permafrost thickness evaluation from well log data on the North Slope.

Figure 3 illustrates how the depth to the base of the permafrost and a methane hydrate stability curve were used to determine the depth and thickness of the zone of potential methane hydrate stability. In this example the depth to the base of the permafrost is 532 m with a mean annual ground temperature of -10.9°C. Assuming that the temperature at the base of the permafrost is -1°C, the geothermal gradient within the permafrost for this bore hole would be 1.9°C/100 m. In Figure 3 a 1.0°C/100 m geothermal gradient within the permafrost has been plotted along with a calculated 3.2°C/100 m gradient below the base of the permafrost. The geothermal gradient changes abruptly at the base of the permafrost due to a change in thermal conductivity. Therefore, the geothermal gradient was modified below the base of the permafrost in the calculation of the thickness of the zone of potential hydrate stability. The ratio used to manipulate the gradient below the base of the permafrost was given by Lachenbruch et al. (1982). This ratio indicated that the gradient increase by a factor of 1.73 from within the permafrost to the unfrozen strata below the base of the permafrost. A methane hydrate stability curve has also been plotted using a hydrostatic pressure gradient of 9.84 kPa/m (Lachenbruch et al. 1982). The lower boundary of the zone of methane hydrate stability is marked by the lower intersection of the geothermal gradient with the methane stability curve. The upper boundary of the zone of methane hydrate stability is defined by the upper intersection of the methane stability curve and the geothermal gradient. In Figure 3 the upper boundary of the zone is marked by H1 at 177 m. While the lower hydrate boundary is marked by H2 at 957 m, delineating a zone of potential hydrate occurrence 780 m thick.

The methane hydrate stability curve indicates that the geothermal gradient must be less than 3.7°C/100 m for methane gas hydrate to form at Prudhoe Bay. For the geothermal gradient to intersect the methane hydrate stability curve the gradient must be equal to or less than 3.6°C/100 m, which would correspond with a minimum permafrost depth of 290 m. In other words methane hydrate should not exist at Prudhoe Bay if the

depth to the base of the permafrost is less than 290 m. The dashed line in Figure 2 represents the 290 m depth contour on the base of the permafrost. If the above line of reasoning is correct, methane hydrate occurrences should be limited to areas north of this contour. The thickness of the zone of potential hydrate occurrence ranged from nothing at the 290 m permafrost contour to more than 1,000 m near Mikkelsen Bay, where the methane hydrate was found to be potentially stable to a depth of 1,119 m.

LOG EVALUATION

The recognition of gas hydrate in well log data is not straightforward, and often the zones of potential hydrate occurrence are not logged, or the quality of the logs may be poor. Another problem in the evaluation of hydrates from well log data is the lack of prior quantitative work.

The work by Bily and Dick (1974) on the evaluation of natural occurring gas hydrates in the Mackenzie Delta is one of only a few papers dealing with the detection of in-situ natural gas hydrates using wire line logs. Bily and Dick discovered that when a hydrate zone was penetrated during drilling, there was a marked increase in the amount of gas in the drilling mud. The hydrate units recorded a relatively high resistivity on the dual induction log and a slight spontaneous potential deflection in comparison to a free gas. Sonic logs also indicated an increase in acoustic velocity.

The first confirmation of the existence of in-situ natural gas hydrate was not until 1972, when ARCO/EXXON were successful in recovering the first natural gas hydrate in a frozen state. The sample was recovered from a depth of 666 m in the Northwest Eileen State #2 well in Prudhoe Bay. The Northwest Eileen well was drilled with cool drilling muds in an attempt to reduce thawing of the permafrost and hydrate. The methane hydrate saturated sample was recovered in a pressurized core barrel, and a simple test was devised to check for the presence of hydrate. The pressure within the core barrel was allowed to equilibrate with the surface pressure, and the core barrel was resealed and warmed above in-situ temperatures. The pressure within the barrel began to rise, indicating the presence of thawing hydrate. This process was repeated several times with similar results. The hydrate sample had a gas composition of 99.17% methane (P. Barker, personal communication, ARCO Alaska Inc., Anchorage, Alaska).

The confirmed hydrate occurrence in the Northwest Eileen well presents itself as an ideal starting point for the development of log evaluation techniques in a hydrate zone. Log responses for the hydrate zone in the Eileen well are graphically represented in Figure 4.

The following list summarizes various log responses, incorporating the methods developed in this study with the evaluation techniques developed by Bily and Dick (1971) in the Mackenzie Delta. The ability of each log to distinguish hydrates from free gas and ice bearing permafrost is also indicated.

1. Mud Log On a mud log there is a pronounced gas kick associated with a hydrate, due to thawing during drilling. The mud log serves as the best tool available for the differentiation of a hydrate saturated unit from gas-free ice-bearing permafrost.
2. Dual Induction Log There is a relatively high resistivity deflection on the dual induction log in a gas hydrate zone, in comparison to that in a free gas zone. The long normal is separated from the short normal due to thawing next to the bore hole. If a unit were hydrate saturated within ice-bearing permafrost, the resistivity response on the dual induction log for the hydrate unit would not be significantly different than the log responses for the surrounding ice-bearing permafrost. Hence, it is impossible without the usage of the mud log to distinguish between hydrate and permafrost. Below the base of the permafrost the high resistivity deflection associated with the hydrate is distinct from the surrounding non ice-bearing zones, but may be similar to that of a free gas.
3. Spontaneous Potential (SP) There is a relatively lower (less negative) spontaneous potential deflection in a hydrate zone when compared to that associated with free gas. The frozen hydrate limits the penetration of mud filtrate thus reducing the negative spontaneous potential.
4. Caliper Log The caliper log in a hydrate interval usually indicates an oversized well bore due to spalling associated with the decomposition of a hydrate. Because the caliper log also indicates an enlarged bore hole in ice-bearing permafrost, it is only useful in detecting hydrates below the base of the ice-bearing permafrost.
5. Sonic Log Acoustic velocities in hydrate are relatively high ranging from 3.1 km/s to 4.4 km/s. Because the sonic velocity of ice-bearing permafrost is very similar to that of gas hydrate, the sonic log cannot be used to detect hydrates within the upper ice-bearing permafrost zone, but it is helpful below the base of the ice-bearing permafrost.
6. Neutron Porosity In a hydrate zone there is an increase in the neutron porosity; this contrasts with the apparent reduction in neutron porosity in a free gas zone. If a unit is hydrate saturated and occurs within the ice-bearing permafrost zone the neutron porosity log would theoretically indicate an increased or reduced neutron porosity, depending on the amount of free gas associated with the hydrate in comparison to that of the surrounding ice-bearing permafrost. Below the base of the permafrost a hydrate unit exhibits a relatively higher neutron porosity compared to water saturated or free gas saturated zones. However, thawing near the well bore complicates the neutron log interpretation.
7. Drilling Rate In a hydrate zone the relative drilling rate decreases, due to the

cemented nature of the hydrate. There is a very similar drilling rate response within ice-bearing permafrost, and therefore drilling rate change is not useful as a hydrate detector within the permafrost.

8. Cross Plots In a cross plot of the resistivity and transit time for a series of stratigraphic units saturated with either hydrate or free gas and below the base of the ice-bearing permafrost, there is a grouping of units with similar constituents. Hydrate saturated units fall in a region of relatively higher resistivity and faster transit times while free gas saturated units fall in an area of lower resistivity and slow transit times. Differences are relative and not absolute; the cross plots show a simple clustering of similar properties. A resistivity/transit time cross plot of units that are above the base of the permafrost is not useful as a hydrate indicator, due to the similarity in resistivity and transit time velocities in hydrates and in permafrost.

In the Prudhoe Bay wells the dual induction and mud log are the most valuable tools available for the detection of gas hydrates; caliper and sonic logs are helpful but less definitive. The neutron porosity log showed great promise, but the lack of neutron surveys did not allow adequate assessment of it as a hydrate detection device. Many problems still exist in the evaluation of in-situ hydrates from well log data, and the addition of new evaluation techniques such as the use of cross plots and the addition of the neutron logs has only slightly improved the subjective nature of hydrate detection.

HYDRATE OCCURRENCE IN PRUDHOE BAY

In this study, a structural-stratigraphic framework of 32 key markers within the Tertiary and Upper Cretaceous strata was picked from the gamma ray logs and was established to a depth of 1,000 m. Thirty-three distinct units were defined and described from direct interpretation of the gamma ray logs. The gamma ray surveys were correlated with three complete sets of drill core chips and four petrographic strip logs.

The upper 1,000 m of strata in Prudhoe Bay is characterized by a gentle dip to the northeast, ranging from 20 to 28 m/km and is dominated by three distinct coarsening-upwards deltaic sequences. Howitt (1971) suggested that deposition of the upper units in Prudhoe Bay was more or less continuous in an aqueous environment.

One hundred twenty-five wells were examined for potential hydrate occurrence, with 102 definite occurrences in 32 different wells. Hydrates occurred in relative porous discrete units. Many of the wells had multiple zones of hydrate occurrence, with each hydrate unit ranging from 2 to 28 m thick.

Hydrate occurrences appeared to be regionally isolated to the Kuparuk oil field to the west of Prudhoe Bay, indicated in Figure 1. In the Kuparuk region there are four laterally continuous hydrate saturated sands and two less extensive

units. The lateral extent of each hydrate saturated unit has been graphically represented in a three-dimensional block diagram in Figure 5. An east-west cross section through the Kuparuk oil field has been plotted in Figure 6, along with associated hydrate accumulations and inferred environments of deposition.

The presence of a structural control on the occurrence of hydrate is apparent upon close examination of all hydrate zones. With several minor exceptions, all hydrate occurrences are below marker 12, which marks the base of a nonporous prodelta shale. Hydrates were found exclusively between markers 12 and 19.

The sediment package between marker 12 and 19 is described as a deposit of shaly sand with thick interbeds of clean sand and shale, which were deposited in a delta front foreshore environment. There are several notable impermeable shale breaks which act as caps for relatively porous sand units which are hydrate saturated. Due to the interbedded nature of the sediments the hydrate occurs in multiple discrete units, within one well there may be as many as eight different hydrate saturated units.

A subjective A, B or C value has been assigned to each hydrate occurrence in an attempt to quantify the degree of hydrate saturation. The magnitude of the resistivity kick and the gas show associated with each hydrate occurrence was used to calculate the relative saturation of each hydrate. The letter A was assigned to a unit if it appeared to be highly saturated with methane hydrate, B and C indicate a relative decrease in hydrate saturation.

In the cross section in Figure 6 the hydrate appears to be concentrated in the southwest up-dip direction, with a decrease in hydrate saturation down-dip to the northeast. The anomalous occurrence of hydrate in the Kuparuk region, along with the greater saturation of hydrate up-dip, suggests that the free gas necessary for hydrate development may have migrated into place. The source for the free gas may be from either local biological decay in the upper units, or the gas could have migrated from a deeper mature gas zone.

As noted in the cross section of Figure 6, there are a number of hydrate occurrences within the permafrost. The occurrence of hydrate within the permafrost represents a time restraint on the formation of hydrate. Since permafrost is impermeable to gas migration, the hydrate must have developed in the upper intervals before the formation of the permafrost to the present depth.

A possible scenario for the formation of hydrate in the North Slope would begin with free gas migration either from local diagenesis or from depth through a relatively permeable sand unit along the base of an impermeable prodelta shale. The overlying shale unit would act as a cap to vertical gas migration.

The migrating free gas could be trapped in the up-dip direction by a series of different trapping mechanisms. The two most probable trapping mechanisms would be a self-forming hydrate trap and an impermeable ice-bearing trap. The existence of a porosity/permeability trap or a fault trap is unlikely.

The rate of free gas migration and the existence of possible porosity/permeability traps in the hydrate saturated sands are not easily delineated due to the lack of data. The only data available on the porosity/permeability characteristics of the upper units are from stratigraphic logs prepared by the American Stratigraphic Company. The porosity within the hydrate saturated sands varies little, from 38 to 46% (American Stratigraphic Company). The existence of a porosity/permeability trap for the up-dip free gas migration is not likely due to the lack of variation in the lateral porosity in the same units. The unconsolidated nature of the upper units would not lend itself to the formation of a porosity/permeability trap.

The evidence that there is little faulting past the Lower Cretaceous reduces the likelihood of fault traps.

The free gas could have formed a trap when the gas entered the hydrate stability field. As the migrating gas moved into the zone of hydrate stability, the gas would be frozen in place. The frozen hydrate would be impermeable to free gas migration and would continue to thicken as free gas is trapped and frozen in place.

The impermeable permafrost could also form an up-dip trap to free gas migration. As the free gas migrated up-dip along the bedding plane, the gas would be trapped at the base of the permafrost and be frozen in place.

The actual occurrence of hydrate does not favor either the self-forming trapping model or the permafrost trapping model. However, the laterally continuous nature of the hydrate occurrences suggests possible reorganization of the hydrate by multiple periods of freezing and thawing.

CONCLUSIONS

The major findings of this study are:

1. Several well logs have been found to be indicative of the presence of hydrate. Although no single log is definite by itself, used in combination they permit at least a subjective evaluation of hydrate occurrences. For example, the development of new evaluation techniques such as the use of cross plots and the addition of the neutron porosity log as a hydrate detector has reduced the subjective nature of the hydrate evaluation. Hydrate occurrences were identified by a variety of different well logs. The internal consistency of their determination, and their application in a large number of wells, indicate the validity of the method.
2. The recognition of the primarily structural-stratigraphic control on the up-dip gas migrational model for the hydrate accumulations was a significant contribution. The correlation of the actual hydrate occurrences identified in well log data with the structural-stratigraphic framework has allowed the development of a conceptual model for hydrate formation in the North Slope region.

3. The method for determining the zone of hydrate stability was refined to take into account both the difference in thermal conductivity between ice bearing and water bearing strata and the shallow depth limit of the stability zone. The method used for estimating the local geothermal gradients allows estimation of temperature profiles during warmer periods in the Earth's history which, in turn, has provided insight concerning the original formation and accumulation of the actual gas hydrate occurrences.

LONG-TERM ACTIVE LAYER EFFECTS OF CRUDE OIL SPILLED IN INTERIOR ALASKA

C. M. Collins

U.S. Army Cold Regions Research and Engineering Laboratory
Fairbanks, Alaska

Two experimental oil spills of 7570 liters each were conducted at a black-spruce-forested site in February and July of 1976. The long-term effects of the spills on the active layer were directly related to the method of oil movement. The winter spill moved beneath the snow, within the surface moss layer, and the summer spill moved primarily below the moss, in the organic soil. The summer spill affected an area nearly one and one-half times that of the winter spill. Only 10% of the 303-m² summer spill area had oil visible on the surface, while 40% of the 188-m² winter spill had visible oil. Thaw depths in the summer spill area increased from 1977 to 1980--average thaw depth was 72 cm vs. 48 cm in the control--and remained essentially the same in 1981 and 1982. Thaw depths in the winter spill area continued to increase until 1982 to an average of 92 cm. Summer temperatures 5 cm under the blackened moss are consistently higher than under the undisturbed surface. Presumably the change in albedo due to the surface oil accounts for the increased thaw in the winter spill area.

Over the past decade a number of studies have been conducted on the effects of oil spilled in the arctic and subarctic environment. This is a direct result of the development of the Prudhoe Bay oil field and the construction of the Trans-Alaska Pipeline.

Much of the work on the impact of oil spills has considered the effects of refined petroleum products and crude oil spilled on arctic and subarctic vegetation (Hunt et al. 1973, Deneke et al. 1975, Hutchinson and Freedman 1975, Walker et al. 1978), and several theoretical and laboratory studies have investigated crude oil spills on snow and ice (Raisbeck and Mohtadi 1974, McMinn and Golden 1973). A number of studies examined the biological and chemical effects of small experimental spills on tundra soils and vegetation, especially in the Barrow and Prudhoe Bay areas (Everett 1978, Sextone et al. 1978, Linkins et al. 1978).

In contrast to these mostly small-scale studies, a series of studies conducted near Norman Wells, Canada, attempted to determine experimentally the effects of larger oil spills (Mackay et al. 1974, Hutchinson et al. 1974, Hutchinson and Freedman 1975). A study of similar scope was conducted to determine the physical, chemical, and biological effects of crude oil spilled on a forested permafrost terrain near Fairbanks, simulating as nearly as possible an actual oil spill (Jenkins et al. 1978, Johnson et al. 1980). This paper is based on a continuation of that study and examines the long-term thermal effects of oil spills on the active layer.

Studies other than those on oil spills have investigated the thermal impact of natural and man-made disturbances on the active layer (Brown and Grave 1979). Most deal with the disturbances caused by vehicular traffic, oil development, and related construction activity (Mackay 1970, Lawson et al. 1978). Fire also plays a major role in the natural

disturbances of permafrost (Heginbottom 1971; Viereck 1973, 1982; Hall et al. 1978; Racine 1981), where increased thaw of the active layer follows the destruction of the insulating organic layer by fire or the construction of fire lanes. Makiyara (1982) studied the modification of surface albedo by coal dust and its effect on the active layer at Prudhoe Bay.

SITE DESCRIPTION

The winter and summer oil spill study was conducted in the Caribou-Poker Creek Research Watershed, within the Yukon Tanana Uplands, 48 km north-east of Fairbanks, Alaska. The study site is located at an elevation of 300 m, on an 8° west facing slope. Two plots, each 10 m by 50 m, were established for oil application. A control plot of the same size was established just upslope (Johnson et al. 1980).

The soil of the study site is a Histic Pereglic Cryaquect with silt loam texture and is typical of the Saulich series found in the lower slopes of the watershed (Rieger et al. 1972). The O1 and O2 layers (moss and peat) average 30 cm thick and overlie a 6-cm A horizon beneath which is a massive, grey silt C horizon that is water saturated above the permafrost. The active layer depth ranges from 20 to 60 cm according to the thickness of the organic (O1 and O2) layers.

The vegetation of the study site (Figure 1) is an open Picea mariana/Vaccinium spp./feathermoss community described by Viereck and Dyrness (1980), a common community type in interior Alaska. Morphologically, it is an open black spruce (Picea mariana) stand with a shrub understory of Ledum decumbens, Ledum groenlandicum, Betula glandulosa, and Vaccinium uliginosum. Mosses and lichens cover 50% or more of the ground surface (Johnson et al. 1980).

FIGURE 1 Vegetation at study site before experimental spill (August 1975). Note elevated walkways installed for access to plot.

METHODS

Crude oil, heated to 57°C in a closed 7600-liter tank, was applied to the first spill plot on 26 February, 1976, at an ambient air temperature of -5°C. Heated oil was applied to the second plot on 14 July, 1976, at an ambient air temperature of 25°C. In each spill 7570 liters of oil was applied at the top of the plot through a 5-m-long perforated pipe at a rate of about 170 liters/min.

The rate and extent of oil flow downslope following each of the spills was determined by probing with wooden dowels in a 1-m grid pattern (Johnson et al. 1980). Thirty-six thermocouple arrays were installed in each plot, with five thermocouples per array to collect ground temperature data. Maximum depth of each array was 1 m.

The active layer depth was measured by probing with a graduated steel rod at 1-m intervals along six cross-sections located at 1, 3, 6, 9, 14, and 20 m downslope from the spill point in each plot. Thaw depth measurements have been made every September since 1976. Air temperature data are available from several nearby climatic stations maintained in the research watershed (Haugen et al. 1982).

RESULTS

Oil Movement

The timing of the two spills affected the mechanism of oil movement and the area covered by each spill. In addition, the amount of surface impact, which later affected the active layer, was different for the two spills.

During the winter spill, the hot oil melted holes in the 45-cm deep snowpack and then moved downslope under the snow without disturbing the snow surface. Most of the oil movement occurred just above and within the moss (O1) layer, above the frozen peat and organic soil (O2 and A1) layers. The oil moved 18 m downslope at a decreasing rate for 24 hr before becoming immobile. Following spring snowmelt, the oil became mobile again and moved an additional 17 m downslope. This latter

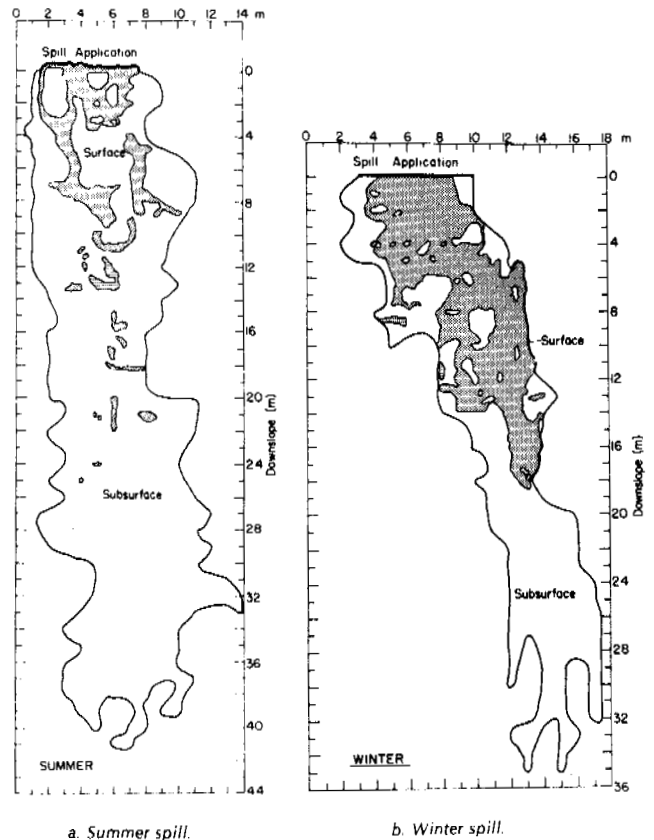

FIGURE 2 Plan views of summer and winter spills showing surface and subsurface oiled areas.

movement was beneath the moss layer and was visually undetectable on the surface.

The oil of the summer spill rapidly penetrated to the peat (O2) layer and moved downslope beneath the moss. The oil was only visible within the first few meters of the plot and in surface depressions downslope. The downslope slope movement of oil was 32 m downslope in 48 hr, with an additional 7 m movement by October 1976.

The winter spill affected an area of 188 m² with about 40% of the area having visible surface oil (Figure 2). The summer spill affected 303 m² with only 10% having oil visible on the surface.

The average concentration of oil in the impacted area of the winter spill was 41 liters/m², considerably more than the 25 liters/m² for the summer spill. When viewed in terms of m²/m³ (area affected per volume of oil applied), both areas are within the range of 20-100 m²/m³ of oil predicted by Mackay et al. (1974) as reasonable for large-scale oil spills. The average concentrations of oil were much greater than many of the small-scale spray spills used to determine the effects of crude oil on vegetation, such as Walker et al. (1978) and Everett (1978).

Thermal Effects on the Active Layer

Effects on the underlying permafrost from the initial spill of the hot oil were not apparent (Johnson et al. 1980). The thermal mass of the warm oil was negligible compared to the thermal mass of

TABLE 1 Degree days of thawing ($^{\circ}\text{C}$), April-September.

Year	No. of days
1976	1583
1977	1453
1978	1223
1979	1356
1980	1153
1981	1249
1982	1163

NOTE: Station located 800 m west of spill site at 50 m lower elevation. Station is called Caribou Main, Alaska. Mean annual temperature is -4.9°C .

In the winter spill were 94 cm in 1981 and 92 cm in 1982. The maximum thaw depths have continued to increase, however, to 170 cm in 1981 and 175 cm in 1982. Maximum thaw in the winter plot has increased 165% since 1976.

Figure 4 shows the long-term average thaw depths for the 1, 3, and 6 m cross sections of the two plots and the control. Average thaw in the first 6 m of the summer plot was 77 cm in 1982. Average thaw in the first 6 m of the winter plot was 115 cm in 1982. The first 6 m are the area of greatest impact and maximum thaw.

Along the cross-section at 3 m, the greatest thaw depths in the winter and summer plots generally correspond to the area of surface oiling (Figure 5). This is presumably due to the decreased albedo of the blackened moss in the surface impacted area.

Degree days of thawing for the study area for the period 1977-1982 range from 1200 to 1500 (Table 1). The consistency of the average thaw depths of the control plot indicate relatively consistent natural depths of thaw each year.

Soil temperatures 5 cm below the surface were consistently warmer under the black, surface oil areas compared to the nonsurface-impacted areas within the spills. Maximum temperatures of 31°C were noted under the oil-blackened moss, as compared to a maximum of 18°C under nonblackened moss areas nearby.

DISCUSSION AND CONCLUSIONS

There are conflicting reports on the effects of oil spills on the thickness of the permafrost active layer. For small experimental spill plots at Barrow, Everett (1978) found thaw depth to increase significantly for 2 years after application of oil with a smaller effect in the third year. He also (Lawson et al. 1978) found that after 30 years at the Fish Creek site, in northern Alaska, thaw under diesel spills dating from the late 1940's was almost double that of undisturbed sites, although it should be noted that there was almost no vegetation cover on the diesel spills to act as insulation.

Mackay et al. (1974) observed little thermal

effect of oil at a forested spill site, but their observations were based on only one season. Hutchinson and Freedman (1978) also observed that spray spill treatments had only a limited effect on the depth of the active layer, which was not maintained after the first postspill growing season. This may have been due to the small amount of oil applied.

Other types of disturbances have resulted in similar increases in the thickness of the active layer. Following the modification of the organic forest floor by fire and mechanical stripping, Dyrness (1982) observed increases in the thickness of the active layer for 4 years with no indications of a decrease in the rate of thaw. There, the vegetation was a black spruce community similar to the oil spill plots in Caribou-Poker Creek. Heginbottom (1973) reports increases in thaw depths due to forest fires and bulldozed firelines at the 1968 Inuvik fire, with a median thaw of 48 cm for undisturbed areas and 61 and 120 cm for burned and bulldozed areas, respectively. Mackay (1977) reports a slight increase was still occurring in the active layer 8 years after the fire.

Viereck (1982) reports somewhat deeper thaw depths for a burned black spruce community near Fairbanks. Maximum thaw in an unburned area was 40-50 cm; in the burned area, 187 cm in 1980; and in a cleared fireline, 227 cm in 1979 and 200 cm in 1980, as vegetation reestablished itself.

These observations are relevant in light of proposed mechanical clean-up procedures (including burning) following an oil spill, which may cause substantial thawing of the permafrost due to disturbance or destruction of the vegetative cover. The thawing due to clean-up procedures may equal or exceed that caused by the spill. This has to be considered when planning a response to oil spills on permafrost terrain.

The maximum thermal impact on the active layer resulting from the two spills at Caribou-Poker Creek occurred in the first few meters of the winter spill, where oil flowed over the moss and beneath the snow cover. Although the total area of the winter spill was smaller than the summer spill, the much greater percentage of oil-blackened moss on the surface resulting from the winter spill has caused a deeper average thaw. Average thaw depths in the summer plot increased from 1976 to 1980 and have since stabilized. Average thaw depths in the winter plot appear to have stabilized by 1982, although the maximum thaw depth has continued to increase under the heavily impacted areas. These trends contrast with those of smaller oil spills in Alaska, generally of lower application rates and in colder areas, where thaw depths did not increase after the first several years; however, the trend is similar to burned areas in interior Alaska and at Inuvik, Canada, that have similar climates.

A MATHEMATICAL MODEL FOR THE PERMAFROST THAW CONSOLIDATION

M. Yavuz Corapcioglu

Department of Civil Engineering, University of Delaware, Newark, Delaware 19711 USA

A mathematical model is developed for temporal and spatial distribution of pore water pressure, temperature, ice content and displacements in an unsaturated thawing deformable soil. The water saturation is related to pore pressure and temperature by retention and phase composition curves respectively. The model is simplified for a one-dimensional vertical permafrost thaw consolidation problem. The use of temperature-dependent rheological stress-strain relations is also discussed.

INTRODUCTION

Heat transfer in soils plays an important part in varied fields. Expanding interest in arctic and near-arctic regions is continuing to provide motivation for research on transport processes in frozen and partially frozen soils. Reducing the transfer of pipeline or building heat to the underlying soil and preventing thawing and associated settlement to utilize the high strength of the frozen soil are the main considerations in permafrost regions. Where thawing of the frozen ground cannot be prevented, the rate and extent of degradation are factors that must be taken into account. Such a problem requires a coupled analysis, i.e., thaw, heat transfer, flow and consolidation. This kind of study involves applying coupled differential equations to describe the field conditions.

The process of transfer of heat in soils is unique, since such a medium presents a combination of components, e.g., ice, water and air. The freezing and thawing of soils are complex phenomena, which may take place over a wide range of temperatures, depending upon the soil type and the water content. Such processes require the extraction or addition of the latent heat of fusion that accompany phase changes. The special features of the geotechnical properties of frozen and thawing soil are the dominant creep characteristics under sustained stress and the marked rate dependence of the strength. These characteristics are attributed to the presence of unfrozen water and the various responses of ice to loading. The rate effects in frozen and thawing ground are temperature dependent and vary with the soil ice content.

Several researchers have spent much effort on the mathematical simulation of permafrost thaw consolidation and developed several models. Works by Tsytoich and co-workers appear to be the first studies on this subject (Tsytoich, 1960; Tsytoich et al., 1966). These studies conclude that the thaw consolidation caused by the abrupt change in void ratio that occurs during thawing of the soil ice and results in settlement is approximately equal to the thickness of ice inclusions, is independent of external load, is proportional to depth of thawing, and occurs at a rate proportional to the square root of time. For a considerable period after complete thawing has occurred, settlement proceeds at a reduced rate and is proportional

to the logarithm of the time. Later, Tsytoich et al. (1965) have shown that the consolidation of thawing soils occurs with practically constant pore pressure and obeys the theory of consolidation.

One-dimensional study of permafrost thaw and settlement has been investigated by various researchers. Some of them approached the problem from a simplistic and practical point of view (e.g., Zaretskii, 1968; Brown and Johnston, 1970), while others preferred a more rigorous theoretical approach. Morgenstern and Nixon (1971) formulated thawing settlement in terms of the theory of consolidation and provided a solution to a moving boundary thaw consolidation problem where the thaw line is assumed to move proportionally to the square root of time as governed by a parameter α . One-dimensional closed form solutions have been obtained for several cases of practical interest. It is shown that the excess pore pressures and the degree of consolidation in thawing soils depend primarily on the thaw consolidation ratio, $R = \alpha / (2\sqrt{C_v})$, where C_v is the coefficient of consolidation. Later Nixon and Morgenstern (1973) extended their study to incorporate arbitrary movements of the thaw line. This approach employs a finite difference technique to obtain a numerical solution. They also introduced the nonlinear compressibility relation into the theory. McRoberts et al. (1978) considered certain aspects of thaw consolidation effects in degrading permafrost by examining two cases.

There are also various studies to simulate the coupled flow of mass and heat in a freezing, deformable soil system in addition to ones for rigid porous media. Studies on deformable media cover the works of Sheppard et al. (1978) and Del Giudice (1978). Sheppard et al. (1978) developed a model that describes heat and water flow in a freezing soil and has provision for incorporating the effect of overburden pressure and deformation of the matrix. Heave is allowed to occur through the use of deforming coordinates. Del Giudice et al. (1978) present the finite element model, formulated for nonlinear heat conduction, to study ground freezing problem by solving the energy equation only. In view of the difficulty of obtaining closed form solutions for two-dimensional problems Sykes et al. (1974a,b) solved two-dimensional problems by the finite element method to determine the effects of settlement and the significance of

variable geometry and forced convection rather than heat conduction only as done previously. The applications of the model include the analysis of a heated oil pipeline buried in permafrost and the analysis of foundations on permafrost. Later, Sykes and Lennox (1976) considered a nonlinear stress-strain relation for thawing permafrost in their model.

Recently, Bear and Corapcioglu (1981) developed a mathematical model for fluid pressure, temperature, and land subsidence owing to temperature and pressure changes in a porous medium. Conservation of mass, energy, and equilibrium equations were developed and the effects of viscous dissipation and compressible work have been included in the formulation. The effects of heat transfer by forced convection as well as conduction were included in the model. Cross-transport phenomena resulting from reciprocal relations had not been considered in their formulation. This paper presents a mathematical model which includes a coupled transport equation in the derivations for a thawing unsaturated porous medium. It is an extension of the theory presented by Bear and Corapcioglu (1981). The mathematical model will be capable of simulating pressure, saturation, temperature, ice content and displacements in a permafrost thaw consolidation problem.

THEORY

The macroscopic unsteady water flow in a partially saturated heterogeneous thawing porous medium can be written as

$$\nabla \cdot \rho_f \underline{q} + \frac{\partial(\rho_f \Theta_w)}{\partial t} - \frac{\partial(\rho_i \Theta_i)}{\partial t} = 0 \quad (1)$$

where \underline{q} is the specific discharge of water with respect to the fixed coordinates. In (1), ρ_f and ρ_i are the densities of water and ice, respectively. Θ_w is the volumetric liquid water fraction, and t is time. Θ_w is a product of the porosity n and the degree of saturation S_w ; that is, $\Theta_w = nS_w$. Θ_i denotes the volumetric ice fraction. Equation (1) has also been used in a similar form by Taylor and Luthin (1978), Sheppard et al. (1978), and Jame and Norum (1980). The frozen component of water, i.e., ice, is assumed to be incompressible and impermeable. In the case of a deforming porous medium where the soil particles move at a velocity \underline{V}_s , it is the specific discharge of the water relative to the moving solid \underline{q}_r that is expressed by Darcy's Law (Bear, 1972, p. 205)

$$\underline{q}_r = \underline{q} - \Theta_w \underline{V}_s; \quad \underline{q} = \Theta_w \underline{V}_f = nS_w \underline{V}_f \quad (2)$$

Inserting this relative flux expression in (1) and assuming that under the pressure conditions during thawing in a frozen soil the water is practically incompressible, $\rho_f = \text{constant}$, and the soil particles and ice are incompressible, i.e., $\rho_i = \text{constant}$, $\rho_s = \text{constant}$ (however, the soil matrix as a whole is deformable, with changing porosity), we obtain

$$\nabla \cdot \underline{q}_r + S_w \frac{dS_w}{dt} + n \frac{dS_w}{dt} + nS_w \nabla \cdot \underline{V}_s - \frac{\rho_i}{\rho_f} \frac{\partial \Theta_i}{\partial t} = 0 \quad (3)$$

where $d_s(\)/dt = \partial(\)/\partial t + \underline{V}_s \cdot \nabla(\)$ denotes the total derivative with respect to moving solid. The fourth term can be obtained from the equation of mass conservation of solid which is given by

$$\nabla \cdot [(1-n)\underline{V}_s] + \frac{\partial(1-n)}{\partial t} = 0 \quad (4)$$

The change in porosity is related to the volume strain (dilatation) ϵ of the porous medium by

$$\frac{d_s \epsilon}{dt} = \frac{1}{1-n} \frac{d_s n}{dt} = \nabla \cdot \underline{V}_s \quad (5)$$

By combining (3) and (5), and an approximation, replacing the total derivatives by partial ones, i.e., assuming $\underline{V}_s \cdot \nabla S_w \ll \partial S_w / \partial t$ and $\underline{V}_s \cdot \nabla \epsilon \ll \partial \epsilon / \partial t$, (3) reduces to

$$\nabla \cdot \underline{q}_r + S_w \frac{\partial \epsilon}{\partial t} + n \frac{\partial S_w}{\partial t} - \frac{\rho_i}{\rho_f} \frac{\partial \Theta_i}{\partial t} = 0 \quad (6)$$

The melting term $\partial \Theta_i / \partial t$ can be expressed in terms of S_w and ϵ by writing down the conservation of mass equation for ice. If we assume ice moves with the velocity of solid particles \underline{V}_s

$$\nabla \cdot \Theta_i \underline{V}_s + \frac{\partial \Theta_i}{\partial t} - \frac{\rho_f}{\rho_i} \frac{\partial \Theta_w}{\partial t} = 0 \quad (7)$$

By rearranging and making use of (5) and previous assumptions

$$\Theta_i \frac{\partial \epsilon}{\partial t} + \frac{\partial \Theta_i}{\partial t} - \frac{\rho_f}{\rho_i} \frac{\partial \Theta_w}{\partial t} = 0 \quad (8)$$

The specific discharge relative to the deforming matrix, \underline{q}_r is expressed by Darcy's law which states that \underline{q}_r is proportional to the total potential gradient. Assuming that linear interactions between the flows are induced by mechanical and thermal effects, the mass flux is not only related to the potential gradient but also to the gradient of temperature. Then

$$\underline{q}_r = - \frac{k}{\mu} (\nabla p + \rho_f g \underline{V}z) - \underline{D}_{MT} \nabla T \quad (9)$$

where p is the pore pressure (suction), k is the medium's permeability tensor, which depends on n and the absolute temperature T , and μ is the water's dynamic viscosity. The vertical direction is represented by z , and g denotes the gravitational acceleration. \underline{D}_{MT} is the thermal liquid diffusion tensor, which is an Onsager's phenomenological parameter. This interference tensor can also be called as the tensor of thermo-osmosis.

The degree of saturation S_w is a function of p and T . Under isothermal conditions, the relation between S_w and p is given by the retention curve. Curves showing the phase composition of the water in the soil for temperatures below 0°C are given by Jame and Norum (1980). Typical curves for S_w are given in Figure 1. Hence

$$\frac{d S_w}{dt} = \left. \frac{\partial S_w}{\partial p} \right|_T \frac{d p}{dt} + \left. \frac{\partial S_w}{\partial T} \right|_p \frac{d T}{dt} \quad (10)$$

The term $\left. \frac{\partial S_w}{\partial p} \right|_T$ can be determined from the retention curve of the soil. $\left. \frac{\partial S_w}{\partial T} \right|_p$ can be obtained from the experimental relationship between unfrozen water content and below-freezing temperature. In addition to these two curves we need expressions for the medium's pressure and temperature dependent permeability and viscosity. Usually the dependence of μ on p is much smaller than on T and may be neglected.

The macroscopic energy conservation equation was developed by Bear and Coxapcioglu (1981), by starting from microscopic considerations and deriving the macroscopic one by averaging the former over a representative elementary volume of the porous medium. It is assumed that the thermal resistance between water and soil particles is small, hence, local water and matrix temperatures are equal. In what will be given below are the terms due to phase changes that have been added for a partially saturated thawing deformable porous medium.

$$\begin{aligned} \frac{\partial [(\rho C)_m T]}{\partial t} + L \rho_i \frac{\partial \theta_i}{\partial t} + \nabla \cdot [(\theta_w \rho_f C_w \underline{v}_f + \theta_i \rho_i C_i \underline{v}_s \\ + (1-n) \rho_s C_s \underline{v}_s) T] - \nabla \cdot [\underline{\Lambda} \nabla T] - p \nabla \cdot \theta_w \underline{v}_f \\ + (1-n) T \gamma \frac{\partial \epsilon}{\partial t} = 0 \end{aligned} \quad (11)$$

where $(\rho C)_m$ is the heat capacity per unit volume of the porous medium, i.e., $(\rho C)_m = \theta_w C_w \rho_f + \theta_i C_i \rho_i + (1-n) \rho_s C_s$. C_w is the water's heat capacity (specific heat) at constant volume. C_i is the heat capacity of ice at constant volume. C_s is the solid's heat capacity at constant strain. L is the latent heat of fusion at a reference temperature, T^0 . $\underline{\Lambda}_m = \theta_w \lambda_f + \theta_i \lambda_i + (1-n) \lambda_s$ is the coefficient of thermal conductivity of the porous medium as a whole. λ_f , λ_i , and λ_s are the heat conductivities of water, ice, and solid, respectively. Note that $(\rho C)_m$ and $\underline{\Lambda}_m$ depend on n , S_w , and θ_i , which in turn depend on pressure and temperature. Also, $\gamma = \left. \frac{\partial \sigma}{\partial T} \right|_\epsilon$, where σ is the total stress tensor on the solid particles of the soil. In writing (11) we assumed that the vapor phase in the soil has no effect (Fuchs et al., 1978). This assumption enables us to neglect the pore vapor pressure, vapor flux, and the transfer of latent heat by vapor movement.

The first term of (11) represents the change in the total heat content. The second term represents the rate of heat production due to melting. The third term represents the transfer of sensible heat by convection and deformation. Again we assume that ice moves with the velocity of the

solid. The fourth term represents the contribution of pure heat conduction.

If we combine (11) with the conservation of mass equations (1), (4) and (7), we obtain

$$\begin{aligned} (\rho C)_m \frac{\partial T}{\partial t} + L \rho_i \frac{\partial \theta_i}{\partial t} - \nabla \cdot [\underline{\Lambda}_m \nabla T] + [(\rho C)_m \underline{v}_s \\ + \rho_f C_w \underline{q}_r] \cdot \nabla T + C_w \rho_i T \frac{\partial \theta_i}{\partial t} + C_i \rho_f T \frac{\partial \theta_w}{\partial t} \\ - p \nabla \cdot \theta_w \underline{v}_f - (1-n) T \gamma \frac{\partial \epsilon}{\partial t} = 0 \end{aligned} \quad (12)$$

Equation (12) may further be simplified by noting that

$$(\rho C)_m \left[\frac{\partial T}{\partial t} + \underline{v}_s \cdot \nabla T \right] \equiv (\rho C)_m \frac{d T}{dt} \approx (\rho C)_m \frac{\partial T}{\partial t}$$

where we have $\underline{v}_s \cdot \nabla T \ll \partial T / \partial t$ and assuming $n \underline{v} \cdot \underline{v}_s \gg \underline{v}_s \cdot \nabla n$ and therefore

$$\begin{aligned} \nabla \cdot \theta_w \underline{v}_f = \nabla \cdot (\underline{q}_r + \theta_w \underline{v}_s) \approx \nabla \cdot \underline{q}_r + \theta_w \nabla \cdot \underline{v}_s \\ \approx \nabla \cdot \underline{q}_r + \theta_w \frac{\partial \epsilon}{\partial t} \end{aligned} \quad (13)$$

where we introduce the assumption $\underline{v}_s \cdot \nabla \epsilon \ll \partial \epsilon / \partial t$. We then obtain

$$\begin{aligned} (\rho C)_m \frac{\partial T}{\partial t} + L \rho_i \frac{\partial \theta_i}{\partial t} - \nabla \cdot [\underline{\Lambda}_m \nabla T] + C_w \rho_f \underline{q}_r \cdot \nabla T \\ + C_w \rho_i T \frac{\partial \theta_i}{\partial t} + C_i \rho_f T \frac{\partial \theta_w}{\partial t} - p \nabla \cdot \underline{q}_r \\ + [(1-n) T \gamma - \theta_w p] \frac{\partial \epsilon}{\partial t} = 0 \end{aligned} \quad (14)$$

The last two terms in (14) express the source of heat due to the internal energy increase per unit volume of porous medium by viscous dissipation and by compression. They may be relatively small in many cases of practical interest.

For a three-dimensional analysis of the problem, we need macroscopic equilibrium equations. Bear and Pinder (1978) develop the macroscopic equilibrium equations by volume averaging the microscopic ones. Neglecting the inertial terms, the total stress tensor σ at a point within the soil satisfies the equilibrium equations

$$\frac{\partial \sigma_{ij}}{\partial x_j} + f_i = 0 \quad i = 1, 2, 3 \quad (15)$$

where f_i represents the body force and the summation convention is employed.

Using $\sigma_{ij} = \sigma_{ij}^e - S_w p \delta_{ij}$ to express the total stress in terms of the effective stress σ_{ij}^e and the pressure p (positive for compression), and separating both σ_{ij}^e and p into initial steady values $\sigma_{ij}^e{}^0$ and p^0 and consolidation-producing incremental values $\sigma_{ij}^e{}^c$ and p^c , we replace (15) by

$$\frac{\partial \sigma_{ij}^o}{\partial x_j} + f_i^o - \frac{\partial S_w^o p^o}{\partial x_j} = 0 \quad (16)$$

$$\frac{\partial \sigma_{ij}^e}{\partial x_j} - \frac{\partial S_w^e p^e}{\partial x_i} = 0 \quad (17)$$

where $f_i^o \equiv f_i$, δ_{ij} is the Kronecker delta.

For a thermoelastic porous medium the stress-strain relationships are given by the Duhamel-Neumann relations

$$\sigma_{ij}^e = C_{ijkl} \epsilon_{kl}^e - \beta_{ij} T^e \quad (18)$$

where ϵ_{kl}^e are components of the incremental strain, $T^e = T - T^o$ is the incremental temperature, and the material coefficients

$$C_{ijkl} = \left. \left(\frac{\partial \sigma_{ij}^e}{\partial \epsilon_{kl}^e} \right) \right|_{T=\text{const}}$$

$$\beta_{ij} = - \left. \left(\frac{\partial \sigma_{ij}^e}{\partial T} \right) \right|_{\epsilon=\text{const}} \quad (19)$$

as calculated. For the sake of simplicity we shall henceforth limit the discussion to an elastically isotropic porous medium. For an isotropic body, (18) reduces to

$$\sigma_{ij}^e = 2G \epsilon_{ij} + (\lambda \epsilon_{kk} - \gamma T^e) \delta_{ij}; \quad \epsilon \equiv \epsilon_{kk} \quad (20)$$

where G and λ are the Lamé constants of the porous matrix and $\gamma \delta_{ij} = \left. \left(\frac{\partial \sigma_{ij}^e}{\partial T} \right) \right|_{\epsilon=\text{const}}$. The coefficient γ is also related to the coefficient of volumetric thermal expansion α_T by

$$\alpha_p = \frac{1}{\lambda + \frac{2}{3} G}; \quad \gamma = (\lambda + \frac{2}{3} G) \alpha_T; \quad \gamma = \alpha_T / \alpha_p \quad (21)$$

α_T includes the thermoelastic coupling term, strain in the porous material due to a unit change in fluid temperature, since both have the same local temperatures. Then, by assuming $\epsilon = \epsilon(p, T)$

$$\frac{d \epsilon_{ij}}{dt} = \left. \frac{\partial \epsilon_{ij}}{\partial p} \right|_T \frac{d p}{dt} + \left. \frac{\partial \epsilon_{ij}}{\partial T} \right|_p \frac{d T}{dt}$$

$$= \alpha_p \frac{d p}{dt} + \alpha_T \frac{d T}{dt} \quad (22)$$

Using the usual relationships between ϵ_{ij} and the components of displacement $U_i (i = 1, 2, 3)$,

$$\epsilon_{ij} = \frac{1}{2} \left(\frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i} \right); \quad \epsilon_{zz} = \nabla \cdot \underline{U} \quad (23)$$

we may rewrite (20) in the form

$$\sigma_{ij}^e = G \left(\frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i} \right) + \left[\lambda \frac{\partial U_k}{\partial x_k} - \gamma T^e \right] \delta_{ij} \quad (24)$$

Equation (22), together with (17), into which we insert (24), provides four equations for eight variables, U_i , p^e , T^e , S_w , θ_i , and ϵ . The mass conservation equations for water (equation (6)) and ice (equation (8)), and the thermal energy conservation equation (14) and expression (10) provide four additional equations in terms of p , S_w , θ_i , T and ϵ . Altogether we have eight equations for the eight variables. We have not mentioned q_r as a variable, as it is easily related to p and T by (9). In addition, we need information on $k = k(n, S_w)$ with n related to ϵ , which is given by (5), and $\mu = \mu(p, T) \approx \mu(T)$.

ONE DIMENSIONAL MODEL

For a one dimensional (vertical) elastic consolidation of thawing soils, governing equations will reduce to simpler forms. The conservation of mass equation for water (6) would reduce to the following form with the use of (10) and (22)

$$\frac{\partial q_r}{\partial z} + (S_w \alpha_p + n \zeta_p) \frac{\partial p}{\partial t} + (S_w \alpha_T + n \zeta_T) \frac{\partial T}{\partial t}$$

$$- \frac{\rho_i}{\rho_f} \frac{\partial \theta_i}{\partial t} = 0 \quad (25)$$

where $\zeta_p = \partial S_w / \partial p|_T$ and $\zeta_T = \partial S_w / \partial T|_p$, which are determined from experimentally obtained curves (see Figure 1). Similarly, the conservation of thermal energy (equation (14)) would reduce to

$$\left\{ (\rho C)_m + \alpha_T [(1-n)(\gamma T + C_i \rho_f S_w) - S_w n p] \right.$$

$$+ n C_i \rho_f \zeta_T \left. \right\} \frac{\partial T}{\partial t} + \left\{ \alpha_p [(1-n)(\gamma T + C_i \rho_f S_w) \right.$$

$$- S_w n p] + n C_i \rho_f \zeta_p \left. \right\} \frac{\partial p}{\partial t} + L \rho_i \frac{\partial \theta_i}{\partial t} - \frac{\partial}{\partial z} \left[\Lambda \frac{\partial T}{\partial z} \right]$$

$$+ C_w \rho_f q_r \frac{\partial T}{\partial z} + C_w \rho_i T \frac{\partial \theta_i}{\partial t} - p \frac{\partial q_r}{\partial z} = 0 \quad (26)$$

with the assumption of $\partial n / \partial t \approx (1-n) \partial \epsilon / \partial t$. The conservation of mass equation (8) for ice would be

$$\left\{ \alpha_p [\theta_i - (1-n) S_w \frac{\rho_i}{\rho_f}] - n \frac{\rho_i}{\rho_f} \zeta_p \right\} \frac{\partial p}{\partial t} + \left\{ \alpha_T [\theta_i \right.$$

$$- (1-n) S_w \frac{\rho_i}{\rho_f}] - n \frac{\rho_i}{\rho_f} \zeta_T \left. \right\} \frac{\partial T}{\partial t} + \frac{\partial \theta_i}{\partial t} = 0 \quad (27)$$

Also, the stress-strain equation would be

$$S_w p^e = \sigma_{zz}^e = (2G + \lambda) \frac{\partial U_z}{\partial z} - \gamma T^e \quad (28)$$

if the vertical total stress σ_{zz} remains constant, i.e., $\sigma_{zz}^e = 0 = \sigma_{zz}^e - S_w p^e$.

In summary, the one dimensional elastic consolidation of thawing soils can be simulated by the governing equations (25), (26), (27), and (28)

to obtain p , T , θ_i , and U_z . The porosity, n is related to ϵ by (5), and S_w is related to p and T by (10).

RHEOLOGY OF THAWING SOILS

In the formulation given above we assumed a time-independent elastic stress-strain relation for the medium. This approach is, of course, the most simple one from a mathematical point of view. The phenomena that control the mechanical behavior of frozen and thawing ground are complex. As a result of ice content θ_i and unfrozen water content θ_w , thawing soils are characterized by rheological stress-strain properties. Various researchers (e.g., Vyalov, 1963; Stevens, 1973; Aziz and Laba, 1976) have studied the viscoelastic behavior of frozen ground. They have introduced several mechanical models to simulate the behavior of a frozen soil under a load. When frozen ground is subjected to a load, it will respond with an instantaneous deformation and a time-dependent creep behavior. It is therefore convenient to distinguish between the elastic and creep properties. Both will depend on temperature and material properties.

Aziz and Laba (1976) have assumed that the solid soil particles may be considered as an elastic material. Ice, separately, as well as in combination with soil particles, will behave as a viscoelastic solid. Unfrozen water, although incompressible, will flow under pressure gradually with time so that the system will display a certain amount of viscous flow continuing for a long period of time. Accordingly, the proposed model of Aziz and Laba consisted of a spring (to represent elastic deformation), a damper (to simulate viscous flow), and a parallel combination of spring and damper (to represent viscoelastic behavior), with all three elements connected in series. One big disadvantage of their model is that it is not temperature dependent.

To represent a temperature dependent thawing isotropic soil mechanically, we can visualize the behavior of the ground as being equivalent to that of a spring placed in series with a parallel combination of spring and damper (a Kelvin body). Then for a one-dimensional deformation

$$\sigma_{zz}^e = E_1 \epsilon_s \quad (29)$$

$$\sigma_{zz}^e = E_2 \epsilon_K + \phi_2 \frac{\partial \epsilon_K}{\partial t} + \phi_T \frac{\partial T^e}{\partial t} \quad (30)$$

where ϵ_s and ϵ_K denote the strains of the spring and the Kelvin body, respectively. The values of E_1 and E_2 are the elastic moduli of the two spring components and ϕ_2 is the viscosity of the Kelvin body. ϕ_T is a thermoviscoelastic coefficient. These parameters have to be determined experimentally. For the series arrangement of the present model the total strain is

$$\epsilon_{zz} = \frac{\partial U}{\partial z} = \epsilon_s + \epsilon_K \quad (31)$$

A more convenient stress-strain relationship can be obtained by solving (31) for any known function σ_{zz}^e and T^e of time.

$$\epsilon_{zz} = \frac{1}{E_1} \sigma_{zz}^e + \frac{1}{\phi_2} \int_0^t \sigma_{zz}^e(\tau) \exp\left[\frac{(t-\tau)}{\phi_2/E_2}\right] d\tau - \frac{\phi_T}{\phi_2} \frac{\partial}{\partial t} \left\{ \int_0^t T^e(\tau) \exp\left[\frac{(t-\tau)}{\phi_2/E_2}\right] d\tau \right\} \quad (32)$$

Note that to obtain (32) we took $\sigma_{zz}^e(t=0) = \epsilon_{zz}(t=0) = T^e(t=0) = 0$. For a rheological soil the term $\partial \epsilon / \partial t$ as given by (22) in the governing equations should be evaluated by employing (32) instead of (28). When $d\sigma_{zz}^e = 0$, σ_{zz}^e in (32) is replaced by $S_w p^e$. τ is a dummy integration variable.

Another alternative to (32) would be the use of thermoplastic stress-strain relations. Interested readers can refer to Corapcioglu (1983) for the use of this type of constitutive equations.

INITIAL AND BOUNDARY CONDITIONS

The solution of one dimensional equations (25)-(28) are subject to initial and boundary conditions. Initially, an unsaturated frozen soil column may have certain ice and water contents, a known pore pressure distribution and a uniform or certain temperature distribution, i.e., $S_w(z,0) = f_1(z)$, $\theta_i(z,0) = f_2(z)$, $p(z,0) = f_3(z)$, and $T(z,0) = T^0$ or $T(z,0) = f_4(z)$ where f_1 , f_2 , f_3 , and f_4 are known functions. The undisturbed soil may initially be free of any deformation, i.e., $U_z(z,0) = 0$. Boundary conditions are defined by the particular physical conditions imposed on the soil. On the soil surface, we may have a constant temperature $T(0,t) = T_1 > 0^\circ\text{C}$, complete thawing $\theta_i(0,t) = 0$, atmospheric pressure $p(0,t) = 0$ or a constant surface loading $p(0,t) = p_1$, and saturated soil $S_w(0,t) = 1$. The surface temperature might possibly be also a known function of time $T(0,t) = f_5(t)$. Theoretically at infinity ($z = \infty$), practically at a certain distance from the soil surface ($z = z_a$) the surface effects will diminish. Hence, $S_w(\infty,t) = S_1$, $\theta_i(\infty,t) = 0$, $T(\infty,t) = T_2$ and $\partial p(\infty,t) / \partial t = 0$, where S_1 is a constant value of water saturation and T_2 is a constant temperature.

CONCLUSIONS

A mathematical model is developed to predict the values of pore pressure, temperature, water saturation, ice content, and displacements for known boundary conditions. The model is simplified for a one dimensional vertical consolidation problem. We should note that the development of the model is subject to various assumptions, such as constant water and ice densities, negligence of pore vapor pressure, identical velocities for ice and solid particles, and others. Most of these assumptions are valid for practical problems.

THERMAL REGIME OF A SMALL ALASKAN STREAM IN PERMAFROST TERRAIN

Samuel W. Corbin^{1,2} and Carl S. Benson¹

¹Geophysical Institute, University of Alaska, Fairbanks, Alaska 99701 USA

²Now at Department of Geology, University of Oregon, Eugene, Oregon 97403 USA

Goldstream Creek near Fairbanks, Alaska is about 8 m wide, 0.25 m deep, and flows 0.3 to 1.3 m³ s⁻¹. From 1963 to 1973, hydrological and temperature observations were made to determine thermal effects of the stream on the relict permafrost that underlies much of the valley. Soil freezing beginning in October causes build-up of ground-water pressure, and the stream overflows repeatedly until about January, forming aufeis deposits 1 to 2 m thick, depending on depth of soil freezing, which is primarily controlled by the amount of snow cover. The data permitted calculations of the thermal diffusivity of unfrozen soil, using Fourier series, numerical step models and differential analyses; average values ranged from 4 x 10⁻⁷ m² s⁻¹ in areas away from the stream to over 15 x 10⁻⁷ beneath the stream. Overflows facilitate heat loss from the ice by removing the insulating snow layer. However, they also add heat as the water percolates through fractures in the ice and releases latent heat as it freezes. The mechanism of adding heat is more effective than conduction which is the only mechanism for transporting heat to the upper surface. Although the surface temperature during summer is lower in the stream than in the surrounding ground (11°C compared with > 22°C) the summer heat pulse penetrates deeper under the stream; this is partly due to the topography of the stream channel. The net effect on the permafrost is to lower the relict permafrost table, from about 4 m away from the stream, to nearly 6 m beneath the stream.

INTRODUCTION

Numerous references are devoted to the thermal effects of large bodies of water on permafrost (Brewer, 1958; Gold and Lachenbruch, 1973; Lachenbruch, 1957) the observations presented here show thermal effects produced by a small stream flowing over relict permafrost.

Goldstream Valley near Fairbanks, Alaska has a fairly flat bottom, about 3 km wide, which is underlain by permafrost more than 50 m thick, with an estimated maximum thickness of 75 m. The active layer is generally about 1 m deep. In localized areas, away from Goldstream Creek, the top of the permafrost lies below this depth (it ranges from 1 to 4 m) and during winter pressure builds up in ground water between the seasonally and perennially frozen ground. Under Goldstream Creek, perennially frozen ground is encountered at depths of nearly 6 m. The creek is typically 8 m wide, with well-defined banks 1 to 2 m high, its average water depth is about 25 cm, its gradient is 2.2 m km⁻¹, and its summer discharge varies between 0.3 and 1.3 m³ s⁻¹. During winter the creek overflows repeatedly to form extensive aufeis deposits. Thickness of the aufeis nearly always exceeds 1.5 m and is sometimes greater than 2 m. The maximum measured cross-sections of aufeis at the end of winter ranged between 11 and 21 m², thus they are an order of magnitude greater than the typical pre-freezeup stream cross-section of 2 m² (Figure 1).

Goldstream Creek, a tributary of the Tanana River drainage system, is fairly typical of creeks throughout central Alaska and was selected for research due to its easy access from the University of Alaska. The research site, established in 1963, was located 9 km northwest

of Fairbanks, Alaska where Ballaine Road crosses the creek, 183 m above sea level. Mean annual air temperature averages about 3°C lower than the -3.4°C observed at Fairbanks International Airport. The mean annual snowcover contains only about 10 cm of water equivalent, but it remains on the ground from October until April. Flat portions of the valley are marshy with numerous icewedge polygons. Soil is mostly silt of low organic content (10 percent or less), vegetation consists mainly of willows and sparse stands of spruce. Hydrological observations, with special attention to winter icing problems, were carried out during the ten years 1963-1973; they lead to three M.S. theses (Kreitzer, 1969; Gilfilian, 1973; Corbin, 1977) and one Ph.D. dissertation (Kane, 1975).

This paper deals with the thermal regime of the stream and a cross-section of the land extending 10 to 15 m on each side of the stream center (Figure 2). A network of thermocouples which, at its maximum, contained 98 probes and over 1600 m of wire was arranged in two parts. (1) The first part was in the aufeis itself; before freezing began, a string of thermocouples was placed across the stream bottom. After freeze-up, a string of thermocouples was frozen onto the ice surface. When the original ice surface was buried by a layer of overflow ice a string of thermocouples was frozen onto this ice surface. Five strings of thermocouples were emplaced in this way during four consecutive winters ending in 1971. (2) The second part was a network of subsurface probes arranged vertically in three pits beginning in 1967 and expanded into ten vertical strings in the fall of 1970 (Figure 2). Measurements were made weekly with a Leeds and Northrup, Model 8646, potentiometer using an ice-water bath as reference.

THE ANNUAL CYCLE

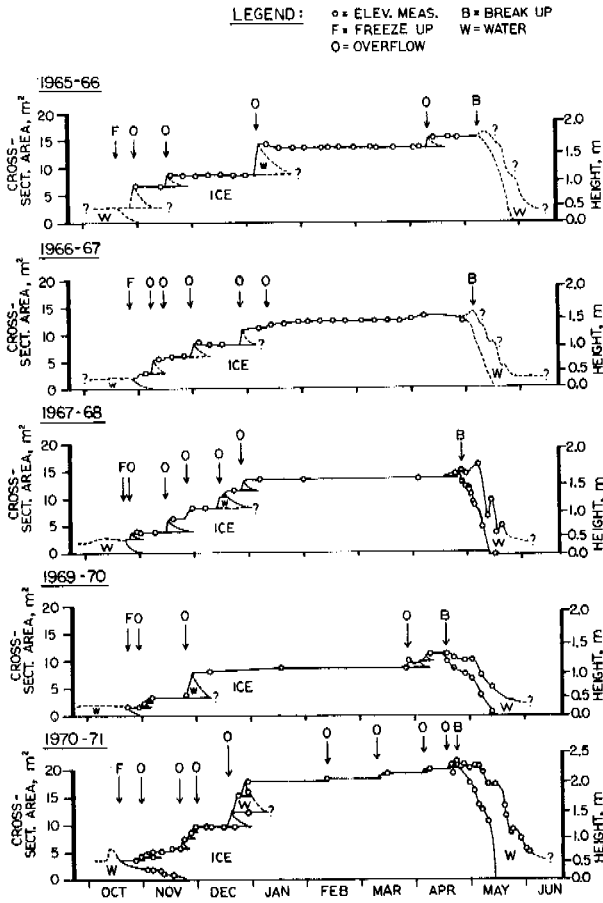

Figure 1. Aufeis formation and break-up (cross-sectional area and height versus time) during five winter seasons -- between 1965 and 1971, no data were taken during the 1968-1969 winter.

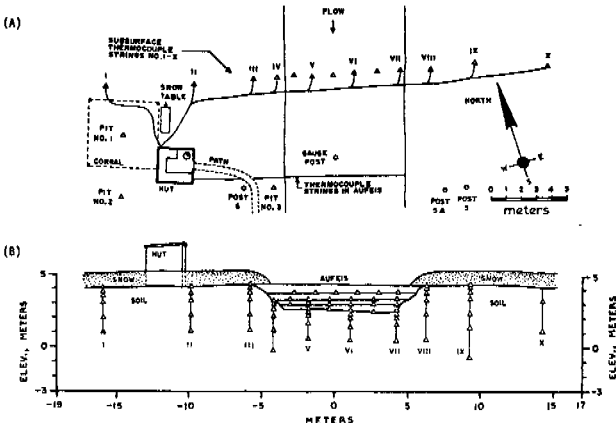

Figure 2. (A) Planar and (B) cross-sectional views of thermocouple network, consisting of pits no. 1, 2, and 3 (installed in fall of 1967) and vertical strings no. I through X (installed in fall of 1970). Elevations refer to an arbitrary datum. The thermocouples in the stream were on a separate cross-section to avoid disturbance of the subsurface thermocouples.

A full annual cycle of temperature changes in the aufeis and surrounding soil was measured from October 1970 to December 1971; four representative cross-sections are plotted in Figure 3. A summary of the annual data at the stream center (column VI) and 16 m west of the stream center (column I) is shown, together with meteorological data, in Figure 4.

The freezing process begins in early October at Goldstream Creek with supercooling of the entire stream to temperatures as low as 0.036°C below the freezing point depression of 0.012°C (Gilfilian, 1973). Supercooling followed by underwater ice formation (frazil and anchor ice) was measured during freeze up nearly every winter between 1963 and 1973; the concentration of underwater ice ranged between 0.9 and 4.7 percent of the stream's volume (Benson, 1967, 1973; Osterkamp et al. 1972; Gilfilian et al., 1972; Corbin, 1977). A permanent ice cover was usually in place by 27 October. The date of its formation was consistent with Michel's (1971) soil-freezing model to within 2 days (Corbin, 1977). Overflow of water on top of the ice cover followed by the build-up of aufeis layers began as early as 24 October and maximum thicknesses were usually reached by the end of December. The petrofabric structure of aufeis from the winters of 1965-66, 1966-67 and 1967-68 was studied by Kreitner (1969). Spring break-up, between mid-April and mid-May, generally began with the overflow of organically stained water followed by snow melt-water. The potential for spring flooding is high because the channels are filled with aufeis which begin to melt and undergo mechanical fragmentation. Within three weeks, the entire body of aufeis is removed; the layers calve away from the top down.

Once an ice cover has formed, the cross-sectional area available for stream flow decreases causing water pressure to increase as the ice continues to grow. When freezing is rapid, pressure bulges may form within a week after freeze-up, as in 1966. Water pressure is relieved when the stream breaks through cracks in the ice (cracks due to thermal stress are common in the upper layers) or at the stream margins to overflow the ice surface and produce layers of aufeis (Benson 1967, 1973). Kane measured ground water pressure adjacent to the stream during the 1971-72 winter; he found the hydrostatic head to vary by several meters and observed its control on aufeis formation (Kane et al. 1973; Kane, 1975).

The aufeis develops rapidly to its maximum (Figure 1); the ice surface then remains essentially constant until overflows occur just before or during spring break-up. The lack of overflows between January and April results from a combination of causes. The rate of channel constriction by freezing decreases as the insulating effect of aufeis layers (1 to 2 m thick) increases. Also, the source of water decreases as soil freezing progresses. The flow apparently can be accommodated by the restricted channels and the ice overburden adequately confines the ground water even though its pressure head varies through a range of about 1.5 m (Kane et al., 1973).

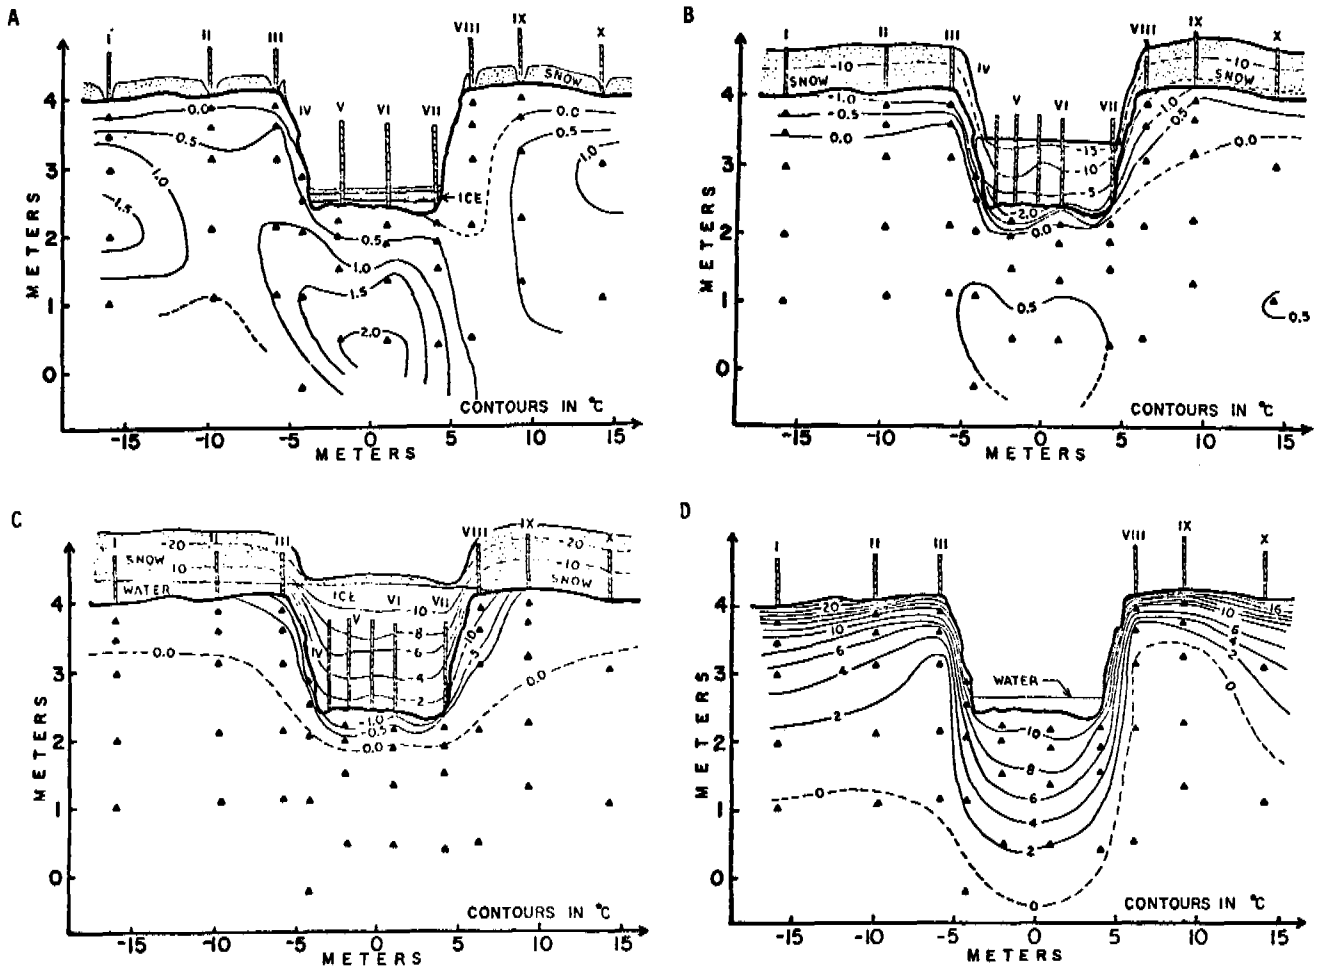

Figure 3. Cross-sectional views of the temperature distributions of Goldstream Creek and surrounding soil during hydrological year, 1970-1971. Parts of Figure 3: (A) 22 October 1970; (B) 15 December 1970; (C) 24 February 1971; (D) 22 June 1971.

THERMAL EFFECTS

The thermal effects of overflows and aufeis formation are complex. If the stream ice is snow covered, the overflow water soaks into the snow, freezes to form an ice layer, and eliminates the insulation which the snow had provided. This contributes to several meters deeper penetration of low temperature isotherms under the stream than under the adjacent snow-covered ground. Conditions varied significantly from one year to the next. The minimum temperature measured on the stream bottom was -10.4°C on 20 January 1967 (between stakes VI and VII, Figure 3); isotherms were inclined in the ice with a gradient of $2.7^{\circ}\text{C m}^{-1}$ along the stream bed and running water at the bottom on the left side, i.e., near stake IV. In this case, when the aufeis surface reached the 4 m level, overflow water oozed out on the left side only, built a dam which prevented it from moving across the stream and spread into the snow by capillary action on the left side of the stream.

The four winters during which temperature observations were made in the aufeis included extremes of snow cover. The winter of 1969-1970 was one of the mildest on record and total snow depth never exceeded 0.30 m. In contrast, the winter of 1970-1971 was the most severe since 1956-1957. Air temperatures 5.2°C below normal were accompanied by a record-breaking snow depth of 1.10 m on the ground. The insulation provided by the snow was such that the snow-soil interface temperature rarely went below -2°C . But, in spite of the milder conditions during 1969-70, the thin snow cover allowed temperatures as low as -8°C at the snow-soil interface. The depth of freezing in the soil may be a contributing factor in determining the total amount of aufeis formed; deeper freezing over the entire drainage area can be expected to reduce the source of winter flow which is available to be stored as aufeis. This is consistent with the observation that the minimum snow depth (0.30 m) in 1969-70 is associated with the minimum aufeis cross-section of 11 m^2 , and the maximum snow

Figure 4. Comparison between temperatures in augeis and soil at stream center (string no. VI) and temperatures in upper 3 m of soil, 16 m west of stream center (string no. I) from September 1970 through December 1971. Supporting meteorological data are from both the Goldstream Site (GS) and National Weather Service, Fairbanks (NWS). Similar diagrams for the winters of 1967-1968 and 1969-1970 also show the thorough warming of augeis to 0°C following each overflow.

depth (1.10 m) the following year is associated with the maximum augeis cross-section of 21 m².

Although overflows enhance heat removal by removing the insulating snow cover, their net thermal effect is to add heat to the system. This is primarily by the release of latent heat while the overflow layers freeze. The heat available from freezing a 20 cm thick overflow was more than twice the amount required to bring even the thick-accumulation of augeis to its melting point. The depth-time diagrams prepared from three years of data (Figure 4 is typical) showed rapid warming to 0°C of the underlying ice following

overflows. The rate and thoroughness of the warming was too fast to be accounted for by conduction alone. Apparently water from mid-winter overflows was able to penetrate from above and release latent heat as it froze within cracks or spaces which were sometimes observed between ice layers. Thus the bottom of the growing augeis is continuous enough to contain the flowing water under pressure but the upper ice surface can be penetrated by percolating overflow waters. This introduces an extremely efficient mechanism of heat transfer into the ice; but heat transfer out of the ice takes place only by conduction.

During several winters, overflows spread over the west bank as well. In January 1971 when this happened, the temperature of the soil below the overflow increased to 0°C and did not freeze again during the winter. Only the lower half of the snow became wetted and turned to ice, the upper half remained snow and served its role of insulation (Figure 4). Overflows preceding break-up in April rapidly brought ice temperature to 0°C. This shows up best in data from 1968 and 1970, but it is also clear in 1971 (Figure 4); by 10 May 1971 all probes in the soil were isothermal at 0°C.

THERMAL DIFFUSIVITY

The detailed temperature data permitted calculation of the summer thermal diffusivity values in unfrozen soil adjacent to and under the stream, with an assumed zero degree boundary at the top of the permafrost. One-dimensional models were used with thicknesses of infinity, 3.5 and 4.0 m. These one-dimensional models were assumed valid where the isotherms were approximately horizontal, directly under the center of the stream (column VI), and well away from the stream (column I), see Figures 2 and 4. Three methods were used.

First, following procedures outlined by Carslaw and Jaeger (1959), Fourier integration at one month intervals was done for various depths. The thermal diffusivity of a layer between two given depths was calculated using 6-month half-wave pulses. In the top two meters the models were in reasonable agreement with each other and with the data. Below two meters the infinitely thick model deviated significantly from measured values; but the 4m thick slab model continued to agree with the data to the lowest depths of measurement (3 m). Diffusivity values from the 4 m slab ranged from 3×10^{-7} to $7 \times 10^{-7} \text{ m}^2\text{s}^{-1}$ away from the stream and from 3×10^{-7} to $11 \times 10^{-7} \text{ m}^2\text{s}^{-1}$ beneath the stream.

Second, using a simple finite difference approximation of the Fourier conduction equation in one dimension, diffusivity was adjusted to give a best fit to the data using 40 cm depth intervals and time intervals of 4 days. The best fits were made by using the 4 m thick slab away from the stream, with diffusivity values of 4×10^{-7} to $6 \times 10^{-7} \text{ m}^2\text{s}^{-1}$; beneath the stream center the infinitely thick model worked best with diffusivities of 10×10^{-7} to $12 \times 10^{-7} \text{ m}^2\text{s}^{-1}$.

Third, diffusivity was also estimated directly from the data by using the ratio of the derivative of temperature with time to second derivative of temperature with depth. Taking smoothed temperatures during June and July 1971 over intervals of 20 cm and 5 days, diffusivities away from the stream ranged from 2×10^{-7} at the surface to $6 \times 10^{-7} \text{ m}^2\text{s}^{-1}$ at 2.60 m depth. Beneath the stream, values ranged from 8×10^{-8} to $6 \times 10^{-7} \text{ m}^2\text{s}^{-1}$ below one meter, but closer to the surface, they were infinite.

The infinite value is a warning that significant, and undetermined, errors exist in these determinations. The uncertainties in the system do not permit detailed calculation. However, if we disregard the infinite value, working averages

from the three methods were $4 \times 10^{-7} \text{ m}^2\text{s}^{-1}$ away from the stream and $11 \times 10^{-7} \text{ m}^2\text{s}^{-1}$ beneath the stream.

The three-fold difference in diffusivity values may result from several factors. The assumption of a one-dimensional model is questionable under the center of the stream; it is certainly not valid near the edges (Figure 3). However, it seems reasonable away from the stream where the isotherms are essentially horizontal and diffusivities compare favorably with accepted values (Kersten, 1952). Another possibility is latent heat exchange in the soil which would be difficult to detect at both ends of the summer period. Finally, there may be vertical movement of ground water under the stream. Order of magnitude calculations indicate that such flow, at rates of only a few meters per year, would introduce heat transfer rates comparable and added to the conductive rates. This could allow the summer heat pulse to penetrate more rapidly under the stream even though the upper-surface temperatures are lower beneath the stream than beneath the adjacent ground surface (Figure 3D). Similar effects on cooling rates would be expected (Figure 3A, B). This effect would diminish rapidly away from the stream; 16 m away, at column I (Figures 2 and 4) the 4 m-thick slab model is consistent with our temperature data, and with observations by us and others (Kane, et al., 1973; Slater, 1974) that the top of the relict permafrost is about 4 m deep.

SUMMARY

The maximum water temperature in Goldstream Creek during summer is significantly less than the maximum ground surface temperatures; but the topography of the stream channel is such that the ground beneath the stream is warmer than ground adjacent to the stream at the same elevation (Figure 3D). During winter, heat removal from ground beneath the stream is less than from ground adjacent to the stream. This is true even though the adjacent ground is continuously snow covered while overflow water periodically destroy the insulating snow cover on the stream ice. The most significant influence is the large heat source provided by latent heat released as overflow water freezes to form layers of aufeis, and the associated non-conductive heat transfer mechanism. Movement of the freezing water downwards into the ice along fracture patterns provides a more efficient means of heat transfer than conduction which is the only mechanism for transporting heat to the ice surface. In spite of the relatively high thermal conductivity of ice, this provides a heat source as well as a thermal barrier against heat loss from the underlying sediments. Movement of groundwater across isotherms may introduce another mechanism for non-conductive heat transfer; its effectiveness would probably decrease rapidly away from the stream.

The net effect appears to be a lowering of the relict permafrost table from about 4.0 m away from the stream to 6.0 m beneath the stream bottom.

ACKNOWLEDGEMENTS

This work was supported by funds from the Office of Water Resources Research, U.S. Department of Interior (Project A-012-ALAS) by the Earth Sciences Section, National Science Foundation NSF Grant No. 30748, and by the State of Alaska funds. We express special thanks to our colleagues in the field: R. E. Gilfilian, J. D. Kreitner, T. E. Osterkamp and D. C. Trabant and for helpful discussions with W. D. Harrison.

GEOCRYOGENIC MORPHOLOGY AT SEYMOUR ISLAND (MARAMBIO) ANTARCTICA

A Progress Report

Arturo E. Corte

Instituto Argentino de Nivología y Glaciología, Casilla de Correo 330
5500 Mendoza, Argentina

At Seymour Island, 64°14' S.L. and 56°38', Antarctica under a mean annual temperature lower than -10°C, various geocryogenic forms are observed including frost-contraction cracks and polygons, frost domes and pingos, gelifluction features, etc. These first forms require cold permafrost with mean annual temperatures below -5°C. The geocryogenic processes at both sides of the Antarctica Peninsula are compared. In the west part, geocryogenic processes of Deception are compared including sorting and gelifluction features, which formed at -2.8°C. On the east side forms requiring lower temperatures are observed, including thermal-contraction cracks and polygons, pingos and frost domes; they are formed under mean annual temperature of -10°C or lower. The mountain chain of the Peninsula works as a barrier for the cold winds of the Weddell Sea resulting in frigid conditions all along the east sector of the Peninsula. On the west side of the chain, with more prevalent anticyclonic conditions, warmer air is brought from the northeast and west producing higher temperatures. Temperature differences about 8-9°C are observed at the same latitude on the east and west sides. The strong southwest winds with a snow and debris load produces a remarkable phenomenon: snow drift-dammed lakes. The lakes behind such dams can be of several hectares. The growth of mounds displaces drainage lines, this process and the water ponded by the snow drifts also cause continual change in the drainage systems. The fluvial system of the island is too dense for the apparently low precipitation.

INTRODUCTION

This is a progress report on a continuing study of the geocryology of Seymour Island. This report deals with an inventory of the geocryogenic forms based on an aerophoto survey and ground inspections. The next stage of this work will be dedicated to excavations, sampling of soils, and ground ice studies.

Geocryogenic conditions on Seymour Island, shown on Argentina topographic maps as "Vice Com. Marambio", which is located (see map incl.) on the east side of the Antarctic Peninsula, differ greatly in comparison with places at the same latitude on the other side of the Peninsula.

Seymour, like other sectors of the east coast of the Peninsula, has a cold climate, with a mean annual temperature below -10°C (Schwerdtfeger, 1975, 1976). By contrast, places situated on the west side of the Peninsula have shown mean annual temperatures 8° to 9°C higher. The low-temperature geocryogenic forms on the east side, i.e. thermal-contraction cracks, pingos, etc. are not observed in the west sector (Corte and Zomoza, 1957). Sorted features produced by freezing, thawing and gelifluction occur in places on the west side of the Peninsula where the mean annual temperature is -2.8°C. (Corte and Zomoza, 1957).

The geocryogenic features described by Péwé (1959) and Black and Berg (1963) in the area peripheral to the Ross Sea of Antarctica include large thermal-contraction polygons (sand and/or ice wedges), but the variety of forms is very small in comparison with Seymour Island.

In the geocryogenic map (Fig.1) it was considered appropriate to honor the great efforts made by the members of the first Antarctic expedition led by Otto Nordenskjöld to this area in 1901. Be-

sides the names of Bodman, Sobral and Larsen, other topographic features are named after Akerlund, Nordjenskjöld, Ekelof, Johansen.

ENVIRONMENTAL CONDITIONS

Meteorology and climate

The available meteorological records for the east sector of the Antarctic Peninsula are restricted to the following places: Snow Hill (Cerro Nevado), (in Schwerdtfeger, 1975) with mean annual air temperatures of -11.5°C; Seymour Island (Marambio, Servicio Meteorológico Nacional) with -12°C (Schwerdtfeger 1975) (Fig.2).

The meteorological conditions on both sides of the Antarctic Peninsula were studied by Schwerdtfeger (1975-1979), who indicated that the mountain chain along the Peninsula acted as a barrier for the cold winds of the Weddell Sea (Fig.2) and that cyclonic conditions were the main cause of the refrigeration of the east sector (Servicio Meteorológico Nacional, 1981) (Fig.3). The west side of the Peninsula is generally under the effects of anticyclonic conditions and receives warmer air from the northwest or west. These conditions account for the difference of about 8-9°C at annual mean temperatures at the same latitude (Fig.3).

Precipitation on Seymour Island has not been measured because of the strong wind; however, the following types of precipitation were observed: snow, graupel (soft hail), rime, and rain. The most significant for this is snow, both directly precipitated and wind blown carried. Though there is no information on their relative importance.

Geology and Soils

Figure 4 LARSEN DELTA, NORTHERN SEYMOUR ISLAND (MARAMBIO) (Servicio de Hidrología Naval)

The island is made of Tertiary and Cretaceous sediments with the greatest elevation at 200 m in the Meseta which occupies about 1/20 of the Island's area. Small areas of till occur on the meseta.

Many of the geocryogenic forms are produced in consolidated and non-consolidated Tertiary sediments, most of which are frost-susceptible. Thus frost heaving due to formation of ice lenses must be an important process in these sediments. The wide distribution of troughs left by the melting of ice wedges indicated that the Tertiary sediments also are subject to frost cracking and development of ice wedges.

Air photos of the meseta show that in 1967 thermal-contraction cracking and the formation of large domes and ice-wedge polygons appear to be the main geocryogenic processes. These polygons form nets 100-200 m in diameter at the border of the meseta; the troughs have been emphasized by erosion.

Active Layer and Permafrost

According to meteorological observers (Servicio Meteorológico Nacional), the depth of the active layer at Seymour is greatest at the end of February and is about 40-50 cm. However annual and regional year to year local variations in the depth of the active layer were observed, under varying meteorological and terrain conditions, at the same latitude as Seymour (Brown, 1978).

Permafrost thickness has not been measured on Seymour Island. However using Lachenbruck's formula (1968) in which permafrost depth can be approximated by multiplying mean annual air temperature (-10°C) by the general geothermal gradient (33 m per Celsius degree), the permafrost depth at Seymour is calculated to be approximately 330 m. This ignores local variations in the geothermal gradient and also the past thermal history.

THE GEOCRYOGENIC FORMS: THE MAJOR FORMS

Frost Domes and Pingos

Frost domes are present in several places but are most abundant and distinctive in Larsen Delta at the north end of the Island. No subsurface sampling has been undertaken yet. The domes of Larsen Delta (Fig.4), are not readily classified as either open systems or closed systems pingos or mounds. They range in diameter from 2 to 10 m. It is intriguing that mounds near the shore contain a circular depression in their center, whereas the mounds near the mountain side do not (Fig.4). The depression is a thermokarst feature (Fig.4).

The domes that have the largest diameter and smallest in height and are closer to the sea (Fig.4) show the largest thermokarst depressions and appear to be the oldest. On the other hand, the domes that are smaller in area, rounder and more symmetrical, and closer to the mountain side show no thermokarst depressions and appear to be the youngest.

The domes are not seasonal mounds; they have existed at least since the first photo flight was made in 1967, (Fig.4). It is possible that these mounds are produced by the freezing of taliks in abandoned channels. (Washburn, personal communication, 1983).

Sections through the domes and depressions and sampling of permafrost ground ice, which is presumed to be present (Corte, 1963), would clarify the origin of the domes.

Larger features of six meters or more in high which may be true pingos with a perfect conical shape, were observed in two places on the island, near Quebrada de Díaz and in Jato river (Fig.1). The domes occur in areas in which refreezing of taliks causes local heaving and shifts of river channels.

Thermal Contraction Cracks and Polygons

The mean annual temperature necessary for the formation of thermal contraction cracks and polygons with ice and sand wedges is below -5°C . (Péwé, 1962, Washburn, 1979-1981). Thermal-contraction produces cracks and polygons of various sizes; on the Larsen Delta there are cracks up to 120 m long (Fig.4) and the polygons have sides of 10 to 30 m (Fig.4). In the deltas close to the Nordenskjöld Strait there are polygons as large as 30 x 100 m (Fig.1).

Thermal-contraction cracks were observed to form after several days with temperatures about -26°C and winds up to 180 km/hr. The observed cracks were 12 mm wide and 15 m long, located in the polygons troughs.

Since these depressions were not trenched, it is unknown if either sand or ice wedges are present. Because snow accumulates in north-south troughs and is blown from the east-west ones, there is a chance that sand and ice wedges may coexist in the same polygons (Pomanovskij, 1973).

Thermokarst depressions left by thawing ice wedges are present in many cliffs and ravines and are especially well developed in north-facing cliffs between Bodman and Nordenskjöld Strait, and on north-facing cliffs of the meseta. Few such forms are present on south-facing slopes.

Snow Dammed Lakes

Lakes dammed by snowdrifts up to several hectares in size, are a characteristic and very dominant feature of the island (Fig.1). Lakes of such magnitude have not been described previously in the periglacial literature.

During storms with winds of 100-200 km/hr, the southwest winds carry snow as an almost horizontal curtain. Material from the soft Tertiary and Cretaceous sediments is also picked up by the wind. When the Weddell Sea is frozen the snow and dirt are carried north and accumulate on the lee side of the island as long drifts, sometimes crossing the rivers and damming the drainage. In some places there are snowdrifts 200 m long and as much as 10 m high. Several dams were observed on the north-facing slope of the meseta. These lakes appear to be a more than one year process.

Nivation Niches

Nivation niches were observed on the east slope of Seymour Island. Below the niche a transport slope leads to an accumulation slope characterized by gelifluction lobes.

Icings and Icing Domes

During the fall and early winter, growth of icings on Seymour Island is a dominant characteristic. The largest icings are those related to freezing of surface water. The freezing of the snow-dammed lakes and other lakes produces icing mounds up to half a meter high and several meters across the base. These icing domes are formed by the expulsion of water confined between the permafrost and the overlying thickening ice as it becomes irregularly anchored to the ground.

During this process of formation of the ice-dammed lakes, the icings act as a cementing agent. The water that is ponded up river from the snow-drift moves across the snow dam and, since this barrier is very cold, the water freezes and cements the snow debris and icings into a solid wall.

Gelifluction

Gelifluction (Washburn, 1979) is not well developed on the island. Only on the northwest slope of the meseta are there gelifluction forms. These comprise debris from till and Tertiary siltstones and sandstones. Gelifluction is clearly observed in places where a large rock is anchored in the permafrost; the debris flows over the boulder almost as a debris fall.

Slope Assymetry

Differential erosion as between north-facing and south-facing slopes produces a marked slope assymetry. The south-facing and southeast-facing slopes (cold) are steep and the north-facing and northwest-facing slopes are more gentle. In these regions there are two factors responsible for the assymetry; (1) the incoming radiation and (2) the accumulation of snow and wind blown debris in the lee of the mountain.

The drainage divide separates the island into two sectors: a northern one that comprises over two thirds of the island, and a southern sector comprising the rest (Fig.1). If the fluvial system has not been stabilized by a vertical diabase dike (Rinaldi et al, 1978), most of the island would have developed a north-flowing fluvial system.

On the north-facing slopes the accumulated snow promotes dendritic erosion, but on the south-facing slopes the erosion is more linear and drainage lines are therefore less numerous.

If reservoirs are build on Seymour Island, they must be located on the north-facing slope with their greater snow accumulation and larger melt-water flow.

Cryoplanation Surfaces?

Cryoplanation surfaces such as those described by Demek (1969), are low temperature geocryogenic forms, requiring mean annual temperature of -10°C or less and low precipitations according to Reger and P  w   (1976). As indicated by Washburn (1980) though, the temperature significance of cryoplanation terraces is not well established.

The most remarkable feature of Seymour Island is its flat top of "meseta". The meseta has a slight slope to the southeast, and an air strip

was prepared with little work by removing some large blocks from the surface. This meseta is sculptured in almost horizontal bedded Tertiary sandstones and siltstones. Glaciers eroded the bedrock and deposited till, which was later subject to cryoturbation. The thickness of the till varies generally from one to three meters, or more in a few places

It is unknown if the glaciers originally left this surface as flat as it is now. For this reason, it is not possible to say that the "meseta" is a true cryoplanation surface. It is interesting to note that at the northwest of Seymour Island, Cockburn Island also has a flat surface with the same slope inclination to the southeast. This surface is also cryoturbated with pingos, sorted nets, circles and gelifluction forms, etc. Nivation is producing a slope with similar orientation to that of Seymour Island. A Pleistocene Pecten conglomerate on the flat Cockburn Island surface indicates that marine processes have been active. (Henning 1924).

The meseta of Cockburn cannot be classified as a cryoplanation surface because it parallels a basalt layer having a slope to the southeast.

Coverd Ice (Burried icings)

Surficial ice, covered with debris, is important in some geocryogenic regions, such as the Central Cordillera of the Andes (Corte, 1976); on Seymour Island it was found to be significant only in two places (Fig.1): Penguin Bay and on the northeast slope at the south end of the runway. In these places there are layers of ice one or more meters thick, covered with debris. It appears that these layers are icings covered with slushflows. The thickness of the debris covering the ice is the same as the present active layer about 50 cm.

THE GEOCRYOGENIC FORMS: THE MINOR FORMS

In several places on Seymour Island there are small sorted polygons, 1 m in diameter, with smaller polygons inside. These polygons are developed in weathered Tertiary rock and gravels whose coarser elements are concentrated in the polygonal depressions. Inverse forms are also present: polygons in coarse materials with their troughs underlain by finer sediments. These patterns result from desiccation cracking (Corte and Higashi, 1964).

The fluvial network of Seymour Island requires a special treatment. The drainage as represented in the aerophoto survey on the scale 1:10,000 (Servicio de Hidrografia Naval) is notable for the many drainage channels (Fig.1).

During April and May the island shows icings on the small and medium river, and by the end of the fall (end of May) the whole fluvial system of the island, including large rivers is outlined by a mantle of icings. In many cases small creeks appear to flow along ice-wedge troughs. This and other observations suggest that melting of ground ice may be significant in the water balance in the island. Presumably there are two sources of runoff: (1) external sources graupel, rain and rime and snow and (2) internal sources due to the melting of various kinds of ground ice.

CONCLUSIONS

1. The Antarctic Peninsula is a barrier that separates two different climatic environments: on the east coast, where Seymour Island (Marambio) is located, the mean annual temperatures is -10°C or less; at the same latitude, on the west coast (Melchior), the mean annual temperature is not lower than -3.7°C .

2. The geocryogenic structures on the east coast are cold permafrost forms: thermal-contraction cracks and polygons, and closed systems pingos. These form at -5°C and -6°C mean annual temperature or less. The cryogenic structures on the west coast can be formed at freezing temperatures above -2.8°C .

3. The present climate of the Antarctic Peninsula where different cryogenic environments exist at the same latitude and elevation on opposite sides of an orographic barrier should be considered when making paleoclimatic reconstructions. It would be interesting to know how the geocryogenic environment differed on opposite sides of the Andes during the cryogenic times of the Pleistocene.

ACKNOWLEDGMENTS

The author would like to thank very sincerely the valuable help given by Dr. Werner Schwedtfeger, Emeritus Professor, University of Wisconsin, Department of Meteorology, Madison, Wisconsin, for information regarding meteorological conditions on the Antarctic Peninsula. The author would also like to thank Dr. Link Washburn for his careful corrections and suggestions to the original manuscript. The final review by William Wayne is also sincerely appreciated. To the reviewers G. Hogdson, and D.A. Hogdson best acknowledgments for their suggested good style.

DESIGN AND PERFORMANCE OF A LIQUID NATURAL CONVECTION SUBGRADE COOLING SYSTEM
FOR CONSTRUCTION ON ICE-RICH PERMAFROST

John E. Cronin

Shannon & Wilson, Inc., Fairbanks, Alaska 99707

In 1976, personnel from the U.S. Navy's Civil Engineering Laboratory erected a building incorporating a subgrade cooling system on ice-rich permafrost near Barrow, Alaska. The cooling system consisted of 15 horizontal, loop-configured, liquid natural convection heat exchangers. The installation at Barrow was heavily instrumented, and data obtained over 3 years allowed calculation of the performance and efficiency of the natural convection heat transfer devices. Experimentation with forced convection (pumping) of the liquid resulted in only a minor improvement of performance. Because seasonal freezing and thawing occurred in frost susceptible material in the subgrade, cyclical settlement and heave were recorded. Since the experiment was completed, foundations incorporating subgrade cooling systems employing air ducts or inclined two-phase heat transfer devices have become increasingly common in the Arctic and sub-Arctic. The liquid system tested compares favorably to two-phase or air duct systems currently in use.

INTRODUCTION

Construction on ice-rich permafrost has relied on pile support and an air space or thick gravel embankments to preserve the integrity of subgrade and structure, but both methods have drawbacks. Elevated support on piles can interfere with the use of the structure, is expensive for heavy floor loads, and can be aesthetically impractical. Prevention of thaw settlement merely by use of a gravel embankment is not feasible. The purpose of this report is to present the investigation of a subgrade cooling system as an alternative means of construction for such structures.

From 1969 through 1976, the U.S. Navy's Civil Engineering Laboratory (CEL) investigated natural convection heat exchange devices for the subsurface thickening of sea ice (Barthelemy 1974). In 1975 CEL began investigating this technology for construction of buildings on permafrost. The primary purpose of the study was to reduce the need for gravel in construction. Laboratory studies (Cronin 1977) resulted in the design of a horizontal, loop-configured, liquid convection device for use in building subgrades. The patent for loop-configured liquid convection devices is held by J. C. Balch. In September 1976 these devices were installed beneath a building erected by CEL at the Naval Arctic Research Laboratory in Barrow, Alaska. The performance of these devices was monitored until September 1979, when research funding cutbacks required termination of the experiment.

DESCRIPTION OF EXPERIMENT

Site Conditions

The site chosen for the building was underlain by ice-rich organic tundra soils covered

FIGURE 1 Generalized subsurface conditions beneath experimental building in Barrow.

by a gravel pad on the order of 0.3 m thick. Subsurface investigations indicated generalized conditions as shown in Figure 1. Numerous ice wedges were noted below 0.5 m, the depth of the active layer in Barrow.

Subgrade Cooling System

The building erected at Barrow was a 12.2 m by 16.5 m metal structure. Fifteen natural convection devices were installed beneath the structure at a 1.2 m spacing, as illustrated in plan view in Figure 2. The below-ground heat "collector" portion of the convection device intercepts heat flow to the ground from the building. Convective flow of an ethylene glycol/water mix in the pipe loop transfers the heat to the above-ground "radiator" portion of the device, where heat is transferred to the cold

FIGURE 2 Plan view of experimental building in Barrow showing layout of buried heat collector pipes of convection devices.

ambient air. Convective heat transfer continues as long as the collector temperature is warmer than the radiator temperature.

The collector of each device consists of two 6.4 m lengths of nominal 2 inch pipe, connected near the center of the building by a 1.2 m length of the same pipe. The radiator portion of each device, as pictured in Figure 3, consists of a vertical piece of 2 inch pipe on one side of the half-loop, two 2.1 m lengths of nominal 4 inch pipe with welded steel fins on the other side of the half-loop, and a 1.2 m length of 4 inch pipe with welded fins joining the two at the top. Total effective surface area of the radiator (taking into account that fin area is less than 100% efficient for heat transfer) is on the order of 6.2 m².

The heat collector portions of the convection devices were buried at a depth of about 0.5 m below the tundra surface, and were sloped at an average of 1.5° downward toward the center of the building to prevent air locking when filled with fluid. The pipes were installed by excavating 20 cm wide trenches into the tundra with a trenching machine and backfilling the trenches with the native ice-rich soils.

Building and Experimental Simulation

The building erected as a test bed for the cooling system was uninsulated and did not require heating for its primary purpose of equipment cold storage. A system of thermostatically controlled electric heating mats was used to simulate heat input to the ground beneath the building. This heating system had a total output when energized of 28,400 watts.

Figure 4 illustrates both the experimental and simulated cross sections of the installation. The heating mats were installed at simulated floor grade, on a 0.3 m thick pad of gravel above the tundra. The thermostat sensors were buried midway between the heating mats and the tundra surface.

FIGURE 3 View of completed installation in Barrow showing finned pipe radiators of convection devices.

The mats were covered by gravel and insulation to reduce upward loss of heat.

The experiment was to simulate a building heated to 20°C, incorporating 5 - 10 cm of insulation in the floor, constructed on a 0.3 m gravel pad. Heat input to the ground for purposes of the experiment was controlled by maintaining a constant temperature at the depth of the thermostat sensors. It was realized that this imposed an unreal boundary condition on the experiment, since the temperature at this depth should vary as a function of thaw depth beneath the building. Although the heating mats could produce about 172 W/m² when energized, the average heat input (as controlled by the thermostats) was only about 33 W/m².

Instrumentation

The building and subgrade cooling system were heavily instrumented to monitor performance. Temperatures were measured by about 150 thermocouples connected to a data logger. Vertical thermocouple strings measured temperature profiles, and a network of 57 thermocouples measured the temperature field in a vertical plane

FIGURE 4 Cross section through floor of building, showing experimental configuration and design being simulated.

perpendicular to the collector of a convection device. Additional thermocouples measured collector pipe, heating mat, and air temperatures.

The electric heating mats were divided into eight separately controlled circuits, generally concentric with the perimeter of the building, allowing more uniform response to variable ground temperature conditions. Electric hour meters allowed calculation of heat input to the ground for modeling purposes.

Settlement or heaving was monitored by elevation measurements of points on the foundation and floor of the building referenced to a stable benchmark.

Chronology and Methodology of Experiment

Erection of the experimental building was completed by the end of September 1976. At that time, the depth of thaw beneath the building was about 0.3 m below the tundra surface. With the onset of below freezing air temperatures the following week, the convection devices began freezing the ground beneath the building. The ground was allowed to entirely freeze back beneath the unheated building for 2 months before heat input was initiated.

In early December 1976 the heating mats were energized, cycling on and off to maintain a nearly constant temperature at thermostat sensor depth. This caused the thaw front to recede to a stable location about 0.25 m below the tundra surface (see Figure 5). Analysis revealed that the heat input to the ground was significantly greater than had been planned, simulating an uninsulated floor. This was attributed to thermostat errors caused by exposure to cold ambient air. To prevent excessive summer thawing, it was necessary to limit heat input to a simulation of a building with at least 5 cm of insulation in the floor. Accordingly, the thermostat setting was lowered in

FIGURE 5 Plot showing average monthly temperatures of air, collector pipes, and soil at 9 meter depth beneath building, as well as average depth of thaw during course of experiment.

late March 1977. This resulted in refreezing of the subgrade to near the depth of the tundra surface by the end of April.

Warming air temperatures during May 1977 resulted in thawing, and by late May convective cooling ceased (see Figure 5). The thaw front deepened through the summer until late September, when cooling resumed. Maximum thaw penetration was 0.39 m below the tundra surface, only about 8 cm above the elevation of the collector pipes.

Convection device operation and thaw front location followed a similar pattern during the next 2 years of the experiment.

PERFORMANCE OF SUBGRADE COOLING SYSTEM

Thermal Performance of Convection Devices

Major problems in evaluating the thermal performance of the convection devices were (1) the unrealistic constraint of constant temperature at thermostat sensor depth, (2) the variations in thermostat temperature due to error, (3) the variable ambient air temperature, and (4) the thermal lag in soil temperature variations. Thermal performance is therefore best analyzed by considering average performance over a period of time. All calculations, as well as the derivations in the later section on design factors, are simplified steady-state approximations based on a semi-infinite horizontal plane.

Heat removal rate was calculated for several situations at different times during the year, with results tabulated below:

TABLE 1

<u>Basis for Calculations</u>	<u>Calculated Heat Removal (W/m²)</u>	<u>Average Air Temp. (°C)</u>
November 1977 freezeback (includes heat mat input, latent heat, and specific heat, averaged for month).	50	-20.5
Total heat mat heat input for one year (Oct. 1977 - Sept. 1978).	52	-18.1 (winter only)
Equilibrium with stable thaw front in March 1978 (heat mat input only).	62	-27
Equilibrium with stable thaw front at higher heat input in March 1977 (heat mat input only).	70	-30

The subgrade cooling system was capable of transferring between 50 and 70 W/m² at air temperatures of -18° to -30°C. These values reflect performance at the average wind speed in Barrow, 20 km/hr. Examination of Figure 2 shows that the heat input is intercepted by the equivalent of 13.5 convection devices. Thus the

heat intercepted by each device can be calculated, and given the total length of the collector pipe of each device inside the building (12.8 m), the heat rejection by each convection device can be described as 58 - 82 W/m of embedded collector pipe.

Ground Temperature Data

Conclusions regarding ground temperature data are difficult to reach because of the relatively short duration of the experiment. Comparison of ground temperatures at the center of the building and in the natural ground allow the following generalizations: (1) from about June through December natural ground and building center temperatures are almost identical from a depth of 1.5 - 9 m, and (2) from January through May the natural ground temperatures average about 2°C colder through these depths than under the building, although from December through April the two temperatures converge at a 9 m depth. The temperature at a depth of 9 m beneath the center of the building did not show any continuous warming trend during the course of the experiment (Figure 5).

The thaw front beneath the building was in almost the identical equilibrium position during all 3 years of the experiment. Likewise, depth of thaw at the end of the summer was comparable during all 3 years (Figure 5).

Level Data

The results of periodic level measurements on the floor and foundation of the building are plotted in Figure 6. As expected, heaving occurs during the winter as the subgrade freezes, and settlement occurs during the summer as the subgrade soils thaw. Over the limited 2 years measured, both the floor and foundation returned to nearly their original elevations at the end of each year.

The maximum magnitude of this cyclical movement was about 27 mm for the foundation and 60 mm for the floor. The lesser movement of the foundation is probably a result of shallower thawing from less heat input under the foundation,

FIGURE 6 Average elevations of floor and foundation monitoring points during course of experiment.

and also the greater load on the foundation. The relatively low magnitude of both is probably due to restriction of freezing and thawing to the original active layer.

While cyclical movements of this magnitude are not ideal, they are minor when compared to the settlement which would have occurred upon thawing of the ice-rich subgrade soils without the convection devices intercepting heat from the building.

DESIGN FACTORS FOR SUBGRADE COOLING SYSTEMS

Heat Removal

Calculations of the thermal performance of liquid natural convection devices are derived and explained by Barthelemy (1974, 1976) for freezing of sea ice and for soil cooling (Barthelemy 1979). A useful relationship from this latter reference is

$$\theta = \frac{Q_d R_d}{T_a} + 1, \quad (1)$$

where θ is the pipe-to-air temperature ratio, Q_d is the heat transferred by one convection device, T_a is the ambient air temperature, and R_d is the overall convection device resistance to heat transfer. An example of the calculation of R_d for a convection device is given by Barthelemy (1976).

The temperature ratio θ is defined by Barthelemy as collector pipe temperature divided by ambient air temperature (both in °C). Calculations from the data in Figure 5 show that θ ranges from about 0.4 to 0.8. However, instantaneous temperature readings are not valid for calculating θ because thermal lag in the frozen soils does not allow pipe temperature to respond instantaneously to a change in air temperature. Barthelemy (1979) examines θ both from empirical data during periods of relatively steady air temperature and by calculations based on heat flow. The calculations yield a θ of 0.6, while the empirical θ averages closer to 0.5.

Barthelemy (1979) used a calculated value of $R_d = 0.012^\circ\text{C/W}$ for evaluating the observed performance of the convection devices at Barrow, and arrived at a value of $\theta = 0.6$. If one uses the empirical value of $\theta = 0.5$, and an effective number of convection devices inside the building area of 13.5, an empirical value of $R_d = 0.015^\circ\text{C/W}$ is derived.

Solving equation (1) for Q_d and incorporating the 14.9 m^2 floor area served by each convection device at Barrow, Q_d can be calculated from the equation:

$$Q_d (\text{W/m}^2) = \frac{T_a (\theta - 1)}{14.9 R_d}, \quad (2)$$

where empirical values of θ and R_d are known.

Using this equation and the appropriate air temperatures to check the calculated heat removal capacities from the previous section on thermal performance, values are obtained which are only a few percent lower than those empirically observed.

It should be kept in mind that the values of θ and R_d given above are based on an average wind velocity of 20 km/hr typical of Barrow, and apply only to the convection devices used in the experiment. Both factors will also change with radiator design and with the ratio of effective radiator area to collector area.

Equation (2) is oversimplified in treating θ as a constant for a given convection device. Barthelemy (1976) shows that the value of θ increases with time (as the resistance to heat transfer of the frozen shell around the collector pipe increases). An interesting observation from equation (2) above is that as θ increases, the amount of heat transferred decreases. Thus θ is an inverse measure of the "efficiency" of the convection device. By using calculated rates of heat transfer during the year to solve equation (2) for θ , values for θ as low as 0.36 are obtained (for the 8 month average). Since higher values of θ predict a lower heat transfer rate than observed, the empirical value of 0.5 might be more conservative for design purposes.

The equations above consider only the heat transferred through the convection device from the collector pipe to the ambient air. Considering the frozen/thawed soil interface as the heat source:

$$Q_s = \frac{T_s - T_a}{R_d + R_{sf}} \quad (3)$$

where Q_s is the heat transferred from the frozen/thawed interface, T_s is the temperature at the frozen/thawed interface (i.e., 0°C), and R_{sf} is the resistance to heat transfer of the frozen soil. Holding all other values constant, as R_{sf} increases, Q_s decreases. Thus the rate of heat transfer will decrease as the soil around the collector pipe is frozen back, since the frozen soil thermal conductivity is lower than the thawed soil conductivity. Once a stable freezing front position is achieved, the rate of heat transfer will vary only with air temperature.

If the source of heat is viewed as the floor of the building, then

$$Q_f = \frac{T_f - T_a}{R_d + R_{df}} \quad (4)$$

where Q_f is the heat transferred from the floor of the building through the devices, T_f is the floor temperature, and R_{df} is the sum of all resistance to heat transfer from the floor to the convection device (floor, insulation, thawed soil, and frozen soil). If one acknowledges that the experimentally observed heat transfer rates presented earlier are actually Q_f , the value of R_{df} in the equilibrium situation in March 1978 can be calculated, and is more than twice the value of R_d . Thus any rigorous design calculations must consider R_{df} . As the depth and spacing of the collector pipes is increased, R_{df} will increase, and the rate of heat transfer will decrease. This becomes a tradeoff which must be considered in the design process.

Natural convection flow rate in the devices was measured to be on the order of 3 - 4 liters/min. by observing the flow rate of

particles in the fluid through a clear sight glass incorporated into the radiator. For part of the experiment, three of the convection devices were fitted with pumps which forced convective flow to about 50 liters/min. This resulted in a lowering of collector pipe temperature of only about 1°C , and a slight increase in heat transfer rate. This supports the argument that the convection device resistance, R_d , is primarily a function of the liquid-to-air heat exchange resistance at the radiator, and not of the internal natural convection resistance.

General Considerations

The configuration of the subgrade cooling system tested at Barrow should not necessarily be considered as a pattern for other designs. Gravel pad thickness was reduced to a minimum, with resultant settlement and heaving of the floor and foundation of the building. This resulted in the use of a very close spacing of the convection devices because of the disastrous consequences should the massive ice in the subgrade thaw. In addition, the nature of the experimental simulation was such that (because of thermostat error) a floor with no insulation was modeled during the winter, while a floor with 5 cm of insulation was modeled during the summer. During the winter, the convection devices removed 5-7 times the amount of heat which would have been transmitted through 5 cm of floor insulation.

It remains a design problem to balance a thickness of gravel pad (with a tradeoff between latent heat and frost susceptibility) with a thickness of insulation and with a configuration and spacing of convection devices to arrive at a stable design on a project-specific basis.

OTHER SUBGRADE COOLING SYSTEMS

At the time of the experimental work reported herein, only one other subgrade cooling system using convection devices was known to the author. These were two-phase devices, McDonnell Douglas "Cryo-Anchors," installed beneath a school building at Ross River in the Yukon Territory in 1975 (Haley 1982). In addition, a few air duct cooling systems were in use. A number of recent installations use either two-phase convection devices or air ducts, but there are still no other liquid natural convection horizontal subgrade cooling systems in use which are known to this author.

Comparison of the performance of different types of heat transfer devices is difficult because thermal performance is very sensitive to such factors as the areas and ratio of collector pipe and radiator surfaces, air temperature and wind speed, and the thermal resistance of the soil or other material surrounding the collector pipe. The following data allow an order of magnitude comparison of performance of various devices.

A loop-configured liquid convection device described herein is capable of heat rejection of 58 W/m of embedded length at an average air temperature of about -20°C , wind speed of 20 km/hr, and collector pipe temperature of -10°C

(based on empirical data during November 1977). Performance data for Model 500 "Cryo-Anchors" presented by Glover (1975) are for still air, and indicate a power dissipation of about 48 W/m of embedded length for that device under otherwise similar conditions. Data from Davison and Lo (1982) indicate that air ducts at Inuvik had a heat removal capacity of about 9 W/m of embedded length when averaged through the winter.

Thermal performance is not the only criterion for selection of one system over another. Cost, ability to field fabricate, installation requirements, construction and supply logistics, maintenance requirements, and other factors should enter into the selection process. Although a complete comparison of these factors is beyond the scope of this paper, some advantages of liquid convection devices should be considered. Compared to two-phase convection devices, liquid devices have the advantages of (1) installation of the collector pipes horizontally rather than at a slant as most two-phase devices require (this requirement is particularly critical when there is a possibility that frost heaving will cause a two-phase device to slope upwards away from the radiator, which would halt the return of the condensate to the heat collector pipe), (2) the ability to easily supplement natural convective cooling with mechanical refrigeration and forced circulation, and (3) the ability to fabricate the devices in the field without the need for welds capable of sustaining high internal pressures. Compared to air duct systems, liquid devices (1) do not require that the gravel pad be elevated above ground surface to provide air flow or avoid problems with groundwater, (2) do not clog with snow, dust, or water, and (3) do not have to be manually disabled during the summer.

Liquid devices have some apparent disadvantages when compared to two-phase devices. Johnson (1971) found that the heat transfer rate of a liquid loop-configured device fell to zero with a temperature potential (between the air and the collector pipe) of several degrees. Results of the experimental work reported herein suggests that while this effect exists, for the devices tested in Barrow the critical temperature potential for the onset of convection may not be as great as for the devices tested by Johnson. Another apparent disadvantage of liquid devices is the potential for loss of an antifreeze type fluid into the subgrade. However, the 15 devices in Barrow were assembled by inexperienced personnel and no measurable fluid leaks occurred.

CONCLUSION

The experimental work performed by the U.S. Navy's Civil Engineering Laboratory on loop-configured liquid natural convection devices has shown that they are capable of preventing progressive thawing of permafrost beneath heated buildings constructed at grade in the Arctic, and that their thermal performance is comparable to that of other types of heat transfer devices. Incorporation of the information gained in this work with the present state-of-the-art knowledge of insulated pad construction should provide

engineers with a useful alternative for Arctic construction.

ACKNOWLEDGEMENTS

The experimental work reported herein was performed with funding provided by the Naval Facilities Engineering Command. Field logistics support was provided by the Office of Naval Research. Mr. J. Barthelemy, formerly of CEL, was instrumental in the design and testing of the convection devices, and in monitoring and interpreting their performance. The staff of the Fairbanks office of Shannon & Wilson, Inc. assisted materially in the preparation and review of this paper. CEL is c/o Naval Construction Battalion Center, Port Hueneme, California 93043. The author was employed as a geologist with CEL 1974-1977.

AN EXPERIMENTAL STUDY OF THE FROST-HEAVE REACTION

Cui Chenghan and Zhou Kaijiong

The Third Survey and Design Institute, Ministry of Railways
Tianjing, People's Republic of China

The existence of the frost-heave reaction has been recognized by many researchers. To evaluate frost-heave quantitatively for the design of foundations in cold regions, in situ frost-heave tests on model foundations were carried out at Jintao Field Research Station in the Da-Xinganling Mountains of northeast China from 1978 through 1980. Test results showed that the frost-heave reaction around pile foundations exhibits a triangular stress distribution. Its peak value occurs away from the foundation center at one-half of the freezing depth. Based on a simplified triangular stress distribution diagram, the authors present equations for calculating frost-heave reaction in both plane- and space-stress cases. Equations for examining frost-heaving stability and tensile strength of foundations, where the frost-heave reaction is taken into consideration, are also presented for both two- and three-dimensional problems.

Heilongjiang Province of China is located in the southern margin of the Eurasian permafrost area, and the freeze-thaw action there is extremely active. Especially unacceptable frost heave deformation have often occurred on the structures built on frost heave susceptible foundations. As a result some of the structures have been damaged. For example, a pier shaft (the part in earth) of 2-10 m deck plate girder bridge in that area failed because of frost heave. According to our investigation there are several other similar examples. To search the cause of this frost damage, we first of all checked our traditional design method, according to which the pull-out fracture ability of the pier shaft is calculated by subtracting the dead load above the calculated section from the total tangential frost heave force, but the calculated result did not show that the shaft should be broken by the pull-out force. Thus we were engaged in research work on the frost heave mechanism of the structures. Through experimental investigation it was found that the basic cause of the freeze damage mentioned above was the frost heave reaction, which had been excluded from consideration during the calculation in the past. So the question how to count frost heave reaction is the focal point discussed in this paper.

STATE OF ART OF FROST HEAVE REACTION STUDY

Although great achievements have been made on the literature of frost soil mechanics, many important problems have not yet been solved properly in practice; for instance, frost heave reaction has not been taken into account by now in calculating frost heave stability. This is because tests and research work on frost heave reaction have seldom been done. Dalmatov (1957) is the only one who is able to give a quantitative formula. Through modelling tests in labo-

ratory, he confirmed the existence of frost heave reaction and gave the quantitative formula with the flexible length caused by frost heave on the ground surface adjacent to the foundation in the field as frost heave distribution zone and on the assumption that frost heave reaction is distributed triangularly and the principle that action and reaction are certain to be in equilibrium, but this formula has not been seen applied currently for lack of verified information data. The existence of frost heave reaction has also been stated in several other documents but no quantitative methods have been given. To find the correct quantitative methods, we have conducted the following experiments.

EXPERIMENTS ON FROST HEAVE REACTION

Results

For the sake of exploring the distribution rule of frost heave reaction so as to determine on quantity, we have conducted several field tests at Jin Tao Frozen Soil Experimental Station on Da Hinggan Ling Mountains of Northeast China in 1978, 1979 and 1980. The dimension of test piles, action-measuring apparatus and the experimental results are shown in Figure 1. It must be pointed out that the frost heave reaction curve of the first year in Figure 1 is under the influence of the back-fill that has not yet fully settled.

Analysis

Before foundation is embedded into the ground the base soil at every layer will heave freely upwards when it is frozen, as a result the vertical pressure stress on the frost front will not change round about the freezing period (omitting the influence of water migration).

FIGURE 1 Experimental results and apparatus

After foundation is embedded into the ground, the heave of the soil to be cemented with the foundation sides will be bound when the base soil near the foundation is frozen. Thus the interaction force between base soil and the foundation will emerge. The principle of the interaction during frost heave will be dealt with below.

The foundation soil in seasonal frost areas is frozen downwards layer by layer as illustrated in Figure 2. We assume that the first layer soil ΔH_1 near the ground surface and the structure sides have already been frozen together and that the soil has achieved its primary volume-heaving quantity in this layer. When the second layer soil ΔH_2 gets frozen, the heaving of its volume would be bound by ΔH_1 , the frozen soil at the first layer above and the thawing soil layer underneath. But the heaving force emerging from earth freezing is so strong that obviously the heaving force between the first layer soil ΔH_1 and the masonry is unable to restrict it, thus the first layer soil is sheared and an up-sliding friction force emerges between the first layer soil and the masonry, which is called tangential frost heave force. At the same time the heaving force of the soil at the second layer not only

FIGURE 2 The interaction between frost heave soil and foundation.

forces the first layer soil to shift upwards but also compresses the thawing soil layer below. The downward force is called frost heave reaction. And the frost heave force of the third layer soil ΔH_3 also pushes the soil at the first and second layers to move upwards. It should be noticed that the frost heave reaction resulting from the tangential frost heave action at the first layer will spread downwards through the frozen soils at the second and third layers (the spreading angle is nearly 45° according to some previous tests). No doubt $\Delta H_4, \Delta H_5 \dots$ will continuously repeat the above mentioned process --- freezing and heaving. Along with the growth of the frozen layer numbers the tangential frost heave force between the frozen soil and masonry gradually increases. The structure will start to heave when the resultant force exceeds the structure weight, the weight of the soil above the foundation margins and the frost heave reaction force dropping on the margins. Based on the principle of the equilibrium of forces, the tangential frost heave action and reaction always exist simultaneously, equal in quantity but opposite in direction. And the force results from the frost heave action of the soil, so some soil layers will move upwards while some other layers move downwards (compression displacement). Such a boundary line always exists from the beginning to the end of the whole frost heave process, which is called frost heave boundary line as shown in Figure 2. It will move downward gradually along with the deepening of the frost from the beginning of the frost. The pier shaft of the structure bears parts of the pull-out force originating from the frost heave action during the frost heave. The peak value of the tangential frost heave force will appear when the boundary line lowers to a certain position which is the most unfavourable condition for the pier shaft being pulled. This boundary line is observed at the position above $2/3$ frost depth in the frost area according to the broken position of a bridge pier in the field.

With regard to the distribution rule of the frost heave reaction, it can be seen in Figure 1 that the ground surface near the structure becomes curved, the length of which is approximate to frost depth. According to the result of the actual measurements for three years in succession, the distribution zone of frost heave reaction is approximate to frost depth too, and its distributing graph appears to be a hump spreading on both sides of the structure or around it, which can be sketched as Figure 3.

From Figure 3 we know that the actually measured frost heave reaction graph is the bdc part, while Dalmatov's (1957) assumed graph is the abc part. As compared with each other, they are different distinctly. This is because Dalmatov (1957) did not take into account the part of the frost heave reaction near the structure that acts on the structure sides through friction between soil at the structure sides

FIGURE 3 A generalized graph of frost heave reaction.

FIGURE 4 Distribution graph of frost heave reaction in two-dimensional problems.

and the soil as well as that between the soil and masonry. If the frictional factor of the structure sides is zero, the stress distribution graph of the frost heave reaction can be generalized in accordance with Dalmatov's (1957) assumption. But the fact is not so. Experiments have proved that the abd part of the frost heave reaction graph acts on the structure sides, and therefore counteracts the tangential frost heave force τ_1 of the same quantity. In fact, the total frost heave reaction should be the sum of the two parts of abd and bdc, i.e. $(p_1 + p_2)$ in Figure 3, and the total tangential frost heave force should be $(\tau_1 + \tau_2)$, and $\tau_1 = p_1, \tau_2 = p_2$, where the two forces, p_1 and τ_1 , act on the same structure side equal in quantity and opposite in direction, so they have no influence on the frost heave stability of the structure but take the decisive action on the pull-out failure of the pier shaft. From this we find out the real cause of the pull-out failures of the pier shafts in the fields. And p_2 and τ_2 are the parts that have an effect on the stability of the frost heave action.

Summarizing what is stated above, the frost heave reaction acting on the foundation should be the volume enclosed by bdc stress graph in Figure 3. It should be pointed out that in the actual measurement for the tangential frost heave force index, τ_2 is measurable, but not τ_1 . Nevertheless, $\tau_1 = \tau_2$ in two dimensional problems while τ_1 and τ_2 should be calculated proportionally in three dimensional problems. The above analysis also indicates a question to be paid attention to, i.e. when measuring the tangential frost heave force index, shorter piles would produce obviously larger tangential frost heave force. Therefore when measuring in the field, the tested piles must be made close in length to the depth of the actual structure, otherwise the measured data are invalid.

Calculation Formulas of Frost Heave Reaction

Experiments have proved that the stress distribution graph of frost heave reaction appears as a hump distributed on both sides of a structure in two-dimensional problems or around it

FIGURE 5 A distribution graph of frost heave reaction in three-dimensional problems.

in three-dimensional problems. For the sake of a convenient application, calculation formulas should be as simplified as possible. So we generalize the stress graph measured in the field as Figures 4 and 5.

1. Formulas in two-dimensional problems

a. If $L < \frac{H}{2}$,
 both sides:

$$P_n = 4Tk \left(\frac{L}{H}\right)^2 \dots\dots\dots T/M \quad (1)$$

b. If $L > \frac{H}{2}$,
 both sides:

$$P_n = 2Tk \left[\frac{2L}{H} \left(2 - \frac{L}{H}\right) - 1\right] \dots\dots T/M \quad (2)$$

where
 P_n is the frost heave reaction; T/M
 Tk is the tangential frost heave force on the lateral sides of the foundation; T/M
 H is the distance between foundation top and ground surface generally no less than $2/3$ of freezing depth; M
 L is the projecting length of the foundation skirt; M
 N is the dead load of structure (including the weight of soil on the foundation skirt). T

2. Formulas in three-dimensional problems

a. If $L < \frac{H}{2}$,

$$P_n = 8\sqrt{RL}^2 T_k \frac{(R + \frac{2}{3}L)}{H^2(2R+H)} \dots\dots\dots T \quad (3)$$

b. If $L > \frac{H}{2}$,

$$P_n = \frac{4\sqrt{RL} T_k}{H(2R+H)} \left[2RL \left(2 - \frac{L}{H} \right) - H \left(\frac{3R}{2} + \frac{H}{3} \right) + \frac{2L^2}{3} \left(3 - \frac{2L}{H} \right) + \frac{H}{2} \left(R + \frac{H}{3} \right) \right] \dots\dots\dots T \quad (4)$$

where R is the radius of column shaft.

The foundation is round. The other symbols are the same as above.

CHECKING COMPUTATION OF FROST-HEAVE STABILITY AND STRENGTH

Checking Computation of Frost Heave Stability

$$n \cdot U \cdot T_k \leq N + P_n + Q_m + Q_t$$

- where
- n is the factor of safety 1.1—1.2;
- U is the girth of foundation within the effective frost heaving zone above foundation top; M
- P_n is the frost heave reaction falling onto the foundation margin on both sides of the foundation or around it; T
- Q_m is the freezing force between foundation and frozen soil; T

Q_t is the friction between foundation and thawing soil;
Other symbols are the same as above.

Calculation of Pull-out Resistance for Structure

1. When calculating in two-dimensional problems

$$P_1 = 2T_k B. \quad T$$

2. When calculating in three-dimensional problems

$$P_1 = \frac{4\sqrt{RL} T_k}{(2R+H)} \left(R + \frac{H}{6} \right) \quad T$$

3. Calculation for Pull Stress of Pier Shaft Section (Referring to the Bridge Piers with Round Ends)

$$= \frac{T_k \cdot U - N_c + \frac{4\sqrt{RL} T_k}{(2R+H)} \left(R + \frac{H}{6} \right) + 2T_k B}{F} \leq \sigma_a \cdot \frac{1}{m}$$

where

- σ is the stress on the dangerous section of structure; T/M²
- N_c is the dead load above dangerous section of structure; T
- F is the sectional area of the dangerous section of structure; M²
- σ_a is the limit pull-out strength of concrete T/M²
- B is the length of straight line segment of pier shaft or wall shaft; M
- m is the factor of safety (3 is taken).

Other symbols are the same as above.

AN INVESTIGATION OF ROCK GLACIERS IN THE KUNLUN SHAN, CHINA

Cui Zhijiu

Department of Geography, Peking University
People's Republic of China

A special form of rock glacier in the continuous permafrost zone is found at high elevations in the Jing Xian Valley of the Kunlun Shan of western China. These rock glaciers generally have a smooth longitudinal profile and lack longitudinal and transverse ridges and furrows. Their gradients are steeper than rock glaciers elsewhere, but their frontal slopes are only slightly steeper than their down-valley gradients. They contain permafrost below a depth of 1.5-2 m, and have interstitial ice contents of up to 57%. These rock glaciers are on north-facing slopes and flow roughly $0.2-3 \text{ cm yr}^{-1}$, primarily because of slope-induced creep facilitated by subsurface water derived from springs above the glaciers. The constituent debris does not originate from rock fragments produced at mountain walls, but instead comes from till and alluvium covering a smooth, rounded ridge just under 5000 m in elevation.

A rock glacier is a tongue-shaped accumulation of rock fragments with a till-like character moving downslope usually in a high mountainous region. Its head may be relatively depressed and its front may be convex, very much like a small ice glacier. Rock glaciers are distributed mainly in the middle and high latitude mountains. The slow downhill creep of rock glaciers may lead to the relatively steep slope of their fronts, generally reaching 20° to 40° , and a few meters to tens of meters in height.

An extensive body of literature exists on rock glaciers throughout the world. Rock glaciers have been reported in the Yukon area of Canada; Alaska, the Sierra Nevada, and the Rocky Mountains of the United States; the Swiss Alps; the mountain areas of northern Scandinavia; as well as in Tian Shan, Qilian Shan, Longitudinal Mountains and Kunlun Shan in China. Probably most rock glaciers can be classified as tongue-shaped or lobate in form, and contain either interstitial ice or a core of glacial ice (White 1976). The rock glaciers in eastern Kunlun ($35^\circ 49' \text{N}$, $91^\circ 00' \text{E}$) appear to be a special type and are the subject of this paper.

CHARACTERISTICS OF THE KUNLUN SHAN ROCK GLACIERS

The rock glaciers studied in this investigation are in the Jing-Xian Valley in the eastern Kunlun Shan. This region has both the special Kunlun-Shan-type rock glacier and those formed by the evolution of talus. Of the 18 Kunlun-Shan-type rock glaciers in this valley, 16 are concentrated on its western flank at about 4850 m elevation (Figure 1), and two are on the eastern flank at about 5050 m elevation. The depressions in their upper reaches average about 4800 m elevation, and the average terminus elevation approximates 4680 m. Table 1 presents some dimensions and other information concerning these rock glaciers.

FIGURE 1 One of 16 rock glaciers on the northern slopes of a highland of Kunlun-Shan, central China.
Morphology

All but two of the rock glaciers are tongue-shaped and have a ratio of length to width greater than unity (Table 1); their average length and width is 298 and 99 m, respectively. Although some have a broad tail, others are widest in their middle parts. In some cases, two join together, while the ends of others are branched (Figure 1). In longitudinal profile, some have an upward convex shape with several steps, which suggests that they are relatively active; others are rather smooth and imply relative inactivity. These rock glaciers tend to lack longitudinal and transverse ridges and furrows, and generally have a smooth, gentle longitudinal profile (Figure 2). Their longitudinal gradients of 13° to 30° (Table 1) tend to be steeper than those of rock glaciers in other regions. Although the slope angles of their fronts range from 8° to 40° , most frontal slopes vary between 17° and 24° (Table 1); it can be seen that frontal slopes are only slightly steeper than

FIGURE 2 Rock glacier No. 6 illustrating smooth, gentle longitudinal profile.

respective longitudinal gradients. The lower frontal slope angles relative to other rock glaciers may suggest lesser amounts of ice, less cohesive force, and/or slower movement.

Volume estimates were made for two representative rock glaciers—the relatively active No. 4 and the relatively inactive No. 1—using aerial photos for area and electrical surveys for thickness. Data collected from 13 points along two transects on No. 4 reveal that the PS values drop abruptly from 1000 Ω to 200 Ω at about 40 m depth; this depth is considered to represent its thickness. With an area of 4.3×10^4 m² and an average depth of 40 m, the volume of No. 4 is approximately 1.9×10^6 m³. Using the same procedure, the relatively inactive rock glacier No. 1 has a thickness of 25 m which, with an area of 2.4×10^4 m², suggests a volume of 0.6×10^6 m³. These volumes are roughly equivalent or a little smaller than those of the tongue-shaped rock glaciers in the Front Range of Colorado (White 1976).

The electrical survey also suggests the depth to permafrost and the ice content in these rock glaciers. Electrical resistance in the depth range of 1.5–2 m increases from 600 Ω to 1000 Ω , suggesting that the permafrost table is at this depth; this is corroborated by the observation of ice in June and July below that depth. A 1.5–2 m thick active layer on the rock glaciers is in accord with data from nearby. At a depth of 10 m, electrical resistance increases to 4126 Ω and implies a high water content. Bore hole data from rock glacier No. 6 show that the ice content in the active layer is greater than 30%. The ice content at 25 m depth is 29%, and is 57% at 39 m depth, where the temperature is -2°C . At the upper reaches of the rock glaciers, the ice content at depths from 20–30 m is probably less than 30% because of greater slope, coarser grain size, and lower water content. The ice within these rock glaciers is in the form of interstitial frozen rain and snow melt. Thus, and because glacial ice was not observed, they may be categorized as ice-cemented rock glaciers.

Grain Size Distribution

Large boulders seem to be predominant on the Kunlun-Shan-type rock glaciers. Large surface boulders are mostly concentrated on the flanks or inner parts of the lower reaches, thereby presenting a crude striped pattern. Some boulders stand erect due to compression or because of frost heave. In a few locations, the surficial debris is locally sorted into circles or overlapping debris islands.

Rock glacier No. 1 seems to be typical in terms of debris size distribution. On this rock glacier, boulders with a diameter of more than 2 m account for 10% of the total, while boulders with diameters of from 0.5 to 2 m account for 45% of the surficial debris; 30% and 15% of the boulders have diameters

of from 0.1 to 0.5 m and less than 0.1 m, respectively. Fine-grained materials are found primarily at depths below 1.5-2 m. In the size fraction less than 2 mm, sand (0.1-2 mm) predominates and accounts for 53-56%; silt (0.005-0.1 mm) constitutes 41-47%, and clay (<0.005 mm) is only 0.07-0.1%. The median granular value (MD) is 0-20 mm, the coefficient of overlap (SO) is 2.6665, and the coefficient of asymmetry (SK) equals 17.095, indicating its poor overlap and multitude of sources.

Source of Debris and Rock Glacier Origin

The debris that makes up these rock glaciers does not originate through the disintegration of bedrock on mountain walls. Instead, it comes predominantly from the middle Pleistocene till deposits on the rounded ridge above them (Figures 2 and 3), and secondarily from Pliocene alluvial gravels underlying the till. The till and alluvium contain such rock types as granite, granodiorite, and pyroxenolite, all of which were derived from the intrusive body of the mountain. The age of the till source shows that these rock glaciers began forming in the late Pleistocene.

The Kunlun Shan rock glaciers developed near the snow line in association with perennial or long-lasting seasonal snow banks. The upper reaches of the rock glaciers are generally at 4800 m elevation, which was also the height of the late Pleistocene snow line. At that time, the ridge crest was only 100 m higher than the snow line. Nivation associated with these snowbanks caused the formation of several wide, shallow depressions that may be considered nivation hollows. Snow melt carries away some finer material and at the same time becomes incorporated in the unconsolidated sediment below the hollows. It is believed that frequent freezing and melting caused the debris on the lower end of the nivation hollows to creep and evolve into either rock glaciers or perhaps large block streams. This origin for the Kunlun-Shan-type glacier is different from that of any other type of rock glacier.

Two periods of rock glacier formation are implied by deposits downvalley from the fronts of the active rock glaciers. The deposit below No. 4 is about 100 m longer than the modern rock glacier; this is also generally true of the other rock glaciers. The history of rock glacier formation agrees well with the local glacial chronology.

FIGURE 3 Diagram of rock glacier No. 5 originating from rounded ridge.

Magnitude of Activity

The activity of the Kunlun-Shan-type rock glacier is weaker and its velocity is slower than rock glaciers elsewhere. These rock glaciers flow principally by creep initiated by their relatively steep gradients. The widening of the middle reaches of four rock glaciers (Nos. 1, 4, 9, and 10), in conjunction with their dome-like appearance, suggests that the surface flows more rapidly than the basal portions. The available evidence implies that they do not move as a unit. Crevasses in these rock glaciers owe their existence first to rainfall, and second to underground water, and are not necessarily indicators of activity. The Kunlun Shan rock glaciers can be classified into three kinds: active, transitional, and relatively inactive, based on the movement of debris at their fronts. The most active ones are Nos. 4, 5, 6, and 10.

The Kunlun Shan rock glacier typically moves slowly and in various ways. The character and form of movement were clearly indicated by triangulation of painted stones on two representative samples: the active No. 4 and the relatively inactive No. 1. The surface of the middle and lower reaches of the eastward flowing No. 1 became higher on the north side and lower on the south side, and all painted stones moved conspicuously southeastward. The mean annual velocity along the direction of flow of No. 1 was calculated to be 0.225-0.3 cm y⁻¹, but the speed of the middle reach was somewhat faster than the lower reaches. The velocity of the very active No. 4 is estimated to be about 10 times that of No. 1.

In general, the Kunlun Shan rock glaciers are believed to move because of creep, but movement may be facilitated by the flow of subsurface water. For example, in summer, springs flow from the headward depressions (nivation hollows) at the contact between till and alluvium, and the water infiltrates the rock glacier below them. In addition, local freezing and thawing may cause some rolling of surface fragments. Frost heave of stones is apparent, especially on rock glaciers Nos. 4 and 5, and some painted stones were observed to have been raised during the period of triangulation. Some of the painted stones were found to have rolled several meters.

These rock glaciers lack the flow mechanisms of ice-cored or typical ice-cemented rock glaciers and, as a consequence, their flow is rather slow. The greatest speed of the Kunlun Shan rock glacier is considerably slower than those in the Alps and the Colorado Rocky Mountains. The annual average discharge of the Kunlun Shan rock glaciers is estimated to be in the range of hundreds of cubic meters, and is comparable to tongue-shaped rock glaciers in Colorado.

ENVIRONMENT AND FACTORS INFLUENCING DEVELOPMENT

In general, an active rock glacier is a good indicator of the environment, showing not only the lower elevation of permafrost, but also suggesting the snow-line elevation. They form below the snow line where temperatures cause permafrost but where

a net accumulation of snow is lacking (Brown and Péwé 1973). Ice-cored rock glaciers in the Alps of Europe extend down to 2700 m elevation, but do not extend more than 400 m below the snow line. In like manner, the lobate rock glaciers on the Kunlun Shan or Tianshan of China flow down to elevations not more than 400-500 m below the snow line; this is also true of the Kunlun-Shan-type rock glacier in the Jing-Xian Valley, where the north-facing snow line is at 5150-5200 m elevation. The average elevation (4682 m) at the ends of the Kunlun Shan rock glacier (Table 1) is about 2000 m higher than the average terminus elevation in the Alps, but the Kunlun Shan snow line is also about 2000 m higher than the snow line of the Alps. The average elevation of the termini of the Kunlun Shan rock glaciers is more than 100 m below the terminus (4800 m) of the glacier on a northern slope 20 km away from the eastern flank of the Jing-Xian Valley.

The Kunlun Shan rock glacier forms in an environment that is colder and more arid than other areas where rock glaciers are common; the mean annual temperature in the Kunlun Shan rock glacier area is -4°C , which is as much as 2°C colder than rock glacier areas of the Alps. The altitudes of the snow line and rock glacier formation are higher in the Kunlun Shan than in the Alps because of the greater continentality of that part of China.

Active rock glaciers are indicators of permafrost because they contain interstitial ice or an ice core. In addition, they may be indicative of the type of permafrost distribution of an area. The elevation of the lower limit of discontinuous permafrost in the western Alps is 2350 m on the northern side of the range and 2550 m in the central areas, where its temperature ranges from 0° to -2°C . Rock glaciers in the Alps have their termini at 2400-2600 m elevation, where their temperatures are lower than -2°C . Because their termini average 50 m higher than the lower limit of discontinuous permafrost, Barsch (1978) held that the presence of rock glaciers is an index of the discontinuous permafrost zone. However, the Kunlun Shan rock glaciers have formed where the lower limit of continuous and discontinuous permafrost is 4550-4600 m and 4200-4300 m, respectively. The ends of the Kunlun Shan rock glaciers are 80-130 m higher than the lower limit of continuous permafrost; therefore, these rock glaciers may be an index of continuous permafrost.

Some of the factors influencing the development of rock glaciers include regional climate, orientation and steepness of slope, lithological character, and geologic structure. Within a favorable area, the slope-related microclimate may play a decisive role, as rock glaciers tend to develop

largely on shady slopes. Topoclimatic suitability is corroborated in general by the observed distribution of rock glaciers, and experimentally by Morris (1981) who found that a multiple regression model incorporating radiation shading and an interaction term (representing the multiple effects of elevation, radiation shading, and bedrock jointing) accounts for 72% of the variance in size of rock glaciers in an area of the Sangre de Cristo Mountains of Colorado.

Regarding the formation of the generally north- and northeast-facing Kunlun-Shan-type rock glaciers, the gentle, low-relief hilltops underlain with thick-bedded, unconsolidated sediments also play a significant role. The subsurface water flow favored by the stratigraphy and lithology at the rock glacier source is also a factor. The Kunlun-Shan-type rock glacier is a special mass movement form affected most by these local factors, and does not resemble typical tongue-shaped and lobate rock glaciers elsewhere. They may constitute a unique form, which needs to be more thoroughly investigated.

ACKNOWLEDGMENTS

I would like to thank S. E. White of Ohio State University for his review of an earlier draft of this report. I would also like to thank A. D. Hyers of the University of North Carolina at Wilmington for his efforts at condensing, revising, and rewriting the manuscript. However, I alone, of course, am responsible for the content of this paper.

VARIATION REGULARITY OF PERMAFROST TABLE BENEATH EMBANKMENTS IN NORTHEAST CHINA

Dai Jingbo

The Third Survey and Design Institute, Ministry of Railways
People's Republic of China

Based on results from an experimental embankment and the experience of two operating railways, the author has analyzed the variation regularity of the permafrost table beneath an embankment and its influencing factors, and proposes measures to protect embankments from damage. When construction is undertaken in the thawing season, the permafrost table beneath the embankment declines to the maximum thawed depth in the same year, begins to rise again in the center of the embankment and on the shaded slope in the second year, rises overall in the third year, and reaches a stable state in 5-6 years. Variations of the permafrost table are closely related to latitudinal zonality, but they also depend on the height and orientation of the embankment, the thermophysical properties of the filling materials, the heat insulation measures adopted, the surface formation after construction, and the hydrological conditions and characteristics of the frozen soil. To protect the embankment from damage, the following measures are available: improving surface drainage, protecting the natural permafrost table near the foot of the embankment slope, and constructing a heat insulation berm.

VARIATION PROCESS OF PERMAFROST TABLE BENEATH EMBANKMENTS IN PERMAFROST REGIONS

An important principle in selecting a railway line in a permafrost region is to use embankment for passage as much as possible. The stability of embankments on permafrost soil depends on the variations in the permafrost table of the foundation during and after construction of the embankment. In the permafrost region in Northeast China, construction is usually carried on in the thawing season, and the cause and process of variation of permafrost table are due to compression of the vegetation peat layer by the filling soil and weakening of the thermo-isolation property. The filling soil carries a considerable amount of accumulated heat, which is dissipated into the foundation. This, together with the heat-absorbing effect of the foundation raises the temperature of permafrost and lowers the permafrost table. There is a general depression of the permafrost table in the year of construction, and a small rise in the center and

shaded slope of the embankment in the next year, with a slight further depression in the sunny slope. In the third year after construction, there is an overall rise of the permafrost table. In the sixth year, the permafrost table rises into the embankment filling soil, as the temperature in the embankment approaches the ground temperature of the foundation has reached a new state of thermal equilibrium. After 5 or 6 years, the permafrost table has become relatively stable, as shown in Figure 1.

FACTORS AFFECTING VARIATION OF PERMAFROST TABLE BELOW EMBANKMENT

Effect of Latitudinal Zonality

Latitudinal zonality reflects the combined effect of air temperature and geological and geographical conditions. In the discontinuous permafrost zone at the northern-most latitudes of this region, the soil itself is relatively stable. After construction of the embankment,

Figure 1. The fluctuations of permafrost table beneath the embankment

the permafrost table rises easily. In the center of the foundation it rises into the embankment filling soil. In permafrost zone in small scattered islands, therefore, permafrost soil is obviously in a state of degeneration and very unstable. After an embankment is built near the southern boundary, it is often difficult to preserve the permafrost soil, and the permafrost table in the embankment foundation and even beyond the slope foot on both sides is depressed considerably. After heat isolation measures are improved in the northern part of this zone, it has been possible to maintain permafrost table in the proximity of the natural table, sometimes with a slight rise above it. In the massive insular permafrost zone, since it is located between the afore-mentioned two zones, once appropriate measures are taken for heat isolation, permafrost table of the foundation will show a slight rise.

frozen soil of the foundation, the result being a drop in the permafrost table. As shown in Figure 2, at the foot of the slope on the left side of the embankment is a big water pit as water seeps through the foundation, considerable lowering of the permafrost table results.

Effect of Orientation, Snowcover and Wind

The direction or run of the line determines the orientation and wind-facing side of the slopes on both sides of the embankment. Therefore, each side is subjected differently to the effect of sunshine, snowcover and wind. The radiation heat of the sun is the principal heat source of permafrost soil. With increasing latitude toward the north, the angle of sunshine is limited; thus there is considerable difference in sunshine time between the sunny and shaded sides of the embankment.

Effect of Surface Water

Embankment construction changes the natural condition of surface water flow. When drainage facilities are poor and water accumulates at the foot of the slopes, horizontal seepage often occurs in the foundation. Precipitation in this zone is often concentrated in the comparatively hot months of June through September, and with it a large amount of thermal energy is accumulated. When water seeps through the foundation, there occurs heat exchange between heat released by the water and heat absorption by the

After erection of the embankment, there is a great difference in temperature between the wind-facing and lee sides. When the direction of the line runs NE, cold air carried over by northwest wind in winter is stopped on the shaded side, thus hastening the dissipation of heat of that side. The wind blowing on snow causes great changes in the thickness of accumulated snow at the foot of the slope. Under the combined effect of the above factors, corresponding changes occur in the permafrost table below the embankment. On the line running NS, the difference between east and west slopes is not obvious, so permafrost table of embankment foundation remains a generally stable straight line with little fluctuations. However, when the run is close to EW, the difference between the two sides is quite obvious, as seen from the fact that ground temperature in both the embankment and the foundation is higher on the sunny side than that on the shaded side. Thus, permafrost table variation is higher on the shaded side than on the sunny side. Generally, on the shaded side it either rises or remains constant, while on the sunny side it drops, as shown in Figure 3. Apart from orientation and snowcover, the direction of wind also has a certain effect. In winter, northwesterly winds are quite frequent, and the windward side of the embankment has a temperature which is correspondingly lower

Figure 2. Permafrost table goes downward when surface water passes through the lower part of the embankment

Figure 3. The depths of permafrost table vary with the orientation of the embankments

Figure 4. The permafrost table goes upward beneath the shady side of the embankment where cold wind always blows seriously

than that on the other side of the embankment. The Luenlin line at a certain point is located where northwesterly winds are strongest and most intense. The shaded windward slope has no heat isolation berm at the foot of the slope. Here the permafrost table rise into the embankment filling soil is as high as 1.5 meters. It is obvious that northwesterly wind is stopped on the shaded side of the slope, playing an important part in hastening the dissipation of heat, as shown in Figure 4.

Effect of the Height of Embankment

The permafrost table varies widely below embankments of different heights. In the case of embankments of ordinary height, once protection is taken, it is possible to stabilize the permafrost table in line with the natural table, sometimes showing a slight rise. This level is generally close to the original ground, or rises slightly into the embankment filling soil (with the exception of the zone adjacent to the southern boundary). In case of failure to take heat isolation measures on the sunny side, the permafrost table on this side often drops to a certain extent.

Low-fill embankment (usually heights of less than 1.0-1.5 m). Due to compression of surface vegetation and peat layer, there is a reduction in the heat conductivity. Both the radiation heat of the sun and the kinetic energy of the moving train are easily transmitted downward, resulting in a stronger heat exchange than is the case with embankments of more height, causing the permafrost table to drop. In a survey of the Yalin line, conducted in 1965 on the lowering of permafrost table at 16 points of the foundation (the height of fill at 11 places is ≤ 1.5 m, while at 5 places the height of fill is ≤ 1.0 m), a general drop in permafrost table was observed. This means that if the embankment is too low, it is not advantageous for the maintaining of the permafrost table. Figure 5 shows the sections of two adjacent low fill embankments somewhere on the Yalin line (located in a discontinuous permafrost zone). In both cases,

there is a drop in the permafrost table. In a low fill with a small area exposed to heat in the entire embankment, the difference between the amount of solar radiation absorbed on each side is not very great, resulting in little variation in permafrost table on both sides of the foundation. The general observation is: the lower the fill, the more likely the permafrost table will drop. Among the different permafrost zones, the drop is most likely to occur in the permafrost zone of small scattered islands.

Embankments with a high fill (usually heights of over 10 m). In such cases, there is an obvious drop of the permafrost table in the foundation. Where the height of embankment does not exceed 18 m, the range of decline is about 1.0-2.5 m in permafrost zones of small scattered islands. When the difference in the level of the permafrost table in the foundation is obvious between the sunny and shaded slopes, decline of the permafrost table on the shaded side is less than that on the sunny side. When

Figure 5. Low-filling embankments cause permafrost table of the foundation to decline

the difference between the two sides is not significant, decline of the permafrost table on both sides in approximately the same. The decline of the permafrost table below high embankments is due mainly to the construction usually being carried out after the spring thaw, when embankment filling carries with it a large amount of heat which is continuously emitted toward the foundation. In winter, though the embankment surface is frozen, its interior remains as loose soil which maintains a temperature always above the freezing point throughout the year. Since the frozen soil of the foundation continually absorbs heat released by the embankment soil, the permafrost table gradually declines under the effect of heat exchange, and then stabilizes at a certain depth after it has reached a new state of thermal equilibrium. In addition, the pressure of a high embankment also has a certain effect on thawing of frozen soil. Once the upper critical height has been exceeded, the higher the fill, the greater the decline of the permafrost table. Among the different permafrost zones, a zone of small scattered islands shows the greatest decline of the permafrost table. The permafrost table will decline more when the embankment is constructed during a warm season than during a cold season.

Effect of the Type of Filling Soil

There are different types of filling soil for embankments, each having a different heat conductivity. This difference depends on the inconsistency of the thermal physical condition of the soil. For example, when clayey loam soil is used, the fill is usually more compact and has a small air volume. Heat conduction is essentially carried on by grains of the soil, and the rate of heat conduction is slow. On the other hand, when coarse-grained soil is used for fill, the porosity is usually higher. Air in the crevices easily produces convection and thus enhances thermal conductivity, resulting in the transmission of thermal energy to a greater depth. Tests of embankments show that, before August in the second year of soil filling, thawing occurs in the sandy soil each month to the extent of 1.0-1.4 m, while thawing in the sandy loam soil is 0.4-1.3 m. The monthly rate of freezing in winter is 1.0-1.5 m for sandy soil, and 0.5-1.1 m for sandy loam soil. Temperature is also lower in loam soil than in sandy soil. The permafrost table will rise again more obviously in a loam soil fill than in a sandy soil fill. Where poor drainage leads to seepage through the foundation, the use of soil for fill may prevent or reduce seepage of surface water into the foundation, thus protecting permafrost soil from the effect of water seepage. However, when drainage is good and under the combined effect of other factors, the permafrost table below different types of soil for embankments of ordinary height may be stabilized in close proximity of the natural table, or with a slight rise above it.

Figure 6. The difference of permafrost table depth between the embankments equipped with and without isolation berm.

Effect of Heat Isolation Berm

The function of heat isolation berm is to reduce the effect of temperature produced by thermal conduction to permafrost soil, prevent decline of permafrost table on the sunny side, moderate the rising of permafrost table, and prevent damage to the surface at the foot of the embankment slope by human activity.

Sections of two permafrost soil embankments at a certain point on the Luenlin line, one with heat isolation berm and the other without, are compared in Figure 6. They are located in the permafrost zone of small scattered islands, separated by a distance of 96 meters, essentially similar in geological condition, filling soil, and running direction of the line. The difference in permafrost table of the foundation on the shaded slope side of the two sections is: the one with berm rises 1.5 m and the one without berm rises 0.7 m. On the sunny side, the one with berm rises 0.2 m and the one without berm drops 1.3 m. This shows that heat isolation berm has the effect of preventing the decline of permafrost table in the foundation.

Effect of Vegetation Peat Layer

The vegetation and peat layer is a good heat isolation material. Under natural conditions it has an obvious effect on the soil freezing and thawing depth. It diminishes the effect of air on soil surface, reduces the amount of heat entering into the soil layer, thus giving protection to the permafrost. Therefore, damage to the vegetation and peat layer near the foot of slope and foundation, or compression of its thickness by the embankment, in addition to the

peat layer for heat isolation in the foundation, will cause variations in the permafrost table. When the surface vegetation and peat layer is damaged or removed, permafrost table declines. After construction of the embankment, the vegetation and peat layer is subjected to compression and thus becomes thinner and more compact with lower porosity. This condition is not favorable for preservation of the permafrost, since the peat layer heat isolation properties are greatly reduced.

CONCLUSIONS

1. When embankment construction is carried on during the thawing season, the natural permafrost table declines to the maximum thawing depth. In the second year, at the center and on the shaded slope side, permafrost table begins to rise, while there is still some slight decline on the sunny side of the slope. In the third year, permafrost table shows an overall rise. After a period of 5-6 years, the permafrost table has become relatively stable.

2. Variations in the permafrost table of the embankment foundation are closely related to latitudinal zonality and are dependent on the height, orientation, thermal physical properties of the fill material, heat isolation measures adopted, surface formation after construction, hydrologic conditions, characteristics of frost soil medium, etc.

3. Water accumulated at the foot of embankment slopes and intense human activities are the main causes of considerable decline of permafrost table in the embankment foundation and the continuous sinking of the embankment. Therefore, the principles of design for preservation of permafrost soil is to make surface drainage more effective and to protect the natural permafrost table near the foot of embankment slopes.

4. The permafrost table can rise into the embankment filling soil only a small distance. While it rises on the shaded side of the slope, it drops on the sunny side of the slope. Therefore, special attention should be paid to heat isolation on the sunny slope side, for which the primary approach is to build a heat isolation berm.

5. Both low and high embankments cause permafrost table in the foundation to decline. The higher the fill, the greater the decline. To prevent the permafrost table from degradation, the lower critical height of the embankment is 1.5-2.0 m. The upper critical height of the embankment should be determined based on local temperature, fill material, mean annual ground temperature, and construction technology.

MECHANISM AND LAWS GOVERNING THE TRANSFORMATION OF UNCONSOLIDATED
ROCKS UNDER THE INFLUENCE OF REPEATED FREEZE-THAW

P. S. Datsko, E. Z. Kouchukov, and Yu. P. Akimov

Geology Department
Moscow State University, USSR

A comprehensive procedure was used to study the mechanisms of the transformation of unconsolidated rocks as the result of repeated freeze-thaw (up to 1,000 cycles) under various external thermodynamic conditions. The latter ensured freezing of samples from both one side and from all sides and also the formation of various types of cryogenic textures. It was possible to establish trends with regard to changes in dispersivity, chemical and mineral composition of the materials, cryogenic structure, plasticity and mechanical properties, depending on their original composition and structure. It was demonstrated that a reduction in the dispersivity of clay soils occurs with an increase in freeze-thaw cycles due to an increase in the amount of secondary silt and secondary sand particles. The most pronounced structural changes are associated with the differentiation of the frozen material into ice and mineral material, thus greatly enhancing the material's heterogeneity. This leads to the formation of a specific structure in terms of porosity and encourages changes in the content of liquid H₂O, lowers the strength and conductivity of the material and increases its susceptibility to saturation and erosion.

The problem of cryogenic transformation of rocks has long been of profound interest to researchers. This is understandable when one considers that solution of the problem will provide the key to the long-term forecasting of cryogenic processes and phenomena. Transformation of dispersed rock/soil under conditions of multiple freeze-melt cycles occurs when interrelated physical, physico-chemical, and chemical processes take place simultaneously, accompanied by changes in the dispersivity, in the chemical and mineral composition of rocks, and in their structure and properties. Conflicting experimental evidence shows that the problem is complex, and that the physico-chemical and chemical aspects of cryogenic weathering have not been adequately investigated.

Results of an all-around cyclical freezing and melting of dispersed rocks and soils have revealed specific transformation features of sand and clay soils. Water-saturated sands are transformed by physical disintegration, which increases the dispersivity, the specific active surface, and the stability of the system. It has been established that repeated freezing and melting tends to reduce the heterogeneity of bi- and poly-dispersed sands, while the non-homogeneity of mono-dispersed sands increases. For example, clean fine-to-medium grained quartz water-saturated sand (sampled at Lyubertzy, Moscow Region) after 50 freeze-melt cycles becomes medium-to-fine grained and does not change again, even after 1,000 cycles. The average size of sand particle ($\bar{\sigma}$) becomes smaller, from 400 to 250 μ , whereas the root-mean-square variation in the size distribution of particles (σ) increases from 0.23 to 0.32, indicating the greater heterogeneity of the material. The intensity of dispersion is much higher at the early stages of the test, demonstrating the subsiding nature of the process of disintegration and points to the forma-

tion of a near-uniform size of quartz grains under the given thermodynamic conditions. It has taken artificially prepared clean mono-dispersed water-saturated fine-grained quartz sand almost as many cycles (887) to become coarse dust (Minervin and Komissarova, 1979). Many researchers claim that this particle size is critical for quartz, being resistant to cryogenic exposure.

A critical size of cryogenically disintegrated minerals is determined by their crystallo-chemical structure, and, according to Konischev (1981), these sizes can be arranged in a single series: minimum size—amphiboles, pyroxenes and quartz; maximum size—biotite and muscovite; medium size—feldspars; this series indicates the changing degree of dispersion of rocks and soils due to freeze-melt cycles.

This series is consistent with the predominance of quartz particles (0.05-0.01 mm) in cryogenic eluvium. Quartz particles that are smaller display relative resistance to physical disintegration and function as centres of cryogenic aggregation in clay soils, producing secondary silty particles (Poltev, 1972).

Cryogenic aggregation of silty, clay, and colloidal particles, resulting in an accumulation of secondary particles of a size smaller than sand, plays a dominant role in changing the degree of dispersion of water-saturated clay soils as a result of freeze-melt cycles (Figure 1). A good illustration of this effect is the change in the degree of dispersion of a polymineralic clay ($m P_2$ kv), which, in the course of repeated freezing and melting, showed an increase in the quantity of particles the size of fine sand to coarse dust. Also, medium sized particles increased from 6 μ to 13 μ while the r.m.s. variations decrease. These results indicate that the particle size becomes more homogeneous. The dispersion

transformation, as a function of the frequency of freeze-melt cycles, is also of a subsiding nature. Thus, rock (soil) as a system reaches a state of equilibrium with the thermodynamic conditions of the environment; i.e. a composition of rock resistant to further cyclical cryogenic effects develops.

We have applied methods of mathematic statistics to process the results of our research and the findings of some foreign authors. Figure 1 shows the direction of change in the dispersion of rock (soil) resulting from repeated freezing and melting. The graph clearly indicates that the particles of most sandy and clay soils tend to develop a mean diameter of about 10-30 μ and an r.m.s. variation close to 0.7, which is typical of loess soils. This is further evidence that cryogenic weathering of dispersed material leads to the formation of loess.

Heavy monomineralic clays such as bentonite and kaolin occupy a special position. For example, the degree of kaolin dispersion (σ_N) increases in response to an increase in homogeneity of granulometric compositions, characterized by a reduction of the r.m.s. variation from 0.72 to 0.64. The change in granulometric composition between 0 and 150 cycles consists of a substantial decline of the coarse dust fraction (up to 40%) owing to its reduction to the size of a clay fraction. On the whole, kaolin dispersion may be described as a characteristic transformation, i.e. the growth of the clay fraction.

Easily-soluble compounds that form part of rock (soil) are subject to fundamental changes as a result of multiple freeze-melt cycles. When judged by the degree of salinity, evaluated on the basis of the dry residue in the water extract, even the classification of the material may change. For example, non-saline kaolin subjected to six freeze-melt cycles becomes slightly saline; a similar treatment turns heavily saline bentonite to excessively saline, while sea clay registers a transition from heavily- to moderately saline.

In general, the quantitative changes regardless of their direction or sign can be said to subside in proportion to the content of unfrozen water in the material, together with a decline in salinity and a reduction in the specific active surface area, in accordance with the mineral composition of the material: montmorillonite > hydromica > kaolinite. The dynamics of these changes corresponds to that of chemical reactions occurring in the material, and is determined by the tendency of rocks (soils) to enhance their resistance to freeze-melt exposure. As with most chemical reactions and solutions, the rate decreases as the steady state is approached. These effects were clearly manifested in the materials studies, in which the rate of the water-extract dry residue transformation during the first six freeze-melt cycles was found to be 10 or more times the rate recorded in subsequent cycles.

When considering the direction of changes in the content of easily-soluble compounds, one should note the growth of such compounds in monomineralic heavy clay soils increasing the salinity, whereas in other materials there is a steady decrease from cycle to cycle. This decrease in the majority of soils is caused by several factors. One factor is the formation of a sizable quantity of crystal

hydrates that accompanies the freezing of moisture. For example, the formation of gypsum from anhydrous calcium sulfate, as in the case of polymineralic sea clay (m P₂ kv), leads to a further reduction of sulfate ions and calcium cations in the water extract. Another factor is the aggregation of colloidal particles at the expense of a reduced thickness of unfrozen water film. Because the solubility of such aggregates is diminished, they are not present to a large degree in the water extract.

In heavy monomineralic clays aggregation may result in increased salinity because of the very small thicknesses of films of unfrozen water, which facilitates active water flow. Positively-charged salt colloids, present in an aggregated state, are only slightly soluble. However, as pH goes down and the temperature in the negative region decreases, the colloids increase their charge and disperse, becoming more soluble. Thus, differences in the thickness of unfrozen water films owing to different particle sizes appear to lead to qualitative changes in the chemical and mineral composition of rocks and soils which are subjected to cyclical freezing and melting.

Substantial changes may occur in the mineral composition of the clay fraction. X-ray diffraction analysis and thermoanalysis indicate that after 5 and 50 freeze-melt cycles montmorillonite, hydromica, and kaolinite undergo a fundamental structural transformation in which mixed-layers and minerals with a mobile crystal lattice are produced. With montmorillonite, interlayer spaces $d(001)$ become larger. Montmorillonite that forms part of the clay fraction of polymineralic sea clay (m P₂ kv), shows an increase of the inter-layer space from 1.227 to 1.550 nm as cations of Na⁺ are substituted by Ca⁺ cations.

The structure of soils (rocks) also undergoes considerable transformations. For example, following a repeated freezing and melting of polymineralic sea clay, the pore space of the frozen material is differentiated owing to the significant growth of the volume of micropores whose radius measures below 0.2 and over 0.5 μ . The number of pores within this band increases, with the mean size of the intraaggregate pores diminishing from 0.20 to 0.15 μ and the homogeneity increasing. The contraction of the intraaggregate pores is due to the "compaction" of clay aggregates and to stronger structural bonds between the particles that constitute the aggregates. The size of large pores, that belong to interaggregate porosity, is a function of the size of the microaggregates themselves. An observed growth of the volume of the pores with a radius over 0.5 μ , and the increase of their percentage in total porosity, are accounted for by the growth of the number of medium-size particles, by more even distribution of microaggregates, and by weak bonds existing between them.

Before freeze-melt cycle treatment, the microstructure of polymineralic sea clay (m P₂ kv) is characterized by the presence of aggregates consisting of dispersed particles measuring from 2 to 5 μ that are uniformly scattered throughout the volume. The degree of aggregation is not high, the aggregates being separated from one another by ice; yet there are no clear inclusions of ice, which would be represented by fine dispersed particles

less than 1μ in size. It takes only 5 freeze-melt cycles for the mineral particle aggregates to grow to 30μ . A process is taking place wherein the ice rid itself of the finely-dispersed mineral particles diffused in it, i.e. the ice undergoes purification. A similar transformation of microstructure occurs with other kinds of polymineralic and monomineralic frozen rock (soil). Whatever the material, a process of matter differentiation is always involved which is due, on the one hand, to increasing aggregation of the soils and the elimination of ice inclusions from the aggregates as they undergo compaction. On the other hand, the process involves ice concentration, with the number and size of ice sections and crystals increasing. Because of the differentiation into ground and ice, the heterogeneity of frozen rock (soil) as a system increases.

The above-described transformations of material composition and of the porous space structure lead to observable changes in the content of unfrozen water in dispersed rocks (soil) (Vrachev and Datsko, 1980). The amount of unfrozen water in the temperature range from -1 to -10°C increases, while below -10°C it decreases. These changes are caused by the contraction of intraaggregate porous space which determines, along with the specific active surface, the content of the liquid phase of moisture in frozen material. The water contained within interaggregate pores (those over 0.5μ in radius) freezes at negative temperatures above -0.3°C . It follows, therefore, that an expansion of the interaggregate pore volume by multiple freezing and melting of the material results in the freezing-out of water contained in these pores even at -0.3°C , resulting in a smaller quantity of unfrozen water at temperatures ranging from -0.3 to -1°C .

Transformation of clay soil dispersivity and chemico-mineral composition affects the plasticity properties of clays. Thus, it was typical of all clay soils analyzed (Figure 2) that moisture content in the upper plasticity range was reduced by 3 and 7% for sand loam and loam, respectively, and by 12% for clay. At the same time, the plasticity index for loam decreased from 17 to 10%; in the case of sand loam this index was approximately halved.

Transformation of rock (soil) composition and structure impairs the strength characteristics. The strength of melted samples of polymineralic sea clay ($m P_2 kv$) decreases from 0.14 MPa to 0.09 MPa when the number of freeze-melt cycles reaches 50. In this case, the coefficient of aggregation of particles smaller than 0.001 mm in size has been found to increase from 1.4 to 1.7, and for particles smaller than 0.005 mm it has increased from 3.1 to 3.8. Such changes of natural dispersivity determine the minimum strength of melted ground after it has been repeatedly subjected to freezing and melting.

The nature of contact interaction influences strength also. The intraaggregate contacts determine only the strength of particular aggregates and their water-resistance characteristics. The strength of the disperse system as a whole depends on the stability of molecular and electrostatic bonding between the aggregates. Therefore, the main type of contact in this case is by coagulation. As the frequency of freeze-melt cycles

increases, the number of such contacts reduces because of the larger size of aggregates and eventually leads to a decreased strength of the rock (soil) in a melted state. There is also a lowering of the strength of frozen material (Vrachev and Datsko, 1980) due both to the increased content of unfrozen water and to the specific transformation of the frozen microstructure.

The intensity of rock (soil) transformations is determined by the inherent and external thermodynamic conditions. For example, the intensity of transformation of dispersivity of polymineral sea clay ($m P_2 kv$) with different initial moisture contents increases progressively from W_T to $1.5W_L$. The most intensive dispersion occurs in samples having maximum moisture content because changes in the thicknesses of adsorbed and unfrozen moisture films in the course of freezing and melting are the greatest. On the other hand, in water-saturated rocks (soils) most of the water turns to ice, whereby maximum crystallization pressure develops which encourages irreversible coagulation.

Clay soils were tested in the temperature range from -5 to $+20^\circ\text{C}$ for 48 hours, and in the temperature range from -50 to $+50^\circ\text{C}$ for 12 hours. Observed changes of dispersivity indicate that the nature of granulometric composition transformation is similar in clays and in rocks (soils).

The data showed that a repeated alternation of freezing and melting processes results in the formation of lens-type textures in clays and solid cryogenic textures in rocks (soils), while qualitative trends governing the transformation of the material composition and structure are basically the same. The intensity of transformations is more pronounced in the formation of lens-type textures as in this case a high rate of moisture- and mass-transfer is involved.

PHYSICAL NATURE OF FROST PROCESSES AND A RESEARCH METHOD

Ding Dewen

Lanzhou Institute of Glaciology and Cryopedology, Academia Sinica
People's Republic of China

The frost process, which includes changes in temperature and moisture fields, the formation of ice layers, and frost heave, develops under certain natural conditions, forming geological and geomorphological phenomena in frozen ground regions. The quantitative study of frost processes involves three aspects: the determination of state parameters, the establishment of a mathematical model by model test or system analysis, and the resolution of the numerical or approximate solutions to the model. Based on a group of combination equations related to heat and moisture flow, the frost-heave process, and the heat-water balance at the thaw interface, and on the principles of thermodynamics and the mathematical model, the author presents approximate solutions for calculating the depth of frost penetration, the amount of migrating water, unfrozen water content, and the amount of frost heave.

The prerequisite for the development of further studying the frost process quantitatively and experimentally is to reveal its physical nature. The frost process is composed of some comprehensive physical processes interrelated to each other closely, so that it must be described by a group of combination equations. Modelling test must follow similar conditions of the physical processes, so it is necessary for us to set up similitude criteria completely.

At present, the approximate analysis solution still has its life in the study of frost processes, especially for the open system.

It is worth while to give more attention to the application of thermodynamics to the study of frost processes because of its advantages in the calculation of the subject with phase change and frost heave.

PHYSICAL NATURE IN FROST PROCESSES

The exchange of energy and mass is actively undertaken between the surface layer of the earth's crust and the atmosphere, and between that and the underlying lithosphere, governing the thermodynamic condition of the surface layer itself. As the exchange reaches a critical state, the surface layer goes into a frozen state, and consequently forms a frozen surface layer and a series of phenomena caused by freezing. Therefore the frozen surface layer is a geological and geographical system.

Frozen soils are mainly composed of mineral particles, unfrozen water, ice (with plasticity) and gas. All the components are interrelated and interact with each other closely, resulting in a non-homogeneous capillary-porous texture. Especially, as there are fine grains, free

ions, polarized water molecules, and ice crystals in frozen soils, so we can consider the frozen soils as a physical-chemical system.

Frost action is a comprehensively physical and chemical process. Considering the chemical transformation in soils during freezing being insignificant, the author considers the frost process as only a comprehensively physical process, which includes the transformation of heat, the phase change of water, water migration, as well as various mechanical processes under certain conditions of loading, temperature, and moisture. Among which, the exchange of heat and the phase transition are primary. Each process is independent, and the law of its change depends upon its intrinsic properties. The important thing, however, is that these processes are interrelated to each other, resulting in a complicated feedback system, and governing the characteristics of the whole soil layer. Generally speaking, interactions within a process tend to keep its balance; on the contrary, the actions outside the process tend to destroy the balance. As a result, frost processes irreversibly evolve to an advanced stage.

The study of frost processes includes three main aspects, i.e., the power or mechanism, the state parameters and determination of their values, and the main laws or natures of the process. Above all, frost action is a natural-historical process, i.e., the frost processes proceed under a certain natural-historical condition, resulting in forming the geological and geomorphological phenomena in a frozen ground region. For a seasonally frozen layer, the frost processes include the changes of temperature and moisture field, the formation of the ice layer, and the frost heave process.

One of the most important advances of

current studies on cryopedology is to study frost processes quantitatively and experimentally. The study methods are as follows: Firstly, the state parameters of the process should be determined. For example, according to the thermodynamics view, the parameters of P, V, N, and T should be determined if we do not take into consideration external electrical (or magnetic) field action. Secondly, the mathematical model has to be established, i.e., the relationship between the time- and space-dependent parameters and their influenced factors must be established by means of the physical-mechanical laws so as to found a set of combining equations. And finally, one has to work out the solutions by experiments and analytical methods.

For the frost processes of a seasonally frozen layer, we give the following equations. Among which, the equations referring to the heat and moisture changes, respectively, are

$$\frac{\partial t}{\partial \tau} = a \frac{\partial^2 t}{\partial x^2} \quad (1)$$

$$\frac{\partial w}{\partial \tau} = k \frac{\partial^2 w}{\partial x^2} \quad (2)$$

the equation to the phase transition of water, and to ice or to the change of unfrozen water content is

$$dg_1 = dg_2 \quad (3)$$

and the equation to the frost heave process or the amount of frost heave is

$$dQ = du + pdv \quad (4)$$

where g, Q, and u are all functions of t and w, and the relations between t and w can be expressed by the heat-water balance equations at the frost-thaw interface.

$$\Sigma \lambda \frac{\partial t}{\partial x} = \left[\lambda r_0 (w_h + k^+ \frac{\partial w}{\partial x}) + Q_0 \right] \frac{dh}{d\tau} \quad (5)$$

$$w(h + \Delta h, \tau + \Delta \tau) = w_h + \Sigma k \frac{\partial w}{\partial x} \quad (6)$$

The comprehensive processes discussed above cannot be dealt with by an analytic method, but the model test is available. In the light of the nature of frost process, the theory of system analysis is perhaps the most prospective. At present, among the analytic ways with which the various processes can be dealt with independently, both the approximate solution and numerical solution are of great importance. The application of approximate solution will be discussed in the next section.

From eqs 1 and 2, we obtain $\partial \tau / l^2 = \text{idem}$; $k\tau / l^2 = \text{idem}$, and from eqs 5 and 4, we have $\lambda \tau / l r w l^2 = \text{idem}$. $p / l r w = \text{idem}$.

According to the "π" theorem on dimensional analysis, there are nine physical

quantities and five dimensions in the above equations altogether, and, therefore, the four criteria above are complete and independent. From the criteria, we can obtain the following equations of similitude multiple:

$$C_t^2 = C_a C_T, \quad C_l^2 = C_k C_T,$$

$$C_l^2 = C_\lambda C_t C_T / C_l C_r C_w, \quad C_p = C_l C_r C_w.$$

Because of the above four restraining conditions, the similitude multiples have only five variables, and the other three are determined by the above-mentioned conditions.

If the model experiments are performed on the undisturbed soil samples, then we have

$$C_\lambda = C_a = C_k = C_r = C_l = 1,$$

and from the above, we obtain

$$C_t = 1, \quad C_w = 1, \quad C_T = C_l^2.$$

The other similitude multiples can be determined by the dimensional combination method. Here, we only give the similar multiple for stress $C_p=1$, and that for water flow $C_l=1/C_l$.

THE APPROXIMATE CALCULATION OF FROST HEAVE

Determination of Frost Penetration Depth and Amount of Migrating Water

If we take a section of soil layers from the ground surface ($X=0$) to the top of ground water capillary zone ($X=H$) as a system, then, according to the nature of transferring heat and moisture in the system, it can be divided into the three interrelated subsystems, i.e., the frozen soil section ($X=X_k$), the freezing soil section (X_k-h) and the thawed soil section ($h-H$).

To make the subject simple, the author proposes the premises as follows

1. The whole system is homogeneous, the heat transmission takes conduction as the main way, the thermal effect during water migration is reflected only in the latent heat of phase transition of water, and, at the same time, the heat exchange within the frozen soils is taken into consideration.

2. The temperatures at the upper and lower boundary of the system, t_0 and t_H , are taken their average values during the freezing process; the temperature at the freezing front, t_h , is 0°C , and the change of temperature in both the frozen and thawed regions (t^- and t^+) follow the linear laws:

$$t^- = -t_0/h. (x-h);$$

$$t^+ = t_H / (H-h). (x-h). \quad (7)$$

3. Moisture migration takes place in both the freezing and thawed soil regions. The upper boundary of the freezing region, X_k , is determined by the level of the temperature t_k , which corresponds to the critical value (w_k) of unfrozen water in the temperature field

$$X_k = (t_0 - t_k)/t_0 \cdot h.$$

The water content (w_H) at the lower boundary is a constant, and the water content at freezing front is $w_h = w_0 - w'$, where w_0 is the initial water content, and w' the amount of water flowing out of the system during thawing. The bonding water content (w_{kp}) of the soils is subtracted from the total water content. The water contents in the two regions, w^- and w^+ , change linearly as follows

$$w^- = w_k + (w_h - w_k)/(h - X_k) \cdot (X - X_k);$$

$$w^+ = w_H - (w_H - w_h)/(H - h) \cdot (H - X). \quad (8)$$

Under the above premises, the balance of heat and moisture at the freezing front can be described by the equations

$$\lambda \frac{\partial t^-}{\partial x} - \lambda^+ \frac{\partial t^+}{\partial x} = (Lr_0(w_h + \Delta w) + 1/2C^- |t_0|) \frac{dh}{d\tau}$$

$$K^+ \frac{\partial w^+}{\partial x} - K^- \frac{\partial w^-}{\partial x} = \Delta w \frac{dh}{d\tau} \quad (10)$$

considering eqs 1, and 2, and letting

$$a = \lambda^- |t_0|; \quad b = \lambda^+ t_H + Lr_0F;$$

$$C = r_0 w_h + C^- / 2 \cdot |t_0|;$$

$$E = K^- |t_0| / t \cdot (w_h - w_k);$$

$$F = K^+ (w_H - w_h).$$

we obtain the equation describing the rate of frost penetration from eqs 9 and 10

$$dh/d\tau = \{ aH - (a+b)h \} / h(H-h)C \quad (11)$$

Integrating eq 11, we obtain the equation for determining the depth of frost penetration

$$h = -C \left(\frac{bH \cdot h}{(a+b)^2} - \frac{h^2}{2(a+b)} + \frac{abH^2}{(a+b)^3} \ln \left(1 - \frac{a+b}{aH} \right) \right) \quad (12)$$

and that for determining the amount of migrating water

$$Q = \Delta w r_0 = r_0 C \frac{(E+F)h - EH}{aH - (a+b)h} \quad (13)$$

From eqs 9 and 10, it can be seen that the applicable range of eqs 12 and 13 is

$$E/(E+F) \cdot H \leq h \leq \lambda^- |t_0| / (\lambda^- |t_0| + \lambda^+ t_H) \cdot H \quad (14)$$

If H is very great, and the moisture migration in the freezing region is not taken into consideration, we have the revised Stephen formula:

$$h = \left(2\lambda^- |t_0| \tau / (Lr_0 w_0 + 1/2C |t_0|) \right)^{1/2} \quad (15)$$

The condition forming the ice layer can be analysed by eqs 12 and 13. From the full condition forming the ice layer, $r_0 w_h + Q \geq r_0 w_b$, we can obtain the location where the ice layer is formed.

$$h^1 \geq \{ a(w_b - w_h) + CE \} / \{ C(E+F) + (a+b)(w_b - w_h) \} \cdot H \quad (16)$$

and, furthermore, obtain the thickness of the formed ice layer

$$L = r_0 / \bar{r}_w \cdot 1.09Cr_0 / r_w \int_{h^1}^h \frac{(E+F)h - EH}{aH - (a+b)h} dh +$$

$$\int_{h^1}^h (0.09w_h - w_b) dh = r_0 / \bar{r}_w \left\{ (w_b - 0.09w_h - 1.09C \frac{E+F}{a+b}) (h^1 - h) + 1.09C \left(\frac{EH}{a+b} - \frac{(E+F)a^H}{(a+b)^2} \right) \cdot \left(\frac{aH - (a+b)h}{aH - (a+b)h} \right) \right\} \quad (17)$$

Determination of Unfrozen Water Content and Amount of Frost Heave

As for the problem of phase change of water in frost process, from the point of view of cryopedology, it is considered as the problem of the formation and distribution of ice, and from that of physics, it is considered as the problem of the balance and transformation of bonding water, unfrozen water and ice in the soil system. This problem is discussed under following premises: Soils system is homogeneous, ice is transformed from pure water (including the migrating water), and the change of gasses in this process is negligible. So the ice in pores of this system possesses the same properties when it is in the free state. The nature of unfrozen water is governed by the features of particle surface, and is characterized by magnetic (thermodynamic) parameters. Therefore, the discussed problem is turned into the problem of phase transformation of water-to-ice in this case without external electrical or magnetic field.

According to eq 3, we have the following relation,

$$(\partial g_1 / \partial T)_{PN} dT + (\partial g_1 / \partial P)_{TN} dP + (\partial g_1 / \partial N)_{TP} dN$$

$$- (\partial g_2 / \partial T)_{PN} dT + (\partial g_2 / \partial P)_{TN} dP +$$

$$(\partial g_2 / \partial N)_{TP} dN \quad (18)$$

According to the well-known thermodynamic relation, eq 18 can be written as

$$(S_2 - S_1) dT + (V_1 + V_2) dp + (\mu_1 - \mu_2) dN = 0 \quad (19)$$

For the temperature and applied pressure being constant, we have

$$(\partial N/\partial P)_T = (V_1 - V_2)/(\mu_2 - \mu_1) = -\Delta V/\Delta\mu; \quad (20)$$

$$(\partial N/\partial T)_P = (S_2 - S_1)/(\mu_2 - \mu_1) = \Delta S/\Delta\mu \quad (21)$$

Since $\Delta S = \Delta H/T$, and $\Delta\mu = RT \ln(P_2/P_1)$, we obtain

$$(\partial N/\partial T)_P = \Delta H/RT^2 \ln(P_2/P_1); \quad (22)$$

$$(\partial N/\partial P)_T = -\Delta V/RT \ln(P_2/P_1) \quad (23)$$

In eqs 22 and 23, because of $\Delta H < 0$, $P_2 < P_1$, and $\Delta V > 0$, so $(\partial N/\partial T)_P > 0$, $(\partial N/\partial P)_T < 0$. Thus, unfrozen water content increases with the temperature or pressure increasing, i.e., in this case ice is transformed into unfrozen water.

Integrating eqs 22 and 23, we can obtain the relations for determining the unfrozen water content (or ice content) in soils at a certain temperature and pressure. At present, however, there are some difficulties in the experimental determinations of a few necessary parameters.

If a soil layer suffered to freezing, because of the moisture redistribution (migration) and ice formation, the volume and density of the soil layer must have changed. It is called the frost heave of soils, and the corresponding frost heave increment in the vertical direction is so-called the amount of frost heave.

The increase of ice volume is the necessary condition for producing frost heave, and the full condition is that the increase of ice volume must be greater than the sum of the decrease of pore volume in the soil and the compressive amount of the underlying thawed soils during freezing.

For a semi-infinite ground body suffered an external load of P , if we take the ice within the soil layer with the thickness of dh , which is taking place the phase change as a system, and the upper and lower soil layers as surroundings, the first thermodynamic law must take the form of eq 4.

$$\text{where } du = \Delta u r_0 (w_h + \Delta w) dh \quad (24)$$

in which, Δu is the intrinsic energy increment of the unit weight of water during phase change;

$$\text{and } dQ = \Delta H r_0 (w_h + \Delta w) dh \quad (25)$$

in which, ΔH is the entropy increment of unit weight of water during phase change.

$\Sigma p dV$ is the sum of the volume expansion work, and it includes the following two parts:

$p_1 dV_1$ is the expansion work of the system done by overcoming the soil weight the applied, load, including the compressive deformation work of the underly-

ing soil layer. It takes the form of

$$p_1 dV_1 = \{P + r_0 (1 + w_h + \Delta w)\} d\ell \quad (26)$$

in which, ℓ is the deformation of the soil layer, i.e., the amount of frost heave of the soil layer.

$P_2 dV_2$ is the expansion work of the system done by expanding to the pore of soil. It states

$$P_2 dV_2 = \{P + r_0 (Hw_h + \Delta w)\} \Delta n dh \quad (27)$$

in which, Δn is the change of pore volume of the soil during freezing, and we have

$$\Delta n = -\left(\ell/h - (1.09\Delta w + 0.09w_h)\right)$$

Substituting eqs 24 - 27 in eq (1-4), we obtain the relation for determining the frost-heaving rate.

$$d\ell/dh = \frac{(\Delta U + \Delta H) r_0 (w_h + \Delta w)}{p + r_0 (1 + w_h + \Delta w) h} + \ell/h - (1.09\Delta w + 0.09w_h) \quad (28)$$

Integrating the above relation, we obtain the equation for determining the amount of frost heave

$$\ell = \int_0^h \frac{d\ell}{dh} dh \quad (29)$$

If it is known how w varies with depth, the above equation can be solved.

For saturated soils ($h=0$), the amount of migrating water is a constant, and then the amount of frost heave can be calculated by

$$\ell = \frac{\Delta U - \Delta H}{+w_h + \Delta w} \ln \left(\frac{P + (1 + w_h + w) r_0 h}{p} \right) \quad (30)$$

CONCLUSIONS

In this paper a mathematical model describing the frost processes in principle has been presented after the analysis of physical nature in frost processes. This model has been founded on the basis of a group of equations. The relationship of similitude multiple, which is used for undisturbed soils in modelling tests, has also been given.

For the open system with the constant underground water level, the obtained approximative solution, which is used for calculating the freezing penetration depth and the quantity of moisture migration, is clear in physical conception. The formula for calculating unfrozen water content, obtained by thermodynamic method, can reflect the effects of temperature, pressure and soil properties, and the formula for calculating the amount of frost heave by the same method is founded under the consideration of factors such as porosity change, solidification of underlying soils, etc.

NOMENCLATURE

X: coordinate of a given soil layer, which original point is at the ground surface (m);
 τ: time (h_r);
 ρ_0 : dry density of soils (kg/m^3);
 ρ : bulk density of soils (kg/m^3);
 t: temperature in soils ($^{\circ}C$);
 T: absolute temperature ($^{\circ}C$);
 α : thermal diffusivity of soils ($M^2/h_r.$);
 λ : thermal conductivity of soils ($k_{cal.}/m \cdot h_r. ^{\circ}C$);
 c: voluminal specific heat ($k_{cal.}/m^3 \cdot ^{\circ}C$);
 L: latent heat of phase change of water ($k_{cal.}/kg$);

w: water content (%);
 Δw : amount of migration water of unit volume of soil (%);
 k: moisture conductivity ($m^2/h_r.$);
 g: isobaric potential;
 μ : chemical potency;
 Q: quantity of heat;
 H: total heat;
 U: intrinsic energy;
 S: entropy;
 P: pressure;
 P_i : steam pressure;
 V: volume;
 N: composition of mass;
 R: general fitting constant of gas;

C_i : geometric proportion coefficient;
 l : quantity of finalizing geometric type;
 -, +: subscripts referring to the frozen and thawed state of soils;
 1, 2: subscripts referring to the phase of unfrozen water and ice.

ACKNOWLEDGEMENTS

Here, the author heartily wishes to thank his colleagues, Xu Xiaozu, Zhu Yuanlin, and Peng Wanhual, for their aid in preparation of this paper.

A STUDY OF HORIZONTAL FROST-HEAVING FORCES

Ding Jingkang

Northwest Institute of the Chinese Academy of Railway Sciences
Lanzhou, People's Republic of China

To investigate the horizontal frost-heaving forces that act on structures, an experimental and a model reinforced concrete retaining wall were constructed at the Fenghou-Shan Field Research Station on the Qinghai-Xizang Plateau in 1976. The experimental retaining wall was 15 m long and 4-5 m high, and the model wall was 3 m long and 1.2 m high. Investigations conducted during three winters (1976-78) indicated that the magnitude and distribution of horizontal frost-heaving forces are substantially governed by the material properties of the backfill and the displacement of the walls. For clayey soil backfill, the maximum horizontal frost-heaving force was 1.4 kg/cm^2 and acted upon the middle or lower middle part of the wall, while for gravel backfill it was 0.76 kg/cm^2 and acted upon the lower part of the wall. Based on the distribution of frost-heaving forces along retaining walls, the author presents three basic models for calculating the horizontal frost-heaving forces acting on structures according to the different working conditions of the structures.

Horizontal frost heaving pressure is one of the frost heaving pressures which act upon foundation of structures during the freezing of soils. According to the condition of emerging and features of functioning, it can be classified into two types---symmetrical horizontal frost heaving pressure and nonsymmetrical horizontal frost heaving pressure (see Figure 1).

The action of symmetrical frost heaving pressures on foundation is the same as that of hydrostatic water pressure so as not to yield direct effect on the stability of foundations. However, because of the symmetrical frost heave pressure the shearing-resistant strength of the interface between permafrost and foundation will be increased, i.e. the tangential frost heaving pressure exerting on foundation will increase and bring about an indirect influence over the stability of foundation.

Nonsymmetrical horizontal frost heaving pressure is the main pressure system acting upon retaining structures in permafrost areas. It is several times, and even tens of times as high as that of Coulomb's ground pressure¹⁾ (see Figure 2). It is, therefore, of great significance to study the magnitude of nonsymmetrical horizontal frost heaving pressure, the law of distribution as well as the condition for emergence while designing and calculating retaining structures in permafrost areas.

To study the problems mentioned above, tests were made on experimental and model retaining walls at site of Qinghai-Xizang Plateau. The experimental retaining walls investigated were reinforced concrete L-shaped ones with a height of 4 m and 5 m respectively and a length of 15m. The soil placed behind the 4 m retaining wall was fine granular soil and that behind the 5 m one was coarse granular soil. The model retaining wall was a multi-layered one made of reinforced concrete with a length of 3 m and a total height

FIGURE 1 Symmetrical and nonsymmetrical frost heaving pressure.
(a) Symmetrical frost heaving pressure;
(b) Nonsymmetrical frost heaving pressure.

FIGURE 2 Comparison of ground pressure and horizontal frost heaving pressure.

of 1.2 m, the height of each layer being 0.2 m. Fine granular soil was placed behind the wall.

INITIATION OF HORIZONTAL FROST HEAVING PRESSURE

It is well-known that during freezing, soil is accompanied by an expansion of volume, i.e. frost heaving. Frost heaving of soil and the resistance of retaining structures to horizontal loads are necessary for horizontal frost heaving pressures to occur. Horizontal frost heaving pressure will not develop unless frost heaving occurs during freezing of soil behind the retaining structure, or retaining structure can deform freely without preventing frost heaving. The two conditions above, however can be hardly satisfied under normal situations, and as a result, horizontal frost heaving pressures cannot be avoided during freezing of the soil behind a retaining wall.

DEVELOPMENT OF HORIZONTAL FROST HEAVING PRESSURE

How does horizontal frost heaving pressure emerge and develop in the course of soil freezing? Figure 3 gives the displacement curve of top of the L-shaped retaining wall during freezing, and Figure 4 presents the developing curve of horizontal frost heaving pressure at different depths on the back of the model retaining wall.

It is seen from Figure 3 that soil body contracts and the ground pressure falls at the beginning of freezing because of decreasing of the soil temperature. The wall deflects towards the fill behind the L-shaped retaining wall (negative displacement) and reaches a maximum (Figure 3 point a) when the ground pressure is reduced to a minimum and the horizontal frost heaving pressure has not yet developed. During this period, the ground surface tends to be stably frozen through exchange of freezing and thawing.

After the emergence of a stably frozen state, the horizontal frost heaving pressure develops and increases with depth of freezing. Under the action of the horizontal frost heaving pressure, the retaining wall deflects away from the fill (positive displacement). The curve rises to point b when the frozen depth reaches the seasonally thawed depth. As freezing progresses, the horizontal frost heaving pressure steadily increases, the curve has an increasing slope from point b to c, which means that the horizontal frost heaving pressure rises rapidly along with decrease of temperature of frozen layer. The curve runs smoothly from c to d, which implies that a basic equilibrium exists between the increase and the relaxation of the horizontal frost heaving pressure; the horizontal frost heaving pressure reaching its maximum at this time.

The course of deflection of the L-shaped retaining wall during freezing reflects the process of the emergence and development of the horizontal frost heaving pressure. Through successive observations for three years an analogous curve was obtained.

The above analysis is illustrated by the developing curves of horizontal frost heaving pressure shown in Figure 4. In Figure 4, the horizontal frost heaving pressure developed along with appearance of stably frozen state. With the seasonally thawed layer freezing gradually from the beginning of October to mid-November, the horizontal frost heaving pressure gradually rises (seasonally thawed layer is completely frozen in mid-November). From mid-November to the end of December, horizontal frost heaving pressure rises rapidly to a maximum along with the decrease of temperature of the frozen ground. From the end of December to mid-January, despite the continuous decrease of frozen ground temperature, the increasing and relaxing of horizontal frost heaving pressures basically reaches an equilibrium, the curve fluctuating within a slight range.

It can be seen from the above analysis that

FIGURE 3 The displacement curve of top of L-shaped retaining wall in the freezing.

FIGURE 4 The developing curves of horizontal frost heaving pressure on the back of model retaining wall. Six layers were tested; (1) is the top layer.

the action of horizontal frost heaving pressure is not synchronous with that of ground pressure. Ground pressure can be considered as zero as horizontal frost heaving pressure develops.

DISTRIBUTION OF HORIZONTAL FROST HEAVING PRESSURE

The distribution of horizontal frost heaving pressure along the back of retaining wall is uneven. Figure 5 gives a distribution curve of horizontal frost heaving pressure along back of L-shaped retaining wall, and Figure 6 that along back of a model retaining wall. It is seen from Figure 5 and 6 that the horizontal frost heaving pressure mainly distributes along the middle and lower parts of the wall. The magnitude of hori-

zontal frost heaving pressure is less along the upper part, and its maximum appears at different places depending upon the fill material used, fine or coarse granular soil. The maximum horizontal frost heaving pressure occurs at the middle or lower middle part of the wall with fine granular soil as fill material, and at the lower part of the wall for coarse granular soil.

The distribution of the horizontal frost heaving pressure is determined by the following factors.

Heat Flow Variations

After the retaining wall is established, the condition for heat radiation during freezing of the soil mass changes to a two-dimensional problem. Figure 7 shows the distribution curve of

Figure 5 Distribution of horizontal frost heaving pressure along back of a L-shaped retaining wall. L₁, L₂, L₃, L₄ are the number of testing walls.

Figure 7 The distribution curve of temperature field along back of the model retaining wall. (October 28, 1978).

Figure 6 Distribution of horizontal frost heaving pressure along back of a model retaining wall.

temperature field along the back of the model retaining wall during seasonal freezing.

It is seen from Figure 7 that during the early stage of freezing the isotherms slope upward from upper part of the wall. This shows that soil body freezes in two dimensions, attaining a maximum rate of freezing. Below the middle of the wall the isotherms are likely to be parallel to wall surface, which indicates that the middle part of the soil mass approximates one-dimensional freezing, its freezing rate being similar to that of the natural ground surface. During freezing the thermal radiation conditions for the soil mass located behind the lower part of the retaining wall (corresponding to the soil mass beneath ground surface in front of the wall) are poor, thus it freezes at a low rate. Such freezing factors of the soil mass behind a retaining wall determine the conditions of moisture flow and ice segregation.

Hydrologic and Geologic Variations

After a retaining wall is built, a new permafrost table inclining toward the wall forms. As

Figure 8 Distribution of water content in soil filled up behind model retaining wall versus depth.

a result, suprapermafrost water converges toward back of the retaining wall above the permafrost table, causing an increase of water content in the soil behind the wall.

On the other hand, the water in the soil behind the wall moves downward under the influence of gravity, which leads to a moisture distribution where the upper part of the fill contains less water, while the middle and lower parts contain more (Figure 8).

Moisture Migration During Freezing

While fine granular soil is freezing, water migrates toward the freezing front. This leads to the increase of water content in soil mass near freezing front. However, during the freezing of coarse granular soil, water flows away from the freezing front, and as a result, a decrease in the water content in the soil near the freezing front tends to occur.

The above three factors determine the distribution of the horizontal frost heaving pressure along back of a retaining wall. With fine granular soil as fill material, the water content behind the upper part of wall is the lowest and the freezing rate is the highest, the water migration rate is slight, and the direction of ice crystal separation slope upward toward retaining wall. This results in the lowest horizontal frost heaving pressures acting upon upper part of retaining wall. At mid depth behind a retaining wall, the freezing rate is similar to that of natural ground surface, because of moderate water content. This increases the flow of water toward the freezing front. Finally, because of unfavorable conditions for thermal radiation from the base of a retaining wall, freezing lags behind that of the soil at mid depth so that there is sufficient time for the water in lower soil mass to migrate to the mid depth freezing front. Therefore, the freezing process at mid depth is analogous to that for an open system having an external water supply. Furthermore, the ice lenses are almost parallel to wall so that the horizontal frost heaving pressure yielded tends to be the highest. As for lower soil mass, the water content decreases because of moisture loss during freezing. In addition, the thickness of lower frozen soil mass decreases so that a smaller horizontal frost heaving pressure occurs.

When coarse granular soil is used as fill material, the development of horizontal frost heaving pressure is dependent upon moisture flow from freezing front downward during the course of freezing, and therefore the maximum horizontal frost heaving pressure occurs at the lower part of the wall.

Main Factors Affecting Horizontal Frost Heaving Pressure

It is evident from the analysis of horizontal frost heaving pressure that the main factors that affect it can be classified into two sorts: first, those determining the heaving properties of fill materials, and second, those deciding the deformation property of the retaining wall. The first is mainly related to different types of soil, water content, temperature, and freezing rate, etc., while the second is primarily related to the type of retaining wall.

Different types of soil have different heaving properties. Under the same boundary conditions, fine granular soils heave more than coarse soils, and therefore higher horizontal frost heaving pressures occur in the former. It can be seen from Figure 5 that both the maximum and mean values of horizontal frost heaving pressure of fine granular soil are larger than those in the coarse granular soil.

The distribution curve of horizontal frost heaving pressure in Figure 5 also reflects the effects of water content. Water content is low behind the upper part of the wall and high in the middle and lower. Correspondingly, the horizontal frost heaving pressures are lower behind the upper part of the wall.

Horizontal frost heaving pressures rise with decrease of ground temperature. From Figure 4, we can see the increasing trend of the frost heave pressure is nearly to the negative increasing trend of the temperature.

The magnitude of the retaining wall deformability is manifested in terms of its resisting effect on heaving. The higher the deformability, the lower the resisting effect, namely, the less the horizontal frost heaving pressure produced.

Distribution of Horizontal Frost Heaving Pressure

It is seen from the observation of the distribution of horizontal frost heaving pressure behind retaining wall that under similar conditions, the frost heave pressures are always low in the upper part and high in the lower, approximating a triangular distribution. Because the locations of the maximum horizontal frost heaving pressure in fine and coarse granular soil are different, the distribution of horizontal frost heaving pressure can be simplified using different triangles (Figure 9). For coarse granular soil, the triangular distribution pattern (Figure 9-3) is adequate for use regardless of buried depth of retaining wall, while for fine granular soil, different distribution patterns—Figure 9-1 or Figure 9-2 are

Figure 9 Calculating patterns of horizontal frost heaving pressure distributed along retaining wall back.

(1), (2) are the fine granular soil.
(3) is the coarse granular soil.

adopted in accordance with the practical burying conditions of retaining wall.

Option of Horizontal Frost Heaving Pressure

The horizontal frost heaving pressure obtained by means of multi-layered model retaining wall and the maximum horizontal frost heaving pressures calculated in accordance with the patterns of wall deformation in Figure 9 are listed in Table 1 and 2 respectively.

From the tables, it is seen, the maximum horizontal frost heaving pressure for saturated gravel soil is 0.76 kg/cm^2 , while that of fine granular soil whose water content is close to the lower limit of plasticity is 1.4 kg/cm^2 .

The maximum horizontal frost heaving pres-

		1977	19.2	0.35	0.18
		1978	28.1	0.50	0.25

tures of fine granular soil were obtained by means of a model retaining wall. The deformation of the model retaining wall was as small as about 0.4 mm, while, in general, the deformations of real retaining wall are larger than this value. Under identical conditions, the maximum horizontal frost heaving pressure in a fine granular soil acting upon a retaining wall will be generally less than 1.4 kg/cm^2 . It is, therefore, proper to choose 1.5 kg/cm^2 as the upper limit of maximum horizontal frost heaving pressure.

The maximum horizontal frost heaving pressures of saturated gravel soil were obtained from experimental retaining wall, in which the fine clayey particle content was 5.9%. Therefore, a maximum horizontal frost heaving pressure of 1 kg/cm^2 is adequate for coarse granular soil on account of the possible maximum content of fine and clayey particles.

Based on the above results, it is suggested that under normal conditions the maximum horizontal frost heaving pressures of $1-1.5 \text{ kg/cm}^2$ and $0.5-1.0 \text{ kg/cm}^2$ be adopted for fine and coarse granular soil respectively provided that the calculation are made with triangular distribution patterns for frost heave pressures.

CONCLUSION

Based on the above discussion, we can conclude the followings:

1. There exists a horizontal frost heaving pressure during freezing of soil behind the retaining wall. It is the main pressure system acting upon retaining wall in permafrost areas. It is several times, and even tens of times as high as that of Coulomb's ground pressure.

2. The size of horizontal frost heaving pressure is only related to the heaving properties of soil, and the deformation properties of the retaining wall are unchanged, irrelevant to the height of retaining wall.

3. The action of horizontal frost heaving pressure is not synchronous with that of ground pressure. Ground pressure can be considered as zero as horizontal frost heaving pressure develops.

DESIGN AND CONSTRUCTION OF PILE FOUNDATIONS
IN THE
YUKON-KUSKOKWIM DELTA, ALASKA

A "reaction beam" type pile load test was conducted in ice-rich silt at Kipnuk, Alaska to determine the load capacity of driven H-piles at the edge of the continuous permafrost region in the Yukon-Kuskokwim Delta. Field test results are compared to existing theories on the design of pile foundations in frozen ground. Additionally, information regarding site conditions, pile installation methods, equipment and construction problems are discussed for the pile foundations of water tanks and auxiliary structures designed and installed in this region at the Eskimo Villages of Kotlik, Hooper Bay, Chevak, Newtok, Tuntutuliak, and Kipnuk. These water tanks ranged from 45,000 to 910,000 liters with accompanying loads of up to 115 kN/pile. Subsoil conditions varied from ice-rich organic silt, and silty sands to poorly graded frozen fine sand with low moisture content.

INTRODUCTION

The Alaska Area Native Health Service designed and constructed water storage facilities, an essential component of most public water supply systems, in the Eskimo villages of Kotlik, Hooper Bay, Chevak, Newtok, Tuntutuliak, and Kipnuk. The design was based on the adfreeze strength method and test results of a pile load test conducted at Kipnuk on driven steel H-piles in ice-rich silt. This paper presents the pile load test results along with theories regarding pile design in permafrost and provides additional information regarding site conditions, methods of pile installation, construction problems, and design parameters at several locations in the Yukon-Kuskokwim Delta of Alaska.

Required water tank capacity was determined on village population, water availability, and quality. Driven or slurried pile foundations were installed to support water storage tanks varying in size from 45,000-910,000 liters with accompanying loads of up to 115 kN per pile.

This paper addresses site conditions and construction consideration that influenced the design and construction of tanks in the region and then will address the pile load test results obtained at Kipnuk.

SITE CONDITIONS

The Yukon-Kuskokwim Delta is located near the southern boundary of the continuous permafrost region of Alaska. The mean annual air temperature is about -1.7°C . The depth of frozen ground, determined from water well logs, was 30-75 m in the six coastal Native villages where pile foundations were installed. These villages span

the vast almost flat, fan-shaped delta as shown on the key map (Figure 1). Many meandering streams, sloughs, and shallow lakes cover the area, which is a complex of river, marine, and windblown deposits. The ground surface is generally covered with a wet organic mat, coincidental with the active layer, 0.3-0.6 m thick, composed of a wide variety of low-growing shrubs, grasses, and sedges

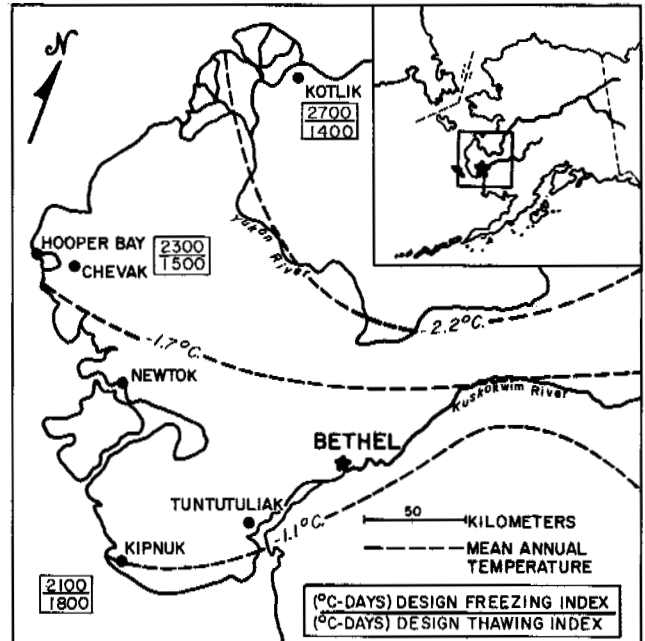

FIGURE 1 Key Map.

rooted in mosses and lichens. Soils typically consist of fine-grained ice-rich silts and sands to the depths investigated (8 m). Soil layers are well defined, ranging from a few centimeters to many meters thick. Typical soil and temperature profiles found at the sites are presented in Figure 2. Soils ranged from well to poorly bonded. Nonvisible and visible ice, both stratified and nonstratified was found. Multi-layer ice lensing with discrete ice lenses of up to 7.5 cm thick was encountered; more massive formations, however, are known to exist.

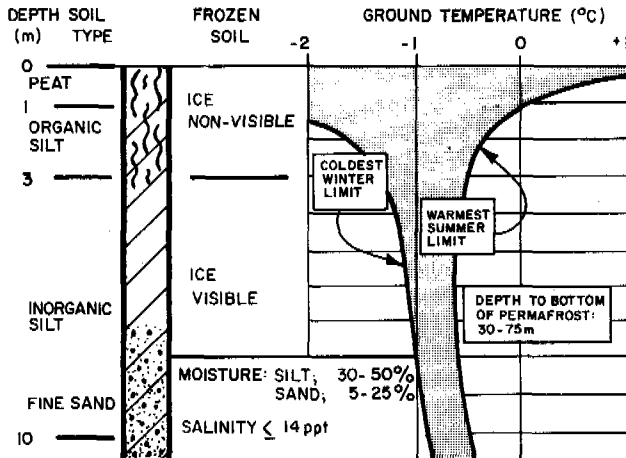

FIGURE 2 Composite Soil Profile and Typical Thermal Regime.

CONSTRUCTION CONSIDERATIONS

Factors such as local transportation, construction season, pile type, and available equipment influence pile foundation installations in this region. Common modes of commercial transportation are barge and airfreight. Overland hauling across frozen trails and rivers can also be used, however, thin ice and severe storms make this method potentially hazardous.

Piling materials are shipped from the Continental U.S. West Coast by barge to village beaches or river bank sites. Pile installation equipment is shipped in a similar manner from Bethel, the transportation center for the region.

Most village gravel runways cannot accommodate large cargo aircraft. Because the thawed active layer is too soft and fragile to support conventional construction equipment during the summer, pile installation normally begins after freezeup in November and can continue until breakup in May. Shipping and construction periods are well defined and, if missed, work can be delayed as much as a year.

Two general methods of pile installation were used: (1) driving and (2) slurry back. The piles were either driven direct or an undersized predrilled holes. Slurry back piles were installed in an oversized hole and backfilled with a sand-water slurry. Installed costs varied from \$2,000 to \$4,000 (U.S.A. 1982) per pile.

Production rates varied from 2 piles/hour (driven H-piles) to 1 pile/5 hours (slurry back piles). Compared with the other installation methods used, driving HP 10X42 piles at Kipnuk required heavier equipment. An open-end diesel hammer rated at 2,000 kg-m for 1.5 m stroke height was used. Difficulties were encountered in starting and running the hammer at cold air temperatures.

The plot of blow counts versus depth for two pile configurations at Kipnuk reflects the winter soil temperature whiplash curve (Figure 3). Blow counts increased linearly with depth in the constant temperature region below 4.5 m. Driving resistance was low, and no significant pile deformation was noticed on any aboveground portions of the piles. However, a bent flange was observed after excavating the colder surface soils around the test pile.

The use of cable tool well drilling equipment was used to drill and drive pipe piles in the same manner as well casing and was capable of delivering 520 m-kg of force. A hole smaller than the diameter of the pipe was drilled 1-3 m deep and the pile then driven to the same depth. The drilling and driving process was repeated continuously until the desired depth was reached. The use of a pilot hole allows driving by smaller and more mobile equipment. Water and a bailer was used to remove cuttings from the hole. Time between driving cycles must be short to avoid higher driving resistance and excessive heat addition. The use of a pilot hole allows driving by smaller and more mobile equipment.

The slurry back method of pile installation requires more attention during construction. The hole diameter must be large enough to accept the backfill and allow compaction of the slurry with a concrete type vibrator. A fine sand either imported or mined locally and saturated with +4°C water was used as the slurry material. Considerable difficulty was experienced when using a solid flight auger to drill to depths below 6 m. Air rotary drilling with compressed air to remove the cuttings proved to be more successful, however, the need for an air compressor added to the logistics problem. Early pile loading was made possible by freezing the slurry with refrigeration equipment.

PILE LOAD TEST

Few pile load tests in North America have been conducted in frozen ground, especially ice-rich "warm" permafrost. The paucity of data can be attributed to testing costs, instrumentation problems, and suitable procedures. In order to obtain better data for design purposes, an axial compression pile load test on driven steel H-piles was performed at Kipnuk during the winter of 1981 at the site where the water tank was planned. Other data on the effects of tensile and lateral loading on driven H-piles were also collected and investigated but are not discussed in this paper.

Load Test Equipment and Instrumentation

A "reaction beam" type load test setup was designed and built of HP 10X42 piles as shown in Figure 4. Two stiffened pile sections welded together and pin connected to the outside support piles formed the reaction beam. The compression test pile was instrumented with 34 thermistors, 5

vibrating strain gauges, and 4 telltales. Protection and access to vibrating strain gauges, thermistors and an inclinometer tube on the test piles were provided by welding angles parallel to the H-pile web. Two reference beams for deflection measurement datums were supported by three additional piles. The test facility was covered with a plywood frame building with insulated floor and oil stove.

Vibrating strain gauges were accurate to ± 1 micrometer. Immediately after driving, measured residual strains indicated a probable 3.8 cm misalignment in the compression test pile at a depth of 6 m. Dial gages supported by adjustable pipe and accurate to $\pm .03$ mm, were used to measure deflection. Clip angles welded to the test pile provided a deflection measurement bench. Errors caused by surface roughness under the gages were reduced after small mirrors were set and plumbed on each measurement bench. Shelter air temperature was held constant to limit expansion and contraction of gage pipe supports. Pile cap settlement for the compression test was measured by four gages placed symmetrically around the pile.

Loads were applied by a 900 kN hydraulic jack with a 5.7 cm cylinder stroke and calibrated to an accuracy of ± 2000 N. The stroke length proved sufficient for the axial load test, but it was too short to apply the necessary load during both the tension and lateral tests. Compressive axial loads became excessively eccentric above 800 kN and the reaction beam twisted beyond the stroke length.

Test Procedure and Results

Axial compressive loads were applied to the instrumented test pile in 45 kN increments and relieved in 90 kN increments. Six cycles of loading and unloading were made. Load cycles I and II were to 130 kN, III and IV to 260 kN, and V and VI to 800 kN. Pile cap deflections were read at frequent intervals immediately following application of each load. Pile strain and temperature readings were also recorded. Loads were increased after pile strain and pile cap settlement rates remained constant.

FIGURE 4 Kipnuk Pile Load Test Setup.

FIGURE 5 Pile Cap Displacement and Shaft Compression for Kipnuk Load Cycle IV.

PILE FOUNDATION DESIGN

Measured pile displacements and computed pile shaft compression during load cycle IV are presented in Figure 5. Measured pile shaft strains found for the same load cycle are illustrated in Figure 6. Shaft compression and cap displacement behavior under higher loads (cycles V and IV) are shown in Figure 7. As expected, the magnitude of shaft compression is generally lower than pile cap displacement. It is interesting to note that the pile cap continues to settle while shaft compression is complete.

FIGURE 6 Measured Pile Shaft Strain (Kipnuk Load Cycle IV).

The design of pile foundations in ice-rich "warm" permafrost has grown from an empirical static analysis approach based on adfreeze strength to a more rational consideration of load-pile displacement behavior based on theoretical creep law models. Attempts to quantify driven pile performance and load capacity in these soils based on dynamic considerations (such as wave equation analysis) lack sufficient data on appropriate soil strength properties and their creep deformation relationships.

Adfreeze Strength Approach

This method is analogous to that used for unfrozen cohesive soils; it is typified by a "floating" pile analysis, makes broad use of engineering judgement and experience, and employs larger factors of safety. Piles are assumed non end bearing unless site conditions reveal otherwise; group effects are also largely ignored. Besides applied load, additional loading due to active layer downdrag and frost heaving are considered.

Known adfreeze strengths based on load tests elsewhere (for example Linell et. al. 1980), are applied to thermally defined increments of depth, and summed to determine capacity. Figure 8 displays this approach for the load test. The circumscribed area of the H-pile was used in this computation to arrive at a short term capacity of 680kN.

Pile capacity may also be assessed directly from short term incremental load test results (which is conventionally the basis for determining unit adfreeze strength values). Using the method of intersecting tangents, the estimated short term capacity found from load cycle V is 650 kN, as shown in Figure 9.

FIGURE 7 Short Term Pile Load Test Results, Kipnuk.

FIGURE 8 Kipnuk Load Test Short Term Pile Capacity Estimated by the Adfreeze Strength Approach Method.

There has been little definitive work on the factors of safety necessary for pile designs based on adfreeze strength in ice-rich permafrost, especially when addressing long term creep. There is a lack of consensus on, and understanding of the transferability of information interpreted from a few load tests applied to sites elsewhere, and to differing pile materials and geometries. For instance, the greater surface area of H-piles does not result in proportionally greater pile load capacity. Between the flanges there is an interaction of shear and adfreeze strength that is not clearly understood.

However, it is known that pile capacities may be increased by mobilizing additional soil shearing stress through the use of protruberances (rings, plates, fins, etc.) or through active or passive ground chilling schemes (Long, 1973).

FIGURE 9 Interpretation of Kipnuk Short Term Pile Capacity.

FIGURE 10 Generalized Creep Behavior of Ice-Rich Frozen Soil.

Pile Velocity Approach

Based on observations, the elastic-plastic response of frozen soils to stress can be schematically represented by Figure 10. Full scale field tests on piles have shown similar behavior (Markin et. al., 1973). In "warm" ice-rich silts, practical designs will operate on the dominating secondary creep surface.

Power flow laws have been proposed to describe steady state creep in incompressible materials at constant temperature as a function of multiaxial stress. Applied to permafrost, this relationship has been more simply stated (Vyalov, 1965).

$$\dot{\epsilon} = \beta \sigma^n \tag{1}$$

where $\dot{\epsilon}$ is secondary creep rate, σ is the level of a general state of stress, and β and n are temperature dependent constants unique to the frozen soil. The secondary creep constants for Kipnuk ice-rich silt as determined from laboratory uniaxial compression tests are shown in Figure 11.

Equation 1 has been transformed and applied to the idealized shearing of concentric cylinders to arrive at an equation describing pile cap velocity (Ladanyi, 1972).

$$\dot{U}_a = \frac{a3^{(n+1)/2} \beta \tau_a^n}{n-1} \tag{2}$$

Where \dot{U}_a is steady state pile velocity, a is the pile radius, τ_a is shear stress, and β and n are temperature dependent constants determined from uniaxial creep data for the frozen soil in question. This equation is insensitive to changes in normal stress on the lateral surfaces of the pile (i.e., overburden pressure) and to pile compressibility. It assumes that soil properties are homogeneous and isotropic with depth and that there is no slip at the pile-soil interface (i.e., tangential stress is less than adfreeze strength). Equation 2 may be algebraically rearranged and applied incrementally to account for variations in soil creep properties with depth. This allows investigation of velocity-load relationships under different thermal regimes. Equation 2 has been further modified to account for pile compressibility (Nixon and McRoberts, 1976) as shown below:

$$\dot{U}_a = D(z, t) \left(\frac{aE}{2}\right)^n \left(\frac{\partial^2 U}{\partial z^2}\right)^n \tag{3}$$

With equation 3, the fundamental relationship between pile strain and shaft stress over time may be explored in terms of pile cap settlement. This information is most helpful in interpreting short term load test data. It is generally assumed that when creep data for a particular ice-rich soil are lacking, the use of pure ice constants instead will yield a safe design. (Nixon and McRoberts, 1976; Morgenstern et. al., 1982). Calculated theoretical creep rates for a 10.5 m pile at Kipnuk (using Equation 2 with site specific secondary creep constants) are shown in Figure 11. However, the ultimate pile capacity must be determined from field testing. Characteristically, pile surfaces have little effect on displacement response at low stress levels. Rough piles will mobilize more tangential

adfreeze shearing strength before shaft slip begins to dominate settlement behavior and the pile plunges.

Figure 11 Comparison of Theoretical and Measured Pile Cap Velocities for Kipnuk.

Pile creep may be addressed empirically by long-term static pile load tests. These are usually conducted at higher than anticipated design stress levels to force measurable settlement over practical time periods. A method of extrapolating the results to lower stress levels is by extending the linear relationship of log long-term creep rate versus log pile-load. The load cycle V data (Figure 7) is plotted in this way in Figure 11. Because the test was of short duration, it is not known whether the pile response is in secondary creep at all loads. This may be indicated by the slight curve, thought to represent a primary to secondary creep transition during the early light loads. Further deviation can be expected when the pile eventually plunges at loads higher than reached during the test. An additional problem with interpretation of any pile load test in permafrost is the assessment of creep seasonality. Short term tests yield explicit behavior for a single soil temperature profile. Long term tests tend to meld the pile settlement-load relationship with changing soil thermal conditions at the site. Creep seasonality is more significant at the fringes of permafrost regions where soil temperature variations are larger and extend to greater depths.

CONCLUSIONS

1. The early spring short term capacity for a 10.5 m pile using published empirical adfreeze strengths and Kipnuk soil temperatures is 680 kN. Theoretically, for the same load, the calculated creep rate limits using Kipnuk soil secondary creep constants and equation (2) are 0.17 m/year at early spring and 0.80 m/year at late summer.

2. The prediction of settlement using pile velocity theories with secondary creep constants for ice is conservative in comparison to the pile load test for Kipnuk.
3. The prediction of settlement using pile velocity theories with secondary creep constants for ice-rich silts (Kipnuk) appears to have a similar trend as the plotted LOAD TEST results; however, the magnitude of settlement was found to be less.
4. H-piles may be driven successfully in "warm" ice-rich silts and sands. The principal advantages are speed of installation, increased practical embedment length, minimal disturbance to the environment, and immediate loading.
5. Kipnuk test results show that more field pile load tests are necessary to better understand the behavior of piles in ice-rich frozen soils.

CREEP BEHAVIOR OF FROZEN SALINE SILT UNDER ISOTROPIC COMPRESSION

L. Domaschuk, C.-S. Man, D.H. Shields, and E. Yong

Department of Civil Engineering, The University of Manitoba
Winnipeg, Manitoba, Canada R3T 2N2

Isotropic compression creep tests were conducted on a prepared frozen sandy silt with a pore-fluid salinity of about 60 parts per thousand before freezing. Single-step and multi-step loadings of pressure from 70 to 700 kPa were applied to soil samples at three different temperatures ($T = -15^{\circ}\text{C}$, -10°C , -5°C). From our results we observed the following: (1) Samples originally in equilibrium underwent attenuating creep upon compression by a superimposed hydrostatic stress; over 70% of the ultimate volume change occurred within the first few hours; a substantial portion of the volume change was not recovered upon unloading. The level of ultimate volume change indicated that volume change during creep could be a significant factor in some problems. (2) A history of loading and recovery had a strain-hardening effect on the frozen soil; so did a history of incremental loading. (3) At -5°C the saline soil was non-bonded but its response to isotropic compression did not seem to be qualitatively different from the way it behaved when it was ice-bonded. This study is part of a broader investigation into the long-term multiaxial creep behavior of frozen saline soils that simulate those beneath the Beaufort Sea.

INTRODUCTION

Frozen soils under conditions of creep are often idealized as incompressible at low temperatures such as in many artificial ground-freezing situations (Vyalov, 1962; Klein and Jessberger, 1979; Klein, 1981). For an incompressible material, a superimposed hydrostatic pressure should have no effect on deformation and flow. For some frozen soils at higher temperatures, experiments indicate that the mean normal stress does have a pronounced effect on creep; yet it is still not uncommon to assume that creep deformation is approximately isochoric, and volume change under creep is neglected. (See, for example, Sayles, 1973; Vyalov et al., 1979.) Perhaps because of this (sometimes implicit) assumption, which we shall hereinafter call the assumption of isochoric creep, many a "general creep equation" in the literature delivers zero strain when the stress is hydrostatic. (See, for example, Ladanyi 1981, Equation (5); Diekmann and Jessberger 1982, Equation (3).) The recent study of Bragg and Andersland (1982), however, shows clearly that the assumption of isochoric creep may have a rather restricted domain of validity. Bragg and Andersland conducted constant-stress uniaxial creep tests on a frozen sand at -6°C , and they measured both the axial and the volumetric strain developed in the samples. Their results showed that while the volumetric strain was quite small when the axial strain was under 2%, it could approach half the value of the axial strain when that value was above 5%.

Our team at the University of Manitoba is currently engaged in a research program to study the long-term multiaxial creep behavior of relatively warm saline frozen soils that simulate those beneath the Beaufort Sea. In our program

we will study creep behavior at relatively large deformations (stretch ratio above 5%). For such deformations we question the validity of the following two a priori hypotheses common in works on the multiaxial creep of frozen soils, namely (1) "the assumption of small deformations" under which the infinitesimal strain tensor could be used exclusively as the measure of "strain" and the stretching tensor could be replaced by the time rate of the infinitesimal strain tensor and (2) the assumption of isochoric creep.

In our program we have completed several isotropic compression tests. Data from isotropic compression tests are necessary both for our viscoelastic modeling and for use in Domaschuk's method of estimating settlement of artificial islands.¹ Our results show that frozen soils could experience moderately large volume change even for creep under pure hydrostatic pressure. Thus many "general creep equations" in the literature are in fact severely restricted in scope, and the assumption of isochoric creep once again exhibits its limitations. Because of all these implications, and because, as far as we are aware, isotropic compression tests on saline frozen soils have never been conducted before, we are communicating these results before the completion of our program.

¹ This method is an extension of that which Domaschuk and Valliappan (1975) developed to provide a nonlinear approximate solution to the ultimate settlement of structures resting on clay. That solution required an isotropic stress - volumetric strain relationship.

EXPERIMENTAL INVESTIGATION

Sample Preparation

A non-plastic, highly frost-susceptible silt consisting of 34% sand, 56% silt, and 10% clay was used in the study. Sodium chloride was added to the soil to produce a pore-fluid salinity of about 60 parts per thousand.

Samples for testing were formed in a cylindrical, split plexiglass mold, 76 mm in diameter and 200 mm high. The silt was placed in 25 mm layers at Standard Proctor optimum moisture content and was compacted by tamping. An attempt was made to saturate the samples under vacuum.

The samples were frozen unidirectionally at an approximate rate of 25 mm per day by using the procedure adopted by Baker (1976). After the samples were frozen, the portion of the top that had dried out by sublimation was trimmed off.

The water contents, dry unit weights, void ratios, and degrees of saturation of the samples after compaction, after freezing, and at the end of the tests are given in Table 1.

Equipment and Testing Procedure

Isotropic compression tests were carried out in a double-walled triaxial cell similar to that developed by Mitchell and Burn (1971) and later modified by Baker et al. (1982). In such a cell, the change in volume of the sample is measured by a corresponding change in the volume of fluid in the inner cell.

Two single-step constant-stress isotropic-compression creep tests were carried out at -15°C on sample A07 and sample A08 at a stress level of 350 kPa and 700 kPa, respectively. One multi-step creep test was conducted on another sample (A02) at -15°C , using ten stress increments of magnitude 70 kPa each. Before the application of each additional pressure increment, the sample was allowed to compress until no further volume change (within an accuracy of ± 0.05 c.c.) occurred within a period of at least 8 hours. After the multi-step test on sample A02 at -15°C was completed, the sample was unloaded, allowed to recover and brought to -10°C . Then another multi-step creep test which followed the procedure of the -15°C test was conducted on sample A02 at -10°C , after which another multi-step test was repeated on sample A02 at -5°C , using the same procedure. In what follows we shall refer to each test by a five-digit code: the first three digits identify the sample, the last two digits the temperature of the test. For example, A0210 refers to the multi-step test on sample A02 at -10°C .

TEST RESULTS AND INTERPRETATION

In each test volume changes were recorded at regular time intervals for each stress increment. A glance at Table 1 reveals that some water was squeezed out from the samples during

compression. Thus a sample during creep, strictly speaking, could not be taken as a "body" in the sense of ordinary continuum mechanics. As a simple and convenient way to represent our data, we define for each stress increment the incremental volumetric strain

$$\epsilon_v^i(t) \equiv (V(0^-) - V(t))/V(0^-) \quad (1)$$

here t denotes the time elapsed since the increment of stress in question, $V(t)$ is the volume of the sample at time t , and $V(0^-)$ is the volume of the sample just before the increment of stress. Here we want to emphasize that we define the quantity ϵ_v^i only as a convenient device to represent our data; although we call ϵ_v^i the "incremental volumetric strain", it carries no further meaning other than that which is defined by (1). In particular, the reader should not confuse it with the "dilatation" or the trace of the infinitesimal strain tensor. We make no hypothesis on the magnitude of the incremental volume change $V(0^-) - V(t)$.

The "incremental volumetric strain" time graphs of the two single-step tests (isotropic stress increment $\Delta\sigma_m = 350, 700$ kPa, respectively; temperature $T = -15^{\circ}\text{C}$) and the first step of the multi-step test at $T = -15^{\circ}\text{C}$ ($\Delta\sigma_m = 70$ kPa) are plotted in Figure 1. Although the 70 kPa test appears to be of extremely short duration, when the results of this test are plotted under an expanded scale (Figure 3), it is clear that a very low rate of "incremental volumetric strain" had been achieved before the next stress increment was applied.

Similar "incremental volumetric strain" time graphs were obtained for each step of the multi-step tests. All the "incremental volumetric strain" time curves are characterized by an "instantaneous" component, a relatively short period of time during which there is a rapid decrease in the rate of "incremental volumetric strain," followed by an attenuating creep at a very low rate. Except for the first few hours after increment of pressure, all the curves are fairly well fitted by an appropriate hyperbolic function of the form

$$\epsilon_v^i(t) = t/(a + bt) \quad (2)$$

here a and b are constants to be determined empirically for each curve; b is the reciprocal of the ultimate value of ϵ_v^i . As examples, the "incremental volumetric strain" time graphs of the two single-step tests are exhibited with their hyperbolic function in Figure 2; the corresponding curve-fitting for the first step of the three multi-step tests on sample A02 ($\Delta\sigma_m = 70$ kPa; temperature at -15°C , -10°C , and -5°C , respectively) are shown in Figure 3. Examples from later steps of the multi-step tests are shown in Figure 4. "Being the k th step of a test" is identified in the figures by the caption " $n = k$."

A comparison of the three curves in Figure 3 indicates that sample A02 developed much larger incremental volumetric strains at the test temperature of -15°C than at the other two warmer temperatures. This is contrary to the intuitive

expectation that warmer soil would be more compressible. This apparent anomaly could be attributed to the fact that sample A02 had been subjected to a history of loading and recovery before it was tested at the two warmer temperatures. One effect of that history of loading and recovery was that some water and solute were squeezed out during compression; this amount of water and solute was never recovered. Another manifestation of the loading-recovery history was the strain-hardening effect, which gave rise to the apparent anomaly above. In light of this strain-hardening effect, no conclusion could be drawn from our results regarding the influence of temperature on the compressibility of frozen soils undergoing isotropic compression.

An examination of the "incremental volumetric strain" time curves indicates that a major portion of the volume change that would result from an increment of hydrostatic stress occurred within the first few hours after the load increment. If we are interested only in the behavior beyond this brief period instead of the function $\epsilon_v^i(t)$, a knowledge of the ultimate value of "incremental volumetric strain" should suffice. Since the "incremental volumetric strain" is defined only for a specific stress increment, another quantity should be defined for an arbitrary loading history. The ultimate volumetric strain ϵ_v^∞ of a sample is defined here for any loading history from time $t = 0$ to time $t = \tau$ as

$$\epsilon_v^\infty \equiv (V_0 - V_\infty)/V_0 \quad (3)$$

where V_0 is the original volume of the sample before loading at $t = 0$, and V_∞ is the ultimate volume should the load at time τ be maintained constant from $t = \tau$ to $t = \infty$. We present our data of ϵ_v^∞ for the three multi-step tests in Figure 5. Here we treat A0215, A0210, and A0205 as if they were tests on three different samples. In other words, sample A0210 at time zero was simply sample A02 after it had been subjected to the multi-step test at -15°C , allowed to recover and brought to -10°C . In Figure 5, for instance, the value of ϵ_v^∞ at $\sigma_m = 350$ kPa for sample A0215 is the ultimate volumetric strain of the sample in question after five increments of pressure, each of which is of magnitude 70 kPa. The data presented in Figure 5 further corroborates the strain-hardening effect incurred on sample A02 by a previous history of loading and recovery.

In the definition of ϵ_v^∞ , the sample in question is supposed to have been subjected to a history of loading that has the following property: for the entire interval $[0, \infty]$ of time under load the isotropic stress takes some constant value σ_m , except perhaps for some finite interval of time $[0, \tau]$ just after loading. For such a loading history we define the ultimate (secant) bulk modulus K^∞ of the sample in question by the expression

$$K^\infty \equiv \sigma_m / \epsilon_v^\infty \quad (4)$$

Values of K^∞ for our tests A0215, A0715, and A0815 are shown in Figure 6. In general, K^∞ as defined by (4) depends not only on the ultimate pressure σ_m but also on that part of the loading

history before the isotropic stress is kept at the constant value σ_m . In Figure 6, however, K^∞ has more or less a constant value. This suggests that as far as the value of K^∞ is concerned a single-step loading and a multi-step monotonic-increasing loading with the same ultimate value of σ_m might have an almost identical effect; likewise, slightly different samples do not seem to make much difference. Yet our data are too scanty to support any definite conclusion. We hope we can clear up this point with further work.

When sample A02 was allowed to recover after the completion of a multi-step test, only about 50% to 70% of the volume change was recovered. We present the data regarding volume recovery in Table 2. That a significant portion of the volume change was permanent suggests that sample A02 could not be treated as a body of material with fading memory. If this fact could be generalized, it would have important implications for any attempt at a viscoelastic modeling of saline frozen soils. For example, a simple nonlinear hereditary creep constitutive equation (e.g., Vyalov, 1962, Equation (1-47')) that ties up attenuating creep under constant stress with ultimate complete recovery after unloading would be inadequate.

When the temperature of sample A02 was increased to -5°C , it was noted that the sample was no longer ice-bonded. Nonetheless, the behavior of the sample under isotropic compression was not substantially different from its behavior at the lower temperatures. The implication is that under isotropic compression the response of warm non-bonded permafrost, which we often encounter in the Beaufort Sea sediments, might be similar to that of its ice-bonded counterpart. From our results, of course, we cannot draw any conclusion on the response of non-bonded and ice-bonded permafrost to stresses other than hydrostatic.

CONCLUSIONS

1. Each of our frozen saline silt samples underwent attenuating creep upon compression by a constant hydrostatic stress. Except for the first few hours of loading, the creep curve could be well approximated by an appropriate hyperbolic function of the form given in (2) above. Over 70% of the ultimate volume change occurred within the first few hours of loading. The level of ultimate volume change (which came near to 4% of the original volume for our sample A08 at 700 kPa and -15°C) indicated that volume change during creep could be a significant factor in problems involving thick deposits.
2. When an additional hydrostatic stress was superimposed on a sample that was approaching equilibrium after creep under an isotropic stress, the soil underwent a new attenuating creep with characteristics substantially the same as those described in the preceding paragraph.
3. When the frozen saline silt was allowed to recover after a history of isotropic-stress loading, it could ultimately recover only part of the volume change occurred during the previous

loading. Our test results showed that up to 50% of the volume change could remain after recovery. This fact has important implications for any attempt at a viscoelastic modeling. A simple nonlinear hereditary creep constitutive equation that ties up attenuating creep at constant stress with ultimate complete recovery after unloading would be inadequate.

4. A history of loading and recovery had a strain-hardening effect on the frozen saline soil; so did a history of incremental loading.

5. At -5°C the saline soil was non-bonded, but the nature of its volumetric strain-time response to isotropic compression did not seem to be qualitatively different from the way it behaved when it was ice-bonded.

6. Even at a temperature as low as -15°C , water was squeezed out when the soil underwent creep under isotropic compression. This suggests that in modeling the creep behavior of frozen saline soils a quasi one-phase approach might be altogether inadequate; mixture theories should be considered.

ACKNOWLEDGMENT

This research is part of a broader investigation to study, by means of triaxial and pressure-meter tests, the multiaxial creep behavior of frozen saline soils that simulate those beneath the Beaufort Sea. The study has been supported by a grant from the Natural Sciences and Engineering Research Council of Canada.

ROCK WEATHERING BY FROST SHATTERING PROCESSES

G.R. Douglas¹, J.P. McGreevy² and W. Brian Whalley²

Belfast BT7 1NN, United Kingdom

We discuss two main types of control on the weathering of rocks by frost shattering. External controls are those concerned with temperature cycling which the rocks experience together with associated moisture variations. With data from Iceland, we show conditions under which air temperatures are a poor indicators of rock temperatures. Rock surfaces can be warmer than the air, even if the latter is below 0°C; or colder than the air. If snow or ice cover the rock surface freezing intensity can be damped. A knowledge of rock properties (internal controls) is important because water may freeze at a temperature other than at 0°C. This temperature may be different for different rocks. In the pores of an Icelandic hyaloclastite water froze at about -4°C, water in rock cracks may freeze at rather higher temperatures than this; tests in 'cracks' in plastic blocks suggest about -2°C.

INTRODUCTION

Frost shattering is central to a consideration of many periglacial phenomena (Washburn, 1979) and has traditionally been considered to be the main process responsible for rock breakdown in cold (high altitude and latitude) regions. There is increasing interest in the geomorphic effects of frost shattering and some geomorphologists are beginning to challenge conventional beliefs (e.g. White 1976, Thorn 1979). Here we comment on current knowledge of controls on the operation of frost shattering. We do not examine actual mechanisms of rock breakdown since these are considered elsewhere (McGreevy 1981). Rather, we discuss controls on the mechanisms which we have divided into two categories; external (temperature and moisture regimes at a local level) and internal (properties of the rocks). To illustrate specific points we draw on work conducted on rocks from Iceland. Attention has been focused upon a rock which is common on Icelandic cliffs but which, unlike basalt, is porous rather than jointed.

GENERAL CONSIDERATIONS

Geomorphologists have adopted two approaches in attempting to assess the geomorphic significance of frost shattering. First, an essentially geographic methodology has aimed at establishing global and continental zonations of frost shattering intensity on the basis of gross climatic parameters such as mean annual or monthly temperatures or precipitation (e.g. Peltier 1950, Brochu 1964). An extension of this approach is the use of standard meteorological data to explain patterns of rock breakdown e.g., small scale rockfalls (Church et al 1979), larger scale, perhaps seasonal events (Bjerrum and Jørstad 1957), or even longer term climatic effects (Grove 1972). In such cases, freeze-thaw frequency (as evaluated by recourse to air temperature data) has been directly related to intensity of rock breakdown, presumably by frost

shattering. However, although rockfalls may be associated with freeze-thaw cycles this does not necessarily indicate that such cycles are actually causing rock breakdown; it may be that pre-loosened blocks are being released by the ice formation. The distinction between weathering of a rock (its separation from the rock mass) and the actual removal of a weathered rock is rarely made.

The second area concerns experimental determinations of micro-climatic controls from laboratory tests (see McGreevy (1981) for review). In its simplest form, this involves placing rocks in water, alternating the temperature above and below 0°C and observing the results (e.g. Martini 1967). Such investigations tell us something about the temperature and moisture conditions most conducive to frost shattering. This approach too has its limitations. There is no general agreement on testing procedures and various workers or laboratories employ different experimental conditions making comparison of results difficult. In addition, test conditions, although replicable may be unrepresentative of those experienced by rocks in the field. For instance, should the rock under test be of a certain size, be cut in a particular way? Should it be saturated with water under pressure? There is a pressing need to link field observations from various environments to laboratory tests. Thorn (1979) has recently indicated that application of 'Icelandic' or 'Siberian' temperature cycles (Tricart 1956) in experimental studies may be grossly misleading. However, further work is needed to define the extent of discrepancies between field and laboratory freezing patterns.

Both external (rate, intensity, duration and frequency of freezing) and internal (rock properties) controls on rock breakdown by frost shattering mechanisms are only now being fully investigated (Lautridou and Ozouf 1982). We consider this to be an important distinction as it helps to separate the complex factors involved in rock breakdown.

FIGURE 1 Rock surface, crack and air temperatures from Esja, Iceland.

EXTERNAL (METEOROLOGICAL AND CLIMATIC) CONTROLS

It has been realized for some time that air temperature data derived from standard meteorological station observations do not provide good indications of local climatic conditions (Washburn 1979). Several workers have identified difficulties in relating air temperature cycles to ground temperatures (e.g. Fahey 1973, Fraser 1959). Nevertheless, some authors still use temperature data from meteorological stations to infer processes some distance away (e.g. Church et al 1979). Data from Iceland (obtained over a two year period and including continuous records over a four month winter period) illustrate some of these difficulties, even with air temperatures being measured adjacent to the rock surface. Figures 1 and 2 show relationships between rock surface, crack and air temperature variations over selected periods, and illustrate ways in which air temperature data can provide misleading information about rock temperatures. Figure 1 shows a south-facing rock surface at a site in Iceland (Esja, 20km N-E of Reykjavik, 650 m a.s.l.) undergoing temperature fluctuations above and below 0°C in the presence of negative air temperatures. The crack temperature regime reflects changes experienced at the rock surface and does not appear to be closely related to air temperature. Here the use of air temperature to indicate the rock 'frost climate' would underestimate the frequency of rock freezing and thawing. Figure 2 shows the converse: air temperature fluctuates around 0°C quite frequently over a short time whilst the rock surface remains below 0°C. Air temperature data therefore

overestimates freeze-thaw frequency in such instances. Clearly, use of air temperature data alone would invite erroneous inferences on the nature of geomorphic activity at the study sites.

There are three basic conditions where substantial disparities between rock and air temperatures would present difficulties in the interpretation of air temperatures and rock freezing characteristics viz:

1. Snow covering the rocks where air temperature fluctuations may be damped to give no or few 'frost changes' (ie., oscillations around 0°C).

FIGURE 2 Rock surface, crack and air temperatures from Esja, Iceland, 14 December 1981.

2. Ice (verglas) covering the rock surface in certain conditions even where the air temperature is several degrees above 0°C.

3. Conditions where ice or snow does not cover the rock and there is relatively free heat exchange between rock, air and available liquid water.

Rock temperatures are damped with respect to air temperatures in the first two cases and exaggerated in the last.

It should be noted that existing data on air and rock temperature variations relate to short time periods. At present, there is no assessment of their variability over several years. Furthermore, we still require knowledge of antecedent conditions which allow freezing waves to penetrate into the rocks and not just fluctuate at or just below the surface (e.g. in Figure 2). Little is known about the moisture content of rocks. White (1976) has drawn attention to possible relationships between weathering and moisture content. He ventured to question whether rocks in natural situations could ever become >50% saturated with water and then experience freezing. At present we have no data from the sites we are examining in Iceland. However, some preliminary data from a site at 850 m altitude in Central Scotland (McGreevy 1982) suggests that a high (up to 92%) degree of saturation can be attained by rocks which are likely to be subjected to freezing conditions. It is certainly significant that most talus production from cliffs exposed to frost-shattering agencies comes from gully or couloir systems. It is under these conditions that water penetration into rocks is likely to be highest. Once a cliff has a coating of ice (verglas) then this is likely to reduce the amount of thermal change as well as water saturation it can receive. In a couloir however, maximum quantities of free water are available and, hence, frost shattering is also likely to be greatest for a given rock type.

INTERNAL (ROCK PROPERTY) CONTROLS

It has been pointed out (McGreevy 1981, McGreevy and Whalley 1982) that most laboratory experiments use rather small pieces of rock which may not be at all representative of field conditions. The samples used (the 'intact rock' of Attewell and Farmer (1976)) are likely to be quite different from the 'massive rock' (the rock in its *in situ* state). Tested samples are rarely > 10cm cubes yet this may be the size of material which, when seen in the field, is that which has already been weathered and transported from the *in situ* position on a cliff. Therefore, such tests ignore the importance of discontinuities such as joints, bedding planes, cleavage and schistosity, all of which provide planar weaknesses on which frost shattering mechanisms can operate. Thus the use of small laboratory-tested rock samples may indicate a much greater resistance to freeze-thaw in the laboratory than if it were possible to test a whole section of cliff. Testing small blocks of rock may yield inappropriate data on which to demonstrate the environmental controls of frost shattering. The testing of large blocks is very difficult and may not be possible for massive rocks.

It should be appreciated that the frost shattering process depends upon water in a rock being frozen (excluding here the hypotheses of hydration shattering or ordered water (White 1976) although these still require water to be in the rock). In this context it has become evident that there is a difficulty in accepting 0°C as a critical temperature which must be crossed before water will freeze within rocks. Several workers have shown that water may not freeze until several degrees below 0°C in rocks and other materials. Various threshold freezing temperatures have been suggested between -2 and -10°C (see McGreevy and Whalley (1982) for details and discussion). Our own investigations have provided some further data. In particular we have examined a rock called 'moberg'; this is a hyaloclastite, a subglacially-erupted tuff (Saemundsson 1979, Allen et al 1981). This type of rock is often of great thickness in the geological succession and is thus well exposed on cliff sections in Iceland.

Samples of moberg, taken from near our temperature recording site at Esja, were tested for freezing point depression characteristics. A small core of saturated moberg was contained in a brass capsule and placed in a freezing cabinet. The temperatures of both rock and capsule were monitored continuously using thermocouples and a data logger. Evolution of heat as water freezes in pores is indicated by a rock temperature increase (c.f. Davison and Sereda 1978, McGreevy and Whalley 1982). Figure 3 shows an instance of water freezing at -3.8°C. Over five tests, the results showed a freezing threshold of $-3.8^{\circ}\text{C} \pm 0.5^{\circ}\text{C}$.

FIGURE 3 Graph of temperature of a saturated sample of moberg during freezing versus time. (The time axis has an arbitrary starting point.)

FIGURE 4 Graph of water freezing in a hole in a plastic block, 0.3cm diameter hole, versus time. (The time axis has an arbitrary starting point.)

The inference is that the rock temperature, at a given depth, must fall to at least -3°C before the water can freeze. Such tests however say nothing about how the presence of cracks which may influence, not only the rock water content, but also the possibly increased susceptibility to damage by virtue of the crack itself. Indeed we do not know how the presence of cracks at various scales affects the breakdown of rocks (again, this is a size problem).

The cliff face at Esja also contains many basalt lava flows as well as moberg. The two rocks differ in terms of the discontinuities within them. The moberg generally lacks all but the regional joint system and mechanical breakdown occurs through the release of small granules of material. The basalt breaks down through the release of blocks of rock, the sizes of which are determined by the hierarchy of discontinuities (faults, joints and microcracks) within the rock mass (Whalley et al 1982). Thus in moberg, water is held and freezes in pores whilst in basalt, cracks of a variety of sizes are more relevant. Water freezing within the moberg can therefore be studied on small samples. As argued elsewhere (McGreevy and Whalley 1982), water freezing to release blocks of basalt is most likely to be associated with larger cracks and fractures rather than fine microcracks. Handling large samples is difficult so we have used

a simple model to obtain some information on the freezing of water in cracks.

Instead of using basalt samples a machined perspex (lucite) block (5.5 x 8 x 12 cm) embedded in a 5cm thick jacket of expanded polystyrene was employed. Four holes (0.2, 0.3, 0.4 and 0.5cm diameter and 5cm length) were drilled into one face the face containing the holes remaining exposed. The holes were filled with water and the block placed in a freezing cabinet. Thermocouples inserted into the water-filled holes provided continuous temperature readings and, as with the moberg (Figure 3), showed the temperature increase due to water freezing.

The temperature curves obtained (Figure 4 is one example) show that freezing is initiated between -0.6°C and -2.5°C . The freezing of water in rock joints would therefore appear to occur at higher temperatures than in microcracks and pores. Clearly, the use of notches and holes in perspex as a model of rock oversimplifies the situation. For instance, the presence of clay minerals along crack walls could significantly reduce the freezing point of water (Anderson et al 1974). In addition, SEM studies (e.g. Sprunt and Brace 1974) show that cracks rarely, if ever, occur in isolation, and usually comprise one element in an intricate network of cracks of varying shapes and sizes. However, continued experimentation with simple models may throw some light on the effects of freezing in rocks so long as such possible complications are borne in mind.

CONCLUDING REMARKS

Field and laboratory studies of frost shattering must be viewed as complementary if its geomorphic significance is to be properly assessed. The degree to which conclusions based on laboratory studies can be extended to comment on rock weathering behaviour under natural conditions depends upon the degree to which simulated conditions approximate those experienced in nature. This must apply to both external and internal conditions as far as possible. Only by monitoring rock temperature and moisture regimes in situations of geomorphic interest (around snow patches, for example) and subjecting rocks to them can their geomorphic significance be evaluated. Ultimately, the weathering effects of temperature and moisture variations depend upon the properties of the rocks under consideration. For this reason it is important to acquire some knowledge of rock properties which are critical in determining the efficacy of frost shattering.

The relevant literature dealing with cold climate rock weathering leaves undefined the relationships between the variables of climate and rock properties. It is certain that much needs to be done to clarify the exact nature of such relationships.

ACKNOWLEDGMENTS

We thank NATO for a travel grant to assist our observations in Iceland, the Northern Ireland Department of Education for a Research Studentship

for J.P.McGreevy and Dr B.J.Smith for constructive comments during our work. Ms J.Orr kindly abstracted data from our chart records, Gill Alexander drew the diagrams and John Allen did the photography.

HYDROLOGY OF NORTH SLOPE COASTAL PLAIN STREAMS
Brent Drage, Jeffrey F. Gilman, David Hoch, Leslie Griffiths

Peratrovich, Nottingham & Drage, Inc., Anchorage, Alaska 99503, USA

This paper presents general hydrologic characteristics of coastal plain streams located between the Sagavanirktok River and the Colville River on Alaska's North Slope. Data presented were gathered over the last five field seasons by the authors and others while working under contract with ARCO Alaska, Inc. Following a general discussion of the geographic and climatic setting for these streams, there is a discussion of several important hydrologic parameters which define the uniqueness of streams flowing in the permafrost environment. Permafrost is a key factor in defining drainage basins. From discharge measurements, values for typical slopes, Manning's roughness factors, and Coriolis energy coefficients are presented. Finally, a flood frequency analysis for these streams has been developed using a Log Pearson Type III distribution in conjunction with a regional skew weighting analysis. The regional skew weighting analysis is based on station skews for all gaged streams in Alaska north of 64° N latitude, a region approximately coterminous with the region underlain by continuous permafrost.

CLIMATE AND GEOGRAPHY

The arctic climate and low relief of Alaska's North Slope are two of the dominant independent variables controlling the evolution of the land surface and its hydrology. These strongly influence runoff and sediment yield which in turn affect the drainage network and channel shape. The larger drainages originate in the northern foothills of the Brooks Range. The drainage divides are easily definable and the streams form a dendritic pattern. Moving from the foothills region to the low relief coastal plain, drainage basins and stream patterns become poorly defined. Continuous permafrost and ground ice play a significant role in determining the hydrologic regime of the coastal plain. Surface features and materials are in a continuous state of change, being incorporated into the cycle of thaw-lake development and ice wedge polygon formation, resulting from changes in ground ice volume.

During the short summer season, the land surface is dominated by lakes and drained or partially drained lake basins. These flooded depressions and shallow lakes rimmed with sedge provide approximately one half of the wetland area suitable for aquatic habitat.

There is continuous daylight at this latitude from mid-April through the end of August. Direct solar radiation thus increases dramatically in the months prior to breakup.

Mean annual temperature ranges from -16° to -9°C. The monthly mean temperatures range from -34° to 10°C. The pronounced temperature gradient with latitude found on the North Slope can influence the timing of breakup. Streams with headwaters in the Brooks Range foothills begin to breakup several weeks before streams originating in the coastal plain.

Precipitation is extremely light along the coast, generally between 10 - 15 cm, but also shows a distinct gradient with altitude to higher precipitation in the Brooks Range. Approximately half of the annual amount falls as snow from September through May. Snowmelt runoff is concentrated in the period of late May and early June. Surface winds are strong along the coast but decrease inland. During the ice-free months, the predominant wind direction is from the east. Walker et al (1980) is a standard reference for climatic parameters of the region.

GENERAL HYDROLOGY

Eight small streams between the Kuparuk River and Colville River have been studied. These are shown in Figure 1 and listed in Table 1, with selected hydraulic parameters.

The difficulty of defining hydrologic parameters for North Slope streams is illustrated by the uncertainties attached to delineating drainage areas. The general terrain has little relief and it is extremely difficult to delineate drainage basins on USGS topographic maps. This is particularly true for the streams in the eastern part of the study area. The cycle of thaw-lake development and polygon formation strongly influence the drainage network shape; and due to the dynamic nature of these processes, there is evidence that the drainage patterns intermittently change. Because of this inherent problem, such characteristics as unit runoff lose some of their accuracy.

Characteristics of Larger Rivers

Three major drainages fall within the geographic area of this study; the Sagavanirktok River, the Kuparuk River, and the Colville River. These rivers differ from the smaller coastal plain streams in that their headwaters are in the northern Brooks Range. Approximately 50% of the Sagavanirktok drainage and less than 10% of the Kuparuk drainage lie above 600 m elevation. This characteristic often gives these drainages a hydrological behavior very different from the adjacent coastal plain streams.

Of these three drainages, the Colville is by far the largest with an area of 60,000 km². The Sagavanirktok and the Kuparuk follow with 14,898 km² and 9802 km², respectively. Spring breakup on these rivers generally occurs before the breakup of the coastal plain streams. This characteristic is due to the location of their headwaters in the Brooks Range foothills. The breakup front begins in this relatively warm and sunny region and proceeds northward at approximately 0.5 - 1 km/hour. Like the smaller coastal plain streams, the hydrographs of these rivers peak sharply during breakup. The majority of the year's discharge occurs at this time, with flows falling off dramatically for the remainder of the summer. It has been estimated that 78% of the Kuparuk's annual discharge occurs during the month of June, with flows decreasing dramatically for the remainder of the summer; 34% of the Sagavanirktok's discharge (at the Sagwon gaging station) occurs during June (Peterson, 1983). The decrease of the summer flow in the Sagavanirktok is more gradual than in the Kuparuk.

Freezeup occurs in late September or early October with little to no flow being recorded by January. Although channel flow is essentially halted by freezing, it is believed that some flow continues through the unfrozen riverbed gravels during the winter.

Characteristics of Coastal Streams

Morphology of the coastal plain streams is controlled by permafrost and ground ice. In tundra regions with high ice content and ice wedge formation, a beaded stream pattern is common which is typically composed of deep thaw pools connected by shallow channels (Figure 2). Pools form in localized areas where the ground has a very high ice content or disruption of the tundra has allowed greater depth of thaw. If the pool is large enough, permafrost beneath and along the sides thaws, pools deepen and expand. Water depth up to 6 meters has been measured in some of these pools. In the connecting channels depths typically range from 0.2 - 0.3 meter. During freezeup of the streams, the deep, low velocity pools form an ice cover first, and it can reach thicknesses of 2 meters by the end of winter. It is within the beaded pools that relatively large and thick ice floes can be generated during the winter and flushed down the streams during breakup.

The coastal streams are frozen for all but 3 or 4 months of the year. The flowing water freezes in September or October, and drifting snow makes the drainages virtually indistinguishable from the surrounding country until the end of May or early June when "breakup" occurs.

Coastal plain streams generally break up after the recession of the Kuparuk, Sagavanirktok, and Colville river hydrographs. Due to the lack of a long-term data base, it is difficult to formulate general statements about the timing of this process. This aspect of the breakup phenomenon, along with the concomitant potential for flood frequency prediction, is a facet of arctic hydrology requiring additional data acquisition and analysis.

The breakup of coastal plain streams can be characterized as a sudden event of short duration (Figure 3). Observations made over the past 4 years indicate the average length of a breakup event to be 10-12 days. Peak discharge is generally reached within 4-5 days after initial flow, giving the typical hydrograph an asymmetrical, right-skewed shape. The increase in discharge from virtually zero up to 100m³/s within a 2- to 5-day period can give the left limb of this hydrograph an extremely steep slope. While bimodal-shaped curves have been observed on the coastal plain streams, this multi-peaked behavior appears to be relatively unusual; breakup, once it occurs, generally advances to a single peak discharge and concludes with a smooth recessional phase of slightly longer duration than the rise.

Breakup proceeds in a south-to-north direction starting with the upper reaches of the streams and proceeding downstream. Pushing slush ice before it, the breakup front has been observed to advance at a rate of up to 1 - 2 m/s. The drainage basins of these streams are choked with deep snow at the time of breakup and the presence of this snow greatly influences the breakup behavior (Figure 4). In its south-to-north migration, the breakup can best be described as a series of surging events: periods of backwater and ponding as water is impounded behind snowdrifts, ice jams, or man-made obstructions (e.g., culverts) alternating with events of relatively rapid advance as flood waters incise and undercut these constrictions (Figure 5). Channel geometry is continuously changing as both the snow and the bottomfast ice is eroded and/or melted by the flood (Figures 6 and 7). Water surface elevation, channel cross sectional area, bed roughness, water velocity, ice load, and backwater effects can change continuously during the dynamic breakup period. The recession of the hydrograph brings the streams back into their banks, and hydrologic parameters attain a stability for the remainder of the ice-free season (Figure 8 and 9).

All coastal plain streams carry an ice load during breakup, although the quantity of this load can vary greatly from drainage to drainage. Likewise, the year-to-year change within a single stream is highly variable. However, in general, the only ice observed of

significant strength and thickness originates from the deep pools. It was observed during the 1981 study that the four major western drainages (East Kalubik Creek, Kalubik Creek, Miluveach River, and Kachemach River) maintained a very significant snow cover (Figure 7). The periodic calving of these formations can add greatly to the ice load of these streams, although it should be noted that such slush floes are considerably softer than bottom ice/surface ice floes. Bottom ice has been observed to be present in the beds of all coastal plain streams throughout the breakup period, although it is observed to diminish significantly throughout the 10- to 12-day breakup period.

An extremely valuable parameter for future study and engineering design is the Mannings "n" value, or roughness factor. Based on measurements taken during the 1981 and 1982 field season, "n" values were calculated for the streams observed during breakup. These are presented in Table 1. An interesting phenomenon is the relatively low values calculated for the peak flows, and the higher values for the rising and falling limbs of the hydrograph. One possible explanation for this might be the roughness induced by snowdrifts, channel ice, and tussock floodplain, so that the net effect would be a higher "n" value when the stream is within its banks or covering the floodplain with depths small relative to the tussock heights. The "n" value is continuously changing due to snowpack melt along stream boundaries, calving from snowbanks, and the melting and release of bottom-fast ice.

The consistency of the computed "n" values (Table 1) and the computed energy coefficients for each stream below demonstrate a reasonable level of reliability for the data gathered thus far. The energy coefficient is a measure of velocity distribution over a channel section. According to Chow (1959), experimental data indicate that the value of the energy coefficient varies from about 1.03 to 1.36 for uniform natural channels. The value is generally higher for small channels such as those characteristic of coastal streams and lower for larger, deeper streams.

FLOOD FREQUENCY ANALYSIS

As additional data and observations of coastal stream behavior are acquired, it is appropriate to review previous flood frequency analyses and revise them if the new data warrant.

Previous analyses utilized a regional approach based on historical data gathered by the United

States Geological Survey at the Putuligayuk River near Deadhorse (drainage area = 456 km²), Nunavak Creek near Barrow (drainage area = 7.23 km²), and Happy Creek at Happy Valley Camp near Sagwon (drainage area = 89.4 km²). Utilizing a modified Log Pearson Type III Flood Frequency methodology, unit runoff values for each recurrence interval were determined and multiplied times the drainage area of each stream to compute the flood magnitudes at each recurrence interval.

It was decided to compute new frequency curves using data from Putuligayuk, Kuparuk Trib. 1, East and Ugnuravik. Nunavak Creek and Happy Creek were eliminated from the analysis because of their distance from the study area and different hydrological regime.

The latest Water Resources Council method as described in their Bulletin 17B "Guidelines for Determining Flood Flow Frequency" (Sept. 1981) was used for the analysis. This technique has been recommended by the Council for use in all Federal projects involving water and related land use and has also been recommended for State and private organizations. Even though one technique may not be applicable to all the various geographical regions within the United States, uniformity of utilizing this technique for comparison with other regions, coupled with our relative sparse data base which makes it difficult to test the technique, it is reasonable to use the Water Resources Council method at this time.

Station skews were computed based on each stream's historical record. These station skews were weighted with a regional skew of 0.0117 based on a mean of station skews for 60 USGS gaged streams north of 64° latitude. The weighted station skews were used in a frequency analysis for the four area streams.

Because the focus of the monitoring program has been on streams with drainage areas between 75 km² and 500 km², unit runoff values have been defined only for this range. Because streams with smaller drainage areas have different basin characteristics, values presented here should not be extrapolated for computing coastal plain stream flood magnitudes with a drainage area less than 75 km².

The upper and lower confidence limits for levels of significance of 5 and 95% are computed by the procedures outlined in Appendix 9 of Bulletin 17B. The confidence limits are expressed in terms of error ranges in Table 2. The 95% confidence limits are excessive due to the small data base.

CLOSURE

The problems in defining the hydrologic characteristics of the coastal streams discussed in this paper only typify the general lack of detailed arctic hydrological data. However, with the existing data in-hand, one can gain an understanding of the general hydrological characteristics of the coastal plain streams. Expanded monitoring programs carried out over a period of years may answer some of the more perplexing problems, and further refinements of

the flood recurrence intervals will be possible. It is hoped that the data presented in this paper will serve as a baseline for future hydrologic studies in permafrost dominated regions such as Alaska's North Slope.

VIBRATORY MODEL PILE DRIVING IN FROZEN SAND

¹Dufour, S., ²Sego, D.C. and ³Morgenstern, N.R.

¹Geocon Inc., 1311 9th Avenue S.W. Calgary, Alberta, T3C 0H9 Canada

²Department of Civil Engineering, University of Alberta
Edmonton, Alberta, T6G 2G7 Canada

Laboratory modeling of vibratory pile driving in permafrost has shown that the strength of the material at the tip has to be overcome by plastic yielding for penetration to occur. This is contrary to the view that melting of the soil at the pile tip dominates the process. Various factors influencing pile penetration have been studied, and the energy balance of the pile penetration mechanism has been developed.

INTRODUCTION

Vibratory driving in permafrost has been applied in the Soviet Union for several years. In North America, vibratory driving was studied in the late 1960s as an alternate piling method on a pipeline project (Huck and Hull, 1971; Hull, 1977). In both these studies and Soviet work (Vyalov and Targulyan, 1968; Vyalov et al., 1969) melting of permafrost was observed around the pile when driving, and it was concluded that penetration was a consequence of soil melting at the tip. Resonant vibratory driving, as used in North America, was singled out as the most efficient method of transforming mechanical energy into thermal energy at pile tips to allow melting and hence pile penetration.

The mechanism that allows transformation of energy at the pile tips is at best unclear. Hence, an experimental program was developed to model vibratory driving of piles in permafrost. The objectives of the program were to find the penetration mechanism of piles driven by vibrations into permafrost and to study the influence of the following variables on the penetration rate (r_p): (1) bias surcharge (m_s) (i.e., the dead weight, not acting dynamically and sitting on top of the driver); (2) driving frequency (f); (3) soil temperature (θ); (4) soil density (ρ_d).

This paper first describes the experimental procedures and then presents experimental results and conclusions.

EXPERIMENTAL PROCEDURES

Experimental Facilities

The tests were conducted in a 3.35 x 4.0 m insulated cold room that was kept cool by two fan-operated refrigeration units capable of maintaining the air temperature within 0.8°C of the required temperature. The room could be kept as low as -20°C. A 24-hour electrical alarm system prevented accidental defrosting of the facility. Access to the cold room was through a double door air lock, which reduces inflow of warm air from outside in order to minimize the temperature variation within the cold room.

The electronic equipment controls were kept outside the cold room, from which visual access to the test set-up was gained through a double thermal-pane window.

A buttress support system for the vibratory exciter and a sample pedestal were supported directly on the concrete floor rather than on the insulated false floor (see Figure 1). A 12.5 mm thick aluminum plate was placed on the concrete sample pedestal to ensure a smooth surface. Finally, a cooling coil was embedded into the concrete pedestal near the surface. The coil is intended to circulate a refrigerant to form a barrier to the heat flow emanating from the concrete floor below.

The model pile driver was an electromagnetic vibration exciter type 4812 mounted on body 4801S as made by Bruel & Kjaer. The exciter was bolted upside down to a piston passing through a guiding box coated with teflon to reduce friction. A 76 mm wide webb belt was attached to the top of the piston on one side and, after travelling over the two rollers, to a counterweight support. The details of the system are shown in Figure 2.

In order to minimize intolerable loads on the exciter core of the exciter, a 9.5 mm thick rubber pad was placed between the exciter table and the pile attachment plate. An electric load cell is used to attach the model pile to the attachment plate, which is bolted to the exciter table. Because of the small diameter of the model pile (25.4 mm), the accelerometer used to measure pile acceleration was placed near the edge of the aluminum plate.

A four-channel FM recorder, Bruel & Kjaer type 7003, was used to record the test signals for subsequent analysis. The channels were used as follows: (1) to monitor the pile acceleration; (2) to monitor the pile load; (3) to monitor the body waves through the sample from a triaxial accelerometer embedded into the sample.

Thermocouples were used to monitor the temperature within the sample. Platinum thermistors monitored pile tip temperatures during driving. A data logger was used to record the vertical pile displacement as measured by using a linear voltage displacement transducer.

Finally, a two-channel oscilloscope displayed the load and acceleration traces of the pile during the experiment. A Polaroid Land camera provided photographs of the waves directly from the oscilloscope screen at appropriate time intervals during an experiment.

Experimental Material

Ottawa sand was used as the experimental material because of its known properties. The material was placed in a loose and dense state simply by changing the water content and the placement technique. A typical grain size curve is given in Figure 3. The samples, 500 mm in diameter and 400 mm in height, were frozen uni-dimensionally from the bottom upward under a high temperature gradient by placing dry ice beneath the sample (see Dufour, 1981 for a complete account of the technique and apparatus). This technique ensures uniformity of the ice distribution and physical character of the sample.

The pile used in the experiments was 300 mm long at the start of the experimental program. The pile was tubular and made of steel with a wall thickness of 1.3 mm and an outside diameter of 25.4 mm. The end of the tube was trimmed flat and was not reinforced.

Driving

The resonant frequency of piles is dependent upon the compressional wave velocity in the pile and the length of the pile (Bernhard, 1967; Kovacs and Michitti, 1970). Hence a model pile would have a resonance frequency in excess of 3000 Hz. The best driving was achieved in the laboratory at the pile-soil resonance. This is called rigid body type and has been described by Schmid (1969). Smart (1969) also found that piles essentially behave as rigid bodies at frequencies less than 25% of resonance frequency.

The four parameters that can be controlled (i.e., density, temperature, bias surcharge (m_s), and driver frequency) were changed to study the influence of each on the pile penetration rate (r_p). Thirty-two model pile driving tests were carried out for this experimental program.

EXPERIMENTAL RESULTS

Observations

On the average, loose samples had a dry density and water content of 1.66 tonnes/m³ and 19.7%, while dense samples had a dry density and water content of 1.80 tonnes/m³ and 11.7%. The total density of all samples was 2.00 tonnes/m³.

After driving, it was noticed that the outside of the pile was worn so as to form a sharp edge. There was no evidence of excessive wear on the inside of the pile tip. It is estimated that the pile abraded in length by 2 to 3 mm during about 25 driving tests.

In all tests, a thawed zone formed around both the outside and the inside of the pile. This film was contaminated by steel dust produced by the abrasive action of sand on the oscillating model pile. The dust gave the thawed zone a grey color that allowed easy measurement of the extent of the melted zone. This is illustrated on Figure 4. The melted zone varies in thickness from 1.5 to 2.5 mm. The maximum temperature recorded at the film-pile interface was +4°C. The average temperature was around +2°C. The film temperature was constant throughout the length of the pile. It is interesting to note on Figure 4 that there was no apparent disturbance of the soil ahead of the pile tip. It was also noted that in addition to very fine steel dust in the thawed film, there was a considerable amount of crushed sand particles. Grain size analyses performed on representative samples of thawed film material, presented in Figure 3, show that 12% of the sand grains were crushed.

Pile Acceleration and Soil Response Load

Since the model pile behaved as a rigid body, as previously explained, the load signal recorded at the top of the pile corresponds to the soil response at the pile tip. Typical soil response signals on the oscilloscope are basically composed of sharp impact peaks separated by periods of negligible force applied to the soil, see Figure 5. The pile acceleration signals are also composed of sharp impact peaks occurring at the same time as the load peaks. Between acceleration impact peaks, there is a slightly distorted half sine wave. This distorted half sine wave corresponds to the upward motion of the pile, during which the pile loses contact with the soil. Those two wave forms are characteristic of the Instability Domain of driving force in which the maximum tip resistance is reached (see Schmid, 1969). Hence driving is due to an elasto-plastic deformation of the soil at the pile tip rather than to melting, which would then occur after penetration. The same conclusions developed by Littlejohn and Rodger (1980) for unfrozen soils apply to frozen soils: penetration will occur as long as the total dynamic and surcharge forces are larger than the soil resistance. Previous observations regarding crushed sand particles and pile wear suggest a bearing-capacity type of failure in the frozen soil at the pile tip. No evidence of melting or soil disturbance was apparent ahead of the pile tip. This evidence supports the yield theory as the cause of penetration.

Penetration

Figures 6 and 7 show typical penetration versus time curves. The curves exhibit in general a constant penetration rate (r_p). Tests were stopped either because the pile had penetrated its full length or because soil reactions developed at the pile tip were sufficient to prevent penetration. The development of resistance is due mainly to an increase in side friction caused by either a change in pile alignment or by damping of vibrations. Details of all tests are given in Dufour (1981).

Effect of Bias Surcharge

The effect of bias surcharge (m_s) on penetration rate (r_p) is summarized in Figure 8. There is a minimum bias surcharge (m_s) below which no penetration can occur. Since impact peaks do not develop on the soil response curve, insufficient energy is delivered to the soil to initiate yielding. As the bias surcharge (m_s) increases, more energy is transferred to the soil and the plastic work done on the soil increases as impact peaks grow. After an optimum bias surcharge (m_s) for a given combination of soil and frequency is reached, a decrease in penetration rate (r_p) is observed. This decrease is associated with a decrease in driver efficiency. The vibration amplitude dampens as the pile is held in contact with the soil.

Effect of Soil Temperature

The effect of soil temperature on penetration rate (r_p) is summarized in Figure 9. The penetration rate (r_p) generally decreases as the soil temperature is lowered because strength increases with decreasing temperature. Depending upon the combination of parameters, the soil can inhibit plastic deformation and hence penetration rate (r_p) converges toward zero.

Effect of Driving Frequency

The effect of driving frequency on penetration is summarized in Figure 10. There is a frequency below which no penetration will occur because the bias surcharge (m_s) becomes too high for the displacement amplitude. As the frequency decreases, the displacement increases but the acceleration

decreases. Hence, the load carrying ability of the driver is reduced. This is also reflected in the fact that the force threshold described by Ghahramani (1967) varies with frequency for a given soil and pile. If at the lower frequency threshold the bias surcharge (m) is reduced to allow vibrations to occur, impact spikes in the load versus time plot do not develop and no penetration occurs. If all variables are held constant and the frequency is increased, the penetration rate increases to a maximum and then decreases as the frequency increases. Displacements at frequencies higher than this upper threshold are too small to allow for transfer of sufficient energy to the soil and, as a result, the pile will not penetrate. Also, impact peaks do not develop at higher frequencies.

Effect of Soil Density

Because of small density variation no influence of density on penetration rate (rp) was detected. When one analyzes the soil response signals, as will be discussed later, it turns out that penetration in dense frozen soil required more energy than penetration in loose frozen soil.

ENERGY REQUIRED TO CREATE A PERMANENT DEFORMATION

It has been shown previously that penetration of the pile was due to an elasto-plastic deformation of the soil beneath the pile tip. If a force deformation relationship is known or assumed, plastic work can be estimated.

The amount of energy spent to penetrate the pile 1 cm can be calculated as a function of the soil response load. From an analysis of the wave form data Dufour (1981) has shown that

$$E_1 = J/100$$

where

$$J = \text{soil response load (N)}$$

$$E_1 = \text{energy spent to penetrate the pile 1 cm (Joule/cm)}$$

$$100 = \text{constant (cm/m)} \quad (1)$$

Hence, the curves on Figure 11 demonstrate that dense frozen soil requires more energy to be penetrated than loose frozen soil. According to the "melting theory," dense frozen sand should have required less energy since its ice content is half that of loose frozen sand.

Analysis reveals that the distribution of energy in the soil-pile system is not simple. Input from the driver is used for strain energy, plastic work, grain crushing, thermal losses from grain to grain and grain to steel friction, and elastic excitation of the soil mass. Some of these features are interactive. Nevertheless, it is apparent that plastic deformation at the pile tip is essential to achieve practical pile-driving in permafrost.

CONCLUSION

This study reveals the dominant mechanism for piles vibrated into permafrost. Several factors affecting the elasto-plastic reaction at the tip were also examined. Only one requirement for penetration transpires from all the studies: the strength of the material has to be overcome by yielding of frozen ground.

The purpose of further research is ultimately to provide good engineering prediction methods for vibratory pile driving in permafrost. A theoretical model that would facilitate prediction of whether or not there will be penetration would allow design of equipment for large scale piling in offshore

conditions for example. Understanding of the mechanics of penetration is now sufficient to allow further work on a theoretical basis. The importance of gathering more experimental data should not be overlooked, and every possible field case must be studied to provide a wider base to the present understanding of vibratory driving of piles in permafrost.

PRINCIPLES OF COMPILING MAPS FOR THE CONSERVATION OF THE
GEOLOGICAL ENVIRONMENT IN THE PERMAFROST REGIONS

Ye. N. Dunayeva and A. V. Gavrilov

Geology Department
Moscow State University, USSR

The paper describes the principles of compilation and contents of a geological environment conservation map of the cryolithosphere, based on studies of the regime of the permafrost and of its predicted changes. The most important components of the map are: the stability of natural complexes and permafrost-engineering-geological conditions and their reaction to technogenic disturbances; allowable engineering loads; and recommendations for the conservation and optimization of the geological environment in terms of its future use. The evaluation of stability is preceded by a classification of technogenic disturbances of the geological environment, this evaluation is based on forecasts of the permafrost-geological processes induced by these disturbances. The results obtained allow classification of permafrost-engineering-geological sites in terms of response of the geological environment to various technogenic disturbances. The resulting classification is used to subdivide these sites in terms of allowable engineering loads. This, in turn, allows compilation of the map, which reflects recommendations for conservation and optimal use of the geological environment and identifies zones and sites which require specific protection. The model of the geological environment conservation map of the cryolithosphere so produced is presented as an example.

Problems of geological environment conservation and the principles of compiling relevant maps are fast becoming very important, as engineering-economic activities in areas underlain by permafrost increase. The principles of compilation and the contents of a small-scale map for the conservation of the geological environment, using the example of the first-priority development of the South-Yakutian territorial industrial complex, were the basis for development of a methodology for the compilation of permafrost-engineering geological maps used to select sites for large industrial complexes and for development of the detailed follow up research programs required for the construction of territorial-industrial complexes along the Baikal-Amur Railway Corridor. This map completed a series of maps which include permafrost-hydrogeological and permafrost-engineering-geological maps, a set of permafrost prediction maps and a map of permafrost-engineering-geological appraisal of an area for land construction. The conditions leading to the formation of permafrost and its predicted changes, which are needed to solve the problems of geological environment conservation in the cryolithic zone, were included in the map. Although the map of the geological environment conservation may apply only to closely related fields, investigations have indicated that the basic elements of this map should be the reaction of geosystems (natural complexes, landscape) and of permafrost to technogenic disturbances; allowable engineering loads on the geological environment and recommendations for its conservation in relation to man's economic activity. This map should also show changes in the geological environment induced by economic development, permafrost-geological processes triggered by these changes and the protected zones and objects.

The authors view the stability of geosystems and of permafrost as a relatively permanent natural

complex that includes rock condition, composition and properties, and the dynamics of permafrost-geological processes acting during the natural and historical development of the area. The stability of geosystems and permafrost-engineering-geological conditions (Garagulya and Parmuzin, 1978; Maximova, 1978) depend on their self-regulatory capabilities. The effects of technogenic disturbances are considered negative when they cause changes in a landscape contrary to its natural development. The typical example is the degradation of thermokarst as a result of a snow cover removal in areas composed of ice-rich rocks which then undergo thermokarst-related changes of their properties and composition. When the changes of geosystems and permafrost-engineering geological conditions caused by technogenic and natural and historical factors act in accord, their effects are considered. This positive reaction to technogenic disturbances determine the progress of cryogenic processes, since the natural evolutionary tendency of geosystems becomes enhanced by these disturbances. Thus, vegetation destruction in the areas composed of ice-rich rocks will identify the thermokarst degradation. Such landscapes may become unstable due to vegetation destruction and other changes causing increased summer heat exchange and, on the contrary, remain stable after technogenic disturbances resulting in the increased winter heat exchange in rocks have been inflicted.

In order to evaluate the reaction of geosystems and permafrost-engineering geological conditions to technogenic disturbances, it is necessary to classify these disturbances, to predict the related geocryological changes and to classify the predicted processes using the character and degree of changes introduced into the landscape and permafrost.

CLASSIFICATION OF TECHNOGENIC DISTURBANCES

Two factors govern the reaction of geosystems and permafrost-engineering geological conditions to technogenic disturbances: the inter-component and inter-system relations and the type of a technogenic disturbance responsible for their changes. Thus, changes of inter-component relations in a geosystem caused by the destruction of vegetation on ice-rich rocks or on slopes may bring about irreversible changes in geosystems, e.g. thermokarst development followed by the gravitational processes. Similar reactions are likely to occur when the inter-system relations are affected, e.g. changes in a natural complex on the upper part of a slope can cause changes in its lower part. These examples demonstrate the need for classification of technogenic disturbances to the natural environment based on the changes in inter-component and inter-system relations. The classification of disturbances, obtained for the Aldan-Stanovoi Region, include the following (Table 1): changes in the rock thermal conditions caused by the increased winter or summer heat exchange (by e.g.: snow packing or removal or by vegetation removal); changes caused by the groundwater rise and flooding (such as embankment construction, filling operations); changes in the groundwater regime (excavation of cuts and foundations, installation of drainage systems); changes in the surface water flow (land levelling); changes in the state of stress of rocks on slopes (slope cuts, excavations and slope angle changes).

After the types of technogenic disturbances and the natural and historical conditions were identified, the permafrost prediction was done using the methodology developed at the Permafrost Studies Department, Moscow University (Kudryavtsev, 1974). Forecasts of a temperature field and the depths of seasonal freezing and thawing are essential for predicting permafrost-geological processes induced by technogenic disturbances. In turn, these predictions are helpful in assessing the stability of the geosystems. The identification of the assessment criteria is especially important for small-scale surveys when large areas are mapped and predictions for every natural complex require a large effort. It is therefore necessary to subdivide the predicted processes by their potential effect on the landscape. When the vegetation is removed or other disturbances are inflicted on flat river terraces or water divides, the summer heat exchange of rocks increases; as a result the increased depth of seasonal multi-year thaw, seasonal frost heave or thermokarst development may begin (or intensify). The former has a seasonal rhythm and its effect on a landscape is limited. In terms of predicted changes, the seasonal frost heave should be classified as a process not leading to landscape changes. However, when the permafrost conditions are most conducive to the development of thermokarst, other effects may be expected. Then, if the thermokarst progresses as predicted, the process is classified as landscape-changing. The conditions favouring the initiation and development of progressive thermokarst may be considered as criteria for evaluating the reaction of geosystems to disturbances which result in the increased summer heat exchange of rocks. These conditions are (Table 1): presence

of large monomineral ice inclusions or deposits with a high excess ice content; predicted seasonal thaw deeper than the depth of subsurface ice or ice-rich horizons; and the possibility of undrained depressions replacing the thawed ice. Therefore, data on the ice content in rocks and subsurface ice, the depth of their occurrence and their thickness, the predicted depth of seasonal and multi-year thaw and the surface morphology are the most important factors for assessing the reaction of the geosystems to disturbances which involve high summer heat exchange of rocks.

Table 1 presents the assessment of the geosystems and permafrost stability. To classify the natural complexes with varying potentials for change, the extent of the predicted processes was considered (local or areal). The degree or extent of the natural conditions which were potential process-forming factors within the limits of the identified geosystem were used to clarify this classification.

The results of several studies have indicated that while some geosystems and permafrost are stable after the ground regime changes and show instability when the winter heat exchange of rocks increases, others react just the opposite way. Consequently, before a map of a geological environment conservation is compiled, natural complexes should be classified according to their reaction to various technogenic disturbances. The map prepared for the first-priority development South-Yakutian territorial-industrial complex (the model is given in Figure 1) distinguishes five groups of landscapes differing in their responses to various disturbances. These groups are presented in the map legend (Table 1).

The second part of the map legend contains recommendations for the optimum conservation of the geological environment during its economic use. It is divided into three sections. The first section characterizes the allowable engineering loads on the geological environment (Table 2), thus determining the degree of suitability of the geosystems and permafrost for development (Golodkovskaya, Demiduk, et al., 1975). The map shows groups of geosystems with minimum, average and maximum recommended loads. The first group is highly unstable when subjected to the technogenic disturbances and may be used only in case of extreme need, preferably only for point or linear objects with a localized development zone; the second group has a limited suitability for development; the third group is suitable for any type of development. The construction principles recommended are given for each group, based on the Construction Norms and Standards.

The second section includes nature conservation measures in relation to the economic development of the area.

The third section describes conservation zones and objects. They are divided, based on reasons for their protection, into natural complexes whose disturbance can initiate or suddenly activate permafrost-geological processes of a disastrous nature; natural complexes whose development may cause groundwater pollution; springs of balneological significance; and natural monuments.

The map also shows contemporary changes in the geological environment caused by development activity and the related permafrost-engineering

TABLE 1 Stability of natural complexes with respect to technogenic disturbance of the geological environment in terms of economic development (industrial, civil and linear construction).

Stability categories of natural complexes	Factors initiating processes caused by technogenic disturbances (criteria of potential landscape changeability)	Stability of natural complexes subjected to technogenic disturbances				
		Changes in the heat balance of rocks		Changes in Surface Flow		Decreased slope stability at shoulders of embankments and excavations, bank scouring of reservoirs, etc.
		Due to increased winter heat exchange following snow removal or packing of snow during pre-construction stage, etc.	Due to increased summer heat exchange following vegetation destruction during preconstruction stage, etc.	Due to ground-water rise and flooding during construction of embankments, fills, reservoirs, etc.	Due to vegetation removal during surface grading and other activities.	
1	Absent	+	+	+	+	+
2	Eluvial/diluvial sands and loamy sands on erodable weathered sandstones	+	+	+	Linear erosion (scour channels, ravines, etc.)	+
3	Saturated, thawed biogenic loamy sands and sandy loams	Multi-year freezing, heaving (mounds, etc.) and frost-induced cracking	+	+	+	+
4a 4b	(a) Disaggregated diluvial-colluvial sandy loams and loamy sands, on slopes $>5^\circ$, diluvial blocks, rock debris of rock streams and structural slopes $>15^\circ$; (b) landslide and talus blocks, rock debris and grus on slopes $>25^\circ$	+	+	+	+	Intensified slope processes: (a) solifluction, block sliding, rock streams. (b) avalanches, talus, slides
5a 5b	Diluvial, alluvial-diluvial and alluvial biogenic ice-rich, peaty, sands, loamy sands and sandy loams, a) $<3\text{-}5\text{m}$ thick b) $<3\text{-}5\text{m}$ thick	Without stratification and ice wedges +	Multi-year thawing, thermokarst (water logging, depressions, lakes).		+	+
6a 6b		With stratification and ice wedges +			Thermal erosion (scour channels, ravines)	+

Note: + indicates natural complex is stable when subjected to technogenic disturbances.

TABLE 2 Allowable engineering loads on the geological environment.

Groups from Table 1	Category	Permafrost-engineering geological stability of natural complexes and their suitability for development	Appropriate principal uses of frozen ground for building and construction (according to the Construction Norms and Standards)
3, 4b, 5b, 6b	minimum	Highly unstable; suitable for point or linear objects with a localized development zone	I
4a, 5a, 6a	average	Unstable; suitable for limited development	mainly I, sometimes II
1, 2	maximum	Stable; suitable for overall development	II

FIGURE 1 Model of the Geological Environment Conservation Map. Description of stability of natural complexes subjected to technogenic disturbances and allowable engineering loads on the geological environment (points 1-6) are given in Tables 1 and 2. Measures for nature conservation in terms of the area of development: 7 - control or prevention of

thermokarst or thermoerosional: maintaining rocks in a frozen state; surface drainage; full or partial replacement of icy rocks; biological and technical recultivation; 8 - erosion control: minimizing area vegetation degradation; surface drainage; land stabilization; biological and technical recultivation; 9 - frost heave control: maintaining rocks in a frozen state; regulation of the rate of freezing; surface drainage; grout curtains; full or partial replacement of heave susceptible rocks; 10 - icing control: groundwater lowering and land drainage, groundwater diversion; explosion works; artificial thawing of ice; freezing of groundwater aquifers; 11 - landslide and rock stream control: maintaining rocks in a frozen state; surface drainage; mechanical landslide-control measures; slope transformation; 12 - slide and talus control: slope stabilization; slope transformation; induced caving; trapping and diversion structures.

Zones and objects under protection: 4b, 5b, 6b - natural complexes which, if affected, trigger intensified permafrost engineering geological processes of a disastrous nature; areas which, when developed may cause: 13 - pollution of groundwater-seepage taliks; 14 - pollution or freezing of groundwater recharge areas or influent taliks; 15 - springs of balneological importance.

Objects of aesthetic value (natural monuments): 16 - landscape of groundwater discharge areas (springs) and rare communities and species of plants; 17 - icings; 18 - suitable for recreation; 19 - picturesque geological outcrops.

Geological environment changes caused by economic activity: 20 - border dividing conditionally unchangeable and slightly-changeable natural complexes from highly-changeable (the mark is directed to the latter).

Major development projects: 21 - towns and settlements; 22 - roads; mineral deposits in the stage of: 23 - industrial exploration; 24 - industrial development.

Building material deposits: 25 - gravel; 26 - stone.

Engineering geological processes: 27 - thermokarst and water logging; 28 - heaving and uneven subsidence; 29 - erosion; 30 - icing; 31 - increased mobility of rock streams.

geological processes (Figure 1). The subdivisions of geosystems, based on the major economic projects and related engineering-geological processes used to characterize changes in the natural environment, are described.

In conclusion, it should be stressed that mapping for conservation of the geological environment is fast becoming a very important issue. The authors consider the work done to date to be only the first step in this field. Discussion of the results obtained in this study will contribute to further improvement of the content and methodology of compilation of the natural environment conservation maps of the cryolithosphere.

BIOLOGICAL DECOMPOSITION AND PLANT SUCCESSION FOLLOWING DISTURBANCE
ON THE ARCTIC COASTAL PLAIN, ALASKA

J. J. Ebersole and P. J. Webber

Institute of Arctic and Alpine Research
and Department of Environmental, Population, and Organismic
Biology
University of Colorado, Boulder, Colorado 80309 USA

Thirty years after abandonment of Oumalik Test Well, vigorous stands of grasses (*Arctagrostis latifolia*, *Poa arctica*) and erect willows (*Salix glauca*, *S. planifolia*, *S. lanata*, *S. alaxensis*) dominate the mesic disturbed areas. We hypothesized that the existence of these communities was due to a higher nutrient availability created by greater decomposition rates in these warm, well-drained sites. Weight loss from three types of materials placed 10 cm deep in disturbed and undisturbed sites for periods of 12 and 13 months showed that decomposition rates in disturbed plots were significantly greater ($p < 0.02$) than in undisturbed plots. Stepwise multiple regression showed that the most important measured environmental factors in explaining the variation in decomposition rates were soil temperature (positively correlated with decomposition rate) and soil moisture (negatively correlated). The greater rates of decomposition presumably indicate increased availability of nutrients which is known to favor species with high rates of turnover such as the grasses and willows. As long as the abiotic conditions favoring high decomposition rates persist, nutrient availability will stay high. We expect that the present communities will not be replaced with communities similar to those of the surrounding undisturbed tundra for several hundred years.

INTRODUCTION

Organic matter decomposes slowly in arctic tundra environments. Low temperature is the primary limiting factor, and moisture is secondarily limiting with decomposition rates being greatest in mesic sites and becoming less in both dry and wet sites (Heal and French 1974). The low rates of decomposition make nutrient cycling slow and produce a system in which nutrient availability limits plant productivity and controls species composition (Haag 1974, Challinor and Gersper 1975, McKendrick et al. 1975, Ulrich and Gersper, 1978).

Disturbance to the tundra surface and vegetation would be expected to affect decomposition rates since disturbed areas have altered temperature and moisture regimes. Damage or destruction of the vegetation layer and peat reduces their insulating value and decreases the albedo of the surface (Brown and Grave 1979). This raises the soil temperature and presumably increases the rate of decomposition (Chapin and Van Cleve 1978). In some cases disturbance improves the drainage of formerly water-logged soils which also would be expected to increase decomposition rates. The work presented here is part of a larger study on the recovery of vegetation following a 30-year-old disturbance. The increased abundance and vigor of erect willows (*Salix glauca*, *S. planifolia* ssp. *pulchra*, *S. lanata* ssp. *richardsonii*, and *S. alaxensis* ssp. *alaxensis*) and the greater abundance of nutrient-loving grasses (*Arctagrostis latifolia* var. *latifolia*, *A. latifolia* var. *arundinacea*, and

Poa arctica ssp. *arctica*) on mesic areas of the disturbance relative to mesic undisturbed areas prompted us to hypothesize that nutrient availability in these areas is increased due to enhanced decomposition caused by disturbance. This paper presents the results of the study to test this hypothesis and interprets the development and future of the plant communities on the mesic disturbed areas in light of these results.

SITE DESCRIPTION

The study was done at Oumalik Test Well No. 1, which is located about 125 km from the Arctic Ocean at 69°50'N, 155°59'W on the Arctic Coastal Plain of Alaska (Wahrhaftig 1965). It lies in the subarctic tundra subzone of Aleksandrova (1980) and in the low arctic zone of Polunin (1951). The mean July temperatures in 1979 (apparently an unusually warm summer) and 1980 at Oumalik were 14.4°C and 9.4°C, respectively (Haugen 1982 and unpublished data).

Permafrost is continuous with the upper 3-4 m containing about 50-90% ice by volume (Lawson 1983, this volume). The flatness of the terrain and the presence of permafrost create poor drainage, and most of the area is sedge marsh with water-logged soils. The few upland areas are covered with tussock-dwarf shrub tundra. Even these areas are quite wet, and strong gleying of the soil indicates anaerobic conditions below the upper layers.

The Oumalik well was drilled in 1949-1950 as

part of the oil exploration in the Naval Petroleum Reserve No. 4 (now the National Petroleum Reserve-Alaska). The site was abandoned in 1950 and not disturbed again until work crews removed solid debris in 1980. Lawson et al. (1978) have described a similar site at Fish Creek. All damage to the surface or vegetation tended to cause melting of subsurface ice. Vehicles were driven extensively on the tundra around the well site. Their tracks broke the vegetation mat and damaged the peat layer. Species diversity on these areas was decreased due to the elimination of many species. The new cover is composed of original species which responded favorably to the new environment and species, especially those listed below, which were not on the site before. Bulldozing of the tundra surface was common in the immediate area around the well and caused the most severe disturbance. Areas lowered by bulldozing now frequently have standing water and have been recolonized primarily by the sedges Carex aquatilis and Eriophorum angustifolium ssp. subarcticum. Mounds of soil created by the bulldozing and slopes reworked by bulldozing were colonized primarily by the willows Salix glauca, S. planifolia ssp. pulchra, S. lanata ssp. richardsonii, and S. alaxensis ssp. alaxensis and the grasses Arctagrostis latifolia var. latifolia, A. latifolia var. arundinacea, and Poa arctica ssp. arctica. The dominance of the grasses and willows and the extreme vigor of the willows are unusual relative to the surrounding undisturbed tundra.

METHODS

To test the hypothesis that disturbance increased decomposition rates in these sites, we used weight loss of introduced substrates as a simple, integrating measure. Three types of decomposition samples were placed into 9 disturbed and 16 undisturbed plots selected to represent the range of decomposition environments at Oumalik (Table 1). The three types were (1) 2.00 g of Agropyron cristatum stems from wasteland in Boulder, Colorado, in a 10 x 10 cm nylon net bag whose largest holes were about 0.7 x 0.3 mm, (2) one cellulose filter paper weighing about 0.56 g in a similar bag, and (3) birch wood tongue depressors weighing 2.4-3.1 g. On July 6, 1980, samples were placed into each of the plots at a depth of 10 cm. The samples were placed at depth because in this study the decomposition of interest occurs in the organic matter mixed into the soil by disturbance rather than in litter on the surface. Ten cm was chosen as the depth of most abundant roots. Each plot contained four replicates of each of the three types of decomposition samples. Two replicates of each type were removed 1 year after emplacement, and two were retrieved at the end of the maximum time available for the experiment on August 3, 1981, which was equivalent to approximately 1.5 growing seasons.

After removal the samples were dried in the field. In the laboratory the tongue depressors and filter papers were rinsed with cold running water to remove adhering mineral soil. The grass

was not washed because of the significant water-soluble fraction (15-19%) it contains. The samples were oven dried and reweighed to determine weight loss. Representative used and unused samples of each type of sample were ashed (450°C for 2 hr). The differences in the weight of ash between used and unused samples were used to correct weight loss of all samples for adhering soil. After correction, the percent weight loss was calculated and used as the basis for the numerical analysis.

A soil sample from 10 cm in each plot was analyzed for pH, organic matter, carbonates, water absorption, hygroscopic water, wilting point, field capacity, cation exchange capacity, and total available ammonium, nitrate, potassium, phosphorus, calcium, and magnesium. Soil temperature, depth of thaw, and date of snow meltout were determined for each plot (Table 2).

RESULTS AND DISCUSSION

Despite the limitation of the small sample size, differences between disturbed and undisturbed sites are sharp. The hypothesis that decomposition is greater on bulldozed slopes and in mounds of bladed material than in undisturbed areas is supported by the ANOVA

TABLE 1. Plots Classified by Microrelief/Vegetation Type. Plots in numbered types do not sum to 25 since not all plots fit into the categories listed.

Code	No. of Plots	Description
D	9	Disturbed
U	16	Undisturbed
1	3	mounds of bladed material; dominated by <u>Arctagrostis latifolia</u>
2	3	mounds of bladed material; dominated by <u>Salix</u> spp. and <u>Arctagrostis latifolia</u>
3	2	undisturbed palsas and high-centered polygon centers; dominated by <u>Betula nana</u> and <u>Ledum palustre</u>
4	2	undisturbed reticulate-patterned ground; dominated by <u>Dryas integrifolia</u> and <u>Carex bigelowii</u>
5	3	undisturbed marshes; dominated by <u>Carex</u> spp. and <u>Eriophorum</u> spp.
6	2	undisturbed tussock tundra; dominated by <u>E. vaginatum</u>

which shows that decomposition rates in disturbed plots were significantly greater ($p < 0.02$) than in undisturbed plots for all three types of decomposition samples over both time periods (Figure 1). Differences between microrelief/vegetation types were not tested for significance because of the small sample size.

The plots with the highest decomposition rates were bulldozed slopes and mounds of bladed material dominated by *Salix* spp. and/or *Arctagrostis latifolia* (Figure 1). These sites have relatively warm soil temperatures (Table 2), and due to their good drainage, the soils of these sites are also well aerated, as indicated by the soil color. The sites with the slowest rates of decomposition were undisturbed tussock tundra, which has cold soil temperatures and anaerobic soil as evidenced by the strong gleying. The greater rates of decomposition in marshes, which also have highly anaerobic soils, were probably due to their higher soil temperatures. The reticulate-patterned ground and the areas dominated by *Betula nana* and *Ledum palustre* were intermediate in decomposition rates, aerobicity as judged from soil color and moisture, and soil temperatures.

The results of the stepwise linear multiple regressions show that temperature is the most important environmental factor in explaining the variation in decomposition rates (Table 3). Other investigations in the Arctic have also shown that temperature is the major limiting factor (Heal and French 1974). Soil moisture is the second most important limiting factor at Oumalik. No samples were in the rare dry sites in which the lack of moisture is limiting so decomposition shows a negative, essentially linear relationship with soil moisture. In studies covering the complete moisture gradient, the response curve of decomposition as a function of moisture reaches a maximum in the mesic sites and declines in both dry and wet sites (Heal and French 1974).

Other factors show weaker relationships to decomposition rate. Phosphorus explains a

significant part of the variation and correlates positively with decomposition rate. Heal and French (1974) also found a positive relationship, and Rosswall (1974) reported an increase in decomposition when phosphorus was added to a temperate bog. However, at Oumalik the increased phosphorus may be an effect, rather than a cause, of increased decomposition rates. Depth of thaw at the end of the growing season also correlates positively with decomposition rates. This may be due primarily to the significant positive correlation of thaw and soil temperature and the significant negative correlation of thaw and soil

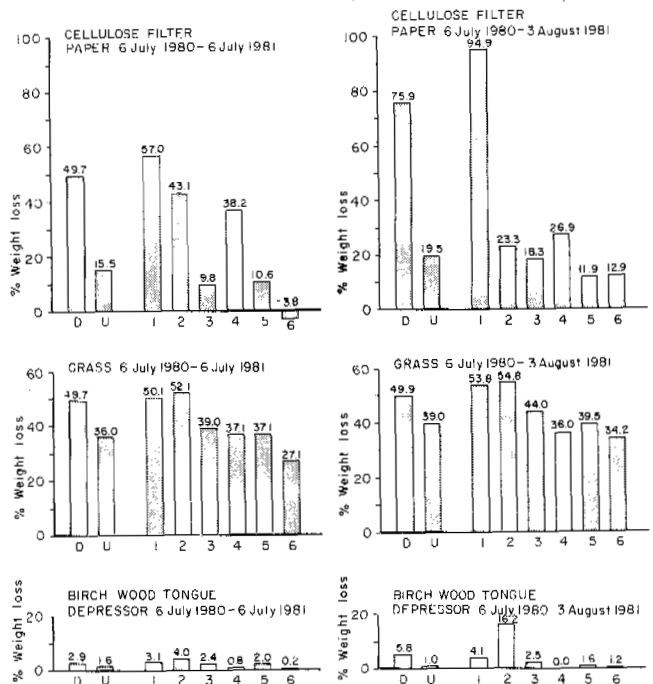

FIGURE 1 Percent Weight Loss of Decomposition Substrates. Plot types are listed in Table 1.

moisture. Plots that become free of snow later have a weak tendency to have greater decomposition rates. One would expect the opposite; that is, plots with an earlier meltout would have greater decomposition rates. This apparent incongruity may be due to the later meltout of high-decomposition disturbed plots which accumulate more snow due to increased surface roughness and greater willow height and density.

The magnitude of the r^2 values for the regressions indicate that 45-78% of the variation in decomposition rates is explained with the variation in the environmental factors measured. The r^2 values tended to be greater for the longer

period of time, perhaps indicating that the longer period of time gave a more accurate measure of decomposition potentials of the plots. Possible sources of the variation unaccounted for are nonlinear responses of decomposition rate to variation in environmental factors, interactions among environmental factors in their effect on decomposition, and random variation in decomposition potential or measured environmental factors on a microscale within a plot or habitat type.

Differences between the 12- and 13-month losses varied with the type of decomposition sample (Figure 1). The grass showed only slightly greater losses over the longer time period, apparently because the easily leached or decomposed fraction was gone within the first year, leaving only the more resistant components. Filter paper and birch wood losses tended to increase slightly to substantially in the additional month. Colonization by decomposers may have taken longer in these substrates compared to the grass in which decomposers were probably already resident.

The greater decomposition rates in disturbed areas presumably create a higher availability of nutrients in a system in which production is limited by nutrients, especially nitrogen and phosphorus (Haag 1974, McKendrick et al. 1975, Ulrich and Gersper 1978, Chapin and Van Cleve 1978, Shaver and Chapin 1980). Other studies in the Alaskan Arctic have shown that enhancing the nutrient regime also changes species composition by differentially favoring the growth of high-turnover species (McKendrick and Mitchell 1978, McKendrick et al. 1975, 1980, Shaver and Chapin 1980, Chapin and Shaver 1981). Thus, the enhanced nutrient regime at Oumalik seems to provide a partial explanation for the presence and vigor of the grass and willow communities on the disturbance. The hypothesis to explain the increased decomposition and the presence and abundance of the willows and grasses is presented in Figure 2.

The grasses and willows are preadapted to natural disturbances and originated on the anthropogenic disturbance from their abundant, wind-dispersed seeds. Once established, these high-turnover species probably quickly formed dense stands in response to the favorable nutrient regimes. The dense communities tend to inhibit colonization by other species, especially the slower-growing dominants of the undisturbed tundra. Thirty years after disturbance there is little, if any, evidence that species from the next successional stage are invading these grass and willow communities. As long as the nutrient regime remains enhanced by the rapid decomposition created by good drainage and high soil temperatures, the present communities will persist. Since there is no indication that the factors creating high decomposition rates will change, replacing the grasses and willows with communities resembling those in the undisturbed tundra is predicted to take several hundred years.

Each step represents a separate equation which includes the variable listed for that step and the previous steps. The r^2 value is for the equation through that step.

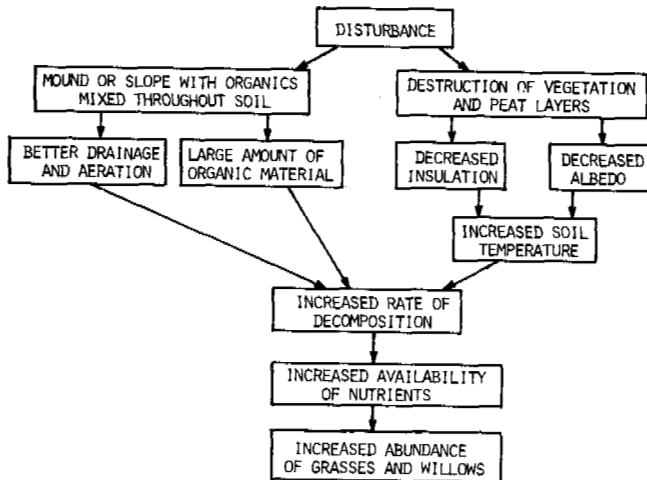

FIGURE 2 Hypothesis to Explain the Increased Decomposition Rates and Increased Abundance of Grasses and Willows of Mesic Disturbed Areas.

SUMMARY AND CONCLUSIONS

Decomposition rates in mesic disturbed areas at Oumalik are significantly greater than in undisturbed areas. Increased soil temperature and decreased soil moisture are the most important factors accounting for the increase. The increased nutrient availability caused by the greater decomposition rates provides a plausible explanation for the persistence of vigorous stands of grasses and willows on the disturbed areas. We predict that the elevated decomposition rates will continue for an extended time and allow the persistence of these communities for many years. In a system such as wet low arctic tundra, in which nutrients are accumulated in organic matter in the soil and in which the slow rate of cycling of these essential elements limits primary productivity and controls species composition, disturbance can enhance the nutrient regime and increase the abundance and vigor of certain plants at the expense of others.

TRANSIENT ELECTROMAGNETIC SOUNDINGS FOR PERMAFROST MAPPING

R. L. EHRENBARD¹, PIETER HOEKSTRA², G. ROZENBERG³

²GEO-PHYSI-CON, LAKEWOOD, COLORADO 80228

³GEO-PHYSI-CON, CALGARY, ALBERTA T2H 0H2

Over the years electrical and electromagnetic methods have been successful in mapping the lateral and vertical boundaries of permafrost over the land. Offshore most electrical and electromagnetic methods cannot map top and bottom of permafrost, because of the low resistivity of the brine saturated, unfrozen sediments overlaying offshore permafrost. Transient electromagnetic exploration is a method of electrical resistivity mapping that can detect resistive layers under highly conductive sediments.

In the winter of 1983 a large survey was conducted on lines onshore and offshore in areas west of Prudhoe Bay, Alaska. Over land the bottom of permafrost which generally occurs at a depth less than 650m (2000 ft) was mapped with good accuracy. Offshore top and bottom of permafrost was mapped under as much as 250m of unfrozen, saturated sediments.

For many geoelectric sections transient EM has a higher lateral and vertical resolution than other electrical methods. For example, for a permafrost section over the land, where a resistive layer (permafrost) overlies a conductive layer (unfrozen ground) a 10 percent change in thickness of permafrost causes a 30 percent change in measured signal. Similar sensitivities are not available in direct current, magnetotelluric, or harmonic frequency methods.

INTRODUCTION

Electrical methods to map the distribution of permafrost have been used for a long time. They rely on the fact that frozen and unfrozen ground have large differences in electrical resistivity. In Canada and the United States the two major contributions for deep permafrost mapping are by Daniels, et al. (1), who used harmonic frequency soundings on the North Slope of Alaska, and by Koziar and Strangway (2), who employed magnetotelluric methods in the MacKenzie Delta in Canada.

In this paper the application of transient electromagnetic soundings, with small transmitter-receiver separations (near-zone), to permafrost mapping is discussed. This method to a large extent has been developed in the USSR (3,4).

Although several case histories of the use of this method are published (5,6), there appear to be no published reports of its application to permafrost mapping in the USSR. U.S. treatises on the theory of transient electromagnetic exploration are found in the papers by Nabighian (7), and Keller (8).

Since the main purpose of this paper is to illustrate the application of transient soundings to permafrost mapping, the theory of the method is discussed in an illustrative manner. The results shown in this paper are selected typical examples of a large survey over lines onshore and offshore west of Prudhoe Bay, Alaska. The survey was performed in the winter of 1982.

PHYSICAL PRINCIPLES

First, the physical basis of the method is explained. A transient system consists of a transmitter and a receiver. The transmitter configuration can be a non-grounded loop or a grounded line. The configuration used in most of our work has been the non-grounded loop. The sensors, in the Geonics EM37 used in our surveys, are multi-turn coils with effective areas varying from 32 to 1,000 m². Figure 1 shows the transmitter-receiver arrangements used for transient soundings.

The current generated in the transmitter is shown in Figure 2. There are two periods of time, time-on and time-off. Measurements are made only during time-off. In accordance with Faraday's law, an electromagnetic induction appears when the current in the transmitter varies with time. When the turn-off ramp is linear, the induced electromotive force is a rectangular pulse.

The electromagnetic induction creates eddy currents in the ground. These induced currents are time-variant and cause a time-varying secondary magnetic field, which is measured as an electromotive force in the receiver coil. It has been shown that the induced currents are horizontal closed rings in the absence of lateral inhomogeneities. There is no vertical component of current flow.

Figure 3 schematically illustrates the

distribution of eddy currents as a function of depth at different times. This figure shows that current maxima move down with increasing time. It must be understood that the currents not only move down, but also out. The current expansion can be described by a diffusion type equation.

The electromotive force measured by the receiver coil is the result of the change of current flow with time. A measurement at time t_0 will mainly be sensitive to the resistivity of near-surface layers. With increasing time, the current maxima diffuse down, and the electromotive force will progressively become more sensitive to the properties of deeper layers. Therefore, by making measurements as a function of time, information about the geoelectric section is obtained. In transient soundings, effective exploration depth is dominantly a function of time.

BEHAVIOR OF THE FIELD

In transient soundings, generally only the time derivative of the vertical component of the magnetic field, B_z , is measured. To understand the procedures of data processing and interpretation, the general behavior of the measured field in the center of a transmitter loop over two-layered ground will be briefly discussed. In Figure 4 the measured signal is plotted versus the dimensionless parameter, $\frac{t}{\tau}$. The parameter τ , is given by:

$$\tau = \sqrt{2\pi\rho_1 t} \quad (1)$$

and ρ_1 is the resistivity of the first and t is time after turn-off. For a certain geologic setting the parameter, τ , is, thus, proportional to the root of time.

Several stages of time can be distinguished in the behavior of the electromotive force (emf). At early time the emf is independent of time; then there is an intermediate range of time in which the emf rapidly decreases with time, and a late range of time in which the emf falls off as $t^{-5/2}$.

Figure 4 shows the behavior of the field for two-layered sections with large differences in the resistivity of the second layer. Yet is it evident that it is very difficult to visualize the geoelectric section from these data. From the different curves it is difficult to tell which curves have a resistive basement and which ones a conductive basement.

APPARENT RESISTIVITY

In all geophysical uses of electrical and electromagnetic methods it has been found convenient to transform the field measured into apparent resistivities, so as to better visualize how the behavior of the field measured differs from the behavior of the field over uniform half-space. Transient soundings are no exception.

To compare the measured response with the response of uniform half-space it is necessary to briefly consider the field behavior of uniform half-space. At all times the behavior of the field, E , over uniform half-space is described by equation (1).

$$E = \frac{3M\rho}{2\pi r^4} \left[\beta(u) - \sqrt{\frac{2}{\pi}} u \left(1 + \frac{u^2}{3}\right) e^{-u^2/2} \right] \quad (1)$$

$$u = \frac{2\pi}{r\tau}; \quad \tau = \sqrt{2\pi \cdot 10^7 \rho t}$$

WHERE r = transmitter-receiver separation
 ρ = ground resistivity
 t = time after turn-off
 M = transmitter moment
 β = error function

At "early stage" and "late stage" the field can be closely approximated by the asymptotic expressions of equations (2) and (3).

$$E = \frac{3M\rho}{2\pi r^4}; \quad \frac{t}{\tau} < 2 \quad (2)$$

$$E = \frac{\mu^{5/2} r M}{40\pi^{3/2} t^{5/2} \rho^{3/2}}; \quad \frac{t}{\tau} > 10 \quad (3)$$

It is evident that the field at late stage is more sensitive to the geoelectric section; the field is proportional to $\rho^{5/2}$.

The asymptotic expressions have been found useful in defining apparent resistivity. For practical purposes, two definitions have been found convenient in our work:

1. A definition of apparent resistivity based on the early stage asymptotic expression.

2. A definition of apparent resistivity based on the late stage asymptotic expression.

In equations (4) and (5) apparent resistivities based on early stage and late stage are defined based on asymptotic expressions for the field given by equations (2) and (3), respectively:

$$\rho_0 = \frac{2\pi r^4}{3M} E \quad (4)$$

$$\rho_0 = \frac{\mu^{5/3}}{4\pi t^{5/3}} \left(\frac{rM}{5E} \right)^{2/3} \quad (5)$$

When the measured emf corresponds to late stage behavior of the field in the first layer over the critical range of time, it is best to use the definition based on late stage. In cases where measurements correspond to early stage behavior in the first layer, it may be more diagnostic to use the definition based on early stage. This situation, for example, arose when measurements were made over a section with a thick, very conductive surface layer. It could also occur when measurements are made at large transmitter-receiver separations.

Figure 5 shows the apparent resistivity curves based on the late stage behavior for the same sections as used in Figure 4. The apparent resistivity curves are plotted in terms of the

dimensionless parameters ρ_a/ρ_1 and T/h_1 . It is evident that from these curves the general geoelectric section can be visualized. The figure shows that, at later times, the apparent resistivity approaches the true resistivity of the basement. At intermediate values of time, the values of apparent resistivity increase when $\rho_2/\rho_1 > 1$ and decrease when $\rho_2/\rho_1 < 1$, so that from the behavior of the apparent resistivity curves, the general geoelectric section can be immediately visualized. This is the purpose of introducing apparent resistivities in electrical prospecting.

At small values of T/h_1 , all curves merge into one corresponding to the behavior of the field of uniform half-space of resistivity ρ_1 . The behavior of this part of the curve is theoretically fully defined by equation (1), and the value of ρ can be obtained from this part of the curve.

Figure 5 has an illustration of two layer apparent resistivity curves. Several albums of 3, 4, and 5 layered apparent resistivity curves are available from the Soviet literature and we have the ability to forward model any n-layered, horizontal sections.

Interpretation of transient soundings from apparent resistivity curves based on early or late stage proceeds in a manner similar to the interpretation of apparent resistivity curves of magnetotelluric or direct current soundings. Interpretation can be done by matching experimental data with master curves, or by inverse solutions. For transient soundings a detailed interpretation manual has been published by Rabinovich (9).

FIELD SURVEYS AND RESULTS

A large number of soundings were conducted on the North Slope of Alaska west of Prudhoe Bay, Alaska. Measurements were made both onshore over the tundra, and offshore over the sea ice. In all these measurements the transmitter consisted of 500 m by 500 m non-grounded loop of 2 gauge wire. The peak current driven through the loop was about 20 amperes, so that the dipole moment was about 5×10^6 amperes - m².

The equipment used was a modified Geonics EM37, which allowed measurements over a range of time from about 0.1 to 800 ms in 40 time gates equally spaced on a logarithmic scale of time. In the Geonics EM37 the receivers are multi-turn air coils and the effective areas of the air coils used varied from 32 to 1,000 m². It was found that with this system in the Arctic, noise was about 0.2×10^{-9} v/m².

A very large number of soundings were made in the winter of 1982. From the large quantity of survey data a section has been selected for illustration and discussion of the data collected. Figure 6 shows a geoelectric section over a survey perpendicular to the coast line at Prudhoe Bay, Alaska. Above the geoelectric section, three typical apparent resistivity curves are shown. These curves will be discussed in more detail below. From about station 3900S the survey line runs over the sea ice. The water depth below the sea ice gradually increases to the north, but never exceeded 10 m along the profile. Over land the geoelectric section can be described by two layers

consisting of frozen ground with resistivities exceeding 200 ohm-m underlain by unfrozen ground of a resistivity of 2.5 ohm-m. Over the bay the geoelectric section consists of unfrozen, brine saturated sediments with resistivities generally less than 2 ohm-m, frozen ground of high resistivities, underlain again by unfrozen ground of a resistivity of 3.0 ohm-m. The profile shows the top to the permafrost to rapidly decrease with distance from the shore line.

The two transient apparent resistivity curves shown above the section have different behaviors, and the behavior of two of these curves will be discussed next. The experimental apparent resistivity data are superimposed on a best fit master curve. For station A the best fit is for a first layer with a resistivity of 400 ohm-m, and a thickness of 600 m, the resistivity of the underlying unfrozen ground is 3 ohm-m. The Manual of Interpretation by Rabinovich (9) shows that for sections, such as shown for station A, the depth to the conductor in kilometers, H_{km} , can be derived from the left descending branch of the curve by equation (6).

$$H_{km} = \frac{\rho_a^{4/9} \cdot \rho_b^{1/9} (\sqrt{2\pi t})^{10/9}}{3.36 r^{1/9}} \quad (6)$$

WHERE ρ_a = apparent resistivity

ρ_b = basement resistivity

t = time

r = transmitter-receiver separation

Equation (6) illustrates several important advantages of transient soundings with small transmitter-receiver separation. These advantages are:

1. Equation (5) shows that ρ_a is proportional to the field measured, E , as $E^{-2/3}$. Combining equations (6) and (4), it is evident that $\rho_a = E^{-9/27}$, where k is a constant. Therefore, a 10% change in depth to the conductor will cause about a 30% change in measured field. That is a sensitivity about 3 three times higher than can be obtained in any other electrical method.

2. The depth to the conductor (H_{km}) is proportional to the basement resistivity to the power $\rho_b^{1/9}$, or a 100% error in basement resistivity will cause only about a 10% error in the value of H_{km} . That is important because in all geophysical methods it is difficult to obtain reliable measurements of basement resistivity. Measurements must be made to very large spacing (direct current), or to very low frequencies (magnetotelluric), or to late time (transient) to obtain a good value of basement resistivity.

Station B is a curve for about station 500S along the profile of Figure 6. Again the experimental data are superimposed on a best fit master curve. The data now must be fitted to a three layer section with a first layer (unfrozen ground) with a resistivity of 2 ohm-m and a thickness of 200 m; the second layer has a high resistivity (frozen ground) and a thickness of 350 m; the third

layer (unfrozen ground) has a resistivity of 2.50 ohm-m. The matching of the experimental data of station B has a larger range of equivalence than the section of station A. The solution is not sensitive to the value of ρ_2 but very sensitive to values of ρ_1 and ρ_3 .

The Gull Island well off Prudhoe Bay is located near the sounding of station B. The E-log from the Gull Island well showed the top of permafrost at 204 m and the bottom at 530 m, in good agreement with the interpretation. The interpretations along all lines could be verified at three other well locations. The agreement at three wells was good.

DISCUSSION

Transient electromagnetic exploration was found to be an effective tool in mapping top and bottom of permafrost onshore and offshore. Features found particularly attractive of the method are:

Lateral Resolution

The measurements were made with a receiver in the center of a 500 m by 500 m transmitter loop. Depth of exploration is mainly a function of time rather than transmitter-receiver separation. A good lateral resolution is maintained with deep exploration.

Vertical Resolution

It was shown that for a two layer section of frozen ground underlain by unfrozen ground, a 10% change in depth to the conductive basement causes about a 30% change in measured field. This high sensitivity translates into a higher vertical resolution.

OBSERVATIONS OF SOIL AND GROUND ICE IN PIPELINE TRENCH EXCAVATIONS IN THE SOUTH YUKON

J. R. Ellwood¹ and J. F. Nixon²

¹Foothills Pipe Lines (Yukon) Ltd., Calgary, Alberta, Canada T2P 2V7

²Hardy Associates (1978) Ltd., Calgary, Alberta, Canada T2E 6J5

During the winter of 1980-1981, Foothills Pipe Lines (Yukon) Ltd. excavated several long trenches in permafrost in order to install sections of 1.22 m diameter pipeline at the Quill Creek test facility in the South Yukon. The authors directed a program of detailed logging of the different soil strata and ground ice formations encountered. A total of 900 linear meters of trench was excavated mostly by wheeled ditcher to a minimum depth of 2 m. The ditch was logged by an experienced technician, and several examples of the logs are given. The variability in surface peat cover, sand and gravel strata, and a seam of volcanic ash are clearly demonstrated. The ash layer was deposited at a reasonably well-defined date in the recent geological past and therefore allows rates of deposition or growth of surface layers to be established. The large area exposed by the trench wall allowed observations of differences between visible ice and excess ice to be made for logging in coarse-grained soils. It is concluded that in these soil types it is often difficult to distinguish pore ice in the large pore spaces, from what is normally considered massive or excess ice. Several photographs are presented to illustrate the location of the different soil strata and the shapes of several massive ice features. Some of the massive ice forms observed in the trench walls are believed to be relict ice wedges. The trench allowed a three-dimensional impression of the ground ice to be obtained, which is not normally possible from boreholes. Some additional observations are made relating to the success of wheeled ditchers in trenching the different soil types at the Quill Creek test facility.

INTRODUCTION

The Quill Creek test site (Figure 1) is located approximately 30 km northwest of Kluane Lake in the southwestern Yukon. The facility was constructed in 1981 by Foothills Pipe Lines (Yukon) Ltd. to test a variety of pipeline designs, construction procedures, and slope stabilization methods in permafrost terrain. The main portion of the test site (including the area where trenching was conducted) is located on a fine-grained, peaty alluvial plain adjacent to a gravel alluvial fan formed by Quill Creek as it exits from the Kluane Range Mountains into the broad Shakwak valley. The entire test site area is underlain by permafrost, approximately 18 m in thickness.

SITE DESCRIPTION

The site is located in the southern discontinuous zone of permafrost, in a region of thin permafrost and mean ground temperatures in the range of 0° to -1°C. The air freezing index at the nearby localities of Burwash Landing and Destruction Bay is about 3000°C-days, and the thaw index is about 1260°C-days. Preliminary borehole drilling indicated the presence of icy subsoils that would permit significant thaw settlement of the near-surface strata. The ground temperature and climatic data confirm the discontinuous nature of permafrost at the site.

During construction of the test facility, 900 m of ditch was opened using either backhoe or a

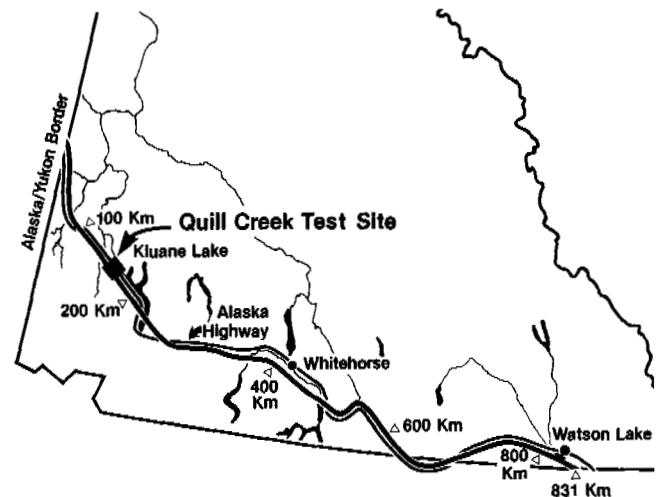

Figure 1: Quill Creek Test Site Location

rotary bucket wheel trenching machine capable of excavating a trench 3 m deep and 2.1 m wide. These wide, deep trenches required for test sections of 1.22 m diameter gas pipeline provided an ideal opportunity for observations and detailed logging of subsurface soil and ice conditions. The soil and ice types were logged according to the Unified Soil Classification System and the National Research Council of Canada Ice Classification System (National Research Council

Figure 2: Generalized Stratigraphy of the Quill Creek Test Site

of Canada 1955, 1963). A two-dimensional log of depth versus horizontal distance was prepared showing significant changes in stratigraphy and ice type or content along one wall of the ditch. Representative samples were taken from the wall of the trench during logging and delivered to a commercial soils laboratory for classification and moisture content testing. A generalized stratigraphic profile for the site is shown in Figure 2 along with the specific areas trenched. Several boreholes which were drilled during preliminary investigations to confirm the suitability of the soils for test purposes are also shown plotted in Figure 2.

STRATIGRAPHY OBSERVED IN TRENCH EXCAVATIONS

Volcanic Ash Layers

Two volcanic ash layers were identified in the trench walls. The more recent White River Ash which was deposited about 1220 years B.P. (Hughes et al. 1972) blankets the entire test site area and in this region is 120-180 mm in thickness. On the extreme eastern edge of the test site this ash is overlain by approximately 2.5 m of sands and gravels, with a thin peat cover forming the present-day surface. These sands and gravels are part of the currently inactive western edge of the Quill Creek alluvial fan.

Across the central and western portion of the test site this ash is overlain by peat and organic silt to an average depth of 500 mm. In the area of the trench designated Q-5, however, the ash is only 100-200 mm below the ground surface.

The earlier layer of ash was deposited between 1850 and 1900 years B.P. (Hughes et al. 1972) and is much thinner, averaging only 10-20 mm in thickness. The lower ash unit was present only as a discontinuous band in some of the trench walls (see Figure 3). Where present, this unit is separated from the White River Ash by 50-100 mm of

peat. It would appear that the growth rate of the peat during the 650 year interval between the ash layers was significantly slower than it is at present. A detailed examination of the visible ice content descriptions for the ditch walls from areas Q-1 and D-2 resulted in the ice (moisture) content profiles shown in Figure 4. Although the absolute value of the ice content profile is different in the two trench walls, the shape of the profile is similar in each case. It clearly shows the position of the White River Ash relative to significant changes in the moisture and thermal regime of the developing soil profiles. The earlier and thinner ash layer does not coincide with any noticeable effect on the ice content profile.

Figure 3: Ancient stream channel in-filled with sand, showing two layers of volcanic ash.

Figure 4: Ice content versus depth for two areas of the site showing similarity of ice profile above and below the White River ash.

Massive Ice Features

Twenty-one rectangular, flat-topped ice wedges were exposed in the trench walls during the ditching operations (Figure 5). All of these wedges were located in a 370 m stretch of the central portion of the test area. Nine of the wedges were greater than 1.5 m wide, four were between 0.5 and 1.0 m wide and the remaining eight were less than 0.3 m in width. The flat tops of most of these ice wedges were 1.5 ± 0.25 m below the ground surface while the active layer depth in this region is between 0.5 and 0.75 m. Except in a very few cases the White River Ash layer above the ice wedges is undisturbed, indicating that the period of major growth of the ice was prior to 1220 years B.P. Four of the ice wedges show signs of recent growth and have smaller wedges or irregular ice masses extending from the top of the main wedge to the base of the current active layer, as shown in Figure 6.

Figure 5: Rectangular ice wedge in Trench Wall.

Trench Q-6 was excavated across an intermittent stream course, and a portion of the log at the top of the east bank is shown in Figure 7. This area contained an infilled stream channel (also shown in Figure 6) as well as a number of irregular ice lenses and massive ice features which were not found at any other location in the test site area.

Figure 8: Geotechnical Logs from two boreholes at site.

COMPARISON OF BOREHOLE RESULTS WITH DITCH WALL LOGS

Several exploratory boreholes were drilled prior to trenching operations, and it is of interest to compare the findings of a conventional drilling investigation with the observations made from a freshly exposed vertical trench wall. Figure 8 presents geotechnical logs from two boreholes (78-A-54 and 81-QC-82) drilled prior to ditching. Although these boreholes were not located on the ditch centerline, they were close enough to illustrate the comparison between the two investigation methods.

Borehole 78-A-54 in Figure 7 is typical of the general stratigraphy in the area and shows a 1.0 m veneer of icy peat and organics overlying a layered sequence of sands and gravels with occasional silty clay layers. This sequence was observed in many of the ditchwall logs, although little appreciation of the three-dimensional nature of subsurface ice could be attained prior to ditching. However, the overall estimate of soil types and ice content in most soil layers was later generally verified by ditchwall logging.

Referring to borehole 81-QC-82, drilled in the same area (location shown in Figure 2), massive ground ice is shown from a depth of 1.8-4.4 m. Clearly, this borehole log indicates an extreme subsurface ice condition, and generalizations based on this log would prove to be completely

erroneous. This becomes very apparent when the ditchwall logs are consulted. Wide, massive tabular ice bodies were not discovered at any point across the terrain where the test pipeline trenches were excavated to depths of around 3 m. However, localized ice wedge features of the order of 1 m wide were delineated at many locations. It is believed, then, that the second borehole selected here for illustrative purposes encountered an ice wedge which penetrated to a depth of a least 4.4 m. This comparison illustrates the hazards of generalizing subsurface ice properties based on a few widely spaced boreholes. Interpretations and generalized stratigraphy should rather be based on a combined appreciation of geological information, other exposures, and a knowledge of geological processes in the area as well as the available borehole data base.

Another important comparison emerged in logging the presence of ice in very coarse grained soils. In gravels containing a significant fraction of cobble size particles, the vertical ditchwall provided an excellent appreciation of the three-dimensional structures of the ground ice. However, on site observers at the trenching operations showed a strong tendency to overestimate the excess ice content of the coarser-grained soils. This resulted from the apparently large extent of ice exposed in the vertical section, which was found to be pore ice on closer inspection. That is, ice in large pores might appear to be excess ice, rather than pore ice, due to the large size of the soil pore spaces.

In summary, some advantages and disadvantages of the two methods of subsurface exploration should be mentioned. Boreholes have the advantage of greatly reduced expense per unit depth investigated but fail to provide a full appreciation of the three-dimensional ground ice structure. Ditchwall logs are extremely expensive if used solely for the purposes of investigation and can only penetrate a limited depth. However, they are of great value in assisting the engineer and geologist in appreciating the overall structure of ground ice features and can help in explaining borehole anomalies and more correctly generalizing soil and ice stratigraphy.

DITCHING

Part of the operations at the test site involved an examination of available ditching methods in permafrost. Therefore, it is of interest to briefly outline the methods used and the success attained. One of the selection criteria used for the site was that it should exhibit a wide variety of permafrost soil and ice conditions, so that ditching success could be monitored in differing subsoil conditions.

A Banister Model 710 wheeled ditcher was used for the pipe trench excavations. The ditch dimensions were approximately 2 m wide and 2-3 m deep depending on test requirements. The ditch sidewalls were clean and vertical, and the trench base generally reflected the topography of the surface right-of-way. Most of the ditches were excavated to partial depth and then completed to full depth by subsequent passes. Some additional excavation tests using drill and blast-assisted backhoe excavation methods were also carried out.

Wheel speeds of the ditcher were maintained around 5 rpm, and the maximum available power at the ditcher wheel was 650 kW (870 HP). Average rates of progress varied from about 30 m/h in predominantly frozen granular soils to 40-100 m/h in predominantly fine-grained or organic icy permafrost. These values are very dependent on the degree of right-of-way preparation, the local permafrost soil properties, ground temperatures, the layout and metallurgy of cutting teeth, etc., therefore the rates quoted here should not be extrapolated for use in other areas where these factors are not well established.

It was observed that soils with excess ice in the form of ice lenses tended to fail through the ice during the excavation process. Soils with substantial excess ice content were therefore easier to excavate. When boulders or cobbles were present, the rock particle fractured in many cases before it became dislodged from the in situ frozen soil matrix. Frozen sands caused higher rates of abrasive wear on the cutting teeth than occurred in frozen silts, clay, or peats.

DISCUSSION AND CONCLUSIONS

The ditching, logging, and field observations of near surface permafrost deposits at the Quill Creek test facility have provided a valuable insight into the soil and ice stratigraphy in this area of the South Yukon. Of particular interest is the presence of ice wedge ground ice features. The site is located in a discontinuous permafrost area, where ice wedges are not generally considered to be actively forming at the present time. Ice wedges actively form in continuous permafrost areas (Washburn 1973), or where mean ground temperatures are -2°C or colder (Romanovskii, referenced by Mackay et al. 1978) or where mean air temperatures are colder than -6° to -8°C (Pewe 1973). In addition, Mackay et al. (1978) state that ice wedges grow on recent alluvial islands in the Mackenzie Delta where mean ground temperatures are -2° and -3°C . Finally, Pewe (1966) concluded that ice wedges in Alaska were most abundant in areas of continuous permafrost where the mean

annual ground temperature is -5°C or lower.

None of the conditions outlined above are realized for present-day conditions at the Quill Creek site, and the ground ice features are indicative of a significantly colder climate in the geological past. This is not surprising, as Mackay (1975) and others have inferred a warming trend in recent geological times from available evidence. Mackay et al. (1978) have summarized the evidence of ice wedges in many countries, and Fukuda (1981) has reported the presence of ice wedge casts in Hokkaido, Japan. The ice wedge features delineated in the trench wall logs in the South Yukon appear to support ideas that the climate has been significantly colder in this area at some time in the past.

Observations of the volcanic ash layer in this area have allowed an estimate of the growth of surface peat. This appears to be generally in the range of 0.5 m in 1,200 years, with a somewhat slower rate prior to this time.

EVALUATION OF EXPERIMENTAL DESIGN FEATURES FOR
ROADWAY CONSTRUCTION OVER PERMAFROST

David C. Esch

STATE OF ALASKA DEPARTMENT OF TRANSPORTATION AND PUBLIC FACILITIES
RESEARCH SECTION - 2301 Peger Road, Fairbanks, Alaska 99701

The side slopes of roadway embankments in warm permafrost areas often cause severe problems from long-term thaw related settlements. Soils underlying the snow-covered slopes do not totally refreeze each winter, as they normally do beneath the cleared portion of the roadway. This results in progressive settlements of the outer edges of the roadway and longitudinal cracking of the roadway surface. Experimental installations of air convection ducts, in conjunction with insulation layers and embankment toe berms, were made during 1973 and 1974 on a newly constructed 7 m high roadway embankment 40 km west of Fairbanks. Performance has been monitored since that time. Results through the thawing season of 1982 are presented. No combination of features tested was totally effective in preventing long-term thaw and settlements of snow-covered embankment slopes. Results indicate that annual refreezing beneath snow-covered side slopes might be achieved by use of the air-duct method. Insulation layers were also installed at different depths in roadway cut sections in ice-rich permafrost at sites approximately 13 km west of Fairbanks. These installations have demonstrated the benefits of placing a 100 mm thick insulation layer at a depth of 1.2 m in a 3 m deep subcut, as compared to installing a similar insulation layer at a greater depth.

INTRODUCTION

Previous studies by the Alaska Department of Highways of roadways constructed over permafrost have shown that progressively deeper thawing generally occurs beneath annually snow-covered roadway side slopes, even in areas where the embankment thickness is adequate to prevent thawing into the underlying permafrost beneath the cleared roadway (Esch 1973, 1978). This side slope thawing results in consolidation and slope settlements in thaw unstable permafrost. Any settlement in the slope areas results in roadway cracking (Figure 1). To study the benefits of different embankment slope designs in controlling thaw beneath side slopes and to evaluate alternative insulated roadway designs for cut sections where the vegetation must be removed, a research project was initiated in 1973. Ten different combinations of insulation layers, toe berms, and air ducting systems were installed on newly constructed highway sections and have been monitored since 1974.

SITE LOCATIONS AND DESCRIPTIONS

The two sites selected are located at Alder Creek and Bonanza Creek, approximately 13 and 40 km west of Fairbanks on the Parks Highway. In these areas, new roadway segments were routed across undisturbed terrain, underlain by ice-rich silt permafrost soils. Alder Creek site freezing and thawing indices and Fairbanks snowfall records during the term of this study are shown in Figure 2.

In the Alder Creek valley the new roadway alignment required short cut sections near the valley bottom at two points approximately 180 m east and 360 m west of the creek crossing.

FIGURE 1 Typical roadway distress from thaw beneath side slopes.

FIGURE 2 Climatological data from Alder Creek Site.

Soils were organic colluvial silts of loessial origin, with a black spruce and sphagnum moss vegetation. Permafrost was generally present beneath a 0.6 m thick active layer. Moisture contents ranged from 30% to 90%. Massive ice was encountered in nearly all borings between depths of 4.5 and 14 m.

In the vicinity of Bonanza Creek the new roadway alignment required an embankment ranging from 6.7 to 7.6 m in height over frozen muskeg. Overlying the permafrost at this site is a 0.3-0.6 m thick peat active layer covered with a surface layer of sphagnum moss, and scattered black spruce. Frozen organic silts were present beneath the surficial peat layer. Frozen water contents of the silt ranged from 30 to 380%, averaging around 100% by weight. No massive ice was encountered.

DESIGN OF EMBANKMENTS

Thermal analyses of the proposed embankments using the "Modified Berggren" calculation approach (Department of the Army 1966), indicated that roadway area thawing could reach to a depth of approximately 4.5 m. The insulation utilized in this study was Styrofoam HI-35, an expanded polystyrene foam from Dow Chemical Company. This product is essentially the only roadway insulation used in North America (Williams 1968) and has a thermal conductivity of 0.029 W/m°C.

At Alder Creek the final roadway grade was only 0.6-1.3 m above the original ground surface, necessitating some excavation and replacement of the underlying soils to prevent settlement problems. Utilizing a fixed depth of subcut of about 3 m below final roadway grade, two alternative insulation depths were selected for field evaluation. The first design type involved placing a 102 mm thick insulation layer as close to the roadway surface (1.2 m) as permitted by construction equipment wheel loadings, and is referred to as the "top-insulated" cut (Figure 3). This design resulted in a thickness of 1.7 m of fill between the insulation layer and the permafrost at the bottom of the subcut, and was used from 326 to 426 m west of Alder Creek.

For comparison purposes, insulation was also installed in a similar cut area located from 326 to 426 m east of Alder Creek. In this area the 102 mm thick insulation was placed at the bottom of the subcut, directly on permafrost at a depth of 3.3 m below final grade (Figure 4).

At Bonanza Creek, a 7 m embankment height was required because of roadway grade restrictions, thermally more than adequate to prevent seasonal thaw penetration into the underlying permafrost. However, problems of slope and shoulder area settlements were anticipated. Three different types of slope modifications were selected for field evaluation to retard this side slope thawing, including insulation layers, toe berms, and air convection cooling ducts.

Toe berms were designed for a thickness of 1.8 m of silt waste, the calculated thickness required to prevent the first year's thaw from penetrating beneath the berm. The full berm width was set at 6.1 m, with a 30.5 m transition length to permit studies of the effect of berm width.

The air convection ducts were included in this study to determine their benefits in removing heat and refreezing the soil beneath the snow cover. A detailed discussion of air ducts for building foundations is presented by the Department of the Army (1966). The ducts function in convection only in winter. The adjacent soil warms the air inside the duct, causing it to expand and rise up the exhaust stack, at the same time drawing in cool air at the inlet. Dampers were included, and are manually closed in summer. Two different layouts for the ducts were utilized on the north and south sides of the embankment, as shown in Figure 5. The ducts were constructed from 0.2 m diameter corrugated metal pipe, installed with the inlet ends above the depth of maximum snow cover, and with 3 m high exhaust stacks.

CONSTRUCTION OPERATIONS

Contract specifications required that excavations into permafrost and the placing of initial 0.9 m thick gravel working pads to be performed during the fall season of 1973. Ground cooling and total refreezing were assured by periodically removing the snow cover from the working pads in the study areas during the 1973-1974 winter.

The insulation layer for the bottom of the subcut area at Alder Creek was also placed during this fall construction period, followed by placement of the initial 1.5 m backfill layer to complete the working pad construction. In all other study areas, insulation placement and berm construction were done early in the spring of 1974, followed by completion and paving in 1975.

Materials utilized at Bonanza Creek included an initial 0.9 m thick working pad of weathered rock placed at 1,790 kg/m³ and 16% moisture, and covered by a 3.0-3.6 m thickness of silt at 1,760 kg/m³ and 10% moisture. The silt soils in the berms had a final density of approximately 1,600 kg/m³ and a moisture content of 15%.

INSTRUMENTATION DETAILS

The thermal performance of the various design features is evaluated from monthly subsurface temperatures measured with a system of 528 thermocouples and 27 thermistors installed in 14 horizontal strings and in 24 vertical borings made through the embankment. Three borings were also made and instrumented in adjacent forest areas to provide comparisons with natural conditions.

Site air temperatures are obtained by battery operated recorders housed in Weather Bureau type shelters placed near each site. Surface temperatures of north and south facing embankment slopes and of the roadway surface are recorded at the Bonanza Creek site.

To provide a basis for repeated measurements of side slope settlements and lateral spreading, cross-section reference hubs and nails were placed at approximately 3 m intervals from the centerline to the toe of the embankment slopes on all study sections, and referenced to a non-heaving benchmark. Thaw depths in the toe of slope and berm areas are measured by means of hand or power assisted probing with 12.7 mm diameter steel rods.

PERFORMANCE COMPARISONS-INSULATED CUTS

The relative performance of similar shallow roadway cut sections made into ice-rich permafrost, and insulated with polystyrene foam layers placed at different depths, was determined by examination of the Alder Creek insulated cuts. Data on thaw depths, settlements, and temperature changes in the underlying permafrost have been obtained over the seven year period since construction.

The section designed and constructed with 102 mm of insulation placed at a depth of 1.2 m beneath the pavement, reached an apparent state of thermal equilibrium within 5 years after construction. Thaw depths beneath the roadway ranged from 3.1 to 3.3 m during the 1979-1982 summers. This annual thawing, which reaches from 1.7 to 1.9 m beneath the insulation, has been totally confined to rock fill placed within the subcut. Full annual refreezing has always occurred beneath the cleared roadway. However, some progressively deeper thawing has occurred each year beneath the side slope and berm areas, and 0.5 m thick talik zones existed beneath these slope areas by 1982. Cross-section settlement profiles since 1975 (Figure 3) indicate that progressive annual settlements are occurring in slope and berm areas, exceeding 0.25 m and 0.33 m, respectively in the 7 years since construction. However, only minor settlements, totaling 58 mm over 7 years, have been observed at the roadway surface. Some longitudinal shoulder area cracks have occurred as a result of the sideslope and berm areas settling much more than the roadway itself.

The bottom insulated cut section, constructed with a thickness of 102 mm of insulation placed directly on the permafrost at a depth of 3.2 m, demonstrated very excessive roadway area settlements (Figure 4) as compared to the nearly stable "top-insulated" cut section discussed above. The relative performance of these two cuts is compared in Table 1, along with data from an adjacent undisturbed forest site. The top-insulated cut design resulted in long-term settlements only 8% as great as adjacent uninsulated roadway areas, while the bottom insulated cut settlements was 48% of the uninsulated area settlements.

The excellent roadway performance of the top-insulated section indicates the benefit of placing insulation layers as near to the surface as practical and providing a thickness of compacted sand or gravel beneath the insulation sufficient to contain the annual thaw zone. Both cut sections design have annually refrozen to the full depth thawed beneath the pavement and shoulder areas.

FIGURE 4 Cross-section details and settlement plots for bottom-insulated cut at Alder Creek.

TABLE 1 Comparative Performance of Cut Sections Between 1975 and 1982.

Condition or Insulation Depth (m)	Max. Thaw Depth (m)	Thaw into Permafrost (m)	Centerline Settlement (m)	Permafrost Temp. Change (°C)	Permafrost Temp. Jan. 1982(°C)	Temp. Reference Depth (m)
102 mm @-1.2 m	3.3	0.00	0.06	+0.26	-0.49	-9.4
102 mm @-3.2 m	4.2	0.70	0.38	+0.12	-0.55	-10.0
No Insulation	---	---	0.79	---	---	---
Forest	0.7	0.00	---	+0.01	-0.46	-9.1

However, taliks have developed beneath all side-slope and berm areas, ranging in thickness from 0.5 to 1.0 m after 7 years. These taliks are growing in thickness in nearly equal annual increments.

Temperature trends at depths of about 10 m below the original permafrost surfaces indicate very minor warming for the subroadway permafrost, ranging from 0.12-0.26°C over 7 years. Temperatures at this depth are still slightly colder than beneath the undisturbed forest. This indicates the roadway to have an average surface temperature very close to the original undisturbed forest condition, although the annual temperature variations and thaw depths for the roadway are much greater.

Embankment Performance--Bonanza Creek

The road routing at Bonanza Creek was essentially east-west, and the slope facing south was most heavily instrumented for temperatures. Major differences in vegetation density have been noted, with much better growth on the south slope.

Continuous recorders were installed in 1975 to measure the surface temperatures of the pavement surface and the north and south facing 2:1 side-slopes. During 4 years of observations the average surface temperatures were 0.5°C for the pavement, and 1.9°C and 5.0°C for the north and south-facing slopes, respectively. Surface thawing season *n* Factors for these points were 1.73, 1.02, and 1.72, respectively, while freezing season *n* Factors were 1.05, 0.40, and 0.45. The mean air temperature over this period was -2.7°C.

Maximum thaw depths observed beneath the roadway centerline at three locations in the study embankment ranged from 4.1 to 4.9 m, averaging 4.6 m. This was roughly about 2.5 m above the original ground surface. There were no indications of progressive increases in thaw depth with time.

Thaw depths at a constant distance of 2.4 m inside the normal position of the toe of slope, as if no berms had been used, are presented for comparison in Figure 6. Thawing of the embankment permafrost foundation soils at this location is considered to be very detrimental to sideslope stability. This figure demonstrates a progression of thawing in spite of all combinations of treatments, as well as progressively greater benefits in reduced thawing from the addition of berms, air cooling ducts, and berm insulation layers. The embankment sections which featured the combination of toe berms and insulation layers were much more effective than uninsulated berms.

Comparisons of the relative benefits of the different sideslope treatments can be made on the basis of several factors, including thaw depths, surface settlements and lateral slope movements. Thaw depth changes beneath the side slopes over the 7 years following construction are shown in Figure 7. Data from years not shown on these plots were intermediate between the years plotted, and were omitted for clarity.

Air Ducts

Air convection cooling ducts were of significant benefit in retarding thaw of the foundation soils, particularly when used in conjunction with

FIGURE 5 Overall view of experimental embankment details at Bonanza Creek.

FIGURE 6 Thaw depths for different embankment designs, at 2.4 m inside normal embankment toe.

insulation layers placed to reduce summertime heat gains in the soils cooled by the duct system. Experimental studies and subsequent analyses of these ducts indicated that a larger diameter duct would have been more effective, and a duct design methodology has since been developed. Roadway surface and shoulder movements indicated that these ducts were located too far from the center of the embankment to control those movements.

Embankment Toe Berms and Insulation Layers

The use of toe berms constructed of silt or waste materials showed only very minor benefits on thaw beneath the sideslopes, retarding the progression of thaw to any given depth by 1-3 years. A 6 m berm width was slightly superior to a 3 m wide berm on a short-term basis, but neither berm type prevented long-term thaw progressions. This might be expected, as berms present increased areas of permafrost surface disturbance, which are elevated, well drained, and poorly vegetated, and therefore warmer than the original muskeg surface covered by

the berm. Berms were marginally effective in reducing settlements and lateral shear-type movements of the lower and mid-slope areas due to their supporting and counterbalancing effects, but had little or no benefit in reducing movements of the critical roadway surface area.

Insulated toe berms provided a major reduction in thawing, with thaw progression into the underlying permafrost delayed by about 4 years by use of 51 mm of insulation as compared to similar uninsulated berms. However, the long-term thawing trends beneath berms and slopes were not arrested by the insulation usage. The placement of 51 mm thick x 4.9 m wide toe insulation layers at a height of 1 m above the toes of a normal embankment without berms, proved of no significant benefit in retarding thaw or related movements.

Observations on Embankment Movements

All embankment measurement points were in a state of progressive movement downward and outward during the 7 years of observations. Vertical settlements of the roadway centerline averaged 29 mm/yr, with little variation between treatments or years. Because observations show no permafrost thawing beneath the center of the embankment, the possibility of these movements being the result of stress-related creep of the underlying warm (-0.6°C) permafrost must be considered.

Sideslope vertical and lateral movements have been very great at this site, with up to 1 m of settlement and lateral movement of some reference points in middle to lower slope areas. Some of these slope movements appear to be related to annual frost action and solifluction type mechanisms, rather than to permafrost thaw and consolidation. Frost action related movements appeared particularly intense on the north-facing slope, perhaps because this was the upstream side of the embankment and had more water availability due to ponding from the dike effect of the frozen embankment. Vertical settlements and lateral movements of the reference hubs are shown by Figures 8 for a normal embankment section and for the full treatment section which combined berms, air ducts, and insulation layers. Intermediate levels of movement were generally noted for other treatments or combinations thereof. At the roadway surface, vertical and lateral movements resulted in the formation of cracks and 20-40 mm deep rutting in the outer wheelpaths, which required patching and levelling of all sections in 1981.

FIGURE 7 Thaw depths beneath lower embankment slopes for various embankment sections.

FIGURE 8 Lateral and vertical movements of normal and bermed, insulated, and ducted embankments, from reference points at various distances left and right of roadway centerline.

SUMMARY

Studies of roadway cuts and embankment movements and thermal changes have been made on 10 instrumented roadway study sections near Fairbanks, Alaska, with continuous records kept from 1974 to 1982. In all cases, the permafrost condition has been maintained beneath the cleared roadway and shoulder areas. Excessive thaw-related settlements were observed in a cut section insulated at a depth of 3.2 m, while a similar section with the insulation placed at a 1.2 m depth has had negligible settlements. Roadway sideslopes have developed residual thaw zones or taliks in all areas, and annually deepening thawing beneath the slopes has resulted in progressive deformation and cracking of slopes and roadway shoulder areas.

The benefits of a combination of insulation layers, air cooling ducts, and embankment toe berms were apparent from these studies. However, no combination of treatments was adequate to prevent the long-term progressive degradation of permafrost beneath embankment slope areas, and the eventual distortion of the roadway surface of the 7 m high road embankment. There is some hope that a combination of insulation, embankment shape, and larger air cooling ducts may be sufficient to offset the annual heat gains of sideslope areas and to provide a thermally stable embankment, even for warm (-0.6°C) permafrost conditions.

ACKNOWLEDGMENTS

Funding for this work was provided by the Federal Highway Administration. The assistance of the many research personnel of the Alaska Department of Transportation and the University of Alaska has been essential in maintaining continuous long-term records and data processing.

SOLAR SYSTEM ICES AND MARS PERMAFROST

Fraser P. Fanale and Roger N. Clark

Planetary Geosciences Division, Hawaii Institute of Geophysics,
University of Hawaii, Honolulu, Hawaii 96822

Infrared reflectance measurements have resulted in identification of CH₄ ice on Pluto and Triton, H₂O ice on satellites of Uranus, Saturn and on three Jovian satellites (one of which may harbor a liquid H₂O zone in its crust). Frozen SO₂ on Io and bound H₂O on the largest asteroid have also been identified. Such diversity is explicable in terms of accretion conditions, degassing history and atmospheric evolution. Ground H₂O ice appears abundant in ubiquitous Mars permafrost but its distribution is controversial. A key issue is how long ice which is unstable with respect to the atmosphere can be preserved by soil cover. We calculate thermal histories for the regolith at all latitudes, depths and obliquities throughout Mars' history. Neither seasonal nor obliquity driven freeze-thaw of systems that are stable with respect to global conditions can occur unless the systems have eutectics <235°K. Either this process does not occur on Mars or occurs rarely owing to unusual brines, episodic H₂O emplacement or atypical regional subsurface thermal regimes.

ORIGIN OF SURFACE AND NEAR SURFACE ICES: PRINCIPLES

Formation of solid planets involved accretion of condensates from a gaseous nebula. The condensation temperature determined planetary bulk volatile endowment (Lewis 1974). Objects formed from high temperature (>1000°K) material are almost volatile free. If condensation occurred <200°K, the final objects are icy because the oxygen abundance is more than needed to make silicates or oxidize metal, and combines with hydrogen to make ice equal to twice the silicate plus metal mass. Then formation of NH₃·H₂O occurs by reaction of NH₃ with ice, and CH₄·8H₂O is formed. If the H₂O is hidden in an already accreted planetary body, then the NH₃ condenses as NH₃ ice and the CH₄ as CH₄ ice (Lewis 1972). The Jovian satellites Ganymede and Callisto have ρ ~1.6 g cm⁻³, or two parts ice and one part silicate. Io and Europa, the two innermost large satellites of Jupiter, are rocky because the early star-like Jupiter disallowed ice condensation near it. Saturn's larger satellites have densities, ~1.0 g cm⁻³, because of condensation of other ices below 100°K and dynamic fractionation which depleted silicates. This ratio (ice > rock) is also relevant to comets, though these objects include CO₂ and CO, suggesting kinetic barriers at very low T and P.

If planets form from materials condensing between 1000° and ~200°K, they are "rocky" but have some volatiles: H₂O from hydration of silicates, and P, S, N., etc. from condensed non-icy materials or reactions with them (Fegley and Lewis 1980). This is how volatiles were acquired by Mars, the Earth, Venus, asteroids, Io and Europa.

In large bodies, decay of ⁴⁰K, ²³⁸U, ²³⁵U, and ²³²Th is typically sufficient to induce melting (e.g., Taksoz et al. 1978) causing volcanism and degassing. Roles for accretional heating in initial melting and degassing (cf. Fanale 1971, Wetherill 1976) and for heat from decay of short lived nuclides such as ²⁶Al (Lee et al. 1977) are recognized. The latter is important because some

sublunar-sized objects are differentiated, yet are too small to melt by accretion and lack the thermal lag to accumulate the heat from U, Th, and K decay. Tidal heating causes current volcanism on Io (Peale et al. 1979, Smith et al. 1979).

Degassing of a body with some water of hydration can produce an object such as Earth, with its hydrosphere a few km deep, or Europa. Although Europa's crust is icy--surface temperatures being ~100°K--it may have a liquid zone beneath the first few km or tens of km (Fanale et al. 1977, Soderblom and Luchitta 1983, Squyres et al. 1983). The most likely source of energy to keep the H₂O from freezing is tidal (Squyres et al. 1983). Io, closer to Jupiter, receives vastly more tidal heating and has heat flow similar to geothermal areas in New Zealand (Matson et al. 1981). Volcanism, atmospheric ionization, sputtering, and other loss to space resulted in virtual dehydration (Pollack and Fanale 1982) and Io's surface currently contains frozen SO₂ (Fanale et al. 1979, Smythe et al. 1979) and sulfur allotropes (Soderblom et al. 1980, Sagan 1979). Icy satellites have melting points so low that a small input of energy should trigger core formation. Ganymede and some Saturnian satellites show tectonic features attributed to volume changes on freezing (Smith et al. 1979, Shoemaker et al. 1982). Liquid H₂O zones may be absent because (1) Ganymede and Callisto (being icy) receive less radioactive heat per gram than Europa, (2) receive far less tidal heating, and (3) their (>1000 km) ice shells are amenable to convection (Cassen et al. 1980).

Condensation models yield a range of H₂O abundances for Mars (Anders and Owen 1977, McElroy et al. 1979, Pollack and Black 1979). Combining these with estimates of degassing efficiency based on atmospheric rare gas analysis yields a global H₂O supply to the surface of 10 to 100 m with most estimates closer to the latter. Much must be present as ground ice (Leighton and Murray 1966, Fanale 1976, Rossbacher and Judson 1981). Thus Mars is like the Earth and Europa, a rocky body

with a outer H₂O shell. Most of Mars experiences net H₂O sublimation in the top meter, so the H₂O is largely invisible (see Mars Permafrost section below).

Volatiles are subject to removal by weathering and exospheric escape (see review by Pollack and Yung 1980). Water destruction by dissociation, H escape and oxidation of igneous rock, can destroy a hydrosphere, as it may have on Venus and Io. Ice loss by particle sputtering also occurs on icy satellites. Thus, diversity of surface volatile regimes is a product of diversity in bulk volatile content, degassing histories, and volatile loss processes.

TECHNIQUES FOR IDENTIFICATION OF SURFACE VOLATILES

Planetary densities indicate whether a planet is rocky or icy. Infrared thermal measurements indicate which ices could be stable at any site. Since ices produce landforms, imaging plays a role. Ultimately, γ -ray measurements from orbit and differential scanning calorimetric (and radiometric) measurements from landers, rovers, and penetrators will provide direct analyses of ices. Imaging spectrometers can provide images with high resolution spectra to several microns for each picture element, enabling phase distribution mapping. Meantime, the key means of remote identification of ices is telescopic planetary surface reflectance measurements in the infrared. Sometimes (e.g., the outer solar system) the planet is a 'point of light' yielding only hemispheric phase identification. In other cases spatial resolution is obtained. Combinations of molecular vibrational overtones in ices result in infrared absorption bands allowing phase identification as in Figure 1 where spectra of H₂O, CO₂, and CH₄ ices are compared. The position of an overtone is controlled by molecular bonds and band strength by the probability of photon absorption per unit path length and the total photon path length, which is controlled by scattering. Scattering occurs when there is a change in index of refraction, as at an ice-vacuum boundary. Mean path length is controlled by grain size and absorption coefficient. The smaller the grain size, the more scattering and the smaller the photon path; hence weaker absorptions. The greater the absorption coefficient, the less photons will be able to penetrate, inhibiting band depth. Higher overtones are weaker absorptions, and probe deeper. Rock minerals generally have higher absorption coefficients than ices; thus their presence in ices is easily detected. In some cases, clathrates are detectable, but since the trapped gas has a low abundance compared to the ice, its features are weak (Smythe 1979). Using radiative transfer models, abundances of phases in mixes can be estimated from the reflectance spectrum. Clark (1983) reviews spectral properties of ice-soil mixtures, and techniques for analysis of spectra.

RESULTS

Application to the solar system has revealed a variety of surface ices. Pluto is covered with CH₄ ice (Cruikshank and Salvaggio 1979). Methane gas

may contribute but if there were that much, at the ambient temperature of 50°K, there would be CH₄ ice anyway. This applies to Triton (a large satellite of Neptune) as well. Long photon path lengths are indicated consistent with large grains, as expected from kinetic theory of ice grain growth (Clark et al. 1983). Water ice is the only ice detected on the Uranian satellites (Brown and Cruikshank 1983). Here the optical path is small, since H₂O grain growth rates are slow at <90°K. These satellites have low albedo (~20%), indicating other minerals mixed with ice. Water ice dominates surfaces of all Saturnian satellites whose spectra were measured (Fink et al. 1976, Clark and Owensby 1981). Here also grain size is small (Clark et al. 1983). Saturn's rings are mostly water ice--countless 'frost balls' with other impurities containing Fe³⁺ (Clark 1980).

Before the satellites of Jupiter were seen by spacecraft, H₂O ice was identified on Europa (J2), Ganymede (J3), and Callisto (J4), and its rarity or absence on Io was indicated (Pilcher et al. 1972). Clark (1980) showed J3 has about 90 wt% water ice on its surface (Figure 2), J4 has 30-90 wt%, and J2's surface is mostly water ice with some impurities containing Fe³⁺, e.g., carbonaceous meteoritic material (see Sill and Clark 1982). The dominant volatile on Io is SO₂ frost and adsorbate (Fanale et al. 1979, Smythe et al. 1979). The 1.04- μ m band depths in the H₂O ice on the surfaces of J2, J3, and J4 appear to be (if L = leading hemisphere in the satellite orbit and T = trailing) J2(T) > J3(T) > J2(L) > J3(L) ~ J4(T) ~ J4(L). This is consistent with the hierarchy of particle fluxes and the idea that atomic particle sputtering destroys small grains created by micrometeorites (Clark et al. 1983).

Jupiter's satellites J6-J14 and Saturn's small satellites have broadband reflectances like carbonaceous meteorites. Adequate data have not been obtained. These objects are low in reflectance, but low albedo surfaces could be 99% or more ice (e.g., Clark, in the volume).

The only asteroid with deep H₂O bands is the largest, Ceres (Lebofsky et al. 1981). The absorption near 3- μ m is due to bound H₂O. An additional weak absorption was seen also which Lebofsky et al. (1981) interpreted as due to a small amount of H₂O ice. This seems inconsistent with short sublimation times for H₂O ice in the asteroid belt where mean T's are ~190°K and maxima are ~250°K (Watson et al. 1961). The spectrum, however, shows the "ice" feature at a slightly shorter wavelength than ice, and too narrow, so ice is questionable.

Mars is spectrally similar to X-ray amorphous weathering products of mafic volcanic glass found on Mauna Kea, Hawaii (e.g., Singer 1982). Bright region soils show weak H₂O ice bands (McCord et al. 1982), but since frosts are unstable at the time the spectra were obtained, the ice must be in pore structure of weathering products. However, Mars' residual north cap contains approximately 2 x 10⁶ km³ of ice, and this is H₂O, not CO₂, based on thermal measurements (Kieffer et al. 1977).

MARS PERMAFROST

Even volatile-poor models of Mars suggest enough degassed H₂O, to produce a global layer of ground

FIGURE 1 Spectral reflectance of ices. Band positions identify the material. Strength of an absorption depends on fundamental strength of transition, photon path length, and abundance. Thus, grain size affects the appearance of the spectrum. The CO₂ spectrum is from Smythe (1979), and the H₂O spectrum is shown in Clark (1983) with frost spectra of other grain sizes. The CH₄ spectrum is from Brown and Clark (personal communication, 1983).

FIGURE 2 The spectrum of Ganymede is compared to frost on ice. The frost layer is 1 mm deep over ice, which increases the 1.04 μm ice band relative to optically thick frost with the same 1.5 and 2.0 μm bands. The strong ice bands indicate purity (~90 wt%). Differences, such as the broad absorption, are due to minerals with Fe³⁺, typical of carbonaceous chondrite meteorite spectra. Spectra are scaled to 1.0 at 1.02 μm (Clark, 1980).

FIGURE 3 The Mars regolith thermal regime below 2 m. Temperature is given as a function of latitude, depth, and obliquity. Assumptions and associated uncertainties are discussed in the text.

ice of 10 to 100 m (Rossbacher and Judson 1981). Its regional presence seems necessary to produce the larger outflow channels (Carr 1979). Also, "nonlunar" ejecta blankets are evident, which suggest fluidization (Carr and Schaber 1977, Mouginiis-Mark 1979). A latitudinal dependence for these has been suggested (Johansen 1978), but many variables still need to be controlled (Mouginiis-Mark 1979). There are thermokarst-like features, (Gatto and Anderson 1975) polygonal patterned ground, curvilinear features, and craters with central pits and debris flows (Carr and Schaber 1977). The distribution of these, and the fluidized ejecta, has been discussed by Rossbacher and Judson (1981) who show some pitted terrain, aligned pits, and curvilinear features in near equatorial zones.

Ground ice is unstable with respect to the atmosphere at latitudes $<40^\circ$ (Leighton and Murray 1966, Fanale 1976, Farmer and Doms 1979). Thus to explain morphology, it was suggested that "fossil" ice exists near the equator (cf. Smoluchowski 1968). The role of soil in preserving buried ice was reviewed by Clifford and Hillel (1983). The distribution of pores in real soils provides a much greater effective pore size than if, as in Smoluchowski (1968) and Toon et al. (1980), the pore size is equaled to that of the smallest grains. Even a 100 m layer of overlying soil would be unable to prevent sublimation of 200m of ground ice. Thus "outliers" of ground ice in low latitudes. This suggests supply of H_2O from depth rather than preservation of initial ice. Study of temporal and spatial relationships among channels, ground-ice-related features and regional volcanism will test this.

The huge scale of some of the Mars patterned ground features may suggest driving by long term astronomically induced insolation variations, (Carr and Schaber 1977, Rossbacher and Judson 1982, Coradini and Flamini 1979). We will first evaluate the chances of periodic freeze-thaw on seasonal and astronomical ($>10^4$ yr) timescales. Figure 3 shows variation of Mars regolith temperature with depth, latitude, and obliquity. Here we assumed (1) surface insolation variations with obliquity cycle given by Ward et al. (1974), (2) thermal conductivity of 8×10^4 ergs $cm^{-1} s^{-1} ^\circ K^{-1}$ (for hard frozen soil), and (3) bulk heat generation rate of 2.6×10^{-7} ergs $cm^{-3} s^{-1}$ (chondritic). We calculated curves in Figure 3 using computational procedure given by Fanale et al. (1982a). The model is sensitive to assumptions: ice free soils range in conductivity from x3 greater to x3 less than assumed. Mars' K content could be lower (Anders and Owen 1977) which could lower the gradient (angle between bundles and abscissa) by x2.

Still, we can draw conclusions from Figure 3. Coradini and Flamini (1979) assumed an approximately 20° global rise in temperature could result from obliquity rise, causing widespread periodic thaw. Our treatment shows that predicted variations based on Ward et al. (1974) are almost that on the pole, x4 less at 60° latitude, negligible at 30° latitude, and of opposite sign at the equator. Where variation is maximum, near poles, maximum temperature in the first 200 m is under $-100^\circ C$. Conversely, at low latitudes, where the mean annual temperature is -60° to $-40^\circ C$, the obliquity cycle does little to vary it. Thus quantitative analysis

of Mars' regolith thermal regime suggests obliquity driven freeze-thaw cycles are implausible.

Analogous argument can be made against seasonal freeze-thaw cycles. The top of any ice choked permafrost on Mars is unlikely to be where the average temperature $\sim 200^\circ K$ because there and above net annual sublimation is positive, resulting in ice depletion (Leighton and Murray 1966, Fanale 1976, Farmer and Doms 1979). The Viking infrared thermal mapper showed mean diurnal T's (applicable ~ 3 cm) to be $\sim 210^\circ - 230^\circ K$ at the equator with an annual mean of $\sim 220^\circ K$. At mid latitude they range from $\sim 170^\circ$ to $230^\circ K$ with an annual mean of $\sim 200^\circ K$, and at polar latitudes, from $\sim 150^\circ$ to $\sim 220^\circ K$ with an annual mean of $\sim 170^\circ K$ (Kieffer et al. 1977). Hence, hard frozen permafrost cannot exist in equilibrium with the atmosphere in low latitude; it must be buried to damp out seasonal variation at mid-latitude, and it can exist in the diurnal zone only at latitudes $>75^\circ$. Since the diurnal average at seasonal maximum is $<230^\circ K$ wherever frozen permafrost exists in equilibrium with the atmosphere and since even that cannot be achieved at the top of the ice owing to thermal blanketing, we conclude seasonal melting, like diurnal melting, must occur (if at all) at $<230^\circ K$. Obviously, periodic freeze-thaw on any timescale is a submarginal process for pure water on Mars.

It is also marginal for brines. A brine can be stable to $210^\circ K$, with a water concentration of 70%. A more likely $MgCl_2 - CaCl_2 - H_2O$ system or $CaCl_2 -$ alkali chloride system would have a eutectic of $218^\circ K$, and for $MgCl_2 -$ alkali chloride systems it is $238^\circ K$. While such systems (barely) satisfy our requirements for freeze-thaw processes they all require equilibrium H_2O vapor pressures about the same as ice at any temperature. This rules out melting at $>235^\circ K$, since that PH_2O is two orders of magnitude higher than Martian atmospheric PH_2O 's. This is critical for the (shallow) seasonal case. Finally, ubiquitous $MgSO_4$ would react with any $CaCl_2$ solution to produce $MgCl_2$ and $CaSO_4$ solutions far less effective at depressing the freezing point (Clark and Van Hart, 1981).

The effect of "circumscribed" sources such as lava flows in melting permafrost on Mars has been investigated by Coradini and Flamini (1979), who found them of limited effectiveness in space and time. Also, they are not periodic. A convection cell of near global proportions (e.g., associated with Tharsis) in conjunction with obliquity driven brine freeze-thaw may suffice. Magmatism may also emplace ice at shallow depths out of equilibrium with the atmosphere. Also, prior to Tharsis the obliquity variation might have been greater (Ward et al. 1979). We plotted points (x's) on Figure 3 corresponding to the enhancement in the T variations at 100 m depth that would result. These do not change our conclusions. Also, the solar constant was significantly lower prior to Tharsis. Other possibilities include periodic warming due to continuous dust storms caused by obliquity driven desorption of CO_2 from the regolith (Fanale et al. 1982a). Also, in earlier Mars history some process seemingly produced a different H_2O regime, since highly dissected terrain seems restricted to ancient Mars history and some process akin to sapping seems involved (Pieri 1976). A chronology of terrain types and a distinction between those which

require periodic freeze-thaw and those which do not, is called for. Our difficulty in rationalizing periodic freeze-thaw on Mars, when it is so common on Earth, reminds us that comparative planetary is a study of differences as well as similarities.

SUMMER WATER BALANCE OF A HIGH ARCTIC CATCHMENT AREA WITH UNDERLYING PERMAFROST
IN OOBLOYAH VALLEY, N-ELLESMERE ISLAND, N.W.T., CANADA

Wolfgang-Albert Flügel

Geographisches Institut, Universität Heidelberg, Im Neuenheimer Feld 348,
D-6900 Heidelberg, Federal Republic of Germany

The water balance of Oobloyah Valley, N-Ellesmere Island, N.W.T., Canada, a high arctic catchment area underlying by permafrost was investigated during the arctic summer 1978. The following results will be presented: (1) three main hydrogeological areas with different sediments, thawing depths, and soil drainage were separated; (2) most of the winter snow cover melted until July 1, thereafter soil thawing and its drainage began; (3) the periglacial streams never had a measurable sediment load, not even during snow melt; (4) considering daily discharges, climatic changes and soil water balance the hydrologic regimes of the three investigated streams were characterized; and (5) summer water balance must include frozen soil water stored in the year(s) before; snow and rain add up to 51 % of the total balance, glaciers contribute up to 48 % and actual evapotranspiration is only 1 %.

INTRODUCTION

During the "Heidelberg-Ellesmere-Island-Expedition" in 1978 to Oobloyah Valley (81.5° N;83.5° W) in N-Ellesmere Island, N.W.T., Canada (Barsch and King, 1981), hydrologic studies were done with the following topics: (1) hydrogeological areas and their physical parameters; (2) climate during field work; (3) hydrological dynamic during snow melt; (4) water balance in representative stations; (5) discharge of streams; and (6) summer water balance of 1978. A measurement method developed for temperate climates (Flügel 1979) based on daily measurements of climatic parameters, soil water balances computed out of tensiometer readings and river discharges. The importance of soil water drainage for arctic water balances is known (Nagel 1979) but often not considered in hydrological studies (Ryden, 1977; Marsh and Woo, 1981). The application of calibrated tensiometers shortly reported by Fügner (1966) in Spitzbergen was till that time not tested under high arctic conditions. By using this method the results of the causal interpretations of the dependency between the components of the water balance were related to the eastern part of Oobloyah Valley, which could not be investigated because of technical reasons.

INSTALLATIONS, MEASUREMENTS, CALIBRATIONS

The following installations were done: (1) two meteorological stations to register precipitation, air humidity and temperature, direction and velocity of wind; (2) four tensiometer stations on three different slopes (Table 1) with tensiometers and temperature cells at 15-, 30-, 60-, and 90-cm depth and each with 3 evaporimeters 5 cm above the surface; (3) one water level gauge in the periglacial Peri Creek with hourly registrations.

Three streams, the periglacial Peri Creek, the glacial Nukapingwa River, and the mixed perigla-

cial Heidelberg River were investigated. Measurements of soil moistures and discharges were done daily as hourly registration was not possible because of technical reasons and because all measurements had to be done only by the author. The streams showed turbulend flow; therefore the distribution of flow velocity was measured all over the cross section (if possible) with a flow meter out of which the daily discharges were computed.

TABLE 1 Inclination and exposure of the stations

Station	Slope	Inclination	Exposure
Ten A	I	46 %	WSW
Ten B	I	26 %	W
Ten C	II	13 %	S
Ten D	III	6 %	E

To calibrate the tensiometers, undisturbed soil samples from the sediments of each station were drained after saturation in a pressure apparatus. With the resulted exponential calibration equations the measured soil suction in mbar, were converted to adequate soil water contents in volume percent.

HYDROGEOLOGICAL AREAS AND THEIR PHYSICAL PARAMETERS

Oobloyah Bay is a geosyncline developed in Heiberg Sandstone (Thorsteinsson, 1971) situated in the region of continuous permafrost. Therefore common groundwater bodies are non existent. The hydrogeological overview in Figure 1 shows:

(1) sandy debris of Heiberg sandstone covering highly inclined slopes between Carl Troll Glacier and Nukapingwa Glacier; (2) moraine sediments

north of Access Lake with vegetation covered drainage ways among them; and (3) silty sediment between Access Lake, Peri Creek and Heidelberg River

CLIMATE DURING FIELD WORK

The course of the meteorological parameters in Figure 2 monitors little precipitation for July, only 3.7 mm during the whole month; but high precipitations for the first days of August (35.4 mm) with a maximum high of 26.2 mm on August 2. Air temperatures never sank below 0° C and were influenced together with air humidities by the degree

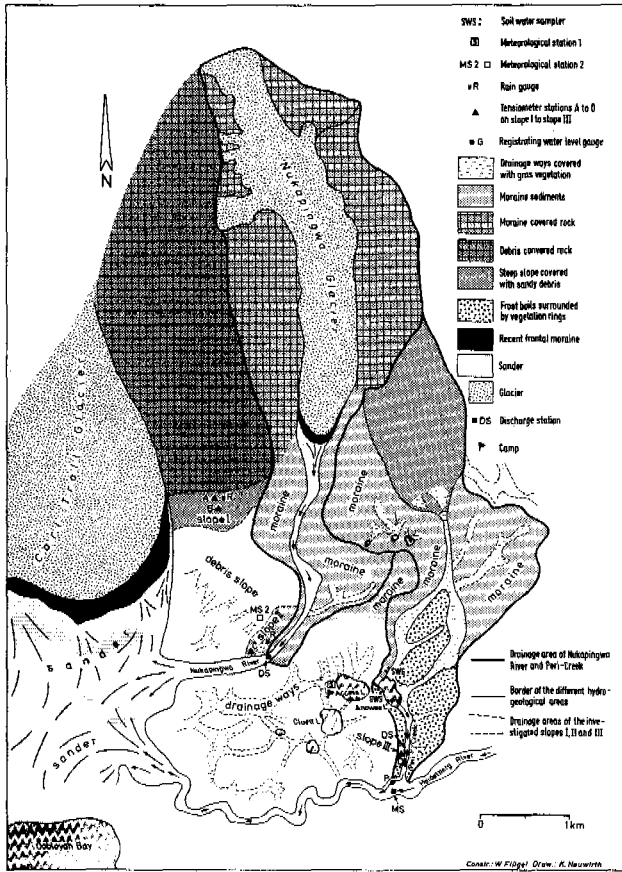

FIGURE 1 Hydrogeological overview

covered with frost boils (Tedrow, 1962, p. 342). Each of them was representatively studied in slope I, II and slope III with mean grain size distributions shown in Table 2.

TABLE 2 Grain size distributions of the slopes

Parameter	Slope I	Slope II	Slope III
Gravel (%)	26.6	27.4	0.5
Sand (%)	35.9	44.6	3.8
Silt (%)	28.5	17.1	62.5
Clay (%)	9.0	10.9	33.2

The sediments of slope I and II had comparable values, but different morphological geneses. Weathering of Heiberg Sandstone is responsible for the debris cover of slope I, glacial transport of moraines for this of slope II (Mäusbacher, 1981). The high amounts of clay and silt of slope III at the valley bottom indicate an aquatic deposition reported by Barsch (1981).

Figure 2 Plot of meteorological parameters

of cloudiness. The following periods will be separated:
 Radiation periods: July 2-6; July 9-10; July 11-15; July 18; July 27-28; July 30-31.
 Cloudy periods: June 25- July 1; July 7-8; July 16-17; July 20-22; July 24-25; and August 1-8.

They regulated the thawing of glacier ice and by that the discharge of melt water. Between June 24 and August 4 we computed
 Mean air temperature, $T = 9.4 \text{ }^\circ\text{C}$
 Mean air humidity, $h = 85.4 \%$
 Mean wind speed, $v = 3.5 \text{ m/s}$
 Sum of precipitation, $P = 50.4 \text{ mm}$

HYDROLOGIC DYNAMIC DURING SNOW MELT

We arrived June 18 in Oobloyah Valley shortly after snow melt began. The expedition area was covered with a nearly 50-cm thick snow layer that had a water content of 37 volume percent, equal to 185 mm rain. This value corresponds to the mean annual precipitation for north Ellesmere Island of 200 mm reported by Hattersley-Smith (1964). Within two weeks, till July 2 nearly all of the snow melted and discharged. Afterward thawing and drainage of the frozen soil began. Although the hydrological

dynamic during snow melt was very complex, the three hydrogeological areas showed significant differences, which can be described as (1) surface runoff with solifluction on steep inclined slopes covered with sandy debris of Heiberg Sandstone; (2) thermokarst phenomena in slopes covered with coarse grained moraines and in older terraces of the Nukapingwa River resulted by infiltrated melt water; (3) surface runoff of melt water in broad drainage ways at the valley bottom which also collected water from the moraines.

The periglacial streams never showed sediment transport, not even suspended load, because melt water flew on the surface of the frozen soil, which was partly protected by a thin ice layer. Washout of fine sand by interflow (Flügel, 1979) was observed downslope of the debris cover north of Nukapingwa River. Measurable solifluction was limited to the period of snow melt and mostly occurred on steep inclined slopes with little vegetation cover.

SOIL MOISTURE BALANCE

Soil tensions were measured with calibrated tensiometers in four stations, representative for the three investigated hydrogeological areas regarding their grain size distributions (see Table 2). Soil moisture in the four stations showed dependency to slope inclination, grain size distribution, and to depth and relief of the permafrost table. Soil suctions had certain characteristics as (1) the beginning values on July 2 were between 0 and 20 mbar, went up during the dry July to maxima between 40 and 250 mbar, but never reached field capacity at 300 mbar; (2) during the high precipitations on August 2-4 (35.4 mm) the instruments of station C and D fell down to 0 mbar indicating water saturation of their active layers; (3) although water input was high enough to saturate also the sediments of station A and B, soil suctions reached only 20 through 50 mbar, indicating that drainage occurred during rain fall resulted by steep inclinations. The soil suctions in each depth were used to compute the average soil moisture content of the active layers of each station as geometric means, shown in Figure 3.

FIGURE 3 Daily soil moisture in station A to D.

Out of Figure 3 and regarding the measured soil suctions the following results will be presented: (1) Drainage of each active layer was almost finished at July 10. (2) The little precipitation that fell in the middle of July compensated evapotranspiration and low drainage. (3) Only the active layers of slope II and III were saturated by the high precipitation on August 2, meanwhile slope I drained also during the rain fall. (4) As field capacity was never reached soil water always moved by gravity, and was not forced by suction gradients.

The sediments lost water by drainage and evapotranspiration. The latter seemed to be limited to the upper 15 cm of the profiles and was computed out of the daily soil moisture balance regarding also the measured soil temperatures up to 0.1 mm per day. This was only 20 % of the mean potential evaporation measured with the evaporimeters.

Most of the drained soil water flew downslope to the receiving streams or drainage ways (Figure 1), but areas covered with frost boils showed a different dynamic. Because under each frost boil a depression developed in the relief of the permafrost table, soil water drained out of the uplifted sediment above flew to the bottom of this mould and couldn't discharge. These areas could not support their streams with drained soil water, what is important for the computation of the yield factor. In Table 3 the soil water balance of each active layer is listed.

TABLE 3 Soil water balance July 2 - August 2.

Parameter	Ten A	Ten B	Ten C	Ten D
Pore volume (%)	40.2	37.2	38.5	59.3
Field capacity (%)	23.2	31.3	18.8	44.1
Active layer (cm)	100	100	80	35
Drainage in July (mm)	40.0	43.0	28.8	13.7
Refill in August (mm)	19.0	28.0	70.4	38.5

Table 3 shows, that soil water drainage during July was much higher than the little precipitations of 3.7 mm indicating that older frozen soil water stored in the year(s) before discharged too and had to be calculated as an additional water input.

DISCHARGE OF STREAMS WITH DIFFERENT REGIMES

Three stream (Peri Creek, Nukapingwa River, and Heidelberg River) were investigated. Their drainage basins were planimetered and those of Peri Creek and Nukapingwa River were mapped in detail during field work (see Figure 1). They can be subdivided as shown in Table 4. Their daily discharges (Figure 4) varied significantly corresponding to their regimes because they had different discharge components (melt water, soil water, and precipitation runoff). Regarding the soil water balances (Table 3) of their hydrogeological areas (Table 4) each discharge regime will be quantified.

Peri Creek

The periglacial Creek showed an exponential falling of daily discharges during the dry July with a little increase on July 16 (2.1 mm precipitation). The falling values are best fitted ($r=0.99$) by the

TABLE 4 Catchment areas of the three streams.

Sediment Area (km ²)	Peri Creek	Nukapingwa River	Heidelberg River
Glacierized	0.00	3.20	38.80
Sandy debris	1.70	4.35	following
Moraines	2.90	2.00	areas all
Silt covered by frost boils	0.90	0.00	together
Drainage ways	0.50	0.00	135.00
Lakes	0.06	0.00	
Total area	6.06	9.55	173.80

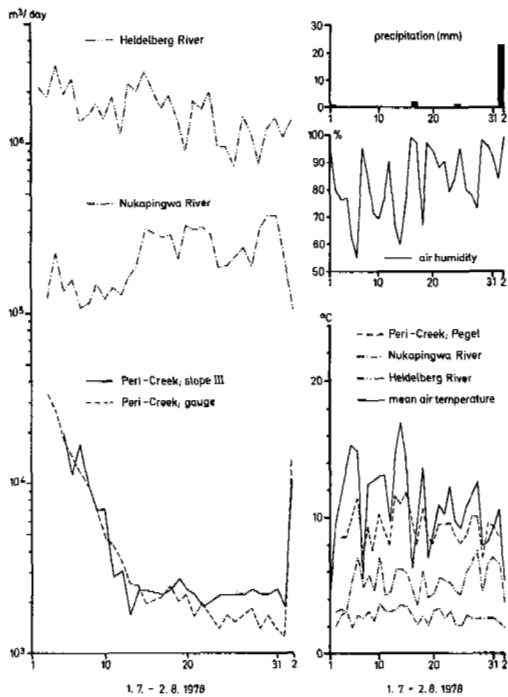

FIGURE 4 Daily discharges of the studied streams.

"Dry Weather Discharge Line" (DWL) in Figure 5 and describes the relation between discharge and duration of dry weather without rain. Baseflow discharge did not limit the DWL, because there was no outflowing groundwater body in this basin with underlying permafrost. By comparing the sum of the computed discharge components with the measured value 10.3 % difference was found, explained by evapotranspiration. Related to the basin area this

Soil water drainage	: 179299 m ³	= 88.7 %
Precipitation runoff	: 22900 m ³	= 11.3 %
Sum of discharge components	: 202100 m ³	= 100.0 %
Measured discharge	: 181200 m ³	= 89.7 %
Difference	: 20300 m ³	= 10.3 %

was about 0.1 mm/day and square meter and corresponds to that value calculated out of the soil water balance.

FIGURE 5 DWL of the Peri Creek

Nukapingwa River

The course of the discharge of this glacial stream is mainly influenced by the climatic changes between periods of radiation and cloudiness. They regulated the thawing of the glacier ice and firn. Radiation periods resulted in an exponential increase of daily discharges, the latter in a corresponding decrease. In Figure 6 they are called "Radiation Weather Discharge Line" (RWL), and "Cloudy Weather Discharge Line" (CWL). RWL and CWL

FIGURE 6 RWL and CWL of Nukapingwa River

describe, how daily discharges went up or sank down in dependency of the duration of radiation or cloudiness. Baseflow out of the glacier storage (clefths filled with water; saturated firn) limited the CWL and supported a minimum discharge from which the RWL begins. Baseflow was calculated out of the low

water discharges during cloudiness up to 0.1 million m³/day. By using the soil water balances of the hydrogeological areas (see Figure 1 and Table 4) the following discharge components were determined:

Run off from snow melt	: 0.255 million m ³	= 4.0 %
Soil water drainage	: 0.172 million m ³	= 2.7 %
Precipitation runoff	: 0.032 million m ³	= 0.5 %
Baseflow discharge	: 3.100 million m ³	= 48.3 %
Radiation discharge	: 2.859 million m ³	= 44.5 %
Total discharge	: 6.418 million m³	= 100.0 %

More than 92 % of the total summer discharge was contributed by melt water from the glacier, which holds water temperatures low.

Heidelberg River

The mixed periglacial-glacial stream drains the eastern part of Oobloyah Valley and a considerable glacierized area of the Krieger Mountains shown in Figure 7. The hydrological regime includes perigla-

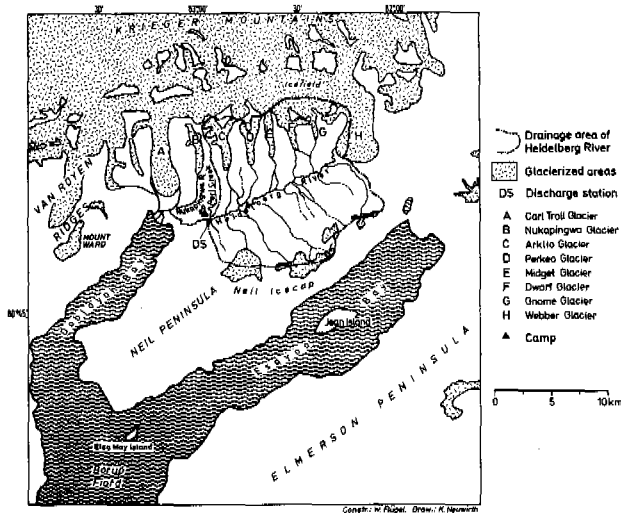

FIGURE 7 Drainage basin of Heidelberg River

cial and glacial components. The periglacial influence stems from the discharge contribution of the periglacial tributaries and is shown by an exponential decrease of low water discharges during July corresponding to the DWL of the Peri Creek. The glacial components are indicated by an exponential increase and decrease of discharges during radiation and cloudiness. Corresponding to the glacial Nukapingwa River a RWL and CWL were defined, both limited by a baseflow of 0.69 million m³, which was melt water coming out of the storage capacity of the glacierized areas. In order to calculate the different discharge components the following random condition was defined, that distribution and soil water balance of the hydrogeological areas of the Heidelberg River corresponds to that of the Peri Creek. This condition can be proved by interpretations of air photographs of the valley and is also supported by re-

ports of Mäusbacher (1981). Employing this random condition soil water discharges of the Heidelberg River were calculated out of the daily discharges of Peri Creek in relation of both land areas. The quotient between the remaining melt water discharge and the glacierized area of Heidelberg River then is approximately the same as that value computed for the Nukapingwa River. This gave an additional support to the prior calculation. The following results were computed:

Runoff from snow melt	: 5.22 million m ³	= 10.6 %
Soil water runoff	: 3.74 million m ³	= 7.6 %
Precipitation runoff	: 2.12 million m ³	= 4.3 %
Baseflow discharge	: 21.01 million m ³	= 42.7 %
Radiation discharge	: 17.16 million m ³	= 34.8 %
Total discharge	: 49.25 million m³	= 100.0 %

Melt water from the glaciers is about 77 %, less than in the glacial Nukapingwa River.

SUMMER WATER BALANCE OF 1978

The computation of the summer water balance is based on the results of the single water balances of the three studied streams under the random conditions: (1) distribution of snow cover and summer precipitation is nearly the same all over Oobloyah Valley; and (2) evaporation from the glacierized areas is comparable to the evapotranspiration estimated from the land areas. Due to a lack of data for the eastern part of the valley and the glacierized areas of the Krieger Mountains (see Figure 7) both had to be defined. My own measurements only supported both of them for the studied region with slope I, II, and III (see Figure 1). The balance had to be subdivided in the duration of snow melt and the following summer period, when the sediments thawed and drained. Input was marked with a plus, output with a minus.

1. Snow melt (20.6.-1.7.1978):

Snow cover, SC	: + 35.04 million m ³
Precipitation, P	: + 2.14 million m ³
Evaporation (0.1 mm/day), E	: - 31.49 million m ³
Discharge, D	: - 31.49 million m ³
Balance computation	: + 5.46 million m³

The resulted plus was unmelted snow, which was brought into the second balance.

2. Water balance July 2 through August 2:

Unmelted snow cover, SC	: + 5.46 million m ³
Frozen soil water, FSW	: + 4.09 million m ³
Precipitation, P	: + 5.66 million m ³
Snow melt discharge, SWD	: - 5.46 million m ³
Soil water discharge, SWD	: - 4.09 million m ³
Precipitation discharge, PD	: - 2.19 million m ³
Baseflow discharge, BD	: - 24.11 million m ³
Radiation discharge, RD	: - 20.02 million m ³
Evapotranspiration, E	: - 0.61 million m ³
Soil water storage, S=P-PD-E	: - 2.86 million m ³
Balance computation	: - 44.13 million m³

This balance shows a minus, resulted by the melt water contribution of the glaciers, which brought an additionally output as a minus factor. Considering the total balance volume input parameters

SC, P, and FSW add up to 38.5 %, 8.5 % and 4.5 %. As evapotranspiration is only about 1.0 %, and soil water storage adds up to 3.1 %, nearly all of the water input discharged. Additionally, the glacierized regions contributed 48.5 % of melt water discharge to the summer water balance.

PHYSICAL AND ECOLOGICAL CHARACTERISTICS OF ALEXANDRA FIORD,
A HIGH ARCTIC OASIS ON ELLESMERE ISLAND, CANADA

Physical and ecological features of an atypically lush high arctic lowland, on Ellesmere Island, are described. Site topography, moisture supply, drainage patterns and radiation input combine favorably to create a highly productive biological oasis amidst a polar desert setting. Growing season radiation and energy balance parameters were higher than those of sites at similar latitudes. Thirteen distinctive lowland plant communities were recognized and divided into a xeric-mesic to mesic lichen-heath-cushion plant dominated series associated with a seasonally discontinuous moisture supply, and a mesic to hydric sedge dominated series associated with a relatively continuous moisture supply. Community species composition, standing crop, and primary production reflected changes in habitat moisture conditions.

GENERAL

This contribution highlights some initial data from a team oriented three year ecological study of a high arctic lowland oasis. The project's objective was to determine and describe the underlying environmental factor(s) contributing to the lowland's diverse and extensive vegetation cover and high productive capacity. The surrounding landscape is characteristically a polar desert/glacier mosaic, with only 46% of the regional study area (ca. 19000 km²) unglaciated (Freedman and Svoboda 1981). Extensively vegetated oases cover only 1-2% of these glacier free sites, a cover percentage comparable to other high arctic regions (see also Murray 1978; Bliss 1981; Aleksandrova 1977). The studies focused on: (1) meso- and micro climate; (2) soil and active layer features; (3) vascular plant community composition, distribution and productivity; (4) autecology of dominant lowland species; (5) vascular plant responses to nutrient, moisture and microclimate enhancement, and (6) breeding bird and invertebrate population dynamics. This paper focuses specifically on meso and microclimatic features and corresponding vascular plant production.

The lowland study site is located adjacent to Alexandra Fiord (78°53'N, 75°55'W), on the eastern coast of central Ellesmere Island, Canada. The site is a relatively flat, roughly triangular periglacial outwash plain covering 8.0 km². The lowland is enclosed by a glacier at its southern extreme; by steep talus slopes and cliffs of a 500 m high eastern and western upland complex; and by the fiord waters along its northern margin.

PHYSICAL CHARACTERISTICS

Total annual precipitation in the region is less than 6 cm and typically less than 1 cm during the growing season (July - August). The relatively insignificant annual moisture contribution, coupled

with rapid runoff of snowmelt, creates xeric growing conditions on the bordering upland desert sites. The lowland has a large influx of meltwaters in the early part of the growing season, the magnitude of which is proportional to the annual variation in winter snowpack accumulation. In 1981, there was little snowpack accumulation in winter, and the lowland was almost snowfree by the first week of June. In 1982, with a more typical snowpack regime, only 6% of the lowland was snow free by May 31; 12% by June 7; 47% by June 13; and 90% (following a chinook) by June 16. Isolated snowbanks persisted until June 25. During the remaining course of the growing season a relatively regionalized but continuous moisture supply of glacial and upland meltwater origin prevails. Thus, the lowland shows characteristic features of a hydrologic oasis in a polar desert setting.

Based on a number of energy budget parameters, the lowland also shows evidence of being a thermal oasis. During the growing season both mean daily incoming shortwave and longwave radiation were considerably higher at Alexandra Fiord than in two comparable regional locations (Table 1). This is partly due to consistently clear skies associated with the presence of a persistent summer high-pressure zone over northern Greenland and north-eastern Ellesmere Island. A small indirect lowland short-wave radiation component was measured from the glacial and fiord surfaces. Similarly, the dark cliff walls of the adjacent uplands contribute an additional long-wave radiation component to the lowland's energy budget. This "oven effect" has been observed and described from a similar lowland setting on northeastern Devon Island (Courtin and Labine 1977).

Net all-wave radiation was consistently higher in the lowland than on either an adjacent upland barrens site or a site (Eureka) 220 km northwest (Table 2). The differences between the Alexandra Fiord lowland and upland are largely due to differences in albedo, while variations in both incoming radiation and albedo contribute to the Alexandra

Fiord and Eureka differences.

Growing season air temperatures were higher in the lowland than at the unvegetated upland plateau and adjacent coastal lowland sites (Table 3). Lowland monthly air temperatures, with the exception of August, were higher than those at Eureka. Lowland soil surface temperatures were higher during the growing season, than in the upland site, but subsurface (-10 cm) temperatures were similar (Table 4).

Measurements were taken of significant energy budget parameters in two dominant lowland communities - mesic heath and hydric sedge meadow. Use of a roving meteorological station (Campbell Scientific CR-5) prevented simultaneous monitoring of both sites. It is therefore appropriate to compare the relative partitioning of net radiation (Q^*) into soil heat flux (G), latent heat flux (LE) and sensible heat flux (H), rather than the absolute values of these parameters. Analysis of the data show G to account for 15% of Q^* in the heath and 11% in the sedge meadow, while LE accounted for 26% and 22% at the two sites respectively, and H accounted for 59 and 67% respectively. The ratio of H and LE (= Bowen ratio) is typically high for tundra areas (Barry et al. 1981; Ohmura 1982), and was 2.3 for the mesic heath and 3.0 for the hydric sedge meadow.

PLANT ECOLOGICAL CHARACTERISTICS

The general characteristics of the thirteen distinctive lowland plant communities are summarized in Table 6. A similar series of communities has been described for another high arctic oasis on Devon Island (Barrett 1972; Muc and Bliss 1977). Spatially, these communities are segregated into a complex mosaic according to interrelated patterns of microtopography, drainage, snow persistence, and substrate characteristics. The majority (70%) of the lowland is covered by communities dominated by lichens, heaths, cushion plants, and dwarf shrubs. Soil moisture conditions are typically xeric to mesic, and mid-July active layer development (ca. 70% of peak season depth) averaged 40 cm. The dominant species are woody, long lived (>100 years), slow growing, vegetatively spreading, and possess high proportions (69% of total biomass in Cassiope tetragona, and 81% in Dryas integrifolia) of attached dead tissue. The latter component may help maintain microhabitat moisture, and facilitate in situ nutrient cycling (Svoboda 1977). Total vascular plant standing crop averaged 412 g m^{-2} , with net production averaging $18 \text{ g m}^{-2} \text{ y}^{-1}$. Species net production: total biomass ratios (P/B) were quite low: 0.02 for C. tetragona, 0.02 for D. integrifolia, 0.05 for Saxifraga oppositifolia and 0.07 for Vaccinium uliginosum.

Approximately 20% of the lowland is covered by sedge dominated communities, and mosses are an integral but minor component in these. Sites range from mesic to hydric, and mid-July active layer depths averaged 37 cm but thawed as deep as 80 cm by late August. Dominant species are Carex stans, C. membranacea, C. misandra and Eriophorum angustifolium. These perennial, shorter lived, herbaceous plants maintain the majority (81%) of their biomass below ground. Total aboveground

standing crop averaged 337 g m^{-2} and net production averaged $27 \text{ g m}^{-2} \text{ y}^{-1}$. Graminoid P/B ratios were low: 0.18 in C. stans, 0.17 in C. membranacea, 0.15 in C. misandra and 0.18 in E. angustifolium. Although maintaining less aboveground biomass than drier tundra communities, wet sedge meadows are typically more productive (Babb and Bliss 1974, Muc 1977, Brown et al. 1980, Bliss et al. 1981).

The remaining 10% of the lowland is almost equally divided between aquatic (rivers, streams, ponds) and ruderal (human, water or ice modified) habitats. Aquatic habitats possess little to no vascular vegetation. The ruderal sites are generally mesic to mesic-xeric in nature and develop mid-July active layer depths of 27 cm. The diverse vegetation is dominated by short-lived, herbaceous species in which standing crop averages 12 g m^{-2} and production averages $5 \text{ g m}^{-2} \text{ y}^{-1}$. Corresponding P/B ratios are high: 0.71 in Cochlearia fenestrata, 0.50 in Cerastium alpinum, and 0.35 in Draba groenlandica (Maessen et al. 1983).

In conclusion, our study demonstrates that within the overall expanse of high arctic desert, relatively lush oases can exist. This appears to be caused by an environmental amelioration in terms of hydrology and meso- and microclimate.

A STUDY OF THE EVOLUTIONARY HISTORY OF PERMAFROST IN NORTHEAST CHINA
BY A NUMERICAL METHOD

Fu Liandi, Ding Dewen, and Guo Dongxin

Lanzhou Institute of Glaciology and Cryopedology, Academia Sinica
People's Republic of China

Based on the essential principles of the unity of formation and the difference of existing conditions of permafrost, the comprehensiveness of freezing processes and the relative independence of each subprocess, the continuity (irreversibility and relative stability) and rhythm of the freezing process, the particularity of contradiction and the main contradiction of freezing processes, and the selection of parameters and mathematic models for the description of freezing processes, and taking contemporary permafrost in large blocks in Northeast China as an example, the authors quantitatively reconstruct the evolutionary history of permafrost in China. Results indicate that the average thickness of permafrost in large blocks was 120 m in the Gu Xiangtun periglacial age. Except in the northern regions, permafrost disappeared during the high-temperature period. The average thickness of contemporary permafrost is approximately 75 m. The data obtained from analyses of the paleoclimate and paleoglacial relics are identical to the data obtained from current field explorations. This method may also be used for other types of permafrost and regions. As long as the change of air temperature is given precisely, the development of permafrost can be successfully predicted.

THE ESSENTIAL PRINCIPLES FOR ANALYZING THE
EVOLUTIONARY HISTORY OF PERMAFROST

From the physical point of view, permafrost is a geological-geographical system that exists on the surface of the earth's crust and keeps in frozen state. In permafrost, the process of heat motion, including phase change, is in a special stage that has an inherent form of energy conservation and a distributive law of quantity. The change of energy within certain limits evolves the history of permafrost and correspondingly the change of its regional distribution, including the change of its thickness, and occurrence and change of its phenomena.

According to our understanding, analyses of the evolutionary history of permafrost should be based on the following essential principles (Ding Dewen and Guo Dongxin 1982).

UNITY OF FORMATION AND THE DIFFERENCE OF
EXISTING CONDITIONS OF PERMAFROST

When the interaction of energy and substance between soils (or rocks) and surroundings reaches a critical state, or when the annual mean ground temperature reaches the freezing point, permafrost forms. On the other hand, the annual mean ground temperature varies with geological, geographical and geophysical conditions, even in the same region and within different periods, or in different regions and within the same period.

CONTINUITY (IRREVERSIBILITY AND
RELATIVE STABILITY) AND RHYTHM
OF FREEZING PROCESSES

In permafrost, each substance in different grade and its motion have an evolutionary history of their own. The interaction between factors or processes (including feedback) evolves irreversibly. But freezing processes have a relatively steady stage (correspondingly the stage of quantitative change) and a certain change of rhythm regularity (non-periodicity) because of the change of the main energy source and the contradictory feature in the inner system.

PARTICULARITY OF CONTRADICTION
AND THE MAIN CONTRADICTION
OF FREEZING PROCESSES

Freezing action is one of the changes occurring on the surface of the earth's crust. It becomes a special lithification in permafrost regions, and produces specific permafrost (geomorphological) phenomena and characterizes a specific geographical view (landscape) in which heat motion, including phase change, plays a leading role. Therefore, heat motion can be considered to be a physical process (especially the transportation) that evolves under a certain natural-historical condition.

SELECTION OF PARAMETERS AND MATHEMATICAL MODELS TO DESCRIBE FREEZING PROCESSES

Because freezing processes are a chain of continuous changes of state, choosing the thermodynamic state parameters to describe them is reasonable. Under the case of no external electromagnetic field, choosing the parameters of pressure (P), volume (V), temperature (T), and humidity (W) is enough. Furthermore, because both processes of temperature and phase play a leading role in the evolution of permafrost, and the process of phase change can be objectively described by isotherm, freezing processes can be described by temperature and humidity fields. In the case, the four parameters: the hydraulic conductivity (K), the thermal conductivity (λ), the thermal diffusivity (a) and the volumetric heat capacity (C) are the main parameters. The mathematical models of processes in one dimension can be expressed as follows:

$$\frac{\partial t^i}{\partial \tau} = a^i \frac{\partial^2 t^i}{\partial x^2} \quad (1)$$

$$\frac{\partial W^i}{\partial \tau} = K^i \frac{\partial^2 W^i}{\partial x^2} \quad (2)$$

Where X is the coordinate; τ is time; i represents phase state: "-" freezing, "+" thawing.

Then,

$$X=h, t^- = t^+ = t^*, W_H = W_0 - W^i \quad (3)$$

$$\lambda^- \frac{\partial t^-}{\partial x} - \lambda^+ \frac{\partial t^+}{\partial x} = L \gamma_0 (W_H + \Delta W) + \frac{1}{2} C t_0 \frac{dh}{d\tau} \quad (4)$$

$$K^+ \frac{\partial W^+}{\partial x} - K^- \frac{\partial W^-}{\partial x} = \Delta W \frac{\partial h}{\partial \tau} \quad (5)$$

Where γ_0 is the dry density of soils; W_0 is the initial water content; W is the quantity of moisture migration per volume, and L is the latent heat.

The initial and boundary conditions can be given out according to features of concrete problems (to set up the condition of the determinative solution).

A DETERMINATIVE SOLUTION FOR THE EVOLUTIONARY HISTORY OF PERMAFROST IN NORTHEAST CHINA

According to our data and those of our predecessors, strata in Northeast China could be divided into two combinations of spore pollen for the periods of the early, middle and late Pleistocene and three for the Holocene. It showed that the climate in this region varied alternatively many times, from cold to warm, from dry to humid, and vice versa and that the fre-

quency of the climate change and the general tendency were the same in the whole region. Permafrost in this region evolved on the background of the climate conditions and formed a general pattern of evolution.

Under influences of the structural system and structural motion within periods of Yian Shan and Himalaya, not only did the local geological, geographical, geomorphological and geophysical conditions tend to be complicated, but also the evolution of permafrost became complicated, among which magma activity and basalt eruption had tremendous influence resulting in higher terrestrial heat, different motion of the earth's crust, and the migration and deposit of the river system, etc.

The component, structure, temperature and thickness of permafrost and its phenomena are representative indexes or marks of freezing processes. According to the data, including the change of palaeoclimate reflected by change of combinations of spore pollen, the relics of paleo-periglacial structures and the change regularity of air temperature with latitude, we can outline the evolution of permafrost as starting from the Gu Xiangtun glacial age in the late Pleistocene, passing through the high temperature period and minor-glacial age in the Holocene, and still developing up to now. In Northeast China, frozen ground can be divided into four types: continuous permafrost in large blocks, permafrost in island-like taliks, island-like permafrost and seasonally frozen ground, all controlled mainly by solar radiation and reflecting obviously the regularities of the horizontal zonation (Guo Dongxin and Li Zuofu, 1981).

The evolution of permafrost in Northeast China can be divided into the following four stages:

First, the late Pleistocene, in which the south limit of continuous permafrost was located near that of contemporary permafrost and reached the San Jiang plain. The south limit of island-like permafrost was situated to the north of Qian Guangtu in the town of Ao Han.

Second, the end of the high temperature period, in which the permafrost all over the region thawed except for sporadic permafrost remaining in the bottom of valleys or wet low-lying land north of Man Gui.

Third, the minor-glacial age, in which the permafrost formed again and reached the south of Man Gui, and superimposed on old permafrost in the North of Man Gui.

Finally, now-a-days, in which contemporary permafrost formed gradually.

Taking contemporary continuous permafrost in large blocks as an example, we reconstruct the evolutionary history of

permafrost quantitatively by using numeric method and equations of temperature field, since the thickness of Quaternary strata is very thin and permafrost belongs to the epigenetic type. Conditions of the determinative solution are as follows:

Geometric and Physical Conditions

The section of strata consists of sandy clay from 0 to 10 meters and granite from 10 to 350 m (the depth of the lower boundary is determined by the transmitted depth of temperature wave in the Gu Xiangtun periglacial period). Physical indexes are as below*:

$$\begin{aligned} \gamma_0 &= 1600 & \lambda^- &= 1.66 & C^- &= 504 \\ W &= 0.25 & \lambda^+ &= 1.47 & C^+ &= 600 \\ W_H &= 0.025 \\ \gamma_0 &= 1800 & \lambda^- &= 2.63 & C^- &= 477 \\ W &= 0.02 & \lambda^+ &= 1.88 & C^+ &= 666 \\ W_H &= 0 \\ Q &= L\gamma_0 (W - W_H) \end{aligned}$$

*Dimensions are in the system of meter, kilogram, hour, and kilocalorie.

Initial and Boundary Conditions

According to the data of the absolute age of strata and of the paleontological fossils, permafrost was well developed in the Gu Xiangtun periglacial age. After that, it disappeared in many places in the interglacial period between the Gu Xiangtun and Dong Gan glacial ages. Therefore, the starting point of computation is 30,000 years ago. The initial conditions of temperature are:

$$\begin{aligned} t(0,0) &= 0^\circ\text{C} \\ t(x,0) &= t(0,0) + gx \end{aligned} \quad (6)$$

Where g was the geothermal gradient in 1/30 degree per meter.

From equation (6), the temperature of the lower boundary was $t_H = gH - 11.7^\circ\text{C}$.

According to the data of paleontology of relics of paleo-permafrost and of contemporary differences between ground-surface temperature and air temperature, conditions of the upper boundary can be estimated as follows:

$$t(0,\tau) = \begin{matrix} -6.0^\circ\text{C} & 30 \tau & 12 & \text{thousand} \\ -3.0 & 12 \tau & 8 & \text{years B.P.} \\ 2.0 & 8 \tau & 2.5 & \\ -3.0 & 2.5 \tau & & \end{matrix}$$

COMPUTATIONAL METHODS AND ANALYSES OF RESULTS

The problem of heat conduction with one dimension mentioned above is computerized by the following format of all-implicit difference:

$$T_j^{n+1} = \frac{1}{h^2 C} (T_{j+1}^{n+1} - T_j^{n+1} + T_{j-1}^{n+1}) + T_j^n \quad (7)$$

Where τ is time step; h is space step; n is time of points in the computational net and j is position of points in the computational net.

Cutting-off error is $E=O(\tau) + O(h^2)$

Although the accuracy of the format has only one grade, the choice of time step τ is not limited by the stability because the state of the temperature field needs to be computerized for 30,000 years. Furthermore, for such a diffusive problem, choosing the implicit format agrees more with the physical model, and for solution of linear equation, three pairs of the angle matrix also have the effectiveness of the tracing method with no requirement for computational time and storage spaces. Therefore, the all-implicit format is suitable for solving the problem of heat condition in one dimension.

In computation, the treatment of parameters is as follows: the thermal conductivity λ and the volumetric specific heat C are constants in the frozen and thawed regions respectively, but vary with soil (or rock) properties. In the phase change region, we have $\lambda^* = \frac{1}{2}(\lambda^- + \lambda^+)$ and $C^* = A + \frac{1}{2}(C^- + C^+)$, where A is the amount of latent heat in the range of -1°C to 0°C . Consequently,

$$\begin{aligned} \lambda^- & & t & -1^\circ\text{C} \\ \lambda = \frac{1}{2}(\lambda^+ + \lambda^-) & & t & -1^\circ\text{C} \text{ to } 0^\circ\text{C} \\ \lambda & & t & 0^\circ\text{C} \\ C^- & & t & -1^\circ\text{C} \\ A + (C^- + C^+) & & t & -1^\circ\text{C} \text{ to } 0^\circ\text{C} \\ C^+ & & t & 0^\circ\text{C} \end{aligned}$$

Computational results are shown in Table 1.

From Table 1, we can see that in the Qu Xiangtun periglacial age, the thickness of continuous permafrost in large blocks was 120 m on the average and more than 150 m in northern regions. In the high temperature period, permafrost disappeared except for the northern regions, in which permafrost remained in the thickness from 0 to 20 m. Permafrost has developed again since the minor glacial age. The thickness of contemporary permafrost is approximately 75 m on the average and 100 m for individual cases in northern regions. The results obtained from the analyses of paleoclimate and paleoglacial relics is identical with the data obtained from present-day field exploration.

The freezing process can be expressed by the following formula:

$$H = \left[\left(\frac{q\tau}{2a} \right)^2 + \frac{\lambda\tau t_0}{2a} \right]^{\frac{1}{2}} - \frac{q\tau}{2a} \quad (8)$$

where $a = LW\gamma_0 + \frac{1}{2}Ct_0$

TABLE 1 Frost Penetration Depth With the Change of Time

Time, years B.P.	29,900	29,500	29,000	28,000	25,000	12,000	10,000	8,000	3,000	2,000	Present
Frost depth, m	10	50	95	105	115	120	75	70	0	55	75

From formula (8), we can see factors affecting the development of permafrost and relationships between them. When heat flow caused by the change of ground-surface temperature inverts, or when the heat flow changes the direction from output to input, permafrost will be thawed in two directions.

The heat in the interior earth plays a leading role in the thawing process of permafrost.

Permafrost can not be developed unless the condition of $\frac{\tau \lambda t_0}{2a} \left(\frac{q\tau}{2a} \right)^2$ is satisfied.

The greater the absolute value of negative temperature on ground-surface is, the faster it will develop.

If the change of the heat flow is not great, the evolution of permafrost will be mainly controlled by the air temperature and soil (or rock) properties. If the soil (or rock) properties are the same, air temperature will become the main

factor and the distribution of permafrost has the obvious regularity of zonation.

In conclusion, the method can also be used for other types of permafrost and regions, and as long as the change of air temperature is given precisely, the prediction of the development of permafrost can be done successfully.

ULTRASONIC VELOCITY IN FROZEN SOIL

Fu Rong, Zhang Jinsheng, and Hou Zhongjie

Lanzhou Institute of Glaciology and Cryopedology, Academia Sinica
People's Republic of China

The propagation velocities of ultrasonic dilatational and shear waves in frozen Lanzhou medium sand and frozen Tibet clay samples were measured at different water contents and temperatures using the SYC-2 sonic wave detector. The variation of sonic velocity with water content and unit weight substantially depends upon the type of soil. In coarse-grained frozen soil, the sonic-wave velocity consistently increases with increasing water content, while in frozen clayey soil, it decreases with increasing water content in the low water content range, then starts to increase with a fluctuation, and finally increases steadily up to the ultrasonic velocity in ice. Tests indicate that the ultrasonic velocity increases with decreasing temperature. Based on this investigation, the authors consider that ultrasonic detection techniques can be used to determine the physical and mechanical properties of frozen soils, such as water content, density, elastic modulus, and Poisson's ratio.

INTRODUCTION

Temperature, moisture (including ice and unfrozen water) and soil structure directly affect various characteristics of frozen soils. To study how these various factors influence properties of frozen soils, we used ultrasonic measurement techniques. An understanding of how water content influences the variability of ultrasonic velocities in frozen samples, was based on tests performed on red clay of Qinghai-Xizang and medium sand of Lanzhou.

INFLUENCE OF MOISTURE ON CHARACTERISTICS OF FROZEN SOIL

A high enough temperature, but still below 0°C, when a large part or all of moisture is unfrozen in soil, characteristics of the soils have no apparent difference in comparison with its under normal atmospheric temperature. As the total water content exceeds the amount of unfrozen water, ice crystals will grow in the frozen soils, bonding the soil particles together. The ice forms a firm soil skeleton structure that causes a great change in characteristics of soils after freezing. Therefore, the strength and elasticity are related to the amount of ice present. In general, the quantity of ice depends upon the total amount of water contained in frozen soils. Therefore, the physical-mechanical properties of frozen soils relate directly to water content.

Pore water can exist in different forms, as either free water or bound and osmotic (loosely bound) water in unfrozen soil. In freezing process, the water

plays different role, with its form different, and the role change with different grain size of soil. As a result, a change of the soil structure occurs. The finer the soil particles, the larger the effect (Thomas et al. 1971). In fact, the smaller the grain size of soil particles, the larger the surface area, and also, the larger its capacity of maintaining unfrozen water (Anderson and Tice 1972). Apparently, as the grain size of soils changes same water content has different influences upon the physical characteristics of frozen soils.

Using a SYC-2 sonic wave detector, we determined ultrasonic velocities and obtained sonic wave propagation speed (Fu Rong et al. 1980) for frozen soils with different properties (temperature, water content and density). In combination with previous measurements (Zhang Jinsheng and Fu Rong 1981) of unfrozen water content, we indirectly established a relationship between sonic wave speed, ice and unfrozen water content.

Appropriate quantities of distilled water were added to dried specimens of sandy soils to obtain samples with various water content as high as the saturated state. Clay samples with the water contents below the liquid limit will be drier than specimens with water content near liquid limit in the shade, hence they had similar dry density regardless of moisture content. Those with water content above liquid limit are directly made up in the similar way.

The samples were prepared in a cylindrical form with a diameter of 5 cm and a high of 5 cm. They were then frozen in a cooler maintained between -20°C and -30°C. After freezing, prior to testing, they were

Medium sand of Lanzhou for construction	2.65			1.36	6.1	0.05

brought to the desired temperature in a thermostatically controlled chamber (degree of accuracy $\pm 0.1^\circ\text{C}$).

The main analytical results of the Medium Sand of Lanzhou and Red Clay of Qinghai-Xizang are shown in Tables 1 and 2.

In the course of measurement, test sample is put on the loading frame specially made, and a pressure about 0.5 kg/cm^2 is exerted to guarantee close contact between sample face and sensor or transducer. couplant is water. In low temperature, the water will freeze and become ice, and couple the sensor and transducer with the sample face together.

ULTRASONIC WAVE VELOCITY IN FROZEN SANDS

The grain size of sands is comparatively large, so the effect of the unfrozen water content can be neglected.

Under a comparatively dry state, increasing moisture in sands does not change its soil skeleton structures: Therefore, the density increases with the increases of water content. When water content is rather high, near saturated state, freeze will result in bulk expansion and displacement among sand grains. If the water content increases unlimitedly, the density will decrease and finally approach that of the ice. At lower moisture contents in

the sands, the influence of ice volume on sonic velocity is small. The sonic wave speed chiefly depends on the sand and its grain contact conditions. With increase in ice content, not only does the density of frozen sand increase due a larger volume of pores being ice filled, but also the structure becomes more solid due to cementation by the ice. These two aspects tend to influence sonic wave propagation. As a result, sonic wave velocities increase with increased density (Figure 1).

For the single factor of water content, when the increment of moisture results in the ice fill-degree in frozen sand approaching to one, its action for increasing sonic wave speed comes to a fixed value. Hence the increasing rate of wave speed gradually decreases. The relationship between them can be expressed as a parabolic curve (Figure 2). In logarithmic coordinates, they are two groups of parallel straight lines. Since the acoustic impedance is equal to the product of the density and the sonic wave speed, the impedances of dilatational and shear waves ρV_p and ρV_s are mutual parallel straight lines, too, in logarithmic coordinates.

Because the density includes the two factors of moisture and structure, the relative lines between the sonic wave speed and the density and between the sonic wave speed and the water content differ greatly.

FIGURE 1 Relations between ultrasonic velocities and density, in the frozen consolidated samples of two frozen soils.

FIGURE 3 Changes of ice content, unfrozen water content and ultrasonic velocities versus temperatures.

FIGURE 2 Relations between ultrasonic velocities and water content in the frozen consolidated Medium Sand of Lanzhou for construction.

SONIC WAVE VELOCITY IN FROZEN CLAYEY SOILS

Differing from coarse-grained soils, the moisture in fine-grained soils can disperse soil grains, so that with the increase of water content, the density of soils decreases gradually, and there is a part of unfrozen water existing in the soil after freezing (Figure 1). Since ice crystals strengthen the integrity of the soil skeleton structure and tend to propagate sonic waves, and the unfrozen water content is in relation to temperature, the sonic wave speed and the ice content as well as the unfrozen water content change with negative temperature (Figure 3).

FIGURE 4 A sketch shown the changes of ultrasonic velocities versus water contents in the Red Clay of Qinghai-Xizang.

Under dry status, the sonic wave speed of fine-grained soils depends mainly upon the integrity of the structure, and the change of temperature has almost no influence on it. When the water content is very low, there are no ice crystals in soils under negative temperature. Increasing moisture can only thicken the unfrozen water film in soils, so that the soil skeleton structure is loosened. In addition, the propagation speed of sonic wave in water is comparatively low (about 1.5 km/sec). Thereby, with the increase of water content, the sonic wave speed decreases.

Within the whole changing process of sonic wave speed versus water content, the sonic wave speed is the lowest in the stage indicated by section AB in Figure 4.

When the water content is greater than the amount of unfrozen water, ice crystals will appear in soils. With the increment of water content, ice crystals fill-degree in voids will also increase gradually. Since the total amount of water content is smaller, the change of moisture does not result in the displacement of relative positions of soil grains, and the soil porosity maintains a certain constant value, and the sonic wave speed depends only on the fill-degree of ice crystals in voids. In this stage, the sonic wave speed increases with the increase of water content, shown by section BC in Figure 4.

It can be seen that the turning point B from section AB to section BC is just the mark occurring ice crystals in fine-grained soils.

According to this principle, the amount of unfrozen water in soils can be roughly estimated by the measurement results of sonic wave speed.

Surpassing section BC in Figure 4, the water content continues to increase and partial moisture in soils begins to crystallize in voids with the lowest pressure. When ice crystals reach a certain extent, the film water will shrink back or occupy a new position along with the frozen front. At this time, soil particles become crumby granular and are surrounded by ice (Orlov et al. 1977). The magnitude of sonic wave speed depends upon the state and size of crumby-granular structures of soils, the size of voids among them, and the condition of ice fill-degree in the voids (Fu Rong et al. 1982).

When the water content of soils is greater than the shrinkage limit, the moisture will disperse soil grains to increase soil porosity and decrease the density as well as the probability of occurring ice crystals in soils increased in freezing with the increment of water content, the structure among ice-wrapped bodies tends toward loosening. In other words, with the increase of the density of ice crystal distribution, the ties among soil crumbs are gradually weakened and the sonic wave speed decreases, too. When it arrives at a certain limit, continuing to increase water content will increase both the ice fill-degree in voids and the sonic wave speed. Therefore, with the increase of water content, values of the sonic wave speed change from high to low and back again to high. Nevertheless, after the sonic wave speed reaches a certain high value in this picking-up process, the increment of water content provides a more advantageous condition for ice formation. But the increase of the density of ice crystal distribution in soils results in further weakening of the bonds between soil crumbs. Then the sonic wave speed again tends to descend, and the above mentioned process reappears. However, at this time the size of the soil crumbs

(ice-wrapped bodies) is much smaller than that of the last period.

Obviously, with the increase of water content, values of sonic wave speeds fluctuate. The soil crumbs gradually become smaller until the soil grains are separated by ice crystals and suspended in ice. After that the change of water content will not lead to the fluctuation of sonic wave speed, and with the decrease of density of soils after freezing, the sonic wave speed approaches that of ice.

SEVERAL VIEWPOINTS

Under the case of adopting the pulse method to measure ultrasonic velocity in frozen soils, the instantaneous energy exerted upon samples is very big. But the loading and unloading rates are great, and the frozen soil is neither able to yield plastic flow, nor to have the needed time for developing plasticization, hence it is in a pure elastic status. On the basis of the sonic wave velocity, according to elastic theory, the basic parameters of mechanics, elasticity modulus, and Poisson's ratio can be obtained. These parameters are very difficult to be precisely determined by traditional methods of statics.

Acoustic impedance is another important index to reflect the fundamental qualities of frozen soils. If it is possible to measure the sonic wave speed and at the same time to survey the acoustic impedance, then the density of frozen soils will be known.

Utilizing correlation course between the sonic wave speed and density and moisture, can give the density (unit weight) of frozen soils and the water content in some soils.

How to make use of ultrasonic velocity to test precisely various physical and mechanical indexes and fundamental parameters in frozen soils is still an important subject in the future. However, this method undoubtedly has its bright prospect in the study of frozen soils and on practice of engineering.

CONCLUSION

1. In frozen soils, sonic wave speed relates to the state of moisture, and its correlative law varies with the diameter of the soil particles.
2. Comparing the change regularity of sonic wave speeds with the unit weight (or density) and moisture can analyse conditions of the frozen soil structure.
3. Measuring ultrasonic velocity can determine elasticity modulus and Poisson's ratio.
4. Utilizing the correlative law of sonic wave speeds can approximately determine the unit weight of frozen soils and water content in coarse-grained soils.

5. The complicated changing of the ultrasonic velocity with water content in frozen fine-grained soils reflects the multi-variation character of frozen soil structures.

ANALYSIS AND CHARACTERISTICS OF CORES FROM A MASSIVE ICE BODY IN MACKENZIE DELTA, N.W.T., CANADA

K. Fujino, K. Horiguchi, M. Shinbori¹ and K. Kato²

¹Institute of Low Temperature Science, Hokkaido University, Sapporo, 060 Japan

²Water Research Institute, Nagoya University, Nagoya, 464 Japan

Distinctive ground features such as polygons, pingos and involuted hills are commonly observed in the arctic regions. Their origins and formation processes remain in question. A massive ice body at Tuktoyaktuk was analyzed to determine its origin. Stratigraphic studies of fabrics, chemical components such as oxygen isotopes, conductivity and pH of core samples of the massive ice body, were investigated.

The results obtained suggest that most parts of the massive ice body originate from superimposed ice by congelation of water in which a snow pack is submerged, and do not support the hypothesis that it is segregated ice. The mechanism of the growth of a massive ice body is also not identical to that of the growth of a pingo in which segregated ice constitutes the core.

INTRODUCTION

Distinctive ground features such as polygons, pingos and involuted hills are commonly observed in the arctic regions, especially around Tuktoyaktuk, Mackenzie Delta, N.W.T., Canada.

Their origins and formation processes remain in need of analysis,^{1,2} but the fact that large ice bodies are found underneath them suggests that water supply from various sources related to long- and short-term climatic conditions plays an important role in their formation.

Stratigraphic studies of ice fabrics and chemical components such as oxygen isotopes, were carried out to find the origin, the formation mechanisms and characteristics of the massive ice body at Tuktoyaktuk, using core samples which were obtained throughout the massive ice body.

SAMPLING

The massive ice body is located, as shown by  in Fig. 1, along a seacoast about 4.5 km southwest of Tuktoyaktuk, Mackenzie Delta, N.W.T., Canada. It was investigated during the joint research expeditions of 1977, 1980 and 1981.^{3,4,5}

FIGURE 1 Location map of Tuktoyaktuk area.

: Sampling site.

Using a newly designed electromechanical core-drill, three holes were drilled into the massive ice body from near the top and continuous cores were obtained in March 1982. One of the holes which were cored throughout the massive ice body, was about 23 m in total length including a 40-cm-thick sand layer of the bed. Cores were arranged and labeled in serial order, put in refrigerated containers and transported to the cold laboratory of the Institute of Low Temperature Science, Hokkaido University, where the following preparations were made.

Stratigraphic features of the cores were described along their entire length, such as bandlike structure, bubble distribution, impurity inclusion, etc. Each piece was cut into halves along the vertical axis. One half was cut perpendicular to the axis at an interval of 10 cm, from which horizontal and vertical thin sections were prepared for the investigation of crystal orientations. Meanwhile, the other half was cut perpendicular to the axis at an interval of 2.5 cm, from which samples were prepared for the determination of oxygen isotopes, conductivity, pH and bubble pressure. Moreover, soil between strata which formed a boundary of the bandlike structure, as well as any impurity inclusions were also prepared for qualitative analysis.

ANALYSES

Characteristics of Stratigraphy and Crystallography

A schematic description of the entire length of core obtained from a single hole is shown in Fig. 2. As is clear from the figure, many bandlike structures, which were separated by sediment, were observed. A stratification defined by bubble-rich layer and bubble-free, clear layers were observed along the entire length of the core, although the inclination and thickness of each layer were not consistent.

Sediment contained in layers between two adjacent ice strata varied and consisted of sand, clay, silt or their mixtures. Also, the configurations of the sediment had various forms, one looked to be

suspended in the ice (Fig. 5), another looked like thick sediment settling down on a concave-convex surface (Fig. 4), a third looked to be trapped on the surface of a snow pack (Fig. 3).

Crystals in each stratum were clearly different in size, shape and c-axis orientation. Strata could be divided roughly into the following three types: (1), strata of granular ice crystals which are commonly observed in a snow pack, having the nearly homogeneous grain size averaging 0.5 cm and being arranged with random orientations (Fig. 6). (2), those of medium size ice crystals having nearly rectangular shapes averaging 2-3 cm on the long axis and being arranged with some orientation (Fig. 7). (3), those of large ice crystals of more than 10 cm, the whole section of the stratum of being occupied by only one or two large crystals (Fig. 8). Distributions of the c-axis orientation of crystal in strata are now being measured. But from the results obtained so far, they seem to be comparatively random except within strata of large crystals.

Distributions of air bubbles in the strata were not uniform. Air bubbles in most strata were spherical, although the sizes and distribution densities of bubbles were different in each stratum. But several strata abounded in elongated bubbles that were arranged parallel to the vertical axis of the core (Fig. 11). Some of those elongated bubbles were intertwined each other like a three-dimensional network and also coexisted with spherical bubbles.

Bubble pressure was measured using a volume difference before and after melting⁷ (Fig. 12). As is clear from the figure, the pressure of those bubbles near the surface is the same as the atmospheric pressure, but increases linearly with increasing depth. Those at the bottom of the massive ice body reach nearly twice the atmospheric pressure. High-pressure bubbles like those in glacier ice were not observed in the cores.

Characteristics of Chemical Components

Ice samples at an interval of 2.5 cm along the entire length of the core were prepared for chemical analyses of the oxygen isotopes, conductivity and pH. Determination of oxygen isotopes is continuing at the Water Research Institute, Nagoya University. Results obtained to date are shown in Fig. 13. As is clear from the figure, the vertical profiles of $\delta^{18}\text{O}$ values abounds in distinctive discontinuities.⁸ They seem to correspond to crystallographic and stratigraphic changes in the core. For example, a discontinuity of the profiles, which occurs at about 13 m depth, corresponds to the presence of sedimentary layer shown in Fig. 2.

Conductivity and pH of the core were also measured on the same samples used for determining the oxygen isotope ratios. Results obtained are shown in Fig. 14. Values of pH remain reasonably consistent with depth. However, values of conductivity show distinctive spikelike projections in many portions of the profile with depth. These distinctive projections seem to correspond to clear band, bubble-free layers of ice in the core.

DISCUSSION

There are three hypotheses concerning the origin

of massive ice bodies. The first one is the snow-glacial hypothesis, which involves the burial of ice, such as stagnant glacial ice, compact snow drift, lake, sea and river ice. The second hypothesis is ground ice such as well developed vein ice. The third is segregated ice from the freezing of drawn up pore water.

Concerning the vein ice hypothesis, there is no evidence favouring it. That is, in the western Arctic, there is no giant syngenetic vein ice as is found in Russia and the conditions which form syngenetic ice wedges have not occurred in the Mackenzie Delta area.² The buried glacial ice hypothesis is also not generally accepted but difficult to completely disregard. That is, the presence of large foliated patterns in an outcropping ice wall of the massive ice body seems to support deformation by a glacier. Also the glacial limits of the glaciations in this area are not completely known. The ice segregation hypothesis which has been illustrated by Mackay¹ is that pore water in soil is drawn up and frozen as segregated ice and such freezing within a closed system of high water content would result in the expulsion of water and form the positive relief features. An explanation is still needed, however, to explain the ice fabrics and the foliation in the massive ice body.

From a crystallographic view point, there are some particular distinctive features in glacier ice, that is, in the ice fabrics, a strong concentration of the arrangement of c-axis are commonly observed. The distribution of ice grains and soil inclusions in each stratum are modified and arranged by shear within glacier, and also the highly pressurized air bubbles are observed in the core even after being kept at an annealing stage for a fairly long period.

The present authors' findings on ice fabrics of the core obtained from the massive ice body are not similar to those of glacier ice. That is, there could not be observed such concentration of c-axis orientation in most of strata as in glacier ice. There also could not be observed pressurized air bubbles in the core (Fig. 12).

These facts indicate that a previous hypothesis that the massive ice body originates from the remnant glacier is probably wrong.

The hypothesis that the massive ice body is segregated ice is also doubtful based upon our observation of ice fabrics.

More than one half of the core samples consisted of layers of granular ice which abounded in spherical air bubbles of various sizes and homogeneously dispersed (Fig. 6). The size distribution, arrangement of c-axes of the ice crystals and the distribution of air bubbles are similar to those within ice formed in a snow pack that freezes after it is immersed in water.

This crystallographic feature is commonly observed in superimposed ice layers such as temperature glacier ice, sea, lake and river ice. Ice fabrics and air bubble distributions of such ice is not uniform because of differences in the amount of water supplied to the snow pack, that is, pores in a snow pack are connected in a three dimensional network and forming a skeleton structure of the snow pack. When the snow pack submerges in water, the pores are isolated and each of them forms an air bubble. The shape and distribution of each air

bubble depends upon how much the snow pack is saturated by water in which it is submerged. If the saturation rate is comparatively high, then the shape of a trapped bubble becomes spherical, otherwise, it becomes irregular, keeping the original, elongated shape of the pore.

It may be interpreted that the granular ice layers which consist more than one half of the core are formed by superimposed ice on the bed of ice, considering ice fabrics, shapes and distributions of air bubbles in the strata. Especially, the particular shapes of elongated air bubbles in many strata support the superimposed ice. These elongated air bubbles can not be formed by segregation (Fig. 11).

There are many facts other than ice fabrics that support superimposed ice formed by congelation of water in which a snow pack is submerged.

Stratigraphic changes in chemical components of the core also support this model.

Spikelike projections which were observed in the profile of conductivity against depth (Fig. 14) were formed as follows: Impurities which were contained in the submerged water rejected as ice formed from the water during freezing and enriched the remaining water with chemical components and complete freezing formed layers of high conductivity.

In the profile of $\delta^{18}\text{O}$ against depth, changes in value were comparatively small and linear profile was observed except for several portions (Fig. 13). In successive snow strata, glacier ice and ground ice, distinctive periodic changes in value of $\delta^{18}\text{O}$ in the profile are commonly observed, reflecting short- and long-term changes in isotopic contents of precipitation which are related to changes in climate.⁵ A linear profile without such periodic changes is often observed in superimposed ice in temperate glaciers.⁸ It develops when the snow or firn was submerged in melt water which, because of mixing, becomes relatively homogeneous in composition and formed superimposed ice.

Formation of large crystals of bubble-free layers may be explained from the concept of superimposed ice as developing from a snow pack layer which is saturated fully by submergence under water or a fairly thick layer of water which is perched upon a bed of ice below the snow pack, which then freezes under a low cooling rate as commonly observed in the case of lake or pond ice (Fig. 10).

The shapes and other stratigraphic features of some soil sediments support the perching of a large amount of water upon a bed of ice.

A thick soil sediment observed at a depth of 12-13 m (Fig. 4) looks like that formed when the sediment is deposited in water on the bed of ice like a lacustrine sediment and frozen. The sediment looked to be suspended in the ice (Fig. 5) is that formed when the snow pack layer is saturated by melt water and the particles are suspended in that water and frozen in the skeleton of the snow pack.

Also, the large foliation bands which were observed in the outcropping ice wall can be explained in terms of superimposed ice layers which preserved accumulation layer of a snow pack or debris of a snow bank.

It may be concluded from ice fabrics, geochemical and stratigraphic analyses that most parts of the massive ice body originate from superimposed ice formed by congelation of water in which it was

submerged. The mechanism of its growth is not identical to that of the growth of a pingo in which segregated ice constitutes the core.

An explanation is still needed, however, to explain the preferred location of massive ice bodies beneath positive relief features such as hills and plateaus and the occurrence of beneath a fairly thick cover of till.

Thus, the formation process of the massive ice body might be assumed as follows. At the initial stage, a large mass of superimposed ice was formed, originating from a snow pack or debris of snow bank on a bed of ice, perhaps produced in a lake or pond. While in the process of aging, new snow or debris of drifting snow is deposited on the ice mass. Then, it attains an ablation stage and the upper part of accumulated snow layers on the ice mass melted away. The melt water supplied from surface perched on the ice mass and submerged in the depositing snow layers remaining there, thereby freezing to become superimposed ice. Through repetition of this process, the ice mass develops recognizable strata containing a soil layer at the boundary of each stratum and distinctive discontinuities in the ice fabric as shown in Figs. 3, 4, 8 and 10. Chemical components such as oxygen isotopes and conductivity develop values as shown in Figs. 13 and 14 in this fashion also. After growing to some extent by these intermittent formation processes, the ice mass is buried by reworked till or glaciofluvial sediment which has been formed by the outwash of a river.

Still, some points remain arguable, for instance, preferred location, an overriding till layer, quantity of water in which a snow pack or snow debris are submerged and time of formation of the ice mass.

More detailed information and investigations on massive ice bodies are needed for clarifying the origin and formation processes of them, together with geological conceptions including stratigraphy and dating.

ACKNOWLEDGMENT

Authors wish to express their hearty thanks to Dr. G.D. Hobson, Director of Polar Continental Shelf Project, Energy, Mines and Resources, Canada; to the Camp Manager and his staff of Tuktoyaktuk Base Camp for helping them carry out field work; and also to Dr. J.D. Ostrick of Inuvik Scientific Resource Centre, Indian and Northern Affairs, Canada for his kind arrangements for field and laboratory work. They are also indebted to Dr. Y. Hiratsuka of Northern Forest Research Centre and Mr. Y. Akao of Marubeni, Canada, LTD. and Messrs. T. Okada, K. Kobayashi of Marubeni Reizo LTD. for their kind arrangements for transporting ice core samples.

THE PORE WATER PRESSURE PROFILE IN POROUS ROCKS DURING FREEZING

Masami Fukuda

Institute of Low Temperature Science, Hokkaido Univ., Sapporo, JAPAN

The frost shattering of rocks was explained by a frost heave mechanism with coupled flow of heat and moisture in porous rocks during freezing. The pore-water pressure profile of the freezing rock was obtained using tensiometers. Pore-water pressures of porous rocks during freezing were monitored by the transducers connected to tensiometers. Both the profiles of temperature and pore-water pressure were obtained simultaneously. From pore-water pressure measurements ahead of the freezing front, the large negative pore-water pressure is suggested as the major driving force responsible for water uptake in porous rocks.

INTRODUCTION

Volume expansion, which accompanies a phase change from water to ice, has traditionally been considered to be a cause of frost shattering of rocks in cold regions (Ollier, 1969). However, conditions under which this mechanism can exist are fairly limited in the field. Thus, other hypotheses are necessary to explain their disintegration as a result of freezing. Everett (1961) proposed the concept of water flow based upon the thermodynamics of water-ice equilibrium. Recently, the process of frost heaving of soils has been studied in detail, and an improved understanding of moisture migration and freezing processes is evolving at both the theoretical and experimental level. The present author has attempted to apply this concept of frost heaving in soils to the frost shattering of rocks. Freezing experiments have been conducted in an effort to verify the application of the concept.

EXPERIMENTS

Neogene Tertiary tuff from central Japan was used in the experiment. It has a high porosity (36%) and is frost susceptible. Column-shaped rock samples (5 cm in diameter and 15 cm in height) were prepared. A sample was first wetted so that the pores were fully saturated with water. Tensiometers were inserted at points 3, 5 and 7 cm from the surface of the rock column. A brass circulation plate through which refrigerant was circulated was placed on the top of the rock column to control the temperature. The rock column was mounted on a water reservoir and maintained hydraulic contact with the water in the reservoir. The temperature of the water in the reservoir was maintained at +2°C with a fluctuation of 0.1°C. Pore-water pressures were measured by pressure transducers, which were connected to the tensiometers by the tubes (Figure 1). The measurements had a resolution of 2 cm H₂O. Fine thermocouples were inserted at intervals of 1 cm in depth in the rock sample. Both read-outs of pore water pressure and temperature were collected by an automatic data logging system controlled by a small computer.

Two different rates of freezing were established under the different cooling conditions on the surface (-3 and -5°C).

At the beginning of each experiment the surface of the rock sample was supercooled, to initiate freezing. If the degree of supercooling exceeded -2°C or below, the freezing front moved down very rapidly. Such a transitional freezing process had to be avoided. Thus, a few drops of liquid nitrogen were applied to the rock surface to prevent supercooling at the beginning.

RESULTS AND DISCUSSION

Changes in pore-water pressure during freezing

More than 20 freezing experiments were conducted. Changes in pressure and temperature were measured every 5 minutes. The frost depths were estimated from the temperature profiles. The initial freezing temperature of pore water was estimated to be -0.08°C. A typical result of the experiments with the slower rate of freezing is shown in Figure 2. During freezing, the rate of advance of the freezing front was 2 mm/hour. The pore water pressure decreased as the freezing front penetrated into the rock. At a depth of 3 cm the pore water pressure decreased continuously. However, at the 7 cm depth no decreases were measured.

The case of the faster advancing freezing front (4 mm/hour) is shown in Figure 3. The pore-water pressure at the depth of 3 cm decreased for 5 hours, then ceased decreasing. At that time, the freezing front was located near the 3 cm depth. At the depth of 5 cm similar changes were noted. At both freezing rates pore-water pressures at locations nearer to the surface were lower than at locations farther away from the freezing front. These pressure differences at different depths suggest that water flows upward.

The result of pore-water pressure measurements during the freezing of Andesite is shown in Figure 4. This rock specimen showed no damage by the freezing-thawing test. In this case, no pressure changes in the rock specimen were observed. This means that there was no water migration in the rock specimen. The pore water

pressure at a 3 cm depth increased after 13.8 hours had elapsed. This indicated that the water in the tensiometer had begun to freeze.

The changes in pore-water pressure with depth in the Neogene Tertiary tuff specimens are shown in Figure 5. A small pore water pressure gradient at the beginning of the experiment (0 hour) was due to both drying of the upper portion of the column and the gravitational potential. Once the freezing started, an increase was observed in pore-water pressure difference between 3 and 5 cm depth. Along this gradient, water must migrate upward. The gradient between 3 and 5 cm in depth increased for 4 hours, but between 4 and 6 hours the increase in the gradient was very small. Additional experimental results, which also illustrate this behavior of the hydraulic gradient between the depth of 3 and 5 cm are shown in Figure 6. The hydraulic gradient increases with time. Each case in Figure 6 indicates that an increase in gradient ceases at a certain time. This time corresponds to the time at which the tensiometer fails due to freezing and depends on the rate of advance of the freezing front. Similar results in the case of soil freezing were reported by Fukuda and Luthin (1980). As the relationship between pore water pressure and water content could not be obtained, it was not possible to estimate the flux of water in a freezing rock from these data.

Estimation of pore water pressure near the freezing front

The hydrodynamic model for soil freezing assumes that the two transport equations, one for heat and the other one for water, are coupled by the relationship between pore water pressure and temperature below 0°C (Taylor and Luthin, 1978). Considering the similarity between the unsaturated soil and the rock, one may apply this model to the rock freezing process. The freezing point depression of pore water in a rock specimen was determined experimentally. The result is shown in Figure 7. The water content is expressed as the degree of water saturation in pores in the rock. The ordinate indicates the freezing point depression, which is the difference in the temperature of freezing of pore water in rocks and bulk water under atmospheric pressure. Thus, if the pores of the rock are not completely filled with water, that water freezes at temperatures below 0°C. Let us apply the Clausius-Clapeyron equation to this situation. If the content of free solutes is negligible, then:

$$dT = (T/L)V_w dp_w - V_i dp_i$$

where T = temperature, Kelvin
L = heat of fusion
p_i, p_w = pressure of ice and water, respectively
V_i, V_w = specific volume of ice and water, respectively

When there is no load on the rock, and the rock matrix does not constrain the ice, the pressure of the ice in the pores of the rock is equal to

atmospheric pressure. Thus, the equation can be modified as follows (Offenbacher 1981):

$$\Delta T = 0.082p$$

where ΔT is the freezing point depression and p is the pore water pressure in bars. This large negative pore water pressure is the driving force for water to move to the freezing front. The equations given here are based upon the thermodynamics of an equilibrium water-ice situation and are assumed to be applicable although the actual freezing process is a nonequilibrium process.

The author attempted to estimate the pore water pressures near the freezing front from experimental results. The decrease in pore water pressure as a function of distance between the freezing front and the tensiometers is shown in Figure 8. As the freezing front descends, the pore water pressure decreases gradually. The pore water pressure at the freezing front is calculated through extrapolation to be more negative than 1 m H₂O. This value was obtained by fitting simple regression curves to the data shown in Figure 8 for the three different tensiometer locations. If this value is substituted in the above equation, 0.08°C is obtained as a freezing point depression at the freezing front. This value corresponds to the actual temperature which was used to locate the freezing front.

Potential gradient near the freezing front

In order to estimate the flow rate of water to the freezing front through the unfrozen part of rocks, hydraulic gradients at various locations were calculated. Typical curves of potential gradients between 3 and 5 cm as a function of time are drawn in Figure 6. At the beginning of freezing, the hydraulic gradient increased very sharply. The hydraulic gradient continued to increase until the pore water pressure at the 3 cm depth reached a minimum; then the increase in the gradient ceased. The maximum hydraulic gradient which was observed between 3 and 5 cm and the mean pore-water pressure across this depth, were recorded for each experiment. All the data are plotted in Figure 9. A simple regression having an exponential form was performed. This curve gave the best fit, compared with other simple regressions. The following empirical relation was obtained between pore-water pressures and potential gradients in the unfrozen part of the rock during the freezing:

$$\partial\phi/\partial Z = A \cdot \exp(B/\psi)$$

where $\partial\phi/\partial Z$ = total hydraulic gradient, cm/cm
 ψ = absolute value of pore water pressure, cm H₂O
A, B = constants
Z = distance, cm

Evidence of water migration during freezing

The migration of water to the freezing front through unfrozen rocks was implied by the measurements of pore water pressures. However, the flux of water cannot be calculated from these results. The water flow in porous rocks takes place under the unsaturated condition, and the functional relation between the hydraulic conductivity of unsaturated rocks and the water content is not known. As an alternative the author attempted to measure the change in water content of samples which froze under conditions which were identical to those discussed above. At first, rock specimens with exactly the same shape as the ones used in the experiments previously mentioned, were prepared. The rock specimens were set as shown in Figure 1 without tensiometers in them. The top surface of specimens were exposed to -5°C . As the freezing front descended downward, the temperature profile of the specimen was measured once every hour and plotted. The position of the isothermal line of -0.082°C , which was estimated as the freezing front, was determined at given times. Once the freezing front reached specific locations the rock specimens were frozen at -30°C . Then the samples were cut into a discs 1 cm in thickness. The weight of each disk was measured before and after drying in the electric oven. The procedure was based upon previous studies involving freezing soils (Dirksen and Miller 1966).

The results of the experiments are shown in Figure 10. Both temperature and water content profiles are drawn. Arrows in the figure indicate the locations of the freezing front. The bulk density and porosity of these rock specimens were measured. Thus the water content on a weight base (weight of water/weight of dry rock) was converted into volumetric water content. The water content profile after a lapse of 18 hours indicates that the water content is low near the freezing front and high in the frozen part (upper portion). This discontinuity in the water content profile at the freezing front is due to the existence of large negative pore water pressures near the freezing front. After a lapse of 21 hours the freezing front descended, and the zone with a depleted water content also descended. The volumetric water content at a 4 cm depth after a lapse of 18 hours was 34.4 %, and increased to 38.14 % after 21 hours. The water content in the frozen part exceeded the saturation level. Water segregated as ice in the pores. It is suggested that the foregoing flow of water in porous rocks in the process of freezing may explain their frost shattering.

CONCLUSION

From pore-water pressure measurements ahead of the freezing front it is estimated that the negative pore water pressures at or near the freezing front exceeds 1 m H₂O. A steady-state freezing front will result in constant movement of water through porous rocks from the water table

and will cause a continuous increase in the amount of segregated ice in pores. Such an excess of water causes the disintegration of rocks. Using a tuff rock with a porosity of 36%, the flux of water through the unfrozen part of each sample was illustrated while it was subjected to freezing. This process of water migration in porous rocks during the freezing is found to be similar to the frost heaving processes of soils.

CONTROLS AND RATES OF MOVEMENT OF SOLIFLUCTION LOBES IN THE EASTERN SWISS ALPS

Martin W. Gamper

Department of Geography, University of Zürich, 8057 Zürich, Switzerland

Rates and processes of present-day movements of solifluction lobes in the Swiss National Park in places lacking permafrost are compared to Holocene movements established by radiocarbon dating of buried soils in solifluction lobes in similar localities. At a depth of 50 cm, corresponding to the depth of most of the buried soils, movement below vegetation was less than the limit of detection (<0.1 cm/yr). Under vegetation free surface, movements varied from 0.0-0.7 cm/yr (average 0.05 cm/yr). In contrast to present-day rates of movement at depth the rates of movement calculated using radiocarbon dates of buried soils along the length of solifluction lobes range from 0.5 to over 3.0 cm/yr in periods of peak activity during the last 5,000 years. The results of the study of present-day solifluction at the two test sites show that movement is controlled by vegetation cover and by the depth to which the soil freezes during the fall and winter. Thus the comparatively larger rates of movement in past periods of peak activity could be explained by a change in the climate with colder temperatures and winters with less snow cover, which would reduce vegetation cover and promote gelifluction.

INTRODUCTION

Movement rates of solifluction lobes during the Holocene can be reconstructed by radiocarbon dating of buried soils (Benedict 1966, 1976, Worsley and Harris 1974, Alexander and Price 1980, Gamper 1982). For a climatic interpretation of changes in movement rates, a comparison with present-day movement rates of solifluction lobes is required. These lobes have to be at the same altitude and over the same bedrock and have to face in the same directions as the lobes used to reconstruct past movement rates. The controls of present-day movements need also to be studied. Because mass movement by solifluction is slow but highly rate-variable, only a long term survey using numerous data points can provide a reasonable base for this comparison. Similarly, the data base for past movement rates has to be quite broad.

Measurements of present movement rates of solifluction lobes have been made primarily in arctic regions with permafrost (Washburn 1979, Harris 1981). Data for alpine regions and especially for the Alps themselves are rare and cover only short periods (Furrer 1972, Stocker 1973). Data for subsurface movements in the Alps are lacking.

The present study was initiated in 1975. Since then, surface and subsurface movements of solifluction lobes in the Swiss National Park (eastern Swiss Alps) have been continuously measured. Since 1978, soil and air temperatures have also been continuously recorded. The data including 1979 were published by Gamper (1981).

At the same time, over 120 radiocarbon dates of buried soils in solifluction lobes mainly in the eastern Swiss Alps have been made. These dates (Röthlisberger 1976, Schneebeli 1976, Beeler 1977, Furrer 1977, Gamper 1981, 1982) were used for this study together with some unpublished dates.

AREA SETTING

The Swiss National Park is located in the southeastern corner of Switzerland, about 200 km southeast of Zürich. The mountains have an average elevation of about 2,800 m. Bedrock is mainly Triassic dolomite. The timberline (larch and Swiss pine) occurs at about 2,100 m. Solifluction lobes are located on all slopes at an elevation of 2,200-2,800 m depending on the directions in which the slopes face. They are most common at the upper margin of closed vegetation cover.

FIGURE 1 Solifluction lobes in the Swiss National Park (test site 2). Surface movement and soil and air temperature measurements were carried out here from 1977 to present.

On the west slope of Munt Buffalora (test site 1) and on the southwest slope of Munt Chavagl (test site 2, Figure 1), two sites for measurements of solifluidal movements have been selected, both at an elevation of 2,400 m. The fronts and sides of the lobes are covered by vegetation. The backs of the lobes are mostly vegetation free. The soil is not perennially frozen. A detailed geomorphological study of those lobes has been made by Furrer et al. (1971).

On test site 2 (Figure 1), measurements have been carried out from 1977 to the present. The soil and air temperature measurements are also made in this area. Test site 1 was surveyed from 1975 to 1979. In the overlapping period, measured movement rates at both sites have been identical (Gamper 1981).

METHODS

Surface movements were measured using 102 wooden cones which are 10 cm in height and are mounted on 10 cm long wooden dowels which were inserted in the soil (Washburn 1960). In addition, 45 test pillars were inserted to a depth of 90 cm (Rudberg 1958) and 118 aluminum foils were inserted to a depth of 40 cm (Gamper 1981).

Thirty test pillars and 49 aluminum foils were used at the first test site, and all the other measurement devices were used at the second site. Measurements were made 2-5 times during the snow free season during July to October of each year, using a theodolite stationed on bedrock. The test pillars and aluminum foils at the first test site were excavated in 1979 to obtain subsurface movement rates (Gamper 1981). Measurements at the second test site are still in progress. All subsurface movement rates are therefore taken from the first test site and cover only the period 1975-1979.

Temperature measurements were started in September 1978 at one of the lobes at the second test site, using 22 temperature sensors (accurate to 0.1° Celsius). Air temperatures at 1, 50 and 150 cm above surface and soil temperatures from a depth of 5-100 cm were measured every 3 hours. Measurements were made on the back of a solifluction lobe in vegetation free area (Figure 1).

CONTROLS AND RATES OF SOLIFLUCTION MOVEMENT

The measurements show that detectable surface movement is restricted to the backs of solifluction lobes. The front and steep sides of the tongues which are covered by vegetation did not move downslope.

Average surface movement in vegetation free areas on the backs of the lobes was much higher than around the edges of the lobes, which are partly or completely covered by vegetation (Table 1). Solifluction was also restricted to the time during and after snow melting in early summer. During summer no detectable movement occurred.

TABLE 1 Average Surface Soil Movement Rates 1975-1982 at Test Sites 1 and 2 in the Swiss National Park (cm/yr).

Year (Oct. 1- Sept. 30.)	No. of Measured Points	Minimum Rate	Maximum Rate
1975/76	75	0.0	8.9
1976/77	75	0.0	11.0
1977/78	140	0.0	15.0
1978/79	155	0.0	40.3
1979/80	99	0.0	15.8
1980/81	175	0.0	48.2
1981/82	179	0.0	37.6

Year (Oct. 1- Sept. 30.)	Average Downslope Movement Rates			
	All Points	Veg.* Covered Areas	Partly Veg.* Covered Areas	Veg.* Free Areas
1975/76	1.5	0.2	1.6	2.9
1976/77	1.8	0.6	1.8	3.0
1977/78	5.1	1.4	5.2	7.4
1978/79	4.7	1.3	4.1	7.0
1979/80	3.8	2.4	3.3	4.8
1980/81	5.0	1.6	2.7	9.1
1981/82	6.5	2.4	4.8	11.1

*Veg. = Vegetation.

The values in Table 1 show remarkable differences in the average movement rates for different years. The changes in the distribution of slow (0-2 cm/yr), medium (2-6 cm/yr), and high (over 6 cm/yr) movement rates for these years are shown in Figure 2. In years with small average movements, during 1975/76 or 1979/1980, over 80% of the measured points showed only low or medium movements (Figure 2A). In years with high average movements, during 1977/1978 or 1981/1982, almost 50% of the points showed high movement rates. This increase in points showing high movement rates is most evident in the vegetation free areas (Figure 2D) and to a lesser extent in the partly vegetation free areas (Figure 2C) on the lobes. This indicates that vegetation cover is the most important factor in controlling solifluction.

Soil and air temperature measurements on a vegetation free back of a solifluction lobe show (Table 2) that in years with large surface movements (1978/1979, 1981/1982, and to a lesser extent 1980/1981) the soil froze to a depth of close to 1 m or more.

In early summer in those years, the soil thawed from the surface downward and stayed saturated with water as long as the ground in deeper horizons remained frozen. During this time (Table 2), gelifluction, saturated flow of debris, could occur. As soon as the impermeable frozen subsoil is completely thawed, the soil dries and becomes stable (Harris 1973). Therefore, during summer no detectable movement could be measured.

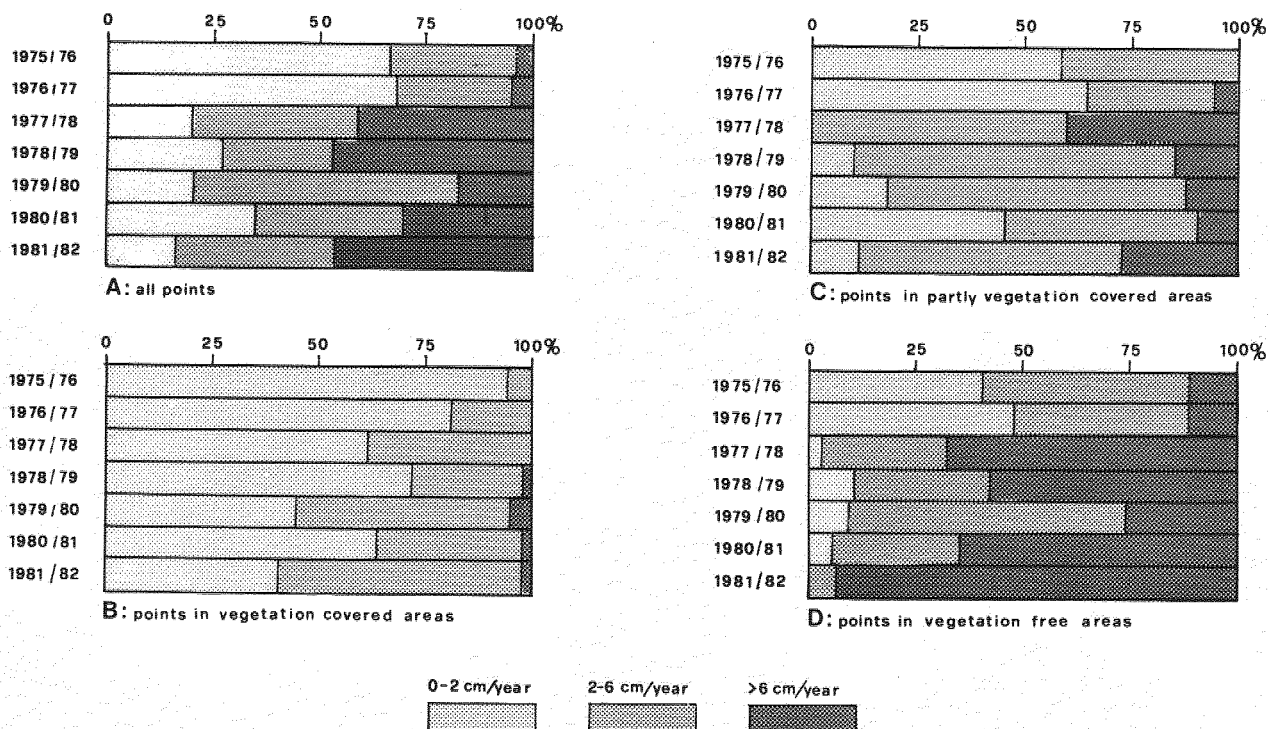

FIGURE 2 Histograms showing the relative distribution of surface movement rates on solifluction lobes at test sites 1 and 2. The figures show that solifluction is mainly controlled by the vegetation cover. Distribution and annual changes of movement rates are controlled by the timing and the duration of the snow cover in winter.

TABLE 2 Soil and Air Temperature Data From Test Site 2 in the Swiss National Park 1978-1982.

Year	Maximum Depth of Frozen Ground (cm)	Days With Gelifluction	Days With Continuous Snow Cover	First and Last Day With Continuous Snow Cover
1978/79	>100	22	186	11/25/78-5/30/79
1979/80	40	0	240	10/17/79-6/13/80
1980/81	85	14	217	10/14/80-5/18/81
1981/82	>100	18	171	12/ 1/81-5/20/82

Year	Mean Annual Air Temperature	Mean Winter Temperature (October 1-May 31) (°C)				
		150 cm Above Ground	2 cm Above Ground	5 cm Below Ground	50 cm Below Ground	80 cm Below Ground
1978/79	-0.5	-4.2	-1.7	-1.4	-0.4	0.2
1979/80	-1.2	-5.0	0.1	0.2	0.6	1.0
1980/81	-0.8	-4.3	-0.7	-0.3	0.2	0.7
1981/82	-0.6	-4.6	-0.9	-0.6	-0.1	0.4

In 1979/1980, a year with small movements, the soil only froze to a depth of 40 cm and thawed from below before the snow melted. Therefore the soil never became water saturated. Only frost creep occurred.

The frost depth itself is controlled by the timing of the onset of continuous snow cover and by the duration of winter snow cover (Table 2). The later in the year that snow falls, the deeper the soil freezes. The shorter the snow cover stays, the better are the chances for a long period of gelifluction. The mean annual air temperature (Table 2) therefore shows no correlation with the average rates of downslope movement (Table 1). The mean temperatures for the winter season (October to May) show that although the air temperature 150 cm above the surface was between -4.2° and -5.0°C , the temperature 2 cm above the ground (the temperature at the base of the snow cover) varied between $+0.1^{\circ}$ and -1.7°C , because of the presence or absence of an insulating snow cover during fall and early winter.

For a comparison of present-day movement rates with rates of movement during the Holocene as reconstructed by radiocarbon dating of buried soils in solifluction lobes, subsurface movement rates in a depth corresponding to the depth of the buried soils have to be used (Table 3). Present-day surface movement slows down to almost zero at the end of the lobes, because of increasing vegetation cover. The maximum depth of movement also decreases simultaneously. As a consequence, debris from the vegetation free areas above the lobes accumulates in the lobes. The lobes in toto do not move downslope.

TABLE 3 Average Subsurface Soil Movement Rates 1975-1979 at Test Site 1 in the Swiss National Park (cm/yr).

Depth (cm)	All Points	Vegetation Covered Areas	Partly Vegetation Covered Areas	Vegetation Free Areas

The rates of movement at a depth of 50 cm, corresponding to the mean thickness of the overburden on buried soils in solifluction lobes, was generally below the limit of detection (<1 mm/yr). Only 3 of 30 test pillars indicated movements of 0.3-0.7 cm/yr.

Altogether the results of the study of present-day solifluction at the test sites show that movement is generally controlled by the distribution of the vegetation cover. Annual changes of movement rates in vegetation free areas are controlled by the timing and the duration of snow cover in winter.

RATES OF MOVEMENT DURING THE HOLOCENE

Previous studies of buried soils in solifluction lobes in the Swiss Alps (Furrer 1977, Gamper 1981, Gamper and Suter 1982) identified during the past 5,000 years times of solifluction activity and times of dominant soil development on lobes. The results of these studies are based on radiocarbon dating of soils in interbedded solifluction lobes. More than 120 radiocarbon dates (see Furrer 1977, Gamper 1981, R thlisberger 1976, Schneebeli 1976) have been used to determine these times of peak solifluction activity, shown in Table 4.

By dating buried soils at several places along the length of the covering lobe, rates of lobe advance can be determined by calculating linear regressions for the relationship between age of the soil and distance of the dated soil sample from the lower end of the lobe (Alexander and Price 1980). In some lobes these time-distance profiles indicate fluctuating rates of soil burial as in the example given in Figure 3. In such cases, rates of lobe advance for different times during the Holocene can be calculated. The radiocarbon dates for the buried soil (Figure 3) between 3.2 and 8.4 m distance from the lower end of the lobe are not significantly different in age. The rate of lobe advance of 3.0 cm/yr is therefore only a minimum estimate for the movement rate around 2000 years B.P. In addition, the radiocarbon dates in Figure 3 show only insignificant differences between the ages of the humic acids and the corresponding ages of the organic residues (not NaOH soluble fraction of soil organic matter). This indicates that the samples are not contaminated by recent organic carbon.

Movement rates were calculated for six more lobes at three locations in the eastern Swiss Alps (Swiss National Park, Albulapass 30 km west of National Park, and Berninapass 30 km southwest

TABLE 4 Past Rates of Front Advance of Solifluction Lobes Calculated Using Radiocarbon Dates of Buried Soils.

Times of Peak Solifluctional Activity in Years Before Present*	Average Movement Rates for Individual Lobes in the Eastern Swiss Alps (cm/yr)

* After Gamper and Suter (1982).

of National Park). Two lobes were active during two periods, so that altogether nine average values of past lobe advance were determined. All lobes are on west or north facing slopes, and in each case, bedrock is Triassic dolomite. For these calculations, 35 radiocarbon dates were

FIGURE 3 Profile of a solifluction lobe (Albulapass, eastern Swiss Alps). The upper radiocarbon date of each pair corresponds to the age of the humic acids, the lower to the age of the organic residues of the buried soil. The radiocarbon dates indicate high rates of lobe advance of 1.5 cm/yr around 3200 years B.P. and of >3.0 cm/yr around 2000 years B.P.

used (Furrer et al. 1975, Beeler 1977, Gamper 1981 and 1982). The rates as shown in Table 4 range from 0.5 to over 3.0 cm/yr. In two lobes, rates for times in between peak activity periods were also calculated (Gamper 1982). They range from 0.1-0.3 cm/yr. Compared to present-day subsurface movement rates in a depth of 50 cm, even these average rates seem to be high. For two periods of solifluction activity (2800-2200 and 350-150 years B.P.) rates could not be calculated, because of insufficient data.

CONCLUSIONS

The rates of movement in past periods of high solifluction activity can be compared with present-day movements. Solifluction lobes show no detectable downslope movement at their fronts. Movement rates at a depth of 50 cm, corresponding to the depth of buried soils, are below the limit of detection (<0.1 cm/yr) even under vegetation free areas.

The high rates of front advance (0.5 to more than 3.0 cm/yr) in former periods of greater solifluction activity may therefore be related to a change in paleoclimate. Present-day solifluction rates in the studied areas with comparable climate are mainly controlled by the vegetation cover and in vegetation free areas by the depth of freezing as influenced by the timing and duration of the snow cover in winter. Former higher movement rates and an advance of lobes could be explained by winters with less snow cover and colder temperatures. Both would reduce vegetation cover

and promote solifluction by increasing the depth of freezing and therefore the duration and rates of gelifluction in early summer.

ACKNOWLEDGMENTS

I thank G. Furrer, B. Camper, and C. Kasper for their help in the field and many discussions. Fieldwork was supported by grants from the Swiss National Science Foundation and the Kommission der Schweizerischen Naturforschenden Gesellschaft zur wissenschaftlichen Erforschung des Nationalparks. This paper was written while I was a research associate at Indiana University sponsored by the Swiss National Science Foundation. R. V. Ruhe critically reviewed the manuscript and made helpful suggestions. S. J. Wintsch and R. P. Wintsch helped prepare the manuscript.

GERMINATION CHARACTERISTICS OF ARCTIC PLANTS

B. L. Gartner

Institute of Arctic Biology,
University of Alaska, Fairbanks, Alaska USA

Germination traits of many arctic plants are similar to those of Eriophorum vaginatum. Eriophorum seeds have the following characteristics: they are wind-dispersed, have weakly developed or non-existent dormancy mechanisms, show optimal germination at 20-30°C when tested at constant temperatures, germinate over a wide range of temperatures in the light, germinate only at greater than 15-22°C in the dark, and remain dormant while buried in organic soil to depths of 0-30 cm. These characteristics probably contribute to the colonizing ability of many arctic species.

The conditions controlling seed germination of various species are among the many factors that determine the composition and relative abundance of species in plant communities. Where and when a seed can germinate determine where and when a seedling will have a chance to establish, which in turn determine where and when a plant will have a chance to produce seeds. Because all species in one ecosystem are faced with the same environment, one might expect the successful species to share some characteristics. For example, all arctic tundra plants have low stature. In this paper I analyze the germination traits that are common in arctic plants.

The "weediness" of arctic vegetation and the ability of many tundra species to colonize disturbances have long been recognized (Griggs 1934, Polunin 1934, Savile 1960). Because landscape disturbances are common in arctic areas, I examined whether the seed germination traits may be adaptive for invading disturbed areas. If so, with further research into arctic seed and seedling biology, more options will become available for revegetating disturbed arctic sites.

Eriophorum vaginatum is mentioned throughout this paper, not because it is necessarily typical of arctic plants, but because its seed and adult biology has been studied from several sites around the world, it is present in numerous vegetation assemblages, and it appears as a colonizer of many kinds of sites.

SEED SIZE AND DISPERSAL

Many northern tundra plants produce small, light, wind-dispersed seeds (Porsild 1951, Savile 1972, Densmore 1979, Chester and Shaver 1982). For example, three native grasses used for revegetation (Calamagrostis canadensis, Arctagrostis latifolia, and Poa glauca) have extremely small seeds, averaging 0.12, 0.25, and 0.34 mg respectively (Mitchell 1979). In a study of 54 Alaskan woody species, a higher percentage of the tundra than taiga species produced small or wind-dispersed seeds (Densmore 1979). Among the eight species making up the majority of vascular plant cover (Chester and Shaver 1982), the average seed weight ranged from 0.02 mg

for Ledum palustre to 8.0 mg for Rubus chamaemorus. In between these values were 0.2 mg for Betula nana and Vaccinium vitis-idaea, 0.5 mg for Eriophorum vaginatum, and 1.0 mg for Carex bigelowii and Empetrum nigrum.

Seed dispersal in arctic plants relies on a number of mechanisms (Savile 1972). Plumed seeds and fruits are common and are found conspicuously in the genera Eriophorum, Salix, Dryas, Epilobium, Erigeron, and Taraxacum. Small, light seeds are found in Diapensia, Pyrola, some Ericaceae and some of the monocotyledonous species. Fleshy animal-dispersed fruits are also found, including Rubus chamaemorus, Arctostaphylos alpina, A. rubra, Vaccinium vitis-idaea, and V. uliginosum. Winged seeds and fruits, adapted to wind travel, are scarce, but are found in Betula, Rumex, and Oxyria digyna. Hooked fruits are almost absent in the arctic. Dispersal by wind is probably extremely important for arctic seed (Savile 1972). In the winter, small seeds can travel along with blowing snow over the hard-packed snow base. The relatively poor development in the arctic of temperate zone wind-dispersal devices such as wings or plumes may result from their lack of value for arctic winter dispersal (Savile 1972).

GERMINATION

Enforced Dormancy

Enforced or easily broken intrinsic dormancy mechanisms more commonly control germination of arctic plants than do complex intrinsic dormancy mechanisms (Billings and Mooney 1968). Enforced seed dormancy as defined by Harper (1977) is an inability to germinate due to an environmental restraint--shortage of water, low temperature, poor aeration, and so forth. Intrinsic dormancy includes the following conditions (Harper 1977): (1) seeds leaving the parent plant in a viable state but prevented from germinating when exposed to moist aerated conditions by some property of the embryo, endosperm, or maternal structures, and (2) seeds acquiring a condition of inability to germinate caused by some experience after ripening.

Enforced dormancy is certainly in effect in the winter, but may be in effect during the growing season as well. In a study of 54 species of woody tundra and taiga plants in Alaska, Densmore (1979) found that germination of all tundra plants that disperse their seeds in the fall was delayed until the following growing season by some temperature-controlled mechanism. Enforced dormancy appears to operate commonly in alpine species as well. Amen (1966) found no intrinsic dormancy mechanisms for 60% of 62 species of alpine plants; the remaining 40% belonged primarily to only three genera, *Carex*, *Trifolium*, and *Salix*.

The optimal temperatures for germination of many arctic species are high (20–30°C), so dormancy in these species may be enforced throughout most of the year and in most microsites. *Papaver radicatum*, *Saxifraga cernua*, and *Oxyria digyna* require high temperatures to germinate (Bell and Bliss 1980), as does *Eriophorum vaginatum* (Wein and MacLean 1973, Gartner 1982). For *Eriophorum*, the optimal temperature varied with population. For three Alaskan and Canadian sites the optimal temperature was about 30°C, but for seed from Scotland the optimal temperature was about 20°C (Wein and MacLean 1973). However, all these tests were made at constant temperatures, and may not reflect germination characteristics under field conditions, where temperature, moisture, and light fluctuate, both during a seed's dormant period and during germination.

Germination in seeds from some populations of *Eriophorum vaginatum* may be controlled by enforced dormancy only, whereas in other populations there are intrinsic mechanisms. For *Eriophorum* seeds from three Canadian sites, viability was highest after dispersal and declined progressively when tested 1, 6, 16, and 19 months later (Wein and MacLean 1973). The viability of one seed lot was reduced by 50% after the first six months of storage at room temperature. In contrast, most seeds from Kuparuk Ridge required a period of continued maturation before they germinated (Gartner et al. 1983). This requirement for additional maturation time was related to color: light brown seeds germinated more readily immediately after dispersal than did black seeds, but only black seeds germinated in experiments with 5-year-old seed (Gartner et al. 1983).

Some species, including summer-dispersing willows, germinate immediately after dispersal and lose viability quickly (Bliss 1958, Densmore 1979). For these species, high temperature thresholds restricting germination would only lessen the overall chances of seed germination.

Intrinsic Dormancy

Intrinsic dormancy mechanisms in arctic plants commonly consist of elapsed time, chilling, scarification, or a combination of temperature and light (Billings and Mooney 1968). Both chilling and scarification are effected through elapsed time, the former during winter and the latter probably through freeze-thaw activity during the spring and/or fall. The importance of elapsed time was shown above for *Eriophorum*, and reviewed for several alpine species in Amen (1966). Two *Trifolium*, two *Carex*, and one *Luzula* species are among the alpine species for which scarification is known to be a germination

requirement (Amen 1966). Species of Leguminosae are among the arctic species known to require scarification (Klebesadel 1971).

In many arctic species, light is required for or greatly enhances germination. The presence of light cues seeds to the fact that they are uncovered, and thus may be located in a site where (1) they will have little competition from established vegetation or (2) cotyledons will be able to reach above the surface to receive light. The latter should be particularly important for species bearing small seeds, which have small energy reserves and thus limited ability to reach the surface from depths. In Densmore's study (1979), nine species having extremely light-weight seeds, ≤ 0.15 mg/seed, required light for germination, regardless of temperature. Overall, 23 of the 52 species she examined required light to germinate, and 26 of the remaining 29 species were in one genus, *Salix*. *Eriophorum vaginatum* seeds do not germinate in the dark at temperatures below 15°–22°C (Bliss 1958, Wein and MacLean 1973, Gartner 1982) (Figure 1). These data suggest that in the field where seeds are buried, such as by litter, mosses, or lichens, or where seeds are dispersed to microsites where the temperatures are low, the seed may become dormant and incorporated into the buried seed pool.

Bliss (1958) found that a higher percentage of species characteristic of arctic river bars germinated in both light and dark at about 22°C than did those common to arctic tundra soils with a shallow active layer. This is in keeping with the hypothesis that species characteristic of upland sites may require light to cue germination, but it suggests a separate hypothesis for river bar sites. At these sites, which are subject to frequent deposition by flooding, seeds may germinate

FIGURE 1 Germination of filled *Eriophorum vaginatum* seeds under controlled light and temperature conditions after 22 days. Mean \pm SE ($n = 4$ groups of 50 seeds). Light treatments consisted of 20 hr light/4 hr dark or 24 hr dark (shaded bars). All treatments were tested at five temperatures. Seeds were stored at 5°C in the dark for 5 yr before start of the experiment (from Gartner 1982).

FIGURE 2 Germination of filled *Alnus crispa* seeds in the light (13 hr light/11 hr dark) under controlled temperature conditions for 21 days. Cold-stratified seeds were incubated in the light after 72 days of cold stratification in the light (from Densmore 1979).

regardless of the light regime if other physical conditions are met.

Chilling the seeds prior to germination greatly increases the proportion that germinate at low constant temperatures. Densmore (1979) conducted tests on cold-stratified (wet and then chilled) and unstratified seeds of woody tundra and taiga species. Cold stratification substantially lowered the temperature requirements (Figure 2) and broke dormancy in most of the species studied. After cold stratification, seeds of some species were able to germinate at 5°C, a condition that would occur soon after snowmelt. These included the arctic species *Empetrum nigrum*, *Potentilla fruticosa*, *Spiraea beauverdiana*, *Salix glauca*, *S. arctica*, *S. phlebophylla*, *Dispensia lapponica*, and *Dryas octopetala*. A second group could germinate when mean soil temperatures reached 10°C: *Alnus crispa*, *Chamaedaphne calyculata*, *Oxycoccus microcarpus*, *Vaccinium uliginosum*, *Cassiope tetragona*, and *Ledum palustre*. Other species would require temperatures around 15°C: *Vaccinium vitis-idaea* and *Loiseleuria procumbens*. Cold-stratification tests are important because they mimic the effect of winter-chilling on seeds that are dispersed in the late fall but have enforced dormancy mechanisms that prevent fall germination.

BURIED SEED

Buried seed pools exist in all four Alaskan tundra sites where they have been sought. The ages of buried seeds are unknown, but longevity may be greater in cold permafrost soils than in soils of

FIGURE 3 Depth profile of germinable buried seed in tussock tundra, calculated from depth profile of seeds in cores from four microhabitats weighted by the relative area of each microhabitat. A total of 118 seeds germinated from 45 cores having a total tundra surface area of 0.14 m² (from Gartner et al. 1983).

the temperate zone. At three of the sites, sedges were the predominant members: *Carex bigelowii*, *C. cf. aquatilis*, and *Eriophorum vaginatum* (McGraw 1980, Gartner et al. 1983, Roach 1983). Buried dicotyledonous seeds were common at two of the tussock tundra sites (McGraw 1980, Roach 1983), including *Ledum palustre*, *Saxifraga punctata*, *Polygonum viviparum*, *Empetrum nigrum*, and *Betula* spp. In a *Carex aquatilis* meadow on the northern coastal plain of Alaska the most abundant buried seed belonged to the dicot *Chrysosplenium tetrandum* (Leck 1980).

The distribution of different kinds of seeds varies with depth. Most dicotyledonous seeds were in the top 5-10 cm of soil (Leck 1980, McGraw 1980, Gartner 1982, Roach 1983), whereas sedges were also abundant down to 30 cm (Gartner et al. 1983). At Kuparuk Ridge, *Eriophorum* made up 38% of the germinating seeds and was found primarily throughout the top 11 cm of soil (Figure 3) (Gartner et al. 1983). This distribution is in contrast to *Carex*

bigelowii seeds (58% of all germinating seeds), which were common at depths of 0-29 cm. In addition, all of the buried seeds were found in the organic soil layers. There were no seeds buried in the mineral soil on this upland slope site, even though the mineral soil was at the surface in frost boils. This suggests that they were buried through deposition and/or growth of organic matter on top of the seeds.

DISCUSSION

In some arctic communities there is a high incidence of natural disturbance, caused mostly by frost activity. Because of this disturbance, different parts of the communities are simultaneously in states of disturbance or regeneration such that a mature climax assemblage cannot be identified (Churchill and Hanson 1958). Fires, floods, animal activity, and other disturbances are probably frequent enough in many communities to create bare areas available for colonization on a time scale that allows perpetuation of certain tundra species by seed.

The germination traits of arctic plants may be adaptive for colonization of unvegetated or sparsely vegetated sites. Densmore (1979) concluded that the germination patterns of arctic woody plants are often the same as for the temperate species of a genus and that these patterns were apparently selected in ancestral species. Nonetheless, a discussion on the ways in which these adapted or pre-adapted traits may benefit a species is still valid.

The presence of seeds at a site, whether due to dispersal or storage in the soil, is crucial for a species' colonization. Thus wind-dispersal, a very effective mechanism, and consignment of some seeds to the buried seed pool are important characteristics of colonizers. The same concept is true in the temperate zone, where weedy plants typically have

small, wind-dispersed seeds. Generally, most of the seed in buried seed pools in the temperate zone are of colonizing species, even in mature forests and mature pastures (Chippindale and Milton 1934, Sauer and Struik 1964, Livingston and Allesio 1968, Whipple 1977).

By having no dormancy mechanisms or very simple ones, seeds can germinate whenever basic requirements of temperature, moisture, and light are met. The requirement for high temperatures prevents germination in sites that may be temporally or spatially unsuitable for seedling establishment. Seeds with short longevity, however, would gain nothing from high temperature requirements. The requirement for light, like temperature requirements, helps cue a plant as to the suitability of its local environment. This trait has also been shown for colonizers in the temperate zone (Sauer and Struik 1964, Grime and Jarvis 1975).

Cold-stratification alters a seed's germination requirements so that it can have one set of requirements the year it is produced and a second set the following year. Environmental conditions that are correlated with germination success in the fall undoubtedly differ from those correlated with germination success in the spring or summer, so this adaptation can add considerably to the species' germination flexibility.

The general seed traits of arctic plants are similar to those of colonizers elsewhere. Grime (1981) distinguished four categories of colonizing species on the basis of their seed size and shape and their germination requirements (Table 1). The seed sizes range from very small to relatively large. Buried seed banks characterize two of the categories, A and B. Enforced and intrinsic dormancy mechanisms are the same as those listed for tundra plants. It is not surprising that arctic seeds have germination traits similar to those of colonizers elsewhere, for arctic disturbances are probably not uncommon over the long life spans of arctic plants.

TABLE 1 Common characteristics of seed morphology and dormancy for plants that colonize disturbed areas (from Grime 1981).

Group	Seed morphology	Buried seed	Dormancies and germination requirements
A	Small	Yes	No after-ripening, no innate dormancy. Germination in light over broad temperature range. Germination in dark with diurnal temperature fluctuations.
B	Very small	Yes	No dormancy. Germination in light at high or fluctuating temperatures. Germination in dark rare.
C	Small, or large with elongated structure	No	No after-ripening, no innate dormancy. Germination in light or dark over a broad temperature range.
D	Relatively large	No	After cold-stratification, germination in the light or dark over a broad temperature range.

CONCLUSIONS

Seeds of *Eriophorum vaginatum* and many other arctic plants have the following traits:

(1) Seeds are wind-dispersed.

(2) Intrinsic dormancy is non-existent or weakly developed. Seeds from some populations are viable immediately after dispersal, whereas only a small proportion of the seeds from other populations can germinate immediately after dispersal.

(3) The optimal constant temperature for germination is variable from population to population, and is between 20° and 30°C. Some seeds germinate at lower above-freezing temperatures in the light.

(4) In the dark, seeds do not germinate at temperatures below 15° to 22°C.

(5) Some viable seeds are stored in the upper layers of soil. They have been found from 0 to 30 cm deep, but most seeds are probably in the top 10-15 cm. No viable seeds are in the mineral soil.

The data on arctic seeds and the syntheses relating the ecology of species to their germination traits indicate that arctic species have traits similar to those of colonizers of the temperate zone.

METHODOLOGY FOR USING AIR PHOTOS AND SATELLITE
IMAGERY IN PERMAFROST SURVEYS

A. V. Gavrilov, K. A. Kondratyeva, Ye. I. Pizhankova,
and Ye. N. Dunayeva

Geology Department,
Moscow State University, Moscow, USSR

The basic principles of a method for using air photos and satellite imagery in permafrost surveys are presented. It is based on the principles developed by V. A. Kudryavtsev and his school for studying rock conditions, the temperature regime and other permafrost characteristics. The method was tested in the compilation of geocryological maps for various permafrost areas in the USSR. A section of a permafrost map for an area in the Central-Yakutian lowland is presented; it was compiled on the basis of laboratory interpretation of multiband satellite imagery taken from the "Soyuz-22" spacecraft. The efficacy of the method is assessed with regard to the north of Western Siberia, and Central and Southern Yakutia.

Intensive economic development of permafrost zones in the USSR requires reliable and quick methods for surveying conditions and characteristics of the natural environment. Aircraft and satellite imagery is especially useful for such surveys of remote areas. The imagery can be used:

1) to analyze the geologic structures and permafrost conditions over large areas since one image may cover areas corresponding to 1:200,000-1:500,000 scale maps;

2) in various spectral bands which provide complementary information on the geologic structures and permafrost conditions;

3) in a series from small-scale satellite imagery to aircraft photography which furnish information on the importance of permafrost-geological features;

4) to extrapolate interpretations over large distances because similar ground features produce similar imagery patterns on synoptic satellite imagery;

5) to make interpretations quicker and more unbiased with optical, optico-electronic and computer techniques;

6) to monitor changes in the natural environment and permafrost conditions, and to follow the development of permafrost-geological processes provided by tele-scanning systems.

Satellite imagery is divided into global, continental, regional, local and detailed (Yeryomin et al., 1978) based on its scale, ground coverage, and resolution. Resolution is a major constraint in permafrost surveys. It drastically limits the application of satellite imagery which is most useful for small- to medium-scale surveys. Local-scale satellite imagery has medium to high resolution, and the utility of medium resolution imagery has already been shown (Haugen et al., 1972). These images, together with the regional and continental photographs, are better for identifying block and fractured structures, for analyzing the geological structures in a region and for permafrost zoning.

Other factors determining the suitability of satellite imagery for permafrost surveys are spectral bands and the number of bands (single- or multiband). The analysis of landscape and geocryological features with aircraft and satellite photographs (ASP) (Gavrilov, 1979, 1980) has shown that multiband and multispectral ASP, obtained in the early summer or early autumn, are most suitable for permafrost surveys. Late autumn is the best time for taking isopanchromatic photographs.

Winter photography is also useful because it shows information on unique winter objects, e.g., water openings in ice. Secondly, winter photography with summer ASP is very useful for distinguishing icings formed by year-round sources from those formed by sources diminishing in a water-critical period. Thirdly, in some cases, winter photography shows more detail on rock lithology, fractures, etc. than some summer photographs.

Geocryological interpretation of ASP is based upon the methodology developed by V. A. Kudryavtsev and his colleagues (Kudryavtsev, 1979) for studying the thermal state and temperature regime of rocks. More precisely, it is based on the identification of cryo-forming factors and the qualitative and quantitative evaluation of the importance of the factors in determining the mean annual temperatures of rocks ($t_{m.a.}$) and the depth of their seasonal thawed or frozen zones (ξ). The methodology is helpful in explaining the existence of permafrost conditions and in analyzing their spatial and temporal changes in light of spatial inhomogeneity and dynamics of natural environment.

It is important to note that information on cryo-forming factors may be obtained through ASP interpretations supplemented by ground truth and the analysis of meteorological data. Photography is useful in identifying cryogenic formations which are often a direct indicator of rock state, and in judging the permafrost series evolution and tendencies in rock temperature regime dynamics. Therefore, the permafrost-temperature interpretations of

ASP depend on the linkage of $t_{m.a.}$ with the elements of the natural environment which govern permafrost formation (cryo-forming factors) and depend on the rock state and temperature regime (cryogenic formations).

Calculation schemes which use parameters that can be determined through ASP interpretations supplemented by ground truth and meteorological data make up the framework of Kudryavtsev's methodology (Kudryavtsev, 1974). His methods define $t_{m.a.}$ by introducing a correction factor for an average annual temperature and an annual air temperature amplitude in light of the effect of natural factors. The ASP analysis is done with the following purposes: 1) interpretation of photos on the basis of field data provides information required for qualitative and quantitative assessment of the influence of the natural factors; 2) the results of the interpretation of cryogenic formations, as indicators of rock state and approximate $t_{m.a.}$, considered in conjunction with the data of thermometry and geophysical prospecting by electrical means and others, while analyzing the calculation results.

This methodology is applied in small-scale permafrost surveys because it is needed to ascertain and further interpret the natural environmental factors that play a key role in determining permafrost conditions. In the tundra environment, key elements are the snow cover distribution and the latitudinal-zonal differentiation of heat exchange. Mapping signs of local permafrost characteristics include such factors as a relative hypsometric location of an area, sizes of relief mesoforms, height and density of vegetation, microrelief, and slope exposure which is responsible for local changes in the snow-cover zonal characteristics.

Factors contributing to the formation of a rock temperature regime in the forest-tundra and taiga zones are more diverse, e.g., snow cover, surface water, rock composition, moisture content and seepage properties, relief, and surface shading.

The complex of cryo-forming factors (and cryo-indicators) in low-mountain areas and plateaus in the southern part of the cryolithic zone with a continental type of heat exchange in the near-ground air layer show the most variety. These are (in respect to the Aldan Plateau and Stanovoi range) absolute altitudes, surface morphology, position in a mesorelief, composition and properties of deposits and surface and ground waters which have maximum effect on a temperature regime in rocks when the rocks have extensive jointing.

In addition to the above, the snow cover distribution, slope exposure and vegetation are also important factors in the formation of $t_{m.a.}$ in low-mountain areas and plateaus. The cryo-indicators in such regions are not individual landscape elements but are composed of complexes of all the external features of the natural environment including relief, vegetation, hydrography, permafrost-geological formations and economic projects (types of earthen roads, in particular).

The above principles of geocryological interpretation of ASP determine the specific nature of comprehensive geocryological surveys at all levels—pre-field, field and laboratory. Experience of

small-scale permafrost surveys has indicated that the use of aircraft and satellite imagery requires more extensive pre-field efforts. As a result, the information from pre-field interpretations rises dramatically. This is shown in a portion of the permafrost map for the Central-Yakutian lowland (Figure 1).

This map was compiled from laboratory-based interpretations of multiband Soyuz-22 satellite imagery taken with an MKF-6 camera and data on natural and permafrost conditions of the region (Interpretation ..., 1982). Two methods of photo-interpretation were employed: the visual method of interpreting synthesized images obtained by a multi-channel MC-4 projector with a five-fold magnification (up to a scale of 1:400,000), and a visual-measuring method ensuring the comparison of zonal photos and establishing spectral images of natural objects (Kravtsova, 1980). The resolving capacity of these photos ranges from 16 m (in the 3rd and 4th zones) to 40 m (in the 5th zone). This enables identification of such cryogenic formations as thermokarst lakes and depressions, thermoerosional polygonal block relief, areas affected by eolian and fluvial activity, as well as some 20 types of plant associations (Interpretation ..., 1982; Kravtsova, 1980) which serve as indicators of permafrost on accumulation plains in the northern and central taiga subzone. The map legend describes all the characteristics used in preparing the final map: geological-genetical complexes and rock composition, their thermal state, type and time of freezing, cryogenic textures and ice content, mean annual rock temperatures and temperature amplitudes on the ground surface, depth of seasonal thawing and freezing of rocks and ground surface features (Table 1). Also very essential is the comprehensiveness in characterizing permafrost conditions and lithological rock types.

Therefore, laboratory methods provide useful pre-field data which reduces the amount of and changes the character of field studies, i.e. the number of key plots and job volume are reduced, and to proceed (while selecting keys) from the need of settling down disputable questions and checking results of a pre-field interpretation.

The methodology developed was evaluated in terms of its effectiveness for compiling engineering-geocryological maps for the north of Western Siberia, Central and Southern Yakutia. These maps were compared with the traditional maps. It was determined that ASP-based maps surpass traditional ones by 1.5-5 times (depending on territorial changeability of geocryological conditions) in terms of comprehensiveness in describing composition, moisture content and state of rocks, extension of frozen series, taliks and newly-formed permafrost areas, the development of permafrost-geological phenomena.

The following conclusions are presented based on the above:

1) ASP is useful for permafrost surveys over vast regions, for obtaining supplementary information on the natural environment, for ranking permafrost-geological features by importance, for improving the reliability of interpretations and extrapolation of results, for studying the dynamics of natural and permafrost features and

conditions.

2) Multiband, local satellite imagery of high resolution is the best for doing small-scale and occasionally medium-scale permafrost surveys. The visual interpretation of synthesized photos of a method based on the visual-instrumental measurements of zonal density of images to determine feature patterns are two basic interpretation methods.

3) The permafrost-temperature interpretation of ASP rests upon the Kudryavtsev methodology for studying the state and temperature regime of rocks which includes the identification of cryo-forming factors and the quantitative assessment of the contribution each of them makes to the $t_{m.a.}$ and ξ formation. The information on cryo-forming factors may be obtained through the analysis of ASP, meteorological and field data for key plots. Also very essential is the fact that cryogenic formations are easily discernible on local ASP since the information on them as an indicator of rock state and approximate $t_{m.a.}$ may be taken into account while analyzing estimates.

4) This methodology is employed for interpreting ASP in the course of small-scale permafrost surveys with an aim to identify and assess the effect with ensuing interpretation of environmental elements being decisive in forming t , as well as to discern cryogenic formations on photos.

5) The methodology described provides essential pre-field level information on permafrost conditions which reduces the amount of costly field work. The field work can then be done to resolve problems which cannot be solved with ASP, and to check the results of laboratory interpretations.

6) The assessment of ASP maps indicates that they show more data than the traditional maps.

MAPPING OF ARCTIC LAND COVER
UTILIZING LANDSAT DIGITAL DATA

Leonard Gaydos¹ and Richard E. Witmer²

¹U.S. Geological Survey, Ames Research Center, 240-8
Menlo Park, California, 94035 USA

²U.S. Geological Survey, 521 National Center,
Reston, Virginia, 22092 USA

The U.S. Geological Survey, with the assistance of several other agencies and institutions, has been mapping vegetation and other land cover in arctic Alaska as a base for assessing development issues. LANDSAT earth resources satellite imagery in digital form were processed by using algorithms that partitioned the data into spectral classes. Fieldwork supported the later association of these spectral classes with actual land cover types and the construction of a classification system compatible with LANDSAT data and responsive to the needs of resource managers. Problems of classification incompatibility between adjacent LANDSAT images were solved by careful designation of classes and editing procedures.

After an initial investigation within the National Petroleum Reserve in Alaska, further development of the techniques was achieved in the region around the Prudhoe Bay oil fields and in the adjacent Arctic National Wildlife Refuge. LANDSAT was initially proposed as a mapping data source for this region because of cost and time factors, and research has demonstrated that it is extremely well adapted to the task. Not only are the mapped classes comparable to what could be obtained through conventional interpretation of aerial photographs; the resulting data are digital and consequently directly usable in geographic information systems.

THE USGS LAND USE AND LAND COVER MAPPING PROGRAM

In 1974, the U.S. Geological Survey (USGS) received funding to begin the first nationwide program of land use and land cover mapping, data production, and analysis. For several years prior to 1974, the USGS had been developing a land use and land cover classification system that could be applied nationwide, which would provide a comprehensive balanced set of categories useful to planners and land resource managers, and which could be employed by using remotely sensed data as primary source material. Research had also been directed toward other aspects of an inventory that needed resolution before a nationwide mapping program could begin, such as mapping techniques, suitable remotely sensed material, product types and user needs, and a geographic information system able to capture, store, and manipulate the resulting information in digital form.

The final version of the land use and land cover classification system (Anderson et al., 1976) consists of nine general level I classes, that are further subdivided into 37 more detailed level II classes. In the nationwide mapping effort, these level II classes are mapped by conventional photo-interpretation methods. High-altitude aerial photographs and other source materials available to the USGS are the typical kinds of remotely sensed

data used. USGS 1:250,000-scale and 1:100,000-scale topographic maps are used as base map materials. Areas as small as 10 acres (approximately 4 hectares) are mapped in urban situation(s), for water bodies, and other areas of typically high target/background contrast. For land use and land cover categories having broader extent, such as forests, rangelands, or tundra, an area of 40 acres (approximately 16 hectares) is the smallest unit mapped.

The final products are as follows: (1) hard-copy maps at 1:250,000-scale, with several areas mapped at 1:100,000-scale. In addition to the land use and land cover maps covering each quadrangle, associated maps showing political boundaries, hydrologic units, census county subdivisions, and areas of Federal land ownership were also compiled; (2) statistical tables giving areas of the land use and land cover category for each of the types of regions shown on the associated maps; and (3) various products such as tapes and plots resulting from the geographic information system.

The classification system, techniques, and products described above have been applied consistently since the program began. Nearly two-thirds of the Nation has been mapped; nearly half of those maps have been converted into digital format, and statistical reports for 16 states are now in production.

LAND USE AND LAND COVER MAPPING IN ALASKA

FIRST OPPORTUNITY--NPRA

During the first year of the mapping phase of the program, the Fairbanks, Alaska, 1:250,000-scale quadrangle was chosen as one of a dozen maps scattered throughout the United States to be compiled to provide early experience in applying the classification system and mapping techniques in a wide variety of situations. After the map was compiled and reviewed, many interpretation problems were found and the map was not published. These problems were due entirely to the compilers' lack of familiarity with the area. Suitable source materials for other parts of Alaska were not available until 1981, when compilation began on the Valdez 1:250,000-scale quadrangle. Several other quadrangles are now being compiled, and the USGS is presently investigating the possibility of entering into a cooperative agreement with the State of Alaska under which land use and land cover maps conforming to USGS specifications would be compiled as part of the State's Integrated Terrain Unit mapping effort.

LAND COVER MAPPING RESEARCH USING LANDSAT

As part of its continuing research into the capabilities of various remote sensors and their data, the USGS has been experimenting with the extracting of land cover information from LANDSAT multispectral data since 1973. The synoptic coverage, availability, and digital format of these spectral reflectance data held early promise as an economical substitute for aerial photographs where such conventional sources were lacking, for remote areas, and for ready adaptation to digital geographic information systems.

During the first few years of this research, land cover maps were constructed by computer-assisted classification of LANDSAT multispectral data for areas centered on Washington, D.C., Phoenix, Indianapolis, San Jose, and for various areas in the Pacific Northwest. These research efforts gave an early appreciation of the relative advantages and disadvantages of this technology for land cover mapping. Apparent advantages included the availability of data after processing by Goddard Space Flight Center and the EROS Data Center, resolution of data near the 1-acre level, and the digital format of the data allowing economical computer manipulation, including area measurement of each category and use of various digital graphic output devices. Disadvantages included early problems with geometric and radiometric fidelity, lack of optimum coverage for specific seasons, an inability to duplicate many of the categories being used in the nationwide land use and land cover mapping program, a lack of success in extending spectral classes from one LANDSAT scene to another, as well as the persistent problem of producing different sets of categories in different areas.

A specific need for land cover data of a large remote region was expressed in 1977 when the Bureau of Land Management (BLM) and USGS became responsible for compiling a resource inventory and a land use study for the 97,000 square-kilometer National Petroleum Reserve in Alaska (NPRA). On the basis of the foregoing discussion of perceived advantages and disadvantages of LANDSAT relative to photointerpretation of high-altitude aerial photographs, it was decided to test the hypothesis that analysis of LANDSAT digital imagery could provide an inventory and map of land cover consistent with planning needs.

Full source material coverage of NPRA was obtained from ten summer-season cloud-free LANDSAT scenes, each measuring 185 km on a side. Acquisition dates of the scenes ranged from early July to late August over a three-year period, 1975-1977. Each LANDSAT scene consists of a matrix of 79 x 57-m cells (pixels) sensed by the satellite in each of four wavelength bands, green, red, and two near infrared. The 7.56 million pixels that made up each scene were partitioned into spectral classes by using a clustering algorithm. Each class was defined by pixels with similar spectral characteristics. After defining these spectral classes, the entire scene was classified by assigning each pixel to the spectral class it most nearly resembled.

After classification, each spectral type was identified as a specific land cover by an analyst viewing the classified scene on a color display. Aerial photographs of specific sites and field notes were used as reference material for identifying the spectral classes.

Two visits to the field were made. The first, in 1977, acquainted the analysts with the tundra landscape and helped in preparing a preliminary classification of land cover. In 1978 the analysts returned to investigate problem areas, verify the validity of land cover classes, and sharpen their photointerpretation skills.

Throughout the process, a land cover classification system for the tundra that could be mapped with LANDSAT data was being devised. It was realized at the outset that the LANDSAT data source might not be perfectly compatible with the land use and land cover classification system used by USGS nationwide and that some modification might be desirable in mapping tundra classes. The final system was based on plant communities that have similar lifeform and contained ten classes. Compatibility with the basic USGS classes was shown.

Once the land cover classes were established, it was necessary to ensure consistency in interpretation among all ten LANDSAT frames. Some areas were reclassified following establishment of new spectral classes based on analysis of patterns noted on aerial photographs. In other areas, misclassifications, such as misclassifying shadows on mountain slopes as water, a situation caused by the spectral similarity of water with shadow, were

corrected by defining geographic regions where certain classifications did not make sense (Morrisey and Ennis, 1981).

A control network established between topographic base maps and the LANDSAT data enabled correction to the Universal Transverse Mercator (UTM) projection. Original pixels were resampled to form square cells 50 m on a side. After the frames had been corrected, they were mosaicked into two data sets corresponding to the two UTM zones covered by the data. Data were also formatted for each of 11 map quadrangles (1 degree of latitude by 3 degrees of longitude) and made available to BLM.

Land managers at BLM have registered each land cover data set to digital terrain data available from USGS and have used the combination to help monitor potential impacts of mineral exploration (Spencer and Krebs, 1982). The same digital land cover data are also available to the public through the USGS National Cartographic Information Center.

REFINEMENT OF TECHNIQUE

While work was proceeding on the NPRA, contacts were made with the U.S. Army Cold Regions Research and Engineering Laboratory (USA CRREL) where vegetation mapping was in progress at Prudhoe Bay and along the Dalton Highway. USA CRREL and their contractor, the Institute of Arctic and Alpine Research, University of Colorado (INSTAAR) were mapping detailed vegetation by using extensive ground surveys. They are able to achieve excellent detail in environmental mapping but were severely limited in the areas they could cover.

A partnership was forged that used the tundra classification expertise of USA CRREL and INSTAAR and the LANDSAT mapping capabilities of USGS. Detailed maps, already prepared by INSTAAR, were used as reference data for interpreting the LANDSAT classification, thus minimizing new fieldwork. The land cover maps from LANDSAT were used by USA CRREL and INSTAAR to extend their vegetation classification system to the vast regions surrounding their original sites, albeit at less detail.

The Prudhoe Bay region, heart of the petroleum development, was the first target for this joint effort. "The Geobotanical Atlas of Prudhoe Bay" (Walker et al., 1980) was used to differentiate land cover classes within spectral classes resulting from clustering of one LANDSAT frame. The detailed reference data made it possible to tailor spectral classes by focusing on specific known sites, something not possible in the NPRA work. A technique known as recluster--splitting one spectral class into several--was also employed successfully in refining the classification.

It was recognized that the key to developing a consistent classification using LANDSAT was a better understanding of the capabilities and limitations of the LANDSAT sensor. Spectral classes mapped by LANDSAT were found to be defined by complex reflectances from the ground associated with vegetation, soils, and land forms. These three types of information were mapped separately by Walker et al., (1980) and then combined into master maps. With LANDSAT, components of all three contributed to the spectral reflectance that was

sensed, though vegetation was seen to dominate. As work progressed, the arctic tundra region seemed ideally suited to using LANDSAT data. Spectral differences were strongly influenced by moisture and shrub component of the plant community, two factors already considered prominently in the classification system used by Walker et al., (1980). That system was extended and modified to accommodate the units mappable with LANDSAT (Walker et al., 1982).

Work at Prudhoe Bay was extended south by using detailed maps previously compiled by INSTAAR along the Dalton Highway corridor. One LANDSAT frame centered over the Sagavanirktok quadrangle was analyzed by using techniques similar to those used for the Prudhoe Bay scene. Field trips over two seasons were used, as in NPRA, to investigate problem areas or to help in the interpretation of aerial photographs.

In 1981, the U.S. Fish and Wildlife Service requested a land cover map of the coastal portion of the Arctic National Wildlife Refuge (ANWR) for use in an Environment Impact Statement (EIS). Since the EIS was due within a year, timing was a critical factor. A seven-day reconnaissance trip to the Refuge in August 1981 was the beginning of the project. Three LANDSAT scenes were needed, each treated separately by using cluster analysis. As before, field data were used to identify the spectral classes.

With the lessons learned previously, the analysis went smoothly and a digital data set corrected to the UTM projection was ready within six months. These data were smoothed to enhance cartographic presentation by generalizing tiny mapped units into their surroundings and then used to produce printing plates for lithography using a color laser plotter (Wray and Gaydos, 1982). The finished map (U.S. Geological Survey, 1982) also contained a table showing land cover areal measurement for survey townships located within the study area, a useful byproduct of the LANDSAT analysis.

LESSONS LEARNED

The experiences gained in using LANDSAT data for mapping arctic tundra have been most rewarding. Although LANDSAT was originally proposed as a data source because of cost and time factors, research has demonstrated that it is extremely well adapted to the task. Not only are the mapped classes comparable to what could be obtained through conventional interpretation of aerial photographs, but the resulting data are in digital form and consequently directly usable in geographic information systems. The area covered by each land cover unit for tracts of interest, such as survey townships, are easily obtained by simply digitizing the boundaries of tracts and counting pixels within each. Furthermore, the digital data can be used by a laser plotter to create color separation plates for map reproduction.

The classification system found optimal for use with LANDSAT data has the desirable attributes of being useful for both large-scale and small-scale mapping and consistently applying the same criteria and method for naming communities and vegetation

complexes. This system has evolved with our mapping experience and is easily compared with other systems in general use.

PERMAFROST CONDITIONS AT THE WATANA DAM SITE

James D. Gill¹ and Michael P. Bruen²

¹Ertec Northwest, Anchorage, Alaska 99503 USA
²Harza Engineering, Anchorage, Alaska 99501 USA

The proposed Watana development, consisting of a 270 m (885 ft) high dam and underground powerhouse, is the first phase of a two dam scheme on the upper Susitna River, located in Alaska, approximately 225 km (140 mi) south of Fairbanks. Extensive geotechnical investigations were conducted at this site to confirm the feasibility of the project. The extent of permafrost throughout the reservoir areas was mapped through the use of air photos, and the effect of thawing on reservoir slope stability was evaluated. Permafrost conditions are an important consideration at the Watana site. Lying in a broad glaciated region, the Susitna River at the Watana site flows east to west in a deep valley cut into the surrounding plateau, which lies above elevation 700 m (2300 ft). The river valley is more than 244 m (900 ft) deep and approximately 150 m (500 ft) wide at river level. At the site the north facing slope contains permafrost to depths exceeding 38 m (125 ft), while the south facing slope with favorable exposure is relatively permafrost free. The permafrost in the rock lies within 1°C below freezing. Temperature data suggest that the average annual air temperature is close to the freezing isotherm, suggesting that permafrost, although extensive at the site, is in a state of delicate equilibrium. On the relatively flat terrain above the valley rim the permafrost is more sporadic with extensive but discontinuous permafrost to varying depths. Although most of the permafrost in the overburden is relatively ice free, there exists at one location several miles downstream of the Watana site, a large, flay-lying, lense of ground ice in the valley slope in excess of 3.0 m (10 ft) thick.

INTRODUCTION

The Watana development, a proposed hydroelectric project on the upper Susitna River, is the first phase of what will ultimately be a two dam scheme with a total power generation output of approximately 1600 mw. The Watana site lies some 200 km (125 mi) northwest of Anchorage and 225 km (140 mi) south of Fairbanks, Alaska. The proposed Watana development includes a high earthfill dam over 250 m (820 ft) high with an underground powerhouse. Between 1980 and 1983 extensive geotechnical investigations were conducted at the site to assist in the assessment of the feasibility of the over-all development and to provide a basis for submission of a license to the FERC for construction of the project. Previous investigations had been conducted at the site as early as 1975 and as recently as 1978 by the U.S. Army Corps of Engineers. The site location is shown in Figure 1.

CLIMATIC CONDITIONS

The Watana dam site is situated in a valley with an elevation of 442 m (1450 ft) at river level and 686 m (2250 ft) on the abutments. Elevation has a significant influence on the existence of permafrost at the site due to the fact that the mean annual temperature is several degrees colder than locations in the lower Susitna river valley much further to the west but only slightly further south. Initial temperature data from existing

sites in the lower valley indicated that the mean annual temperature was close to the freezing isotherm, suggesting that the permafrost at the site was in a very delicate state of equilibrium. A more detailed review of actual temperatures at the Watana site indicates a freezing index of 1873°C days and a thawing index of 1212°C days, with a mean annual temperature of -1.8°C (29°F) averaged over the past 3 years. Although only 3 years of data are available from the newly established climatic station at the Watana site, it is apparent that the site lies within the generally accepted zone of discontinuous permafrost. (Ferriano, 1965)

The southern boundary of discontinuous permafrost is found to coincide with the -1°C annual air temperature isotherm (Gold and Lachenbruch, 1973). Since the Watana site has a mean temperature approaching -2°C, it is apparent that the thermal regime at the site is in equilibrium with the present climatic conditions in most instances. It is possible that in some areas large ice lenses and ground ice were formed at a time when the climatic regime was more conducive to the growth of permafrost and that such occurrences would not form under present conditions. Examples of these conditions are deep ice lenses in the overburden area to the north of the site and a large flat lying lense of ice, estimated to be at least 3.0 m (10 ft) thick near the Fog Creek area. The location of the ground ice is shown in Figure 2.

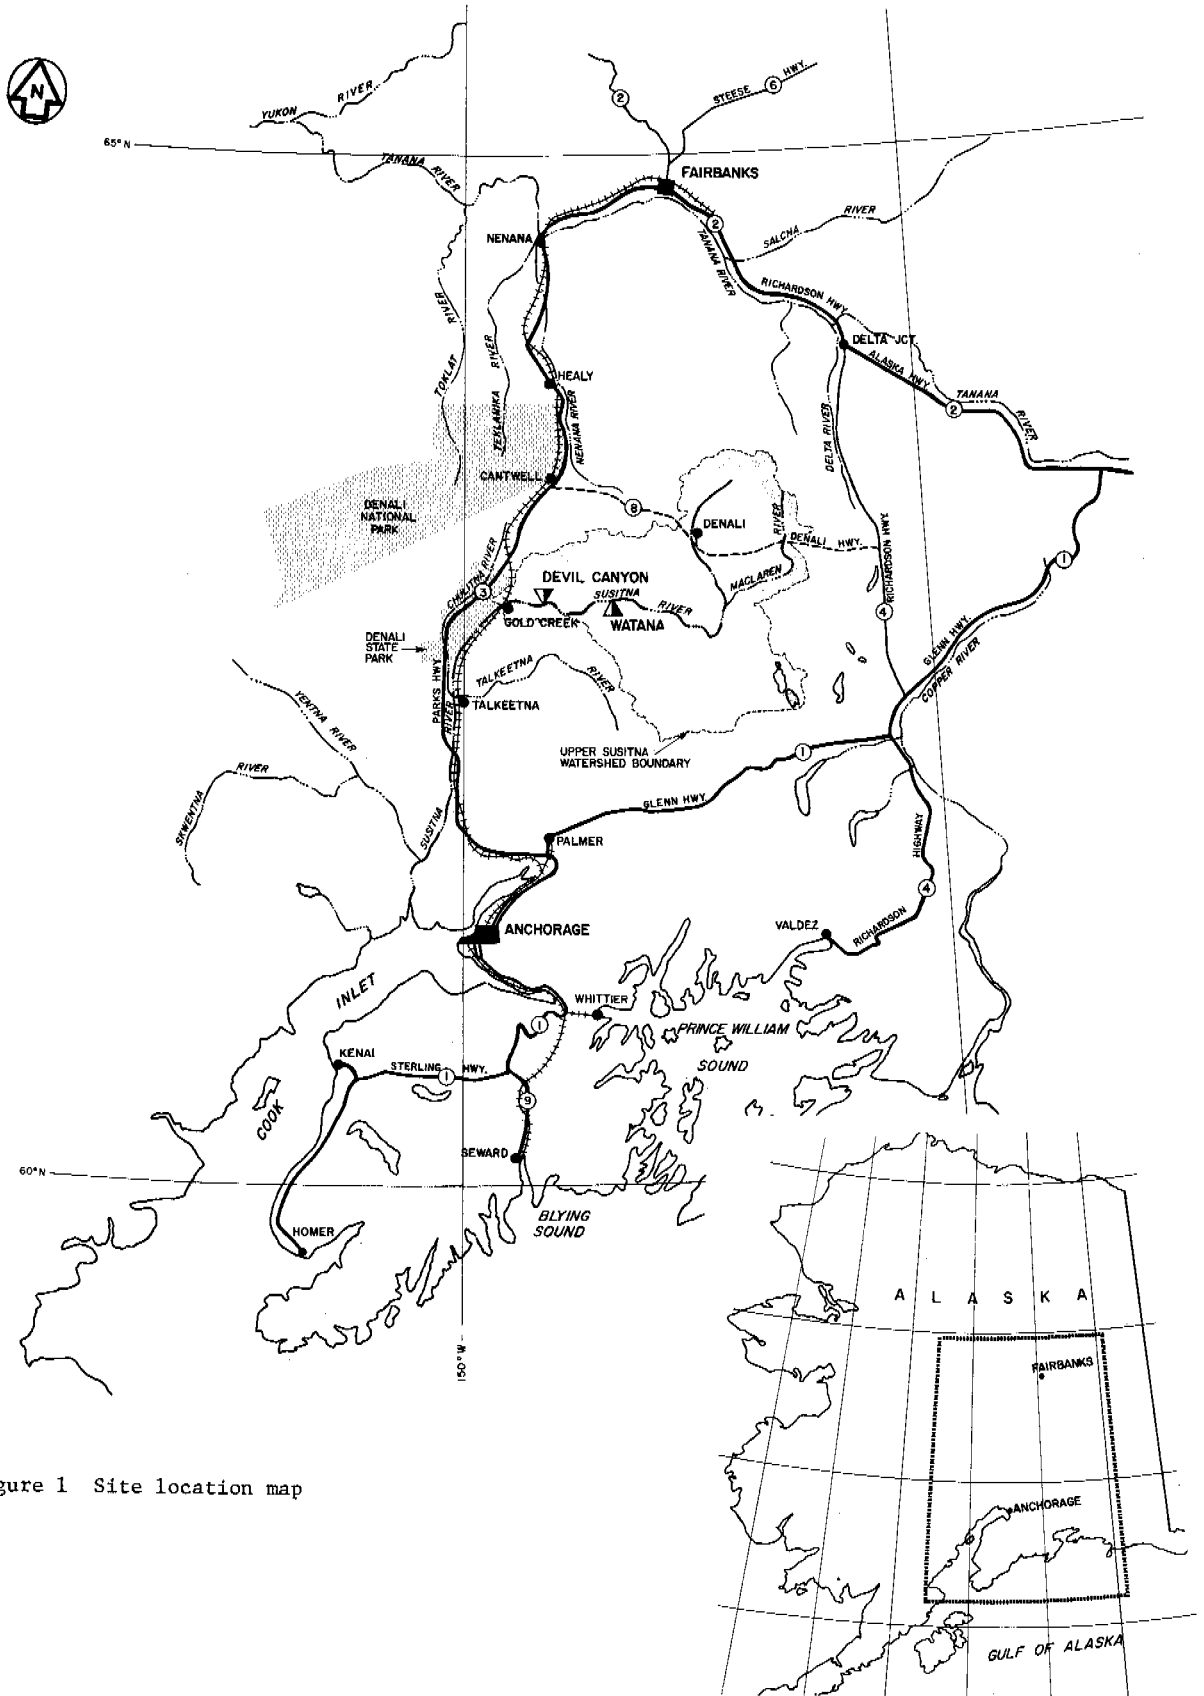

Figure 1 Site location map

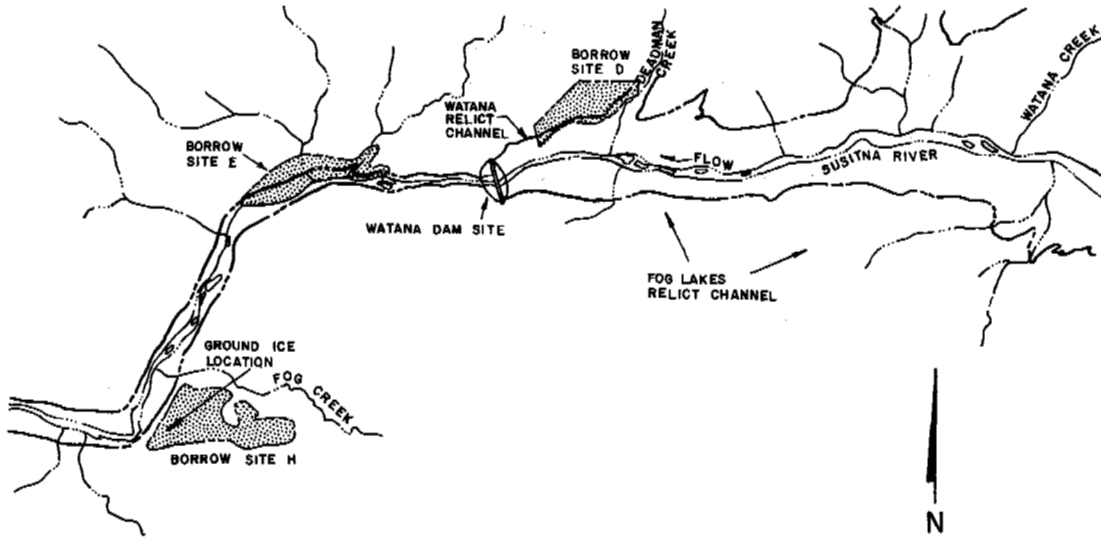

Figure 2 Site area

SOIL AND OVERBURDEN CONDITIONS

The depth of alluvium at the dam site within the river channel is a minimum of 27 m (90 ft) and consists of sand, silt, coarse gravel, and boulders. On the lower valley slopes, the overburden consists primarily of talus. The upper areas of the abutments near the top of the slope are comprised of glacial till, alluvium, and talus deposits. Sub-surface investigations show the contact between the overburden and the bedrock to be relatively un-weathered.

Just to the north of the Watana dam site a deep relict channel exists. The location of this buried, preglacial channel, is also shown in Figure 2. The maximum depth of overburden in the thalweg channel is approximately 137 m (450 ft). The channel stratigraphy is composed of a series of glacial outwash and till and alluvial deposits. Within the glacial deposits frozen ground has been detected in borings to depths of 34 m (110 ft) and has been verified to depths of 18 m (60 ft) in instrumented borings.

In addition to the area above the channel, designated as borrow area D, a number of other borrow areas near the site were investigated and the permafrost conditions were defined in these areas. They include borrow site E near the mouth of Tsusena Creek, and borrow site H near Fog Creek, both of which are shown in Figure 2. Borrow site E contains alluvial gravels, while H consists primarily of glacial till. The alluvial gravels contained no permafrost due primarily to the coarseness of the material and the southerly exposure of the area. Borrow site H contains permafrost to over 8 m (25 ft) depth due to its location at a higher elevation and, the flat lying terrain, and the thermal properties of the material.

PERMAFROST IN ROCK

Since overburden depths are very shallow on the valley walls, permafrost depths have penetrated well into the underlying rock on the south abutment. Although no thick ice lenses were observed, it is possible that lenses do exist on preexisting joints in the bedrock. Drill holes in the south abutment indicate that the depth of permafrost exceeds 60 m (200 ft). This depth is unusually deep for the climatic conditions at the site but it is primarily the result of slope aspect. The valley runs almost exactly east to west at the site and hence the south abutment, or north facing slope, is not exposed to solar radiation for many months of the year. Microclimatic effects have been known to influence permafrost distribution (Johnston 1981). Beaty (1977) addresses similar microclimatic effects on slope stability. An air photo of the site is shown in Figure 3.

EFFECT OF SLOPES AND GROUND COVER

The most dramatic and pronounced characteristic of permafrost at the Watana site is the asymmetrical distribution at the proposed dam site. Although ground cover has some influence on the depth of permafrost, permafrost distribution in the valley is a consequence of aspect, a characteristic observed by Johnston (1981). Figure 3 shows the Watana site area oriented with north at the top of the figure. The south facing, or north slope, with a minimum of soil cover, direct exposure to the summer sun, and hence, a shorter duration of snow cover, has very little evidence of permafrost. The north facing slope, with a slightly greater depth of insulating overburden and poor exposure to solar radiation, has evidence of permafrost in rock down

Figure 3 Air photo of site area

to depths of more than 38 m (125 ft).

The exact distribution of permafrost near the river's edge is not known. Although it is normally expected that the influence of a river, or body of water, is to create thaw bulbs below and adjacent the water body, the occurrence of anchor ice during freeze-up has been observed at several locations, suggesting that permafrost may be very close to the water's edge on the south side of the river. This ice develops below the water, firmly attached to the stream bed.

TEMPERATURE OBSERVATIONS

Temperature measurement instrumentation was installed in both soil exploration holes in the overburden and core holes in rock. For holes in rock, thermistor strings were attached to the outside of casing used to install deep piezometers or grouted internally inside 50 mm (2 in) diameter pvc pipes to protect leads from the deep piezometers. Open standpipe-type instrumentation pvc pipes were installed in most vertical soil drill holes. These were filled with an antifreeze fluid permitting the use of a temperature probe to measure the thermal properties of the surficial deposits. The temperature profile from BH6, a deep borehole in rock on the north side of the river, and angled beneath the river, is shown in Figure 4. It is interesting to note that the temperature

throughout the length of the hole is at or near freezing, while the annual or seasonal amplitude reaches down to 24 m (80 ft), presumably because of the influence of the river. Although it is considered that the hole is in permafrost, it is likely that interstitial fluids, such as groundwater in the fractures, are not frozen. This was evident when examining the permeability test results which indicated that fractured areas took water during the test, although it may be frozen in some locations. This hole and the area covered by its depth are low enough down in the valley to be affected by a screening effect from the south abutment cliffs, i.e. shade factor reducing incoming solar radiation (Wendler and Ishikawa, 1974).

Typical south abutment temperature profile in the overburden to the north of the dam site are shown in Figure 5.

Figure 4 Temperature profile BH6

Figure 5 Temperature profile south slope

STABILITY OF RESERVOIR SLOPES

The existence of permafrost throughout the reservoir area has an influence on the future stability of reservoir slopes during the ultimate impoundment of the reservoir. A study was made of reservoir rim stability during the course of the Susitna Feasibility Studies. To aid in the determination of thaw-susceptible slopes, an assessment of permafrost areas was made utilizing aerial photographs and limited field reconnaissance.

As a generalization, a high percentage of the glacial till and lacustrine deposits bordering the reservoir rim are frozen. The south facing slopes based on vegetation characteristics and limited field reconnaissance are better drained and because of slope aspect, permafrost is not as widespread or where found, as deep. Current slope instability in these materials indicates that aspect is important for the distribution of permafrost but aspect relative to incoming solar radiation, is not the key factor for instability and all slopes are susceptibility to mass movement.

The instability of thawing slopes in permafrost has been addressed by McRoberts and Morgenstern (1974). They indicate that bimodal flows, solifluction and skin flows are characteristic of slope instability due to thawing permafrost. Shoreline erosion in permafrost areas has been studied by Newbury et al. (1978). A study was made on the potential for slope instability due to reservoir-induced thawing of permafrost slopes in the Watana reservoir. Most of the problems to be encountered will occur on the sheltered slopes, particularly on the south side of the valley.

Thawing permafrost can generate excess pore pressure in ice rich soils. In cases where the soils are potentially liquefiable such as sands and silts, liquefaction during earthquakes is possible, resulting in additional landslides during seismic activity.

Historically, numerous small slides have occurred around the reservoir rim due to thawing permafrost. One of the largest slides of this type occurred in 1982, and is shown in Figure 6. Although the exact cause of this instability, which is approximately 320 m (1050 ft) long and contains 1.4 million m^3 (1.81 million yd^3) of material, is not known, it was found that the blocky material in the slide is frozen and contains ice lenses. The slide occurred on a northwest facing slope and has a very distinct failure plane sloping at an angle of 15° . Since a large icing appears on the backscarp of the slide it seems that groundwater played a role in the slide, either by inducing thaw along a weak plane and/or creating excess pore pressure along the sliding plane.

Figure 6 Watana Creek slide area

THAWING EFFECTS AND SEEPAGE PROBLEMS

The existence of permafrost in the borrow areas for the proposed dam does not present a problem. The material, although frozen in places, does not contain a great deal of ice and the temperature lies within $1^\circ C$ below freezing, hence frozen areas can be thawed prior to removal.

The thawing of permafrost in the overburden areas to the north of the dam site does not present serious engineering problems. During excavation of construction materials in borrow site D, the insulating vegetation cover should be stripped during the summer months, to allow the materials to thaw. Proper orientation of the cut face, to a semi-circular south facing slope, will enhance permafrost thaw during development of the borrow source. Some settlement will eventually occur in disturbed areas and design consideration must be given under the freeboard dike required at elevation 2210. However, design techniques for such structures are well established (Macpherson et al 1970).

The thawing of permafrost in rock below the dam foundation requires the greatest attention. The design implications of the thawing of the foundation of dams has been addressed by Johnston et al. (1982) and was carefully considered in the preliminary design of the Watana dam.

The principal results of permafrost thaw in the

Figure 7 Proposed dam cross section

rock foundation of the dam will be increased seepage through previously ice-filled fractures. One solution to this problem is an effective group curtain. However, in order to be effective, the zone around the grout curtain must be thawed prior to grouting. This can be accomplished by choosing a close arrangement of boreholes in a single or double row curtain. The spacing of the boreholes would depend on the time available for thawing, the temperature of the thaw-water and the economic constraints of additional holes vs. heating and time (Sayles, 1978). The circulating of water into the open boreholes prior to grouting, coupled with a series of holes to monitor temperature will allow for improvements in the thawing process as the operation proceeds. In addition to these precautions during the grouting operations, the preliminary design of the dam includes a gallery in rock below and in the abutments of the dam from which drain holes, as well as the grouting operation, will be undertaken. This tunnel permits observation of the increased in seepage which may still occur after thawing in the abutment. Additional drain holes or remedial grouting may be performed from the gallery. The arrangement of the proposed drainage and grouting tunnel is shown on Figure 7.

ACKNOWLEDGEMENT

The studies for the feasibility and licensing of the Susitna Hydroelectric Project were conducted by Acres American Incorporated for the Alaska Power Authority. The authors wish to thank the Alaska Power Authority for permission to present this paper.

THERMAL PERFORMANCE OF A SECTION OF THE MACKENZIE HIGHWAY

L. E. Goodrich

Division of Building Research, National Research Council of Canada, Ottawa, Ontario K1A 0R6

The thermal performance of a shallow road embankment constructed on permafrost in the discontinuous zone of the Mackenzie Valley was monitored over a 5-year period. The shallow (1.2 m) embankment consisted of clean borrow material end dumped on a right-of-way which had previously been cleared of trees. The road was never opened to general traffic; consequently snow removal was minimal. Measurements included hourly ground temperatures recorded with a data logger operating unattended. Settlements were monitored and thermal conductivity probes were installed to yield information on seasonal trends within the embankment and in the various natural materials comprising the active layer. The data indicate that degradation of the permafrost is under way and provide information on the relation between road surface temperatures and climatic factors for this region.

INTRODUCTION

In 1972 the Mackenzie Highway Environmental Working Group was established by the Department of Indian Affairs and Northern Development to monitor the environmental impact of the proposed Mackenzie Highway joining Fort Simpson to Inuvik and the Arctic coast. The Division of Building Research of the National Research Council of Canada was invited to carry out a limited study of the thermal aspects. At that time no case studies of shallow embankments constructed on permafrost had been carried out in the Fort Wrigley region. It was expected that although degradation would not pose serious problems in the zone south of Fort Wrigley, the data collected could be used to anticipate problems in the more difficult soils to the north. Although, as originally planned, the road was to be a graveled, all-weather road, construction was halted and during the final two winters of this study there was only minimal snow removal.

OBJECTIVES

The specific objectives of this study were:

1. to observe the changes in temperature regime in the ground underlying the road embankment as well as in the surrounding right-of-way in order to assess the thermal disturbance caused by the embankment;
2. to collect data on temperatures within the embankment for design purposes;
3. to assess the settlements of the embankment;
4. to obtain basic soil information for the site, including profiles of ice content, soil density, and composition; and
5. to measure thermal conductivities both in the natural ground and in the embankment and to assess seasonal and year-to-year variations.

FIELD INSTRUMENTATION

Field work was begun in March 1976 at mile 419.5, near the northern end of the proposed new construction on the Mackenzie Highway (Figure 1). Earlier reconnaissance had indicated the presence of permafrost. This location also offered important logistic advantages. The Hire North camp at River-Between-Two-Mountains could serve as base of operations, and in addition, a winter road facilitated access to Fort Simpson, the nearest point with land connections to the south. For these reasons this site was selected, even though more sensitive terrain could be found to the north.

FIGURE 1 Location map.

To compare thermal conditions under the future embankment centerline, the shoulder, the previously cleared right-of-way, and the original undisturbed terrain, four holes were drilled approximately 8 m deep (the maximum achievable with equipment at hand). These locations correspond to profiles A, B, C, and D in Figure 2. Nearly continuous core was recovered from hole A (centerline), and grab samples were collected from holes B and D. The soil type, moisture content, and density were determined on site. In addition, representative core samples were shipped to the laboratory for further evaluation, including thermal conductivity measurements. The holes were instrumented with Yellow Springs #44033 thermistors mounted on multiconductor cable to a depth of 7 m. The cables were cased in PVC plastic tubing for protection from mechanical damage, and the boreholes were backfilled with dry sand. A prefabricated instrument hut made of fiberglass-styrofoam sandwich panels was erected at the site.

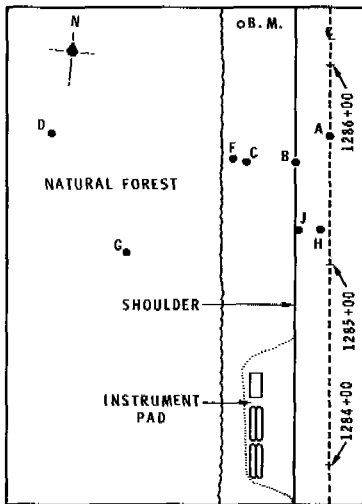

FIGURE 2 Site layout.

A Monitor Systems 9400 data logger using a lower power Digi-Data tape drive was installed in September 1976. Power was provided by a 3M propane-driven thermoelectric generator which simultaneously charged a bank of Gel-Cell batteries serving as a backup power supply. A propane furnace was installed to maintain ambient temperatures within the hut at levels adequate for the data-logging equipment. At this time also, three small pits (E, F, and G in Figure 2) were dug to a depth of approximately 1 m. The pits were instrumented with thermistors potted into metal tubes mounted horizontally on vertical wooden stakes. These installations were intended to provide more reliable information on near-surface temperature conditions than that available from the deep cables A-D. The pits were also instrumented with thermal conductivity probes (Goodrich 1979) to measure the seasonal variation of conductivity for the different materials comprising the active layer.

In June 1977 the final grade was completed past the instrumented section. A trench was dug across

the road and stake-mounted thermistor probes, similar to those used in the shallow pits, were installed in the trench wall (Cables H and J in Figure 2). The addition of four thermal conductivity probes completed the thermal instrumentation. Finally, settlement plates were installed on the centerline and near the shoulder to monitor total settlement of the embankment.

The test site was operated, with some interruptions, from September 1976 until March 1981. During this time the data-logging equipment and thermoelectric power supply were left to function unattended for periods of 3-4 months. Approximately 80 channels, including 3 used to verify the equipment, were recorded every hour. Thermal conductivity measurements and level surveys were made whenever possible during site visits.

RESULTS

Figure 3 shows the soil profile for the centerline borehole (profile A). Conditions at the three remaining boreholes were similar, as inferred from split spoon sampling. The profiles consist primarily of silts and sands with some layers of gravel. Fine-grained materials are prevalent in the upper part of the profile, while the gravel layers are found only below 4 m. Correspondingly, the total volumetric moisture content varies from nearly 80% in the upper levels to less than 40% at depth. While some small ice lenses (<5 mm) are present in the silt layers, most of the ice is dispersed, and the soil is well bonded with ice throughout.

FIGURE 3 Soil conditions: mile 419.5.

Daily mean temperatures for all channels were computed from hourly data recorded on the original tapes. Data processing included a check of each scan for instrument drift, channel sequence, range and sign bit, and clock errors. If more than five unsatisfactory scans occurred in a daily period, the

entire daily record was rejected. Since the manufacturer claimed an interchangeability error of less than $\pm 0.1^{\circ}\text{C}$, thermistor linearization was done using the same formula for all channels. Examination of Figure 4 reveals, however, that overall errors may be considerably greater. The temperatures for channels 8-10, all of which are located at levels within the active layer (also channel 11 from 1979 onwards), should be near or at the freezing point during the autumn freezeback period (zero-curtain effect). Although this is well verified for channels 8 and 10, the error for channel 9 is rather more than 1°C , and that for channel 11 is nearly as great. It can also be seen that the errors increase with time. Errors of similar magnitude were found in other profiles for several channels in the active layer where a well-defined zero-curtain existed; nearly a third of these channels required corrections of more than 0.2°C . For channels below the active layer there is no certain reference temperature. In a few cases, corrections could be inferred from an examination of the annual mean profiles along with observation of the temporal behavior. In most instances, however, the data for these points were rejected. Typical corrected data are shown for the centerline profile in Figure 5.

FIGURE 4 Errors in raw data of profile A C/L.

FIGURE 5 Corrected profile A C/L.

As regards equipment reliability, Figures 4 and 5 indicate that a nearly complete record was obtained, with two major exceptions. The long gap from mid-November 1977 to mid-September 1978 was the result of three separate circumstances. The data logger had to be removed for repairs in November 1977. All the equipment, except the defective data logger, was lost when fire destroyed the site in March 1978. Further delay resulted when plans to abandon construction of the road were announced. The second major gap, during early 1979, was purely the result of human error and not of equipment malfunction.

Thermal conductivity measurements were made whenever possible during routine site visits. Fifteen probes were eventually emplaced in a variety of materials, including the natural lichen mat and the decomposed peat layer, as well as at several depths in the natural soil and in the embankment. Figure 6a shows results obtained both in natural peat and in the peat layer underlying the embankment. Data for all years have been plotted on the same axes. The data can, in both cases, be reasonably well represented by constant frozen or thawed values. The thermal conductivity of the compressed peat beneath the embankment is 2-3 times that of the natural peat. In addition, the ratio of frozen to thawed conductivity is reduced from approximately 4 for the natural peat to approximately 2 for the compressed peat. Figure 6b shows thermal conductivities measured near the surface and near the base of the embankment. The data suggest that for the level near the surface the thawed conductivity is remarkably similar from one year to the next. Frozen values are distinctly greater but also show more scatter. It is interesting to note that for the lower level no distinct seasonal pattern is evident. The greatest year-to-year variation is, however, again found in the winter values.

FIGURE 6 Thermal conductivity variation.

Some level survey results for the embankment centerline are summarized in Figure 7. The curves suggest similar trends at the embankment surface and base. (The increase in surface level in mid-1979 reflects road maintenance operations.) Total settlement from construction in mid-1977 to the

final survey in mid-1980 was approximately 0.3 m. At many stations in the 200 ft (~60 m) section surveyed, there was considerably more settlement near the shoulders than on centerline. By mid-1980 the road surface had become a series of bumps and hollows with elevation differences of approximately 0.15 m over 10 m intervals.

FIGURE 7 Settlement: C/L STN 1285 + 17.

DISCUSSION

Hand probing carried out during the initial reconnaissance (autumn 1975) indicated that the active layer in adjacent undisturbed terrain at the site was typically about 50 cm thick. There was, however, evidence that significant thermal degradation was under way following removal of the black spruce cover some 2 years earlier. Near the eastern side of the cleared right-of-way, advanced degradation was evident along the route of the former Canadian National Telegraph line. Here the ground was thawed to depths of 2 m or more.

The annual progress of the zero isotherm within the embankment and in the underlying ground is shown for the centerline profile in Figure 8. Although the term "zero isotherm" is used here and elsewhere for convenience, the graph, in fact, shows the isotherm for -0.15°C , this value being consistent with the zero-curtain "calibration" of Figure 5. The isotherm histories were computed from the adjusted daily mean temperatures with no temporal or spatial smoothing. This explains some of the apparent scatter in the curves. Note also that the cuspidal shapes, seen especially in the advancing thaw fronts, are merely artefacts of the method (linear interpolation) used to calculate the position of the isotherm. This procedure will necessarily overestimate isotherm depth, except when the isotherm traverses a measurement level.

It can be seen from Figure 8 that prior to embankment construction the subgrade thawed to a depth of less than 1 m. Since construction, the thaw has progressed to successively greater depths each year so that by 1980 the total thaw reached 1.4 m.

Annual mean temperatures computed from the 3 years of nearly continuous records are shown for the embankment and subgrade centerline profile in

FIGURE 8 Centerline zero isotherm.

Figure 9 and shoulder profile in Figure 10. In 1979 and 1980, annual mean temperatures at the embankment surface were approximately $+1.5^{\circ}\text{C}$ on centerline and $+3^{\circ}\text{C}$ at the shoulder. A substantial increase (about 1°C) has occurred in the upper 1-2 m of the subgrade since the embankment was built. A similar trend is seen in the embankment shoulder profile (Figure 10). While shallow subgrade temperatures under the shoulder are not more than 0.3°C warmer than those at the centerline, near the surface the difference is substantially greater. The reversed curve in the upper levels of the 1977 profiles seen in both Figures 9 and 10 reflects the fact that construction activities took place during the first half of that year.

FIGURE 9 Annual means: centerline.

Figure 11 shows the annual mean temperatures for the deep datum cable located in the nearby partially cleared bush. It should be noted that the

FIGURE 10 Annual means: shoulder.

FIGURE 11 Annual means: deep datum.

results for 1979 are nearly identical to those for 1977. This may be interpreted as evidence that the large differences between the temperatures for these years in the embankment profiles are indeed caused by the presence of the embankment and are not merely a reflection of different weather conditions. Note, too, in Figure 11 that in successive years the near surface temperatures are a fraction of a degree warmer. In addition, there is some tendency for the active layer to deepen, as seen in Figure 12.

At all three sites, annual mean temperatures exhibit a strong tendency to decrease sharply through the active layer. This may be, at least in part, a manifestation of the thermal rectification effect resulting from temperature-dependent thermal

FIGURE 12 Deep datum zero isotherm.

conductivity. When the frozen conductivity is greater than the thawed conductivity, as it is here, annual mean temperatures will decrease with depth. The fact that profile distortion is confined primarily to the active layer suggests that thermal rectification is indeed the principal mechanism at these sites.

Profile curvature may, in addition, indicate that deep temperatures are not yet in equilibrium with long-term conditions at the surface. The 1980 profile at the deep datum site, Figure 11, suggests that mean temperatures will probably continue to rise somewhat and that, not unexpectedly, this datum site is far from being "undisturbed."

Figure 13 shows a comparison of temperatures at 1 m depth below the original ground surface for the embankment centerline, the shoulder, and the deep datum site. From the shape of the curves it can be inferred that thawing did not occur at the deep datum site during the first 2 years, but did occur in 1979 and was more intense in 1980. The data also indicate that some slight thawing occurred at the shoulder profile even before construction. There was no thawing prior to construction at the centerline 1 m level. Finally, it should be noted that the subgrade temperatures are warmer than the datum values not only in winter but also in summer; the shallow embankment enhances summer heating while reducing winter cooling.

Table 1 presents approximate values of "n-factors" for the site. The n-factors are computed as the ratio of the thawing or freezing index at the road surface (that is, beneath the snow cover) to that of the air. Surface temperatures were estimated by extrapolation from measurements starting at a level 20 cm below the surface. Since the air temperature records at the site were incomplete, data were extracted from the published records for Fort Simpson (200 km south of the site), the nearest regularly reporting standard meteorological station. The values in Table 1 should therefore be considered with caution. They can, however, be used for relative comparisons. Table 1 implies that the gravel surface had a thawing n-factor only 16%–19% greater than that of the original terrain. The difference is smaller than expected, and this may, in part, reflect disturbance at the datum site.

ACKNOWLEDGMENTS

Prior to 1978 this study was financed by the Mackenzie Highway Environmental Working Group. After suspension of construction activities, financing was continued by the National Research Council of Canada. The author gratefully acknowledges the contribution of G. H. Johnston, whose help with site selection, and initial planning and field work was indispensable. A special thank-you is also due to T. L. White, J. C. Plunkett, W. G. Cooke, and T. Ireson for their unstinting assistance in the field and with essential chores in the laboratory. This paper is a contribution from the Division of Building Research, National Research Council of Canada, and is published with the approval of the director.

Year	Thawing Index (°C·day)	Freezing Index (°C·day)	C/L		Datum	
			n_t	n_f	n_t	n_f
1978-79	1970	3250	1.08	0.50	0.93	0.56
1979-80	2080	2920	1.02	0.56	0.86	0.64

CONCLUSION

The data suggest that for the climatic and soil conditions in the Fort Wrigley area, road construction results in degradation of the permafrost in spite of special precautions taken to minimize disturbance of the organic cover. For the present conditions of road operation (winter road) with infrequent traffic and limited snow removal, annual mean road surface temperatures are up to 3°C above the freezing point. Since there may, however, be a significant thermal rectification effect associated with temperature-dependent thermal properties at shallow levels, it is possible that mean temperatures at depth will remain negative.

The maximum thaw penetration is about 50% greater beneath the embankment than at the datum site. During the study period there was an evident tendency for the active layer to deepen with time. This tendency, however, in addition to implying a long-term increase in deep-ground temperatures, also mirrors the increase observed in summer air temperatures; consequently, it cannot be stated unequivocally that the active layer beneath the embankment will continue to deepen significantly. Further monitoring of the site would be required to establish the long-term trends with certainty.

Not all the data have been examined at this time. Further analysis, including numerical model simulation, may shed light on the ambiguities noted in this paper and provide useful guidance in designing future embankments in the Mackenzie Valley region.

ROCK GLACIERS OF THE MOUNTAINS OF MIDDLE ASIA

A. P. Gorbunov

Permafrost Institute, Siberian Branch,
Academy of Sciences, Yakutsk, USSR

About 10,000 active rock glaciers exist in the mountains of Middle Asia. Their total area is about 2,000 km². There are 20 to 30 km³ of detritus and almost 20 km³ of ice concentrated in them. The altitude range of active rock glaciers is from 2,300 to 3,500 m in the northern part of the area, and from 3,300 to 4,500 m in the southern part. The largest rock glacier is 4.4 km long and the rate of advance in certain years is up to 1.3 m per year. The ice content of lobate rock glaciers is 50 to 75% by volume. Waste material from huge excavations on the Rusvumcherr Plateau was dumped on slopes of 30 to 40°. Lower down, the slopes decrease to 15 to 20° and the ice-rich waste material in this permafrost region formed "rock glaciers" with typical form and motion. Locally, an increase downslope to 30° inclination caused the artificial rock glaciers to rupture and a huge body of debris (4,000,000 m³) to catastrophically advance. Such rapid motion in an artificial rock glacier may also have occurred in natural rock glaciers in the past if such changes of slope are present. It is thought that such a catastrophic advance is recorded by a rock glacier of the Uzunvulak Valley, perhaps caused by an earthquake.

In the USSR, rock glaciers are known to exist in the Caucasus, Pamir, Tien Shan, and Dzhungarskiy Alatau, in Altai, Sajany, in the mountains of Transbaikal, in Dzhugdzhur and Cherskiy Ranges in the Karyak upland. However, they are the most common in the mountains of Middle Asia.

The mountains of Middle Asia are Saur Tarbagatay, Dzhungarskiy Alatau, Tien Shan, Pamir-Alai, and Kopetdag. There are no rock glaciers in the first and in the last regions because of either low altitude or the absence of permafrost.

The rock glaciers of Middle Asia have not yet been closely studied. There is more or less detailed information on the rock glaciers of Dzhungarskiy and Zailiyskiy Alatau, Kungey and Terskiy Ala Too, Kichik Alai Range, Ob'-Khingou basin and some other areas (Brukhanda 1976, Glazovskiy 1978, Gorbunov 1970, 1979, Iverova 1950, Palgov 1957, 1961, Suslov 1966, Shultz 1947). For most of the territory, however, there is little or no information on the rock glaciers. Therefore, only an approximate quantitative assessment is possible, although detailed studies of some regions permit generalizations at this time.

A preliminary estimate indicates that there are about 10,000 active rock glaciers in the total area of 2000 km² of the mountains of Middle Asia. They compose about 20-30 km³ of rock material and approximately 20 km³ of ice.

The altitudinal range of the active rock glaciers extends from 2300 to 3500 m in the Dzhungarskiy Alatau in the north and from 2500-3850 m in the Zailiyskiy Alatau to 3300-4500 m in the Pamirs in the south. Thus, the maximum altitudinal distribution is about 1000 m.

Inactive rock glaciers are much less common and occur only by 100-200 m lower than the active ones. In Zailiyskiy Alatau they total about 15% of all rock glaciers of the Ridge. Some of them have been destroyed, and others are buried under the recent active rock glaciers.

The author (Gorbunov 1979) has suggested that

the term "specific density" of these formations should be used as a comparative index of the degree of development of the active rock glaciers. This is the relationship between the total area of active rock glaciers, in m², and the area of the basin of a given valley above the lower limit of distribution of these forms in km². For Zailiyskiy Alatau this index is equal to 14,550 m²/km².

From the reports of Barsch (1977), Kershaw (1978), Higuchi et al. (1978) it is possible to determine the approximate specific density for the Switzerland Alps—3333, for the Seluins (Canada)—13,772, and for the Himalayas (Everest region)—1430 m²/km². Thus, the increase of mountain climate continentality creates better conditions for the formation of rock glaciers. This relationship has been known before, but "specific density" enables a quantitative assessment.

Besides climate, conditions affecting the development of rock glaciers and their location are relief features, lithology, and avalanche processes. The most favorable conditions for rock glacier formation, besides climate control, are deeply dissected mountain massifs with steep talus and rock slopes; slightly fissured solid rocks that form large amounts of debris; moderate snow cover; and moderate avalanche activity. Thick snow cover creates perennial freezing of talus and hinders its transformation into rock glaciers. Large avalanches suppress the processes of formation of the classic rock glaciers.

Local factors (relief, lithology, snow cover and avalanches) vary from one river basin to another within the same mountain country, thereby considerably altering the specific density of rock glaciers. Thus, within the Zailiyskiy Alatau it varies from 41,610 in the Issyk River basin to 6,500 m²/km² in the Kargaul'dinka River basin. Rock glacier occurrence substantially depends on slope position. In Zailiyskiy Alatau 72.5% of all active rock glaciers are confined to the north-facing slopes, and 15.6% to the south.

Such correlation is determined by the fact that permafrost is more common and extensive on north-facing slopes. A similar situation exists in other mountains of the Northern Hemisphere. In the Rocky Mountains of Canada, the former comprise 79.8%, the latter 5.9% (Luckman and Crockett 1978), in the Selwyn Mountains (northwest of Canada) these values are equal to 63.4% and 14.6% respectively (Kershaw 1978). In some instances, however, this regularity breaks in the mountains of Middle Asia. Thus, in Ob'Khingou basin (Darvas, Western Pamir) rock glaciers prevail on the south-facing slopes (Brukhanda 1976).

Rock glaciers have been recently divided into two major groups: those next to talus slopes and those next to end moraines of present glaciers (Barsch 1977). The former, according to Krasnolobodtsev (1971), are referred to "near-slope," and the latter to "near-glacier" rock glaciers. These terms imply not only genesis of rock glaciers but also their location. In the papers of foreign authors the former are usually called "lobate," and the latter are termed "tongue-shaped" rock glaciers.

Those rock glaciers which look like a continuation of end ice moraines and gradually flow together with them, belong to tongue-shaped rock glaciers. It is this kind of rock glacier that is commonly taken for end moraines. But the active rock glaciers differ from the moraines by their mobility, steep active frontal slope, arched barriers and depressions, as well as by inner structure, about which in most cases we can only guess. The identification of tongue-shaped rock glaciers often becomes difficult during periods of glacier advances, which commonly results in temporary smoothing of the "corrugated" surface of the active rock glacier and superposition of end moraines on it. Besides, the inner structure of rock glacier alters as well, i.e. buried massives of glacial ice can appear to be inside.

It commonly happens that a typical lobate rock glacier formally becomes a tongue-shaped one due to glacier advance. Such a phenomenon was observed when a large lobate rock glacier moved down the valley; then later a glacier advanced and pushed against the rock glacier. Such a lobate rock glacier destroyed by a glacier will be accepted as a typical tongue-shaped one. Hence, the rock glacier position near the glacier edge does not allow one to solve a problem of its genesis. Only petrographical analysis of rudaceous rock and its correlation with surrounding slopes and glacial moraines can clarify the origin of the given rock glacier.

Tongue-shaped rock glaciers are not as common in the mountains of Middle Asia as are the lobate rock glaciers. Only 172 active rock glaciers out of 429 in Zailiyskiy Alatau are tongue-shaped ones. The average length, width and area of the tongue-shaped rock glacier in Zailiyskiy Alatau are 630 m, 280 m and 0.1897 km² respectively.

The largest tongue-shaped rock glacier in Zailiyskiy Alatau, and the largest one in the area under discussion, is Prjamoy shcheli (right influx of the Issyk River). It is 4400 m long, the largest width 1320 m, the least width 220 m, mean width 400 m, and area 1662 m². The total volume of the rock glacier is estimated to be no less than

8.3 x 10⁷ m³.

The rock glacier of Prjamoy shcheli is in a trough valley inclined to the north. Its upper part is at 3500 m, the frontal bench foot at 2500 m. The rock glacier is tree-shaped in cross-section.

At present, the area of rocky slopes, providing source material is nearly 7 km²; in periods of maximum glacier retreat it could reach 11-12 km².

Active lobate rock glaciers include forms that originate at the foot of talus slopes of valleys and empty cirques.

In Zailiyskiy Alatau the average size of an active lobate rock glacier is 380 m long, 180 m wide, with an area of 0.0667 km². One of the largest rock glaciers of the region is situated in the valley of the Kebin River (Chilik basin). Its length is 1750 m, the largest width is 200 m, average width of 150 m, and an area of 0.2775 km². The height of the frontal bench is about 40 m. The upper part of the rock glacier lies at the altitude of 3600 m and the frontal bench at 3050 m.

Lobate and tongue-shaped rock glaciers in Zailiyskiy Alatau comprise 59.9% and 40.1% of the population respectively. By comparison, in the Swiss Alps they comprise 60.6% and 39.4% (Barsch 1977); in the Rocky Mountains of Canada (Jasper and Banff National Parks) 45.5% and 54.6% (Luckman and Crockett 1978).

An active rock glacier is so named because it shows current motion. The motion is expressed by down valley movement and by vertical rising and lowering of separate parts of the surface.

The usual rate of rock glacier advance is 20-30 cm per year, though in some years it may be substantially higher on some rock glaciers. The central part of the rock glacier of the Gorodetskiy glacier (Zailiyskiy Alatau) advanced at a rate of 1.1 m per year from 1923 until 1977. In some years the rate is likely to be considerably more.

Vertical motions of rock glaciers usually do not exceed a few centimeters per year. According to Palgov (1957), rising and subsequent lowering of points on the surface of the "Nizkomorenniy" rock glacier (Jungarskiy Alatau) was 1-2 cm per year. The average rate of vertical motion of the Murtel rock glacier in the Alps was 2-6 cm per year (Barsch and Hell 1975).

It is necessary to emphasize that the horizontal and vertical motions in the rock glaciers are notable for changing over the years. The rate of the front advance of the Gorodetskiy rock glacier during the period 1923-1946 ranged from 0.4 to 0.9 m/yr; from 1946 to 1960, 0.9 m/yr, and during the period from 1960 to 1977 the rate was 0.7 m/yr (Titkov 1979). According to Palgov (1961), the rate of the advance of the "Nizkomorenniy" rock glacier slowed from the period 1953 to 1959 about 36-37% of the 1948-1953 period.

Progressive (horizontal) motion of the rock glacier is controlled by the plastic and ruptural deformations of the contained ice. Vertical motion is generated due to different reasons. Among them are thawing or formation of ice, as well as formation of lateral swells and hollows on the surfaces of rock glaciers due to a difference in the rate of motion between the center and margins of the rock glaciers.

The least known part of a rock glacier is the

inner structure including the amount and type of ice. At present there exists two main concepts for the origin of rock glaciers: (1) a rock glacier is part of an ice glacier buried under rock waste and still has the ability for motion; and (2) a rock glacier is a concentration of detritus, cemented with ice of a different origin and moves by plastic and ruptural deformations within the ice.

Data on the inner structure of rock glaciers are extremely rare, although in the past few years drilling has been undertaken to obtain such information. Two holes, 10.4 and 7.0 m deep were drilled in rock glaciers in the Alps (Barsch, Fierz and Haerberli 1979). These rock glaciers appeared to be composed of perennially frozen rudaceous material containing segregated ice lenses with thicknesses up to 30 to 60 cm. Maximum ice lense thickness is thought to reach 150-170 cm. Segregated ice lenses were found in permafrost of a rock glacier in the South American Andes (Wayne 1981). Such ice lenses also occur in the rock glaciers in Middle Asia.

The studies carried out in the Zailiyskiy Alatau reveal that the rock glaciers are composed of perennially frozen rudaceous rocks. The ice content is up to 50-70% by volume. Ice cement, segregated ice in the shape of lenses (up to 15 cm thick and possibly more), and congelation ice that fills fractures in permafrost are the most typical types of rock glaciers. The fractures may be due to permafrost fracture during rock glacier motion and during earthquakes.

Investigations of the structure, dynamics, and physical-mechanical properties of rudaceous debris containing ice, carried out on the slopes of the Khibiny, are of an extreme interest for understanding of the inner structure and motion mechanism of rock glaciers. Great amounts of debris containing ice formed during formations of huge artificial excavations on the Rusvumcherr Plateau and the accumulation of the detritus dumped on slopes attaining angles generally between 30° to 40°. With the slopes decreasing to 20-15° the talus-shaped piles formed into "rock glaciers" with typical horseshoe bars and frontal benches (Otvaly ... 1975, Semekhin, Mjagkov and Vashchalova 1979).

These "technogenic" rock glaciers of the Khibiny originate only on the northern slopes of the mountains where permafrost exists. Perennial ice occurs in the rudaceous material. The volumetric ice content commonly exceeds 50% and occasionally reaches 77%. Ice lenses up to 1.5 to 2.0 m thick occur. This high ice content leads to an abrupt qualitative change of ice-rock mass strains, i.e. the overall mass may behave as a plastic under the stress of 1.6 kg/cm² at temperature -1.2°C. Forward motion rates of 120 cm per day are known.

Change in slope steepness from 10 to 15° to 20 to 30° for the artificial rock glaciers caused a sudden increase in rate of flow and rupture of the frozen body. A body of about 4,000,000 m³ of debris came down, in a mass. The debris form resembles something between an earth flow and a rock slide.

From this observation it follows that under certain conditions the "technogenic" piles are strikingly similar in their appearance and interior structure to natural rock glaciers. Disastrous advance of the artificial rock glacier

indicates that such an event can occur in natural conditions as well. Although such rapid advances of rock glaciers have not been registered up to now, it does not mean that they are impossible. Perhaps they occur under certain conditions when the moving rock glacier reaches an abrupt increase in steepness of a slope.

Analyses of aerial photographs of different areas of the Tien Shan and Jungarskiy Alatau let us surmise that some rock glaciers have been subjected to the aforementioned rapid advances.

One of the best examples of a past disastrous advance concerns the rock glacier of Uzunbulak Valley (the Jungarskiy Alatau). A typical near-slope rock glacier of about 1 km long and 150 m wide formerly extended from 2800 to 2600 m. The rock glacier was supplied with detritus from steep slopes.

For some reason, perhaps an earthquake, the rock glacier advanced rapidly. There formed a zone of rupture 600 m long, which looked like a trench confined by swells on both sides. Downslope from the trench exists a typical rock glacier 800 m long and 80-100 m wide. It extends to the low altitude of 2100 m; this is abnormally low for the Jungarskiy Alatau where rock glaciers usually do not descend lower than 2400 to 2500 m.

Active and inactive rock glaciers represent two generations of late Holocene time. The first one (forms that are inactive now) started to develop during the period of mountain glacier retreat approximately 2500 to 3000 years ago, when the firn line was no more than 100 m lower than at present. The beginning of the active rock glaciers formation falls on the last stage of glacier retreat (1500 years ago) when the firn line was near the present level. Absence of rock glaciers more than 2500 to 3000 years old indicates that when the firn line is 300 to 400 m lower than present, the glaciers and snowpacks are more widespread and prevent rock glacier formation because ice covers rock slopes. As the firn line rises, more and more bare rock becomes available and become sources of detritus that form rock glaciers. Rock glacier evolution is then asynchronous to the stages of mountain glaciation. The recent advance of rock glaciers occurs in the period of general retreat of the glaciers in the region. Therefore, rock glaciers are to some extent the antagonists to mountain glaciers and knowledge of their history permits us to know more about retreat of mountain glaciers.

A THEORETICAL MODEL FOR PREDICTING THE EFFECTIVE THERMAL CONDUCTIVITY
OF UNSATURATED FROZEN SOILS

Fabio Gori

Department of Energetics, University of Florence
Via S.Marta 3, 50139 Florence, Italy

The model assumes the soil as a cubic space with a centered cubic solid grain. The hypotheses of parallel isotherms and heat flux lines in the determination of the effective thermal conductivity are discussed. The comparison with several experimental results on saturated two-phase media indicates that the assumption of parallel isotherms gives a good agreement. The unsaturated frozen soils are investigated taking into account phenomena of adsorption and capillarity. The predictions of the present model are finally compared with experimental data on unsaturated frozen soils available in the literature. The model gives better agreement to the data than that found using the expressions of Johansen and Frivik (1980) and the electrical conductivity analogy of De Vries (1963). Some characteristic results are presented for soils studied by Kersten (1949) and Penner et al. (1975)

INTRODUCTION

The prediction of the effective thermal conductivity of unsaturated frozen soils is fundamental for heat transfer engineering in frozen areas. Previously published works on this topic do not seem to resolve the choice of a prediction method.

The work of Johansen and Frivik (1980), which incorporates the features of the Kersten one (1949), is a combination of empirical and interpolating rules. It needs several empirical constants that depend on the kind of soil investigated.

The method of De Vries (1963) uses the Maxwell equation or the analogy with the electrical conductivity. Although it contains some empirical constants, its use is generally acceptable for saturated two-phase media. Unsaturated frozen soil is a porous medium with phenomena of adsorption and capillarity and the electrical conductivity analogy is no longer applicable.

The present work investigates the effective thermal conductivity of unsaturated frozen soils considering phenomena of adsorption and capillarity. The analysis takes into account the conductive heat transfer only, i.e., convective and radiative heat transfer are neglected.

THEORETICAL ANALYSIS

Saturated Frozen or Dry Soils

The soil is represented by a cubic grain inside a cubic space as in Figure 1. The ratio ℓ_t/ℓ_s varies with the porosity of the soil and is given by

$$\beta = \frac{\ell_t}{\ell_s} = \sqrt[3]{\left\{\frac{1}{1 - \epsilon}\right\}} = \sqrt[3]{\left\{\frac{\rho_s}{\rho_d}\right\}} \quad (1)$$

FIGURE 1 Saturated soil.

The effective thermal conductivity of the soil can be determined with the hypothesis that the isotherms are horizontal or the heat flux lines are vertical. These two cases are the extremes for the geometrical assumption adopted (Crane and Vachon 1977).

Unfrozen water, eventually present in the frozen soil, is dispersed along the length of the cell, ℓ_t , as shown in Figure 1. Hence, if u_w is the ratio of the unfrozen water volume to the total volume of the cell, the section of unfrozen water is

$$S_u = u_w \ell_t^2 = u_w \beta^2 \ell_s^2 \quad (2)$$

The effective thermal conductivity for horizontal parallel isotherms is

$$\frac{1}{k_T} = \frac{\beta - 1}{k_c \beta (1 - u_w) + k_w \beta u_w} + \frac{\beta}{k_c \{\beta^2(1 - u_w) - 1\} + k_s + k_w \beta^2 u_w} \quad (3)$$

while for vertical parallel heat flux lines it is

$$k_Q = \frac{1}{\frac{\beta(\beta - 1)}{k_c} + \frac{\beta}{k_s}} + k_c \frac{\beta^2(1 - u_w) - 1}{\beta^2} + k_w u_w, \quad (4)$$

where k_c is equal to k_i for frozen soils and to k_a for dry soils.

The hypothesis of horizontal parallel isotherms is finally chosen because of the good agreement with the experimental data (see Table 1).

Unsaturated Frozen Soils

Unsaturated frozen soils are divided into two groups depending on whether the ratio V_w/V_v is lower or greater than a certain amount of adsorbed and dispersed water. The adsorbed water increases with the specific surface of the soil; hence, a different value should be used for the various soils. In order to simplify the analysis, an empirical constant value, equal to $V_{wA}/V_v = 0.083$, is used in this work.

Unsaturated Frozen Soils, $V_w/V_v < V_{wA}/V_v$

In this case the ice is supposed to be distributed on the six lateral surfaces of the cubic grain, as shown in Figure 2. Because of the hypothesis of horizontal parallel isotherms, the position of the ice in the cell is not significant but the important assumption is the absence of ice-bridges among the adjacent grains.

The unfrozen water is supposed to be distributed along the length of the cell, as shown in Figure 1. The thickness of ice on the grain surface, l_{ia} , is given by

$$l_{ia} = \frac{\delta}{6} l_s = \frac{l_s}{6} \frac{V_i}{V_s}, \quad (5)$$

where $\delta = V_i/V_s$ and

$$\frac{V_i}{V_s} = \frac{w \rho_d - u_w \rho_w}{(1 - \epsilon)\rho_i}; \quad (6)$$

the effective thermal conductivity is

$$\frac{1}{k_T} = \frac{\beta - 1 - \frac{\delta}{3}}{\beta \{k_a(1 - u_w) + k_w u_w\}} + \frac{\beta \delta}{3 \{k_a(\beta^2 - 1 - \beta^2 u_w) + k_i + k_w \beta^2 u_w\}} + \frac{\beta}{k_s + \frac{2}{3} \delta k_i + k_a(\beta^2 - 1 - \frac{2}{3} \delta - \beta^2 u_w) + k_w \beta^2 u_w} \quad (7)$$

Unsaturated Frozen Soils, $V_w/V_v > V_{wA}/V_v$

If the water content is higher than V_{wA}/V_v , the liquid water accumulates at the points of contact of the grains in the form of biconcave lens (or liquid cups). The curvature of the lateral surfaces and the surface tension between liquid water and air contribute to the capillary pressure of the

FIGURE 2 Unsaturated frozen soil, $V_w/V_v < V_{wA}/V_v$.

liquid. The liquid cups coalesce when the liquid water, V_{wf}/V_v , is in the range 0.183 to 0.226, respectively, for $\epsilon = 0.4764$ and $\epsilon = 0.2595$ (Luikov 1966). For soils with different porosities the liquid water, accumulated at the points of contact among the grains, is assumed proportional to the porosity of the soil and is evaluated by the following interpolation:

$$\frac{V_{wf}}{V_v} = 0.183 + (0.226 - 0.183) \frac{0.4764 - \epsilon}{0.4764 - 0.2595}. \quad (8)$$

The interfacial tension between ice and water, σ_{iw} , is reduced, in relation to that between water and air, σ_{wa} , in the proportion

$$|\sigma_{iw}| = 0.052 |\sigma_{wa}| = |\sigma_{wa}| \phi, \quad (9)$$

where $\phi = 0.052$ according to Walden's rule (Perry 1963). Hence the capillary pressure that maintains the ice among the grains is reduced in the same proportion.

The ice accumulated among the grains, V_{if}/V_v , is a fraction of the liquid water content

$$\frac{V_{if}}{V_s} = \frac{V_{wf}}{V_s} \phi = \frac{V_{wf}}{V_v} (\beta^3 - 1) \phi, \quad (10)$$

and the remaining ice is disposed around the grain, as in Figure 3. Unfrozen water is again distributed along the cell, and its section is given by equation (2). The ice volume around the grain is given by

$$l_i^3 = l_s^3 \gamma^3 = l_s^3 \left(\frac{V_i}{V_s} - \frac{V_{if}}{V_s} + 1 \right), \quad (11)$$

where V_i/V_s is given by equation (6), from which it is determined $\gamma = l_i/l_s$. The ice disposed among adjacent grains is distributed on the six surfaces of the cube, yielding a surface of contact given by

$$l_{if}^2 = l_s^2 \gamma_f^2 = \frac{V_{if}/V_s}{3(\beta - \gamma)} l_s^2. \quad (12)$$

The ratio $l_{if}/l_s = \gamma_f$ can be lower or greater than unity giving two different expressions for the effective thermal conductivity. For $\gamma_f < 1$

$$\frac{1}{k_T} = \frac{\beta^2 - \beta \gamma}{k_a(\beta^2 - \gamma_f^2 - \beta^2 u_w) + k_i \gamma_f^2 + k_w \beta^2 u_w} +$$

$$\frac{\beta\gamma - B}{k_a(\beta^2 - \gamma^2 - \beta^2 u_w) + k_i \gamma^2 + k_w \beta^2 u_w} + \frac{\beta - \beta\gamma f}{k_a(\beta^2 - \gamma^2 - \beta^2 u_w) + k_i(\gamma^2 - 1) + k_s + k_w \beta^2 u_w} + \frac{\beta\gamma f}{k_s + k_i(\gamma^2 - 1 + 2\beta\gamma f - 2\gamma\gamma f) + A} \quad (13)$$

with

$$A = k_a(\beta^2 - \gamma^2 - 2\beta\gamma f + 2\gamma\gamma f - \beta^2 u_w) + k_w \beta^2 u_w$$

and for $\gamma_f > 1$

$$\frac{1}{k_T} = \frac{\beta^2 - \beta\gamma}{k_a(\beta^2 - \gamma_f^2 - \beta^2 u_w) + k_i \gamma_f^2 + k_w \beta^2 u_w} + \frac{\beta\gamma - \beta\gamma f}{k_a(\beta^2 - \gamma^2 - \beta^2 u_w) + k_i \gamma^2 + k_w \beta^2 u_w} + \frac{\beta\gamma f - \beta}{k_a(\beta^2 - \gamma^2 - 2\beta\gamma f + 2\gamma\gamma f - \beta^2 u_w) + B} + \frac{B}{k_s + k_i(\gamma^2 + 2\beta\gamma f - 2\gamma\gamma f - 1) + C}$$

with

$$B = k_i(\gamma^2 + 2\beta\gamma f - 2\gamma\gamma f) + k_w \beta^2 u_w$$

and

$$C = k_a(\beta^2 - \gamma^2 - 2\beta\gamma f + 2\gamma\gamma f - \beta^2 u_w) + k_w \beta^2 u_w.$$

FIGURE 3 Unsaturated frozen soil, $V_w/V_v > V_{wA}/V_v$.

Previous Works

Among the previous works on unsaturated frozen soils, those of De Vries (1963) and Johansen and Frivik (1980) are considered for comparison.

The analysis of De Vries (1963) has been applied to frozen soils by Penner (1970) and Farouki (1982), and it is reported in detail,

$$k_e = \frac{u_w k_w + F_i x_i k_i + F_a x_a k_a + F_s(1 - \epsilon)k_s}{u_w + F_i x_i + F_a x_a + F_s(1 - \epsilon)} \quad (15)$$

where

$$F_s = \frac{1}{3} \left\{ \frac{2}{1 + (k_s/k_c - 1)0.125} + \right.$$

$$\left. \frac{1}{1 + (k_s/k_c - 1)0.75} \right\}, \quad (16)$$

$$F_i = \frac{1}{3} \left\{ \frac{2}{1 + (k_i/k_c - 1)0.125} + \frac{1}{1 + (k_i/k_c - 1)0.75} \right\}, \quad (17)$$

$$F_a = \frac{1}{3} \left\{ \frac{2}{1 + (k_a/k_c - 1)g_a} + \frac{1}{1 + (k_a/k_c - 1)g_c} \right\}, \quad (18)$$

$$g_c = 1 - 2 g_a, \quad (19)$$

$$g_a = 0.333 - x_a \frac{0.333 - 0.035}{\epsilon} \quad (20)$$

for $0.09 \leq x_c \leq \epsilon$

$$g_a = 0.013 + 0.944 x_c \text{ for } 0 \leq x_c < 0.09, \quad (21)$$

and x_c and k_c are relative to the continuous medium. For unsaturated frozen soils, $k_c = k_w$ if $u_w \neq 0$ and $k_c = k_i$ if $u_w = 0$. For dry soils, $k_c = k_a$.

The expression of Johansen and Frivik (1980) for unsaturated frozen soils is

$$k_e = k_d + (k - k_d) S_r, \quad (22)$$

where

$$k_d = 0.034 \epsilon^{-2.1} \quad (23)$$

$$k = k_c^\epsilon k_s (1 - \epsilon) \quad (24)$$

$$S_r = \frac{w \rho_d - u_w(\rho_w - \rho_i)}{\epsilon \rho_i} \quad (25)$$

$$\text{with } k_c = k_i \quad \text{if } u_w = 0 \quad (26)$$

$$\text{and } k_c = (k_w - k_i) \frac{u_w}{\epsilon} + k_i \quad \text{if } u_w \neq 0 \quad (27)$$

For saturated two-phase media, the expression recently found by Muzzio and Solaini (1982) is used as comparison,

$$k_e = \frac{k_s}{a\{1 + A(k_s/k_c - 1)\}} \left\{ a - \ln \left[1 + A \left(\frac{k_s}{k_c} - 1 \right) (1 - e^a) \right] \right\} \quad (28)$$

with

$$A = \frac{\epsilon}{1 - (e^a - 1)/a} \quad (29)$$

and

$$a = 3.3 + \ln \left[(1 - \epsilon)^{7/3} \left(\frac{k_s}{k_s - k_c} \right)^2 \right]. \quad (30)$$

The thermal conductivity of the solid grain, k_s , used in the above expressions is given by

FIGURE 4 Experimental data and theoretical predictions versus degree of saturation.

$$k_s = k_q^q k_r (1 - q) \quad (31)$$

where q is the quartz content of the soil and k_q and k_r are the thermal conductivities of quartz and rest of the soil respectively. For air the value $k_a = 0.046$ is used as proposed by De Vries (1963).

Several purely empirical constants are recognizable in the expressions of De Vries (1963) and Johansen and Frivik (1980), while the empirical expression of a , equation (30), is obtained from the exact analysis of Muzzio and Solaini (1982), reported in the same paper.

A recent analysis of the author of the present work (Gori 1983) can predict the effective thermal conductivity of saturated two-phase media with ratios k_d/k_c lower than 40, i.e., it is to be used for saturated frozen and unfrozen soils but not for dry soils.

RESULTS AND DISCUSSION

Saturated and Dry Soils

The predictions of the effective thermal conductivity are compared with experimental data on saturated and dry soils. Because for dry soils the ratio k_s/k_a can be equal to 160 and in order to test the general validity of the equations used, the comparison is extended to saturated two-phase media with ratios of discontinuous to continuous thermal conductivities, k_d/k_c , ranging from 0.38 to 191.1.

The experimental data used, which amount to 158, have been taken from the review of Farouki

(1982) and from the works of Crane and Vachon (1977), Okasaki et al. (1982), and Muzzio and Solaini (1982).

The maximum, Δ_{max} , the average, $\Sigma\Delta/n$, and the mean quadratic errors, $\sqrt{\Sigma\Delta^2/(n-1)}$, given by the expressions (3), (4), (15) and (28) are reported in Table 1.

Equations (3) and (4) predict results that are generally lower than the experimental data, but the lowest maximum error is found with equation (4) and the lowest mean quadratic error with equation (3). From the comparison of Table 1, the hypothesis of horizontal parallel isotherms is chosen to predict the effective thermal conductivities of unsaturated frozen soils.

TABLE 1 Comparison with 158 Experimental Data on Saturated Two-Phase Media

	eq.(3)	eq.(4)	eq.(15)	eq.(28)
Δ_{max}	80.6	-63.9	167.1	148.4
$\Sigma\Delta/n$	-5.9	-16.2	8.4	4.5
$\sqrt{\left\{\frac{\Sigma\Delta^2}{n-1}\right\}}$	19.8	26.9	25.3	24.7

Unsaturated Frozen Soils

Experimental data (115) on unsaturated frozen soils have been considered; some of them are presented in Figures 4 through 6. To justify the present work, the predictions obtained with the analysis of De Vries (1963) and Johansen and Frivik (1980) are reported on the same figures.

Figure 4 presents the experimental thermal conductivities of Kersten (1949) on Ramsey sandy loam, as reported in Farouki (1982), versus the saturation degree, S_r . The present analysis, equations (7), (13), (14), gives effective thermal conductivities that are in good agreement with the experiments up to $S_r = 0.75$; for nearly saturated frozen soil the predictions are higher than the experiments with a maximum error of 42.6%. As evident from Figure 4 the results of De Vries (1963) are the highest, while those of Johansen and Frivik (1980) are intermediate.

Figure 5 shows the experimental data of Kersten (1949) on a Fairbanks silty clay loam, as reported in Farouki (1982). This kind of soil can have some unfrozen water, which has been evaluated as ranging from 0.022 to 0.06 per cent of water volume to total soil volume. In the analysis of De Vries (1963) and Johansen and Frivik (1980) the presence of unfrozen water produces a decrease in the effective thermal conductivity at every degree

FIGURE 5 Experimental data and theoretical predictions versus degree of saturation.

of saturation. Such a decrease is in the right trend with respect to the experimental data, but both the predictions remain much higher than the experiments.

The results of this work for $u_w = 0$ are lower than the experiments for $S_r < 0.65$ and higher for $S_r > 0.75$, with a better agreement with the experimental data. The introduction of some unfrozen water in the unsaturated frozen soil decreases the effective thermal conductivity for $S_r > 0.5$ and increases for $S_r < 0.5$. These two effects depend on the assumption that unfrozen water is dispersed on the whole length of the cell. At very low saturation degrees the bridge of unfrozen water increases the effective thermal conductivity of the soil because k_w is greater than k_a . Near the saturation the same bridge of unfrozen water decreases the effective thermal conductivity of the soil because k_w is smaller than k_i . The increase of k_T for $S_r < 0.5$ and the decrease for $S_r = 0.5 - 0.65$ are not decisive, while its reduction for $S_r > 0.8$ produces a remarkably better agreement with the experiments.

Figure 6 presents the experimental thermal conductivities of Penner et al. (1975) for three soils, classified as 8, 9, 10. The conclusions of Figure 6 are similar to those of Figure 5 with a generally better agreement between the theoretical predictions and the experiments.

The comparison between the theoretical predictions and 115 experimental results are finally reported in Table 2.

TABLE 2 Comparison with 115 Experimental Data on Unsaturated Frozen Soils

	Δ_{max}	$\Sigma\Delta/n$	$\sqrt{\Sigma\Delta^2/(n-1)}$
This work	81.5	-1.15	24.99
Johansen and Frivik (1980).	86.7	31.44	41.81
De Vries (1963)	291.6	82.96	106.68

The analysis presented in this paper gives average and mean quadratic errors that are lower than those obtained with the expressions of De Vries (1963) and Johansen and Frivik (1980).

A GEOCRYOLOGICAL ASPECT OF THE PROBLEM OF
ENVIRONMENTAL PROTECTION

N. A. Grave

Permafrost Institute, Siberian Branch,
Academy of Sciences, Yakutsk, USSR

A system is proposed for mapping areas of permafrost in the USSR on the basis of surface stability following the removal of vegetation and soil. The lowest degree of stability is typical of areas of fine-grained deposits with high ice contents and substantial moisture at the surface; here minimal disturbance will lead to the development of thermokarst. The levels of surface stability in permafrost areas are: 1A - very unstable; 1B - very unstable; 2 - unstable; 3 - slightly stable; 4 - relatively stable. Some recommendations for monitoring permafrost are made.

The zone of seasonal freezing and permafrost is an important part of the biosphere. The permafrost phenomenon determines some substantial features of northern landscapes, including their great vulnerability to development.

The development of cryogenic processes within permafrost affects the stability of the surface and landscape.

Cryogenic processes that deform the surface arise and intensify particularly dramatically in the presence of technogenic disturbances. Technogenic impacts can be mechanical, chemical, hydrological, pyrogenic, acoustic, or climatic in nature. In the area under development, mechanical impacts are the most widespread: disturbance of the plant, snow and soil covers; excavation and redeposition of earth; and disturbance of rock masses. Hydrological disturbances, i.e. change in moisture content of the surface, are almost always associated with mechanical ones.

Maximum destruction of the surface and landscape is due to thermokarst, which, under favorable conditions, spreads over large areas and extends deep within the earth. Slope processes, frost heaving and fracturing of soil have a substantial influence upon the stability of the structures built, but do not cause such strong landscape transformations as thermokarst does. Therefore, when speaking about the stability of the surface and landscape in permafrost areas, we are referring mainly to the process of subterranean ice thawing and related topographic deformation.

In order to evaluate surface stability in permafrost areas one should primarily have knowledge of thermally induced settlement of permafrost, depending on its ice content and the lithological composition of ice-bearing materials.

If the ice content of the soil and its lithological composition determine the potential for thermokarst-induced topographic deformation, then the actual degree of decay will depend on the intensity of soil thawing and the speed of the thermokarst process itself. With a variation in surface conditions, for example, when the vegetation is removed, the thawing depth depends on a number of physiographical and geocryological factors.

Feldman (1977) has most completely demonstrated this dependence in the expression that includes relationships between the ice content of the soil, the thermal properties of the soil and surface, the air temperature and radiation balance, evaporation, the permafrost temperature, and the properties of the snow cover.

The actual amount of permafrost settlement that occurs when plant and ground cover is removed is generally less than the potential amount, and under some conditions it can be insignificant. If, after removal of vegetation, the thawing depth reaches ice-bearing levels in the permafrost, then further thawing occurs due to the development of thermokarst, thermal erosion and thermal abrasion. These processes can develop only under certain hydrological and topographical landscape conditions.

Prediction of the appearance and development of thermokarst, the most frequently occurring of the processes just mentioned (Methodological recommendations 1981), depends on the geocryological environment where it develops. In regions with ice streaks, the thermokarst manifests itself in a gradual settlement of the surface without forming "funnels" or hollows. In regions with large ice masses (sheet ice, wedge ice, etc.), the thermokarst is more sharply manifested, with shallow depressions, hilly microrelief with cemetery mounds, and cave-in lakes. The main condition necessary for the development of thermokarst is the accumulation of a sufficient amount of water on the surface so that seasonal soil thawing depth exceeds the depth of seasonal freezing. The thermokarst process within deposit-formed ice is able to proceed until the ice mass thaws out completely. However, as the thermokarst process goes on, it is accompanied by slope processes, solifluction and ground slip, with sediments accumulating on the surface of the thawing, ice-containing soils. This may be the reason for cessation of the thermokarst process at various stages of its development.

After stabilization of cryogenic processes at some stage, the depth of seasonal thawing of soil can decrease and become fixed at some level corresponding to the existing thermal balance on the surface. As indicated by previous studies

(Sukhodrovsky 1978, a.o.), cryogenic morphological processes arising from or aggravated by technogenic impacts on the surface gradually decay following vigorous development during the first 2 or 3 years, and terminate within about 10 years. This is true in cases where disturbance of the surface is halted. If they continue, then the process is able to progress rather deep into the earth, sometimes to the point of complete thawing of subterranean ice.

Thus, observations and analyses of natural and technogenic changes of the parameters mentioned above can be made (Feldman 1977). And on the basis of data on the ice content and lithological composition of permafrost, it is possible not only to gain insight into the causes of variations in thawing depth, but also to predict the future direction and intensity of development of the process.

All the pertinent studies are unified in the problem of permafrost zone monitoring. Permafrost zone monitoring includes observation, analysis, prediction and control of cryogenic processes in the permafrost region during natural and technogenic changes in the geophysical condition of the permafrost.

The object of monitoring in this case is the permafrost zone and cryogenic processes, which are closely associated with natural landscapes and biogeocenoses, and their natural and man-determined development. Therefore, permafrost zone monitoring should be regarded as a part of biosphere monitoring. Scientific investigations in this direction should be carried out with close attention paid to biospheric changes, and, it seems, on common biospheric monitoring sites.

In order to gain a general idea of the degree of stability of the surface in different permafrost zones, necessary in planning monitoring studies, we can use a mapping system devised for the USSR permafrost region (Grave 1982).

The system (Figure 1) categorizes surface stability by generalizing the data reported in the literature on cryogenic structure, ice content, and thermal settlement of soil at the time of thawing; experimental and calculated data on soil thawing following disturbance of plant or snow cover (depending on the factors of physiological environment and geocryological conditions); and data on the development of cryogenic processes caused by terrain development.

Least stable are regions with soils of high ice content, where minimal surface disturbance (removal or damage of plant cover) is enough to initiate the thermokarst process, with subsequent deterioration of the relief. The maximum potential surface disturbance is determined by a complete thawing-out of subterranean ice. Therefore, territories with thick soil-forming subterranean ice are most vulnerable to exploitation.

In this connection, evaluation of the degree of stability of the surface under technogenic impacts should be based on the ice content of the underlying permafrost. The response to minimal disturbance will depend on climatic, hydrological, geobotanic, lithological and general geocryological conditions in the area.

The surface stability is intimately related to the stability of the landscape. However, changes in the landscape caused by mechanical disturbance

of the surface are not always associated with surface failure. They can be produced by technogenic changes of the plant cover in comparatively stable areas.

The following regions are delineated on the map of USSR permafrost regions (Figure 1) according to the degree of vulnerability to the disturbance or removal of surface material.

1A: Regions with a very unstable surface. These are found on the lowland plains of Siberia—the Yamal and Gydana Peninsulas, the North Siberian lowland, the Lena River delta, the littoral lowlands of Yakutiya, the Chaunskaya depression, and the Anadyr lowland. Widely distributed are shallow, thick masses of wedge and streak ice enclosed within suglinok deposits of high ice content of post-Pliocene, Holocene and contemporary ages. A cold climate, subarctic tundra and forest tundra, prevails. The most stable surfaces in these regions occur on floodplains and low terraces within river deltas, formed by sand deposits and deposits of low ice content, as well as on boulder-pebble moraines and ledge rock outcrops.

An example is the middle and southern part of the littoral lowlands of Yakutia (Kuznetsova 1980, Tomirdiaro 1980). The majority of the surface consists of "edoma" (eroded terraces), with post-Pliocene suglinok soils containing thick ice (15-25-40 m or more). The region is forest tundra with permafrost temperatures of -6° to -8°C . A smaller area consists of lake-bog plains with a cover of ice-bearing lake-bog deposits of Holocene and present-day age. A naturally recurring thermokarst that is due to thermal abrasion and thermal erosion periodically destroys the "edoma." Technogenic impacts intensify these processes, gradually destroying the landscape of a relatively well drained forest tundra and changing it into barely passable lake-bog plains and badlands with ravines, cemetery mounds, and decaying and growing wedge ice.

1B: Regions with a very unstable surface. These occur on lowlands in the northernmost parts of Taimir, the North Siberian Plain, the littoral lowlands of Yakutiya, the Novosibirsk and Severnaya Zemlya islands, and in the central parts of the Yakutsko-Vilyuiskaya depression. The structure and composition of the underlying surfaces of the deposits are similar to those of category 1A. In the northern regions the climate is very cold, with a short summer (Arctic desert, Arctic and subarctic tundra). The permafrost temperature is -12° to -15°C . In Central Yakutiya the climate is very dry and relatively cold (taiga). The permafrost temperature is -3° to -5°C . The cold in the north and the aridity in Central Yakutiya impose some constraints on the development of thermokarst following deterioration or removal of vegetation, and it either subsides in the early stages or does not arise at all. In the north, most stable following plant removal are surfaces typical of edoma, deltas, and portions of river terraces and coasts formed by sandy deposits, as well as bedrock outcrops. On sunken lake-bog plains the thermokarst process developing through thermal abrasion and thermal erosion contributes to a decrease of the surface stability during technogenic impacts. In Central Yakutiya the most stable surfaces accompany alluvial and river terraces, formed by sands. Removal of forests during agrarian development leads

to the appearance of barren "badlands" and to xerophytization of landscapes and salinization of soils.

2: Regions with an unstable surface. These occur both in lowlands and in hills at about 200-500 m above sea level, in which subterranean ice, as a rule, is not as thick or widespread as in the previously mentioned regions. They occur in different climatic and geobotanical zones and are characterized by different conditions of subterranean ice occurrence. In the mountains, such areas accompany inter-mountain hollows and depressions intersected by river valleys with their beds at about 400-600 m above sea level. Technogenic thermokarst develops everywhere, but as a rule does not exceed the boundaries of the disturbance contour nor critically change the landscape. In the northern part of Western Siberia the landscapes remaining stable during technogenic disturbances include bogs, meadows, and swampy tundras with underlying deposits of low ice content. According to data reported by Moskalenko (Grave, Melnikov and Moskalenko 1983), a deteriorated landscape here recovers within 10 years, and along long-ago-constructed gas lines the natural shape of disturbed bogs and the original geocryological conditions have returned within 20 years. In eastern Siberia, where the composition of the upper part of the permafrost in these regions is coarser, surface settlement deformations are not deep.

3: Regions with a slightly stable surface. These are found in low mountains and elevated plateaus at about 500-600 m to 1000-1200 m above sea level and at lower levels in the Arctic. Thin deposits, mainly deluvial (talus) and eluvial and generally of coarse composition, frequently contain vein and wedge ice. Exploitation of these regions leads to an intensification of thermokarst and (mainly) slope processes, particularly when slopes are cut (Gravis 1976).

4: Regions with a relatively stable surface. These are mainly in mid- and high-altitude areas. In the lowlands they occur where there are deposits of low ice content and bedrock outcrops. In the mountains, when vegetation is removed and slopes are cut, thermokarst intensifies on relic ice veins and rock streams, at whose bases there is buried glacier ice as well as slope processes (talus, landslides, crumbling and solifluction) (Gravis 1976).

5: Regions with permafrost islands and sporadic permafrost. These are mainly in a broad belt along the southern boundary of the permafrost zone. Taiga and forest tundra occurs in the lowlands and mountains, and tundra and sparse forests at high altitudes. The permafrost temperature is high, 0° to -2°C, and decreases in the mountains. Permafrost islands occur in hilly peatlands and dense, dark coniferous forests with a thick moss cover, while in the Far East they occur with "maris." A large role is played by the snow cover in the freezing and thawing of this permafrost.

In Western Siberia, according to Moskalenko's observations, the surfaces that are most unstable under technogenic impacts are hilly peatlands and hilly surfaces covered by forests. Here removal of vegetation intensifies settlement phenomena and erosive processes, and accumulations of snow within these settled areas further contribute to the formation of ravines and shallow

depressions. Deforestation in places with no permafrost, or where permafrost occurs deep within the earth, leads to an intensification of freezing of the surface, frost fracturing, and heaving.

In the northern part of the Amur region, after removal of the moss-peat cover on the maris there is deep (sometimes complete) thawing of the permafrost, and thermokarst develops. The snow cover in areas under development becomes dense and disappears earlier than usual, which contributes even more to permafrost thawing (Balobaev et al. 1979).

In nature, the proposed gradation system lacks well-defined boundaries. Evaluating large territories from this point of view, we can speak only of the predominance in a region of surfaces with a certain degree of stability; any territory can have areas of almost all degrees of stability in different spatial proportions. Some examples are provided by large-scale classification systems described by Kuznetsova (1980) and Parmuzin and Sukhodolsky (1980).

It is advantageous to select areas in the permafrost zone for systematic long-term observations. This zone is the most susceptible to the impact of man, as cryogenic processes, particularly thermokarst, can develop the most intensively and can extend very deep into the earth. Such areas might, for example, include the banks near the mouths of the Yana and Kolyma rivers, where one should expect a combination of thermokarst and thermal erosion and abrasion. Observations are also pertinent in the northern part of Western Siberia (Yamal, Gydan), and in Central Yakutiya. In the southern part of the permafrost zone an area could be chosen in the eastern part of the BAM zone, possibly within shallow depressions in the North Amur region.

The areas selected for monitoring of the permafrost zone should have large-scale maps of their surface stability (or permafrost stability) prepared. And every 2 to 3 years they should be checked for landscape changes using sequential satellite or aerial photography. In places where processes are proceeding particularly rapidly, repeated topographic surveys would be useful. Monitoring of fluctuations in the temperature of the permafrost zone requires systematic long-term observation of the dynamical behavior of thermal and cryogenic processes, both within the permafrost itself and on the surface, under natural and disturbed conditions. For that purpose, stations should be set up with deep boreholes that pass completely through the permafrost. Unfortunately, such systematic geocryological observations are lacking; and occasional temperature measurements fail to produce a reliable picture of long-term developments in the permafrost zone.

In areas under development, it is advisable to observe geomorphological processes using benchmarks. Of special importance here are observations of the soil conditions and the formation of "kriopegs" (bodies of liquid saline water below 0°C associated with permafrost, or ice-free permafrost with saline pore water) in soils and earth materials as a result of the development activity.

Analysis of data from observations in both undisturbed and developed regions will form a reliable basis for predicting cryogenic changes and for working out protective measures. Therefore,

the development of an area should be preceded by a geocryological prediction in the form of maps of the stability of the surface or permafrost during technogenic impacts.

Medium- and small-scale maps of surface stability in some parts of the permafrost zones of the USSR, Canada and Alaska have been generated using various techniques. They show that as a rule, highly unstable surfaces occupy about 30-50% of the area in the most vulnerable regions of the Arctic belt. Preliminary zoning of development areas according to the stability of the surface and landscape will permit a reduction in expenditures for maintaining rational land usage and accomplishing revegetation of deteriorated landscapes.

In summary, when decisions are made that affect the northern biosphere, it is necessary to take into account the geocryological properties of the landscape.

PERMAFROST, FIRE, AND THE REGENERATION OF WHITE SPRUCE AT TREE-LINE NEAR INUVIK,
NORTHWEST TERRITORIES, CANADA

David F. Greene

Department of Geography, University of Calgary, Calgary, Alberta, Canada, T2N 1N4

Adjacent burned and unburned upland stands were studied at the southwest corner of the 1968 Inuvik burn. Shallow active-layers are poorer habitat than are deep active-layer sites for white spruce because of a slower rate of thaw (effective growing season length), lower seed dispersal capacity, lower cone production, and poor seedbed creation (because of the depth of the Of) by fire. Fire delimits the range of white spruce by restricting it to areas where the probability of surviving fire is high, e.g., the steeper valley sides and the most deeply incised or sinuous perennial creeks. Areas where survival through fire is likely also tend to possess deep active layers. Although such sites are not uncommon, many remain uncolonized because of the poor seed dispersal capacity of these white spruce stems.

INTRODUCTION

Although most of the work on tree-line determination has been concerned with black spruce (*Picea mariana*), white spruce (*Picea glauca*), forms the conifer arctic tree-line across almost half of North America. There is a general consensus among investigators that the ultimate determinant of arctic tree-line is arctic air-mass frequency, and that the more proximate determinant is the rarity of sexual reproduction and/or successful establishment of seedlings (e.g., Elliott 1979, Nichols 1976, and Larsen 1980).

Van Wagner (1979), Rowe (1971), and Viereck (1979) have speculated that low intensity forest-tundra fires may provide too little optimal (i.e., mineral soil) seedbed, or cause too much mortality, and thus may be important in tree-line determination. Viereck and Schandelmeier (1980) speculated that low seed dispersal capacity and, therefore, survival of seed sources through fire, may be important.

Van Cleve et al. (1981) have shown that soil temperature and rate of soil thaw may be crucial determinants of vegetative vigour in black spruce in the zone of discontinuous permafrost. The stems on a permafrost-free site were more vigorous than those on a nearby permafrost site.

The present investigation focused on the relative importance of fire (and fire-created seedbeds), active-layer depth, and rate of soil thaw in determining the distribution and demography of white spruce near tree-line in the Inuvik area. Additionally, the potential importance of seed dispersal capacity and survival through fire of seed sources were examined.

STUDY AREA

The main study area was in Boot Creek Valley, 2 km east of Inuvik, N.W.T. (68°21' N, 133°40' W). For a general introduction to the Mackenzie Delta area, see Mackay (1963) and Kerfoot (1972).

The uplands around Inuvik are in the zone of continuous permafrost. The climate is cold and dry. Average yearly precipitation is 27 cm;

approximately 75% of this amount falls as snow. The area experiences short, cool summers, with only 665 degree-days above 5°C (Burns 1973).

Surficial deposits above permafrost in Boot Creek Valley consist of silty loams. In this area, deep active-layers are typically found on steep (usually greater than 8°) south-facing slopes and along the edges of incised or highly sinuous perennial creeks. At Boot Creek Valley, the steepest slopes are 20°. The Of layer is thin or absent on deep active-layer sites, and the soils are Static Cryosols (Canadian System of Soil Classification 1978). At Boot Creek, such sites are dominated usually by white spruce or paper birch (*Betula papyrifera*).

Shallow active-layer sites include north-facing slopes, gently rolling tablelands above the valleys, and the more or less flat alluvial and colluvial areas between creeks and valley sides. These sites tend to be dominated by black spruce and dwarf ericaceous shrubs. The Of layers are typically thick and the soils are usually Organic or Turbic Cryosols.

A secondary study site was located 30 km north of Inuvik in an unnamed valley in the Caribou Hills escarpment. The soils at this site are sandy loams. The composition and distribution of vegetation is similar to Boot Creek Valley. The slopes at the Caribou Hills site are, however, much steeper than at Boot Creek. Slope angles can be as great as 30°. The south-facing slope is much more deeply gullied than in Boot Creek Valley. The sandy inter-gully spurs are frequently unvegetated. Both Boot Creek Valley and the Caribou Hills site are asymmetrical valleys with the north-facing slope steeper than the south-facing slope.

Reconnaissance indicated that the great majority of white spruce stems in the uplands around Inuvik are found on mesic to xeric sites. They are especially common where the terrain is well-dissected (i.e., steep south-facing slopes) or along the edges of lakes and perennial streams. Northeast and east of Boot Creek Valley, aerial reconnaissance indicated comparatively few vigorous stands of white spruce. North of Boot Creek Valley, however, the deeply dissected

Caribou Hills escarpment has vigorous, dense white spruce stands extending as much as 70 km north of Inuvik.

For an introduction to the vegetation of the Mackenzie Delta area, see Lambert (1972). Vegetation recovery in the 1968 Inuvik burn is discussed by Wein (1975). Soils in the Inuvik area are discussed by Tarnocai (1973) and Day and Rice (1964).

METHODS

The main study site consisted of adjacent burned and unburned areas at the southwest corner of the 1968 Inuvik burn. Two subjectively chosen transects were run from the creek bottom upslope to the rolling tableland above the south-facing slope in the unburned and burned areas. A fire-guard lay between the two sites. Plots 10-m² were sampled every 20 m along each transect for slope angle, altitude, and percent cover of each plant species present. Four 1-m² quadrats were located at the corner of each plot. The Of, Om, Oh, or LFH depths, and the depth of the permafrost were recorded for each quadrat. All permafrost measurements were made from 3 August to 6 August 1982.

At the unburned transect, all white spruce stems taller than 3 m were cored, and their diameter at breast height (dbh), height, and evidence of cone production or chlorosis recorded. Sections of the unburned transect (10 x 30 m along the flat, and 10 x 20 m on the steep south-facing slope) were intensively sampled for white spruce. In these intensively sampled areas, all white spruce stems, regardless of height, were aged. For white spruce taller than 3 m, cores were taken 30 cm above the root-collar. Stems less than 3 m but greater than 30 cm in height were cut at the root-collar. The very smallest stems were aged by counting the terminal bud scars.

In the burned area, a 50-ha section adjacent to the fireguard was studied for the distribution of white spruce survivors and seedlings. This was necessary because no seedlings were found in the burned transect. For the seedlings, 12 equidistant 10-m-wide transects were walked parallel to the creek. Each of these transects was walked simultaneously by two investigators. The location of seedlings and their distance from a tall, potential seed source were recorded. Survivors taller than 5 m were mapped with binoculars from the opposite slope. Seedlings within the burn were randomly sampled for age determination using a random numbers table. The sampling sites were 10-m². Additionally, seedlings from the southeast corner of the burn, from the fireguard, and from recent mud-flows were aged.

Six soil pits were dug in early August. The methods employed in the soils analyses are detailed by Greene (1983).

At the Caribou Hills site, a single transect was used. Stands and quadrats were located on the transect in the same manner as at Boot Creek. The vegetation data that were collected are not included in this paper (but see Greene 1983). Active layer depth measurements were made in the quadrats on 25 June and 6 August 1982. The snow

had melted throughout most of this valley by approximately 3 June.

For convenience, south, west, and southwest-facing slopes are referred to as south-facing slopes. All other slopes are called north-facing slopes. A deep active-layer is one that was more than 50 cm deep as of 6 August 1982. Shallow active-layers were less than 50 cm deep. Seed dispersal capacity is defined as that distance from a seed source within which the great majority of the seed rain occurs; magnitude of the seed rain is not implied, and wind direction or velocity is ignored. Fire severity or intensity is defined solely in terms of the depth of the organic layer remaining immediately after a burn. Seedling establishment is defined arbitrarily as the survival of a seedling beyond 4 years of age.

RESULTS AND DISCUSSION

Seedling Establishment

Figure 1 depicts the ages for smaller stems from the unburned transect that were cut at the apparent root-collar. Because of extreme variability in early growth in tree-line white spruce, these stems more closely approximate exact ages than do stems cored at 30 cm. However, because of problems such as adventitious rooting and missing or false rings, the data in Figure 1 should not be interpreted as exact ages. They should be, however, typically within a year or two of the exact age.

As can be seen in Figure 1, seedling establishment events have been common during the last 70 years. The youngest age classes (say, less than 4 years) were undoubtedly underestimated, as these youngest seedlings are extremely difficult to find in deep moss. There is no evidence in the literature of a seed bank in white spruce (Johnson 1975). Further, assumptions of perfect synchrony in flowering, or of increasingly long seed production intervals with increasing latitude are perhaps unwarranted (Harper 1977). The age structure for the older stems cored at 30 cm is (allowing for the increased mortality) similar, but less persuasive because of the tremendous variability in growth to 30 cm.

Of the 185 seedlings younger than 13 years old in the burned area, 94.1% are from the years 1971, 1972, and 1973. This temporal distribution was not a local artifact, but was similar for burned areas at the southeast and northwest corners of the burn, and for unburned areas adjacent to the southwest (Figure 1) and northwest corners.

These tree-line stands are not the "reproductive cripples" one might have expected. Seed production, at least among the more vigorous stems, can be inferred to be adequate for good establishment.

The Relationship of Active-layer Depth to Vegetative Growth and Seed Dispersal

The relationship of active-layer depth to height of stems for the unburned transect is shown in Table 1. These ages are uncorrected, i.e., they represented the age at 30 cm above the apparent

FIGURE 1 Ages of stems along the unburned transect. Only those stems which were cut at the root-collar or aged by terminal bud scars are included.

root-collar. Stems cut at the base are not included. Only the stems in the age classes 50 to 95 years are used for the comparison because the steep slope and footslope experienced a fire in approximately 1880 whereas the rest of the transect was unburned.

The greater height achieved by the stems on the steep slope cannot be merely an artifact of increased insolation, because stems along the creek have equivalent stature. Taking the original observations ($n=53$), active-layer depth predicts tree height with an r^2 of 0.473, whereas slope angle predicts tree height with an r^2 of 0.321. If a greater number of creekside stems in these age classes could have been included in the transect, the disparity in the correlation coefficients may well have been greater. As with height, differences in dbh are marked between deep and shallow active-layer sites (Greene 1983).

Suppression of growth by shade should only be a factor along the creek where the old-growth (older than 300 years) stand has a cover value of 80%. The stunted stems on the flat and footslope achieve cover values of only a few percent. The stems on the steep slope seeded in after a fire dated at approximately 1880.

Seed dispersal capacity in white spruce is roughly related to tree height; the majority of the seed rain should be limited to within a horizontal distance approximately twice the height of the tree (Viereck and Schandelmeier 1980). Because of low stature, the seed dispersal capacity of white spruce is severely curtailed in these tree-line stands. The tallest trees are 15 to 17 m in height. Examination of the seedling distribution in the 1968 burn showed that 96% of the 470 seedlings enumerated were within 30 m of a tall survivor, and that approximately 80% were within 15 m. No seedlings were found on the burned transect (no survivors were nearby). Seedling density tended to be greatest near the greatest densities of tall survivors.

The vast majority of the seedlings found in the burn were clustered on sites that had exposed mineral soil or retained only a thin veneer of an organic

layer. Local seedling densities could be much greater in the burned area (e.g., 0.9 per m^2 for seedlings 8 to 10 years old) than in the unburned area. In the burn, white spruce seedlings were rare where the post-fire vegetation was dominated by asexually reproducing survivors, i.e., where a thick Of layer was maintained.

Survival Through Fire

Given the low seed dispersal capacity of these trees, survival of fire appears to be crucial for maintaining occupancy of a tree-line valley. It is however, probably rare that fire ever kills the entire population of a steep-sided valley, because fires at tree-line burn extremely unevenly (Wein 1975).

In the western third of the burned portion of Boot Creek Valley, 4 out of 5 south-facing gullies had tall surviving white spruce. Approximately half the length of the creek in this area had survivors. All of the 245 surviving tall stems (i.e., taller than 5 m) were clustered along the gullies (12%) or creek (88%). The distribution of the survivors helps explain the tendency of white spruce in this area to be restricted to or near steep south-facing slopes and along the edges of water bodies. The steeper the south-facing slope, the more deeply it tends to be gullied. Additionally, the very steepest slopes make it difficult for a fire to burn downhill, and the more xeric spurs (often unvegetated in coarse soil material) can act as fire-breaks.

Reconnaissance indicated that this pattern of survival was common throughout the 1968 burn. Examination of a new burn (late June 1982) about 30 km southeast of Inuvik showed the same pattern: steep south-facing slopes and the edges of water bodies seldom burned. Such sites were often dominated by white spruce. It would appear that a steep north-facing slope will burn more readily than an equally steep south-facing slope, perhaps because of the deeper and more continuous Of layer. Desiccated cryptogams, if the cover is continuous,

TABLE 1 Selected Tree Mensuration Data from the Unburned Transect for the Age Classes 50 to 95 Years.

	Landscape Element				
	Creek Edge	Alluvial Flat	Colluvial Flat	Footslope	Steep Slope
Avg slope (°)	0	.75	4.3	9	18
Avg depth of Of or LFH (cm)	3	20	27	24	13
Avg active-layer depth 4 August 1982 (cm)	50	27	30	28	58
Number of trees (50 to 95 yr)	3	6	3	23	18
Avg height of stems (m) (50 to 95 yr)	9.8	2.5	5.0	6.3	11
Density of stems per m ² (all ages)	0.02	0.015	0.004	0.03	0.02
Evidence of recent burning	None	None	None	Surficial charcoal	Surficial charcoal
% of trees (>2 m) with no evidence of cones on branches or near base (all ages)	8	68	100	62	0
% of cone-bearing stems with long axis of cone >2.5 cm (all ages)	92	19	0	50	96
Chlorotic needles (all ages)	No	Common	Common	Uncommon	No

have an important role in supporting a fire in the northern forest-tundra and low arctic (Wein 1975).

It is commonly assumed that fire frequency is extremely low in the northern forest-tundra and low arctic (Wein 1975). The present author found no fire-scarred trees, yet evidence for old fires was common. For example, a soil pit in a white spruce stand that did not burn in 1968 showed 3 buried charcoal horizons.

Approximately 500 m east of the fireguard, the south-facing slope becomes more gentle, there is no gullying, and there is no evidence (burnt stems) of white spruce having recently been on these slopes prior to the 1968 burn. These gently sloping south-facing slopes have tundra vegetation similar to that found on the flatter areas. Mineral soil was seldom exposed, as the fire typically burned only the desiccated upper portion of the thick Of. Thus, white spruce should only be found in steep-sided valleys or valleys with well-incised or highly sinuous perennial creeks. These sites are more optimal because of the high likelihood of some stems surviving through fire and the presence of deep active-layers.

The Effect of Shallow Active-layers on Cone Production

As there was virtually no cone crop during the investigation, conclusions about differential

reproductive capacity for stems on deep versus shallow active-layers must rely on indirect evidence and be regarded, therefore, as very tentative. However, the local distribution of stems leads to the conclusion that the more vigorous stems appear to be responsible for a disproportionately large share of the seedling establishment.

The taller trees (i.e., on the deep active-layers) have many more old, opened cones evident on their branches or around their bases than do the more stunted trees on the shallow active-layer sites. The stunted trees commonly show chlorotic needles, smaller needles, and much smaller cones (Table 1). Dead or dying stems younger than 150 years are common on the shallow active-layer sites.

Although the seed-crop in conifers is usually negatively correlated with vegetative growth during and for some time after the crop, the relationship between vegetative vigour and long-term reproductive activity is usually positive (Kozlowski 1971). Environmental conditions that favour rapid vegetative growth in conifers tend to induce earlier flowering (Schmidtling 1969). The more vegetatively vigorous individuals tend to have earlier reproduction (Harper 1977) and larger seed crops (Larson and Schubert 1970, Fowells and Schubert 1956).

In Boot Creek Valley, differences between sites in pH and texture were small. The forested sites and burned deep Of sites tended to have much more

exchangeable P, K, NH₄, and NO₃ than did the unburned deep Of sites. This may explain the widespread chlorosis observed in the leaves of the stunted stems on the unburned deep Of.

At the Caribou Hills site, thawing was much more rapid on the steep slope (shallow Of) than on the more flat areas (deep Of). By 25 June, the steep slopes averaged 22.6 cm of thaw, while the gentle to flat slopes averaged 9.8 cm. Similar results have been reported by Van Cleve *et al.* (1981) and Bliss and Wein (1971). Fine roots of seedlings on the steep slopes tended to be concentrated in the upper few cm, whereas fine roots of seedlings in the deep Of sites were most densely concentrated at about 7 cm below the surface. This difference may be due to the frequent desiccation of the upper few cm of the deep Of substrates. Consequently, the effective growing season for shallow Of sites may be a few weeks longer than for deep Of sites. Additionally, the poorly aerated, perched water table immediately above the degrading ice may retard growth early in the season (Lees 1972).

If stems on the shallow active-layer sites produced seeds as readily as those on the deep active-layer sites, then it follows that isolated stunted stems (say, more than 100 m from a deep active-layer site) should show local densities and/or age structures similar to those found on deep Of sites with nearby tall stems. Nothing like this appears to occur in the Inuvik area. Invariably, the isolated white spruce stems (e.g., on the tableland or north-facing slope) have no younger stems nearby. Dense yet stunted stands were only found in close proximity to tall trees located on nearby deep active-layer sites, e.g., on narrow sections of alluvium/colluvium between a steep south-facing slope and a creek.

In summary, it would appear that differences in vegetative vigour and (perhaps) seed production on shallow versus deep active-layer sites may be attributed to rate of thaw and, to some degree, nutrient availability. Aeration immediately above the degrading ice may also be important. The rate of thaw should be governed primarily by potential insolation and ice content. In non-gravel substrates, a deep Of layer is more important than either mineral soil texture or slope angle in determining both surficial ice content and relative active-layer depth (Greene 1983). The Of depth, then, is of tremendous consequence in both the demography and spatial distribution of white spruce in the northern forest-tundra.

CONCLUSIONS

Tentatively, it would appear that active-layer depth and fire frequency are the proximate determinants of white spruce tree-line in the uplands around Inuvik. Shallow active-layers delimit the range of white spruce because of a slower rate of June thaw (i.e., effective growing season length), lower seed dispersal capacity, lower cone production (probably), and poor seedbed creation (because of the depth of the Of) by fire. Fire delimits the range of white spruce by restricting it to areas with

relatively low fire frequency such as the steeper valley sides and the more deeply incised or highly sinuous perennial creeks. Deep active-layer sites tend to coincide with areas of low fire frequency. In the most heavily dissected terrain in the Inuvik area, such sites are not rare but their distribution is often very disjunct. If fire removes white spruce from an optimal site, the site may remain uncolonized for very long periods because of the low seed dispersal capacity of these stems.

ACKNOWLEDGEMENTS

Funding was provided by the University of Calgary and the Arctic Institute of North America. Logistical support was provided by the Inuvik Scientific Resource Centre and the Department of Forestry in Inuvik. I was assisted in the field-work by D. Privette and M. Bosch. I thank S.A. Harris, E.A. Johnson, and A. Limbird for their criticism of the thesis design and the manuscript.

AN INVESTIGATION OF MIDLATITUDE ALPINE PERMAFROST
ON NIWOT RIDGE, COLORADO ROCKY MOUNTAINS, USA

L. A. Greenstein

Department of Geography, University of Colorado, Boulder, Colorado USA 80309

A broad ridge in the Colorado Front Range is the site of a detailed permafrost investigation based on freezing and thawing indices. A 30-year record of temperature data from a station at 3,750 m above sea level is used along with a set of representative lapse rates to determine mean daily temperatures for 12 hypothetical stations on the ridge at different altitudes and with different aspects. Freezing and thawing indices computed for these sites indicate that continuous permafrost may be found down to 3,600 m on south-facing slopes and 3,550 m on north-facing slopes. The discontinuous-sporadic boundary was found to lie at 3,300 m on south-facing slopes and 3,200 m on north-facing slopes. These boundaries are somewhat lower than those proposed in a previous study. It is possible that the freezing and thawing indices used in higher latitude alpine settings as representative of the lower limits of the permafrost zones may overestimate the presence of permafrost in midlatitudes because of higher daily maximum temperatures.

INTRODUCTION

Permafrost research began in the mountains of North America in earnest with Retzer's 1956 study of alpine soils in the Rocky Mountains. Other early work included Pierce (1961), Retzer (1965), and Johnson and Billings (1962). More recently, ground temperature data have been collected by Ives and Fahey (1971), Ives (1973), and Harris and Brown (1978). Harris (1979, 1981a,b,c,d) has continued with extensive studies of climatic relationships and geomorphic indicators and Péwé (in press) has recently written a review of available data on alpine permafrost in the contiguous United States. The present study is a detailed examination of the lower limits of permafrost occurrence in a small area of the Colorado Front Range.

THE STUDY AREA

The Colorado Front Range is an area of north-south-trending mountains approximately 250 km in length. The Indian Peaks region, roughly in the middle of the Front Range at lat. 40°N, encompasses many individual summits higher than 4000 m, U-shaped valleys, and broad ridges that narrow into arêtes. One such ridge, called Niwot Ridge, was selected as the focus of this study because of the availability of a 30-year climatic record for a high-altitude (3,750 m) site. The ridge itself is 10 km long, oriented perpendicular to the Continental Divide. Timberline lies at approximately 3,300 m with the forest-tundra ecotone extending in places up to 3,450 m (Ives and Hansen-Bristow, 1983).

Niwot Ridge experiences a midlatitude continental climate with long winters and cool summers. At high altitudes, the area is very windy throughout the year. Westerly airflow is strongest in winter, with average wind speeds of 14m/s on the tundra. On a knoll on Niwot Ridge, winds at 6 m above the surface exceeded 18m/s during 50% of a 4-month period. The average daily maximum for

this same period was 39m/s, and the extreme gust was 62m/s (Barry 1973, 1981). Consequently the ridge is extremely windswept, allowing for only limited snow accumulation in hollows and on the lee slopes of small hills. The summer months are less windy, with July wind speeds averaging 6m/s. Wide daily and seasonal temperature variations are characteristic. Freezing temperatures can occur in all months. The daily range decreases with increasing altitude as a result of greater windiness and increased mixing of free air.

TECHNIQUES FOR ALPINE PERMAFROST PREDICTION

It is defensible to base continental- or global scale maps of high-latitude permafrost distribution on a theorized relationship between mean annual air temperature and the presence of permafrost, despite the inherent inaccuracies of such an approach (Ives 1974). With decrease in latitude and increase in altitude, however, mean annual air temperature has less and less value for permafrost prediction. Assuming a constant relationship between mean annual air temperature and the ground temperature regime in a level, relatively homogeneous subarctic setting will result in an expected error of 100 km or more in delineation of the equatorward limit of permafrost for each 1°C error in extrapolation (Ives 1973). In the more heterogeneous alpine environment, however, these inaccuracies could be magnified considerably. Large discrepancies result when attempts have been made to define a particular isotherm as the lower limit of alpine permafrost. Furrer and Fitze (1970) found the -1 to -2°C isotherm as the lower limit of permafrost in the Alps, while more recently Haeberli (1978), working also in the Alps, placed it between -7 and -8.5°C. The effects of factors such as soil characteristics, vegetation, snowcover, and wind, all of which play roles in the formation of permafrost, are greatly magnified by the high local relief of the alpine environment. In particular, aspect, degree of slope and solar

METHODS

angle, and wind effects on snowcover become very important factors, as they cause drastic changes in climates over very short horizontal distances.

The winter freeze and summer thaw are the two basic energy flows experienced by the soil in mid- and high-latitude settings with low winter snowcover. These basic flows can be represented by the freezing and thawing indices (the sums of the mean daily temperatures below and above freezing, respectively, expressed in degree centigrade days per year). Harris (1981a,b,c,d) has assembled an extensive collection of freezing and thawing indices from known permafrost and nonpermafrost sites in Canada, Greenland, Iceland, Mongolia, USSR, Scandinavia, Spitzbergen, and Switzerland. By plotting freezing indices against thawing indices, Harris was able to determine clusters of data points indicating the continuous, discontinuous, and sporadic zones. This method was applied to the 30-year temperature record from Niwot Ridge.

This technique is only reliable on sites with low winter snowcover. A very thin snowcover has the effect of cooling the soil by reflecting incoming energy (Kudryavtsev 1959). As the snowcover deepens, however, its capacity to reflect energy changes little while its ability to insulate the ground from winter low temperatures increases until the net effect is a warming of the soil. Based on data collected by Harris (1981a,b,c,d) from numerous sites in southern Alberta, 50 cm is indicated as the critical thickness of winter snowcover above which this technique will yield inconsistent results. Snow density and the mean annual range of the air temperature affect the insulating capacity of snow (Kudryavtsev 1959). Consequently, this critical depth would be expected to vary somewhat from one alpine site to another, particularly from a continental to a maritime regime. Krinsley (1963, p. 146) found 15 to 18 cm of snowcover to significantly affect the ambient air temperature fluctuations at low altitude sites in Alaska's interior. Atkinson and Bay (1940) found 25 cm to be the critical thickness at a low altitude site in Wisconsin. Harris (1981a,b,c,d) has found the data from different areas, representing both continental and maritime regimes to agree very well. Harris (1982, personal communication) has recently tested his findings with data from numerous thermister strings installed in the western Yukon territory.

A detailed ground temperature investigation was undertaken by Ives and Fahey (1971) (Ives 1973) on a section of Niwot Ridge. They installed thermister strings at several sites over a 300-m altitudinal range. They encountered permafrost at 3,750 m at a 3.8-m depth, and at 3,500 m at a 1.8-m depth. Ives (1973) was able to infer the presence of permafrost with relative certainty at two other sites located at 3,800 m and 3,750 m and the possibility of its occurrence at 3,485 m.

The above-mentioned study used direct measurements to establish the presence of permafrost on Niwot Ridge. It is the aim of the present study to expand on the previous work, using indirect prediction methods to extend the boundary of the study area outward.

The first step was to compute the mean daily temperature for each day of the year from the 30-year record available. The specific station used is referred to as D-1. This site was established in 1953 by John Marr (1961). It is located on a ridgetop knoll at 3,750 m, 1.5 km east of the Continental Divide. The site is very exposed and windy with a mean annual air temperature of -3.5°C .

Temperature data for numerous other high-altitude sites on Niwot Ridge are available for limited periods. These data were used by Kiladis (1980) along with the data from D-1 to produce four temperature maps of Niwot Ridge and the surrounding area showing average daily minimum and maximum temperatures in January and July. The maps were in part developed from representative lapse rates computed by Kiladis (1980) from the station data available. These representative lapse rates were further refined by Kiladis and this author for the purpose of this study. One important factor in these adjusted lapse rates was the subtraction of the cold air drainage effect common in this and many other alpine settings (Barry 1981, Harris 1982). This results in the temperature estimates, as well as the permafrost predictions, being conservative in those areas that are prone to cold air drainage.

Six separate lapse rates were used in the present study. Above the elevation of D-1 (3,750 m), conditions are similar to those of the free air because of the consistent windiness. Lapse rates computed from these exposed stations were used for temperature estimates above 3,750 m. The average lapse rate of maximum temperatures above 3,750 m is very close to the dry adiabatic rate of $1.0^{\circ}\text{C}/100\text{ m}$. The average lapse rate for minimum temperatures is slightly less at $.8^{\circ}\text{C}/100\text{ m}$. When estimating temperatures downward from D-1, it was necessary to use separate lapse rates for the north and south slopes as well as for minimum and maximum temperatures. These lapse rates are approximately as follows:

North-facing slopes--maximum	$.5^{\circ}\text{C}/100\text{ m}$
	minimum $.6^{\circ}\text{C}/100\text{ m}$
South-facing slopes--maximum	$.6^{\circ}\text{C}/100\text{ m}$
	minimum $.8^{\circ}\text{C}/100\text{ m}$

These six separate lapse rates were then used to estimate mean daily temperatures for 12 hypothetical stations. The mean annual air temperatures of the stations are plotted against elevation in Figure 1. As the lapse rates were calculated with data from the tundra and the forest-tundra ecotone, the estimates become less reliable close to timberline.

Freezing and thawing indices were then computed for each of the 13 sites (D-1 and the 12 hypothetical stations). Figure 2 shows the freezing indices plotted against the thawing indices for each of the sites, as well as the limits of the continuous, discontinuous, and sporadic permafrost zones from Harris (1981a,b,c,d).

DISCUSSION

The lower limit of the continuous permafrost zone is indicated at approximately 3,600 m on south-facing slopes and 3,550 m on north-facing slopes. Above these elevations, permafrost would be expected at most sites. Exceptions would be found in areas with lakes, glaciers, or a substantial winter snowcover. This altitudinal zone, however, is characterized by consistent windiness. On the broad ridges such as Niwot Ridge, very little snow accumulates at these elevations. More snow, and therefore less permafrost, can be found in the cirques and nivation hollows.

The discontinuous permafrost zone appears to extend down to 3,300 m on south-facing slopes and 3,200 m on north-facing slopes. In this zone permafrost occurrence would be patchy in response to the characteristics of the immediate environment. On the ridge itself, some snow accumulates in this zone in areas that are protected from the wind. One such area, referred to as the Saddle (approximately 3,500 m), is the site of a snow study currently under way by J. Halfpenny. Snow depths up to 3.6 m were found in the Saddle in mid-March of 1983 (1983, personal communication). The Saddle would be expected to represent a permafrost-free patch within the discontinuous zone. The thermister studies by Ives and Fahey (1971) and Ives (1973) of three sites in the Saddle confirmed the presence of permafrost at 3,500 m, a possibility of its occurrence at 3,485 m, and a permafrost-free site at 3,490 m.

The lower limit of the sporadic permafrost zone was not determined, as this would have required extending the lapse rate estimates below timberline. In the sporadic zone, small, isolated patches of permafrost would be expected in only the most favorable locations. Frozen ground was encountered late in the summers of 1962 and 1965, 3 to 4 m below the surface during the bulldozing of till for dam fill, on the south side of Niwot Ridge at 3,140 m (Ives and Fahey 1971). Pierce (1961) reported permafrost in a peat deposit at 2,950 m just 5° of latitude north of this study site.

These results indicate a more extensive permafrost cover than that presented in Ives's initial conclusions (1973, 1974, Ives and Fahey 1971). Ives concluded that the lower limits of the continuous and discontinuous zones lie at 3,750 and 3,500 m respectively. Being the first detailed study of permafrost in the Colorado Rockies and based on a limited number of thermister strings, these estimates may have been designedly conservative.

Mention should be made of the possible overestimation of the presence of alpine permafrost using freezing and thawing indices in Colorado. With the exception of the USSR and Mongolia, the data used by Harris (1981a,b,c,d) in defining the indices representative of the three permafrost zones came from significantly higher latitude sites than Niwot Ridge (40°N). While both the Canadian and the Colorado Rockies exhibit cool, continental climatic regimes, incoming energy is temporally allocated quite differently in this more southerly location. While mean annual temperature may be identical between 3,750 m on Niwot

FIGURE 1 Mean annual air temperatures for 13 sites (D-1 and 12 hypothetical stations) on Niwot Ridge, Colorado Front Range. An "N" in the site name indicates a north-facing slope and an "S" indicates a south-facing slope.

FIGURE 2 Freezing and thawing indices for 13 sites on Niwot Ridge, Colorado Front Range, in relation to the lower limits of the continuous, discontinuous, and sporadic permafrost zones (after Harris 1981a,b,c,d).

Ridge and a somewhat lower elevation at a higher latitude, Niwot Ridge experiences a more distinct diurnal radiation pattern superimposed on a slightly less severe seasonal regime. Niwot Ridge is affected by higher sun angles and the possibility of higher daily maximum temperatures than a higher-latitude site with the same mean annual air temperature. While the effect of these higher maximum temperatures would be reflected in the freezing and thawing indices, it may be somewhat minimized, as the indices are based on daily mean temperatures. While the use of freezing and thawing indices appears to be valid for midlatitude mountains, the curves representing the lower limits of the permafrost zones may need to be shifted slightly.

ENGINEERING PROPERTIES AND FOUNDATION DESIGN ALTERNATIVES IN MARINE SVEA CLAY, SVALBARD

Odd Gregersen¹, Arvind Phukan², and Torbjørn Johansen³

¹Civil Engineer, Norwegian Geotechnical Institute, Oslo, Norway

²Professor of Civil Engineering, University of Alaska, Anchorage, Alaska

³Civil Engineer, Norwegian Geotechnical Institute, Oslo, Norway

A new coal mining plant is under planning in Svea, central Spitsbergen, Svalbard. A major part of the plan area is underlain by a marine clay containing ice in vertical cracks. The cracks, 10-20 mm wide, are parallel at a spacing of about 50 mm. This particular structure of the marine clay encountered at the area is related to the geologic history of the region. With a water content of 50% and a high salt content, the engineering properties are extremely poor. At mean annual surface temperature, -6°C , about 40% of the pore water is unfrozen. The long term strength of the clay is determined by creep tests under uniaxial and triaxial conditions. For example, at a temperature of -4°C , the long term strength is as low as 80 kN/m^2 for a design life of 10 years. Based on field and laboratory data, three viable foundation alternatives are investigated. Spread footings, ventilated gravel pad, and slurried pile foundations are evaluated, and typical design solutions are given.

INTRODUCTION

Svea lies in the inner part of the van Mijen-fjord on Spitsbergen, Svalbard, and is one of the three Norwegian communities on the Svalbard Islands. The other two are Ny-Ålesund and Longyearbyen. All three are based on the coal mining industry. Longyearbyen, the largest with a population of about 1,200, is the industrial and administrative center, see Figure 1.

Future expansions will take place in Svea. Considerable coal resources have been detected and plans are being made for a large exploitation. This implies extensive construction activities, such as a coal treatment plant, harbour, air field, accomodation, roads, and other service systems.

Svea is located at 78° north and has a mean annual temperature of about -6°C . The relatively pleasant climate (considering the extreme location) is due to the warm Gulfstream passing along the western shores of Svalbard.

FIGURE 1 Svalbard Islands

GEOLOGIC HISTORY

A major part of the construction activities will take place within an area of marine clay. This clay was originally sedimented at the bottom of the van Mijenfjord. A surge of the Paula Glacier, from across the other side of the fjord, pushed the fjord-bottom clay in front and onto the Svea Lowland (see Figure 2). This surge is dated to between 600 and 250 years ago (Haga 1978, Pewe 1981).

The clay has a very special structure. A system of parallel, almost vertical, ice filled cracks is present throughout the whole of the deposit. The cracks can be up to 20 mm wide and are more than 5 m (probably 10 m) deep. Investigations done at different sites within a 2 km length indicate that the cracks have the same orientation throughout the deposit, that is, parallel to the shore line (see Figure 3).

The development of the vertical crack system is believed to be related to the glacial surge referred to above. Squeezed between the glacier and the mountain, the clay was subjected to extremely high horizontal pressure. As the glacier withdrew, the horizontal pressure was released, resulting in a lateral expansion of the clay and subsequently giving rise to vertical cracking of the deposit.

ENGINEERING PROPERTIES

Basic Data

Figure 4 shows a soil profile of the clay, giving the results of laboratory investigations. It should be noted that the water contents have been determined from the gross sample as well as from the actual clay (excluding the ice cracks). The gross water content is, as shown, above the liquid limit.

FIGURE 2 Sketch of Paula Glacier surge, 600 to 200 years ago.
a) Presurge stage b) Maximum spread

FIGURE 3 Detailed view of ice-rich marine clay, with parallel ice seams

FIGURE 4 Results of laboratory tests

The distribution of salt within the deposit was also evaluated. Salt contents were measured on the gross sample, on the ice in the cracks, and on the actual clay. The gross salt content was found to be 30-40 grams per litre, equivalent to the salinity of saltwater. The ice in the cracks, however, is practically free of salt, while the clay pores have a salt content of about 60 grams per litre. This separation of water and salt is a result of the freezing process. Impurities, in this instance salt, are forced out of the crystals and hence give rise to almost saltfree icelenses.

Grain size distribution tests were made. Figure 4 gives the clay fraction content with depth. As seen, it is about 40% and fairly constant with depth. That is, the material is homogeneous and is defined as a clay. The mineralogic composition is found to be illite (15-40%), clorite (20-30%), and kaoline (10-40%). Small amounts of quartz and felt-spar were also detected.

The determination of unfrozen water content as a function of temperature was performed on three samples. The clay specimens were melted and re-moulded prior to testing, ensuring a uniform distribution of water and salt within the test samples. The results from tests of one representative specimen are shown in Figure 5. At -2°C, 100% of the water is unfrozen, i.e. the freezing point depression of this saline clay material is 2°C. At -6°C, the mean annual temperature of Svea, 40% of the water remains unfrozen. The clay in its natural state will show somewhat different behaviour. The clean ice in the vertical lenses will remain frozen up to 0°C, while the saline pore water will be completely melted at above -3°C. These data agree with field observations, that the clay remains

soft and can be cut easily with a tool at temperatures a few degrees below 0°C.

FIGURE 5 Unfrozen water content as a function of temperature

Strength and Deformation Properties

To obtain the long term strength parameters needed for foundation design, a relatively extensive test program was run. The program included short term compression tests as well as unconfined and confined creep tests. Tests were run at two different temperatures. The compression tests served as reference for the creep tests. Preparation of samples and all testing were performed in a cold room at test temperature.

All tests were run on cylindrical soil samples with typical dimensions; diameter = 7 cm and height = 14 cm. The unconfined compression tests were performed with a constant rate of strain of $\dot{\epsilon} = 1\%/min$.

The major part of the creep tests were performed in a specially made triaxial creep apparatus. The constant axial load is applied through a Bellofram air cylinder on top of a standard triaxial cell. The apparatus is equipped with electrical transducers. A computer records and processes all the data from the test and produces report-ready plots (Johansen 1981 a). The duration of the creep tests varied from only a few hours up to more than 5 weeks.

A limited number of tests were run with different confining pressures. In Figure 6 the tests with load of 300 kN/m² had confining pressures of 0 to 300 kN/m². The results from those tests indicated that the Svea clay behaved as a true cohesive material. Therefore, all remaining tests in the program were performed as unconfined creep tests only.

Svea clay was tested at two temperatures, -5°C and -3°C. Most of the tests were performed at -5°C (1°C above the mean annual surface temperature). The latter temperature, -3°C, is the freezing point of the saline clay and was chosen to obtain information on the behaviour of the Svea clay, near melting.

The results of the creep tests are shown in Figures 6 and 7. The scatter in the results of tests at -3°C is a result of different ice structures in the samples, as a large proportion of the deformation is sliding between the ice lenses and the clay. The test results are used to obtain

FIGURE 6 Results of creep tests at -5°C

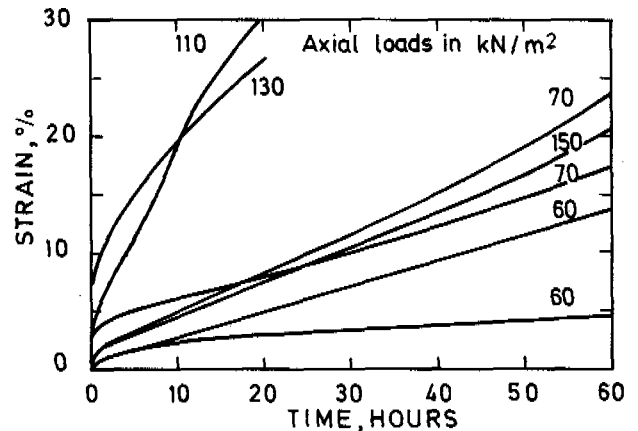

FIGURE 7 Results of creep tests at -3°C

long term strength of the clay by using methods proposed by Vyalov et al. (1966). The method is slightly modified by using a "20% strain criteria" instead of the inflection point between secondary and tertiary creep, in evaluating the creep parameters. This modification is introduced because the tests with low loads did not arrive at the tertiary creep, and often not at the secondary creep, within 20-30% strain. The highly unhomogeneous Svea clay was very difficult to test to a strain larger than approximately 30%.

Figure 8 shows the calculated long term strength for Svea clay based on the creep tests. Each line in the figure represents 1, 10, and 100 years time to failure (defined as 20% strain), respectively. The corresponding short term compressive strength at -5°C and -3°C is 900 kN/m² and 380 kN/m².

Based on the laboratory test results, the long term strength of the Svea clay is low, even at -5°C. This is mainly due to the high salinity of the solid portion of the clay, and the influence of the thick, vertical and continuous ice lenses.

At -3°C the clay itself is almost totally unfrozen. And in the interface between the clay and the ice, a thin film of unfrozen water is present, strongly influencing the deformation behaviour

FIGURE 8 Calculated creep strength values as a function of temperature

leading to extremely low creep strength (Berggren 1980, Johansen 1981 b, and Furuberg and Johansen 1983).

Only field tests and monitoring of constructions at Svea can give the necessary feed back of data to correlate laboratory strength parameters and in-situ parameters.

FOUNDATION DESIGN ALTERNATIVES

The assumed subsoil profile consists of clay with engineering properties as described above. The design ground temperature, based on measurements for several years, is shown in Figure 9.

Three most viable foundation types for different structures considered for the Svea clay soil are spread footings with an air gap and directly placed on permafrost, forced air ventilated gravel pads, and slurried pile foundations.

A typical spread foundation is illustrated in Figure 10. Based on the strength given in Figure 8 and considering a 20-years design period, the allowable soil pressure on the spread footing will be on the order of 100 kN/m².

FIGURE 10 Proposed spread footing design

The heated structures with heavy floor loads may be founded on gravel pad with forced air circulation, as shown in Figure 11. The foundation design of such ventilated gravel pads in permafrost zones is principally concerned with two aspects: the pad design for the summer period and the ventilation requirements for the winter periods when the ducts are operative (Phukan and Andersland, 1978). The following data are assumed for a typical case, as shown in Figure 11.

- Freezing Index = 3180°C days
- Length of freezing season = 255 days
- Mean annual air temperature = -7.5°C
- Floor concrete thickness = 0.2 m
- Air duct diameter = 0.30 m
- Gravel density = 2000 kg/m³
- Gravel water content = 3%

The methods given by Phukan and Andersland (1978) were used to determine the relationship between the thickness of the gravel pad and insulation for a 40 x 20 m gravel pad with ducts 0.3 m in diameter, and with c/c = 1 meter (see Figure 12). The air velocity required to refreeze the gravel pad was also analysed and is illustrated in the same figure. These relationships show that considerable savings may be obtained by using insulation.

Another viable alternative foundation design will be the slurried pile commonly used in Arctic

FIGURE 9 Measured temperature profiles from Svea

FIGURE 12 Relationships between insulated gravel pad and required air velocity

conditions. It is normally designed based on the adfreeze bond between the pile surface and adjacent frozen slurry, which is placed in the annular space between the drilled hole face and the outside of the pile surface. The design philosophy consists of:

the applied shear stress along the pile surface must be below some acceptable shear strength for the site soil conditions or the imposed loading does not exceed the adfreeze strength for the pile-soil contact, and

the allowable load will maintain the anticipated settlement at the end of the design period within tolerable limits.

A typical slurried pile design for the assumed soil and temperature profiles is presented in Figure 13. Assuming an uplift force of 200 kN/m², the required effective length of slurried pile in Svea clay will be on the order of 2.5 m below the active layer (factor of safety used = 2).

We have developed an instrument based upon the principle of electromagnetic induction to measure the three-dimensional position of a sensor. This sensor can be buried in the active layer of periglacial areas to study frost heaving, mass movement, and the evolution of patterned ground. The system is sensitive to sensor displacements of 1 mm, a very high resolution relative to anticipated heave rates. The present system is effective at ranges of up to 1 m, and this range could be easily extended. Laboratory tests show the system to be insensitive to variations in temperature, and calibration results are independent of the state of the soil, whether frozen or thawed.

INTRODUCTION

The principal geomorphic processes characteristic of periglacial areas, including frost heaving, solifluction, and the generation of patterned ground, involve the bulk motion of soil and the relative motion of rocks through the soil (Washburn 1980). Valuable information about total subsurface displacements over extended time periods has been obtained from studies of surface displacements (Fahay 1974, Nicholson 1976), from excavations that reveal displaced geologic markers both in the field (Shilts 1978, Washburn 1980) and in the laboratory (Pissart 1970, Burrous 1978, Washburn et al. 1978), and from measurements of pressure and moisture regimes within the active layer (Mackay and MacKay 1976). In spite of this substantial data base, our understanding of patterned ground development and the upfreezing of objects has been limited by the dearth of precise knowledge of the rate, direction, and timing of these subsurface motions.

We have developed an experimental technique that will allow ongoing nondisruptive observation of subsurface displacements in the active layer. The scheme uses electromagnetic induction to measure the three-dimensional position of a buried sensor coil, enabling one to determine its trajectory with high resolution. The sensor can be made to track soil movement or to simulate a rock that may move relative to the soil. Heave rates commonly range up to 50-150 mm yr⁻¹ for rocks of a size (diameter ~0.1 m) similar to that of the sensor (Burrous 1978, Washburn 1980), and our system can readily resolve displacements of 1 mm. The present system can be used to a depth of 1 m, which typically covers most of the range of interest in the active layer (Ferrians and Hobson 1973, Washburn 1980). In addition to obtaining precise information about subsurface movements, much could be learned about the underlying driving mechanisms by simultaneously monitoring temperature, pressure, and moisture content with appropriate transducers incorporated in the buried sensor.

APPARATUS

General

The principle of electromagnetic induction is used to measure the position of a buried sensor. The device is shown schematically in Figure 1. We use two wire coils, one as a drive coil on the surface and the second as a sensor that is buried in the active layer, simulating a clast. An ac current in the drive coil produces an oscillatory magnetic field. The component of this field vector normal to the plane of the sensing coil, B_z , induces an electromotive force (EMF) \mathcal{E} in the sensing coil. The EMF is proportional to the time derivative of the magnetic field. For a sensor of fixed area, A (Jackson 1975),

$$\mathcal{E} = -A \frac{\partial}{\partial t} B_z. \quad (1)$$

FIGURE 1 Schematic diagram of present system. The drive coil and its associated circuitry lie above the soil surface, while the sensor is buried in the active layer. The physical parameter measured by the system is z , the separation between the drive and sensor coils, once they are coaxial. The horizontal sensing coils are omitted for clarity.

For a sinusoidal drive current of constant amplitude and frequency, when the drive coil is directly above the sensor, the induced EMF is a measure of the separation between the two coils (Jackson 1975). In this configuration the sensor essentially functions as a magnetometer, and the spatial variation of the field amplitude yields vertical position information.

The horizontal position of the sensor is provided by two additional mutually orthogonal accessory coils, wound orthogonal to the main sensor coil already mentioned. When the drive coil is directly above the sensor, no EMF is induced in the accessory coils, since the component of the field normal to each of these coils is zero. The system is very sensitive in this respect, since the EMF scales with $\sin \gamma$, where γ is the angle between the plane of the coil and the incident field vector. Conversely, the signal in the vertical sensing coil is less sensitive to small horizontal displacements, as $\sin \gamma$ has a broad maximum at $\gamma = \frac{\pi}{2}$. This is to our advantage.

The sensor's position in the horizontal plane is measured on the surface by moving the drive coil horizontally until a null is obtained in both accessory coils. The drive coil is then directly over the sensor, and its horizontal position can be measured. The vertical separation is then determined by measuring the voltage induced across the main sensor coil and comparing it with a calibration curve. To ensure that the sensing coils maintain the proper orientation, the sensor system is mounted on gimbals in a housing like a boating compass.

Electronics

The drive circuitry consists simply of an oscillator and a power amplifier. We use an RC timer (XR 2240) in conjunction with a voltage regulator (μA 7805) to produce a square wave of fixed amplitude. The power amplifier has a variable gain stage (LM 324) and a unity gain buffer (μA 759). The drive system runs on ± 12 V and is quite field portable. The drive coil is placed in series with a tuning capacitor, giving an RLC series circuit.

This circuit has a resonant frequency, $\omega_0 = (LC)^{-\frac{1}{2}}$, at which its impedance is at a minimum. The square wave generator is tuned so that its fundamental frequency coincides with ω_0 . Thus the current drawn by the drive coil is sinusoidal at the frequency ω_0 , even though the drive voltage is a square wave. This produces a sinusoidally varying magnetic dipole field. We use a 1 μf series tuning capacitor, which in conjunction with the inductance and stray capacitance of the coil produces a resonant frequency of $f_0 = \frac{\omega_0}{2\pi} = 298$ Hz.

The drive coil itself consists of roughly 3,000 turns of #18 magnet wire evenly distributed on a cylindrical plexiglass coil form 0.12 m in diameter and 0.3 m long.

The sensor's coil has about 200 turns of #24 magnet wire wound around an iron core 30 mm in diameter and 120 mm long. The EMF across the sensor is processed through a preamplifier (LM 324) of

gain 200, and a rectifier. This dc voltage bears the vertical position information and is carried by coaxial cable to the measurement device on the surface. The horizontal information for the two smaller accessory coils is handled in the same fashion.

A calibration coil at a fixed position relative to the drive coil and similar in construction to the sensor is used to render the system insensitive to small variations in drive current amplitude and frequency. This is achieved by taking the ratio between the EMF induced in the sensor and that induced in the calibration coil. This ratio technique provides good immunity to the circuitry drifts that may occur under harsh field conditions.

Both the sensor signal and the calibration signal are conveniently measured by a microprocessor-based field data acquisition system (Polycorder by Omnidata) which averages each signal for 250 ms and stores the data in memory. It is worth noting that a multimeter will suffice for single measurements.

Mechanical

Ideally the drive coil should be rigidly mounted on a permanent installation for long-term monitoring of the sensor's absolute position, since the system measures the separation between the drive and sensor coils. Periodic adjustments of the drive coil's horizontal position could be made as necessary, followed by vertical position measurements. The most stable configuration would involve a nonmagnetic frame anchored in either bedrock or permafrost.

One drive coil could service an array of sensors, some of which could be outfitted with "fins" in order to determine bulk soil motion. The others would have their density, texture, and thermal characteristics tailored to mimic clasts of interest. Alternatively, sensors could be designed to explicitly investigate any dependence on a given variable. The use of sensors of varying size and shape, for example, would allow comparison with past studies (Burrous 1978 p. 83, 84). Sensor size is somewhat constrained, as sensitivity drops with a reduction in coil area, but sensors of dimension 50 mm on a side seem reasonable.

By mounting the drive coil on the frame the sensor's absolute position is measured. To determine its position relative to the soil surface, surface heave can be measured by using linear potentiometers fixed to the frame and coupled to the ground through rods that move freely with the soil surface. Two adjacent sensors, one with fins and one without, would distinguish between bulk and relative motion. If the vertical position of the sensor relative to the surface suffices, no frame is necessary.

Some disturbance of the soil is unavoidable during the installation of the sensor. This may be minimized, however, by implanting it while the soil is frozen; a soil core could be extracted, and replaced after positioning the sensor in the borehole. Coring at an angle to the anticipated path of the sensor's travel would further minimize the disturbance. After installation, data can be taken at will without further disruption.

Presently, some provision must be made to ensure that the wires do not impede the sensor's motion.

This is probably best achieved by packing a spiral of wire in a grease-filled compartment on the sensor so that it will feed freely. The modifications proposed in the section on future work eliminate external wire entirely.

ELECTROMAGNETIC AND THERMAL CONSIDERATIONS

Magnetic Susceptibility

In general, substances respond to an applied electromagnetic field, and the internal and external fields differ (Jackson 1975). As we will measure the field in the soil, such effects must be considered. The soil's effect is most readily expressed in terms of its magnetic susceptibility, χ , except when a substantial amount of iron is present. Most media perturb a magnetic field only slightly, causing intensity changes of a few parts in 10^4 or 10^5 . Table 1 lists the magnetic susceptibility of some substances of interest.

We expect that most soil, frozen or otherwise, in which the sensor is buried will cause a relative field perturbation of less than 0.1%. For a region with a large or inhomogeneous concentration of iron, our technique is of limited use. The actual maximum tolerable field perturbation in such a case will depend upon the desired resolution and accuracy. We made measurements in both air and soil and found no measurable difference between the two (see section on results).

For a particular soil type, a field calibration of one or two data points should establish a scaling factor, if any, to apply to laboratory calibration curves. This scaling factor should be essentially temperature independent and should serve to reduce an already small error.

Eddy Currents

The drive coil's magnetic field generates electrical eddy currents in the earth, which are 90° out of phase with the drive current. These currents have magnetic fields of their own associated with them, which will be detected by our sensor. This is essentially the operating principle of previous permafrost electromagnetic induction work (Hoekstra and McNeill 1973), but is a source of noise for our experiment. Our sensor will be so close to the drive coil, at most 1 m away, that the drive coil's field will dominate by a very large margin. In the unlikely event that this noise source must be actively suppressed to attain higher resolution, synchronous detection of the induced EMF would surely be effective.

†Clark (1966).

The eddy currents also extract energy from the drive coil's field, since the earth is a resistive medium. Hence in earth the magnetic field amplitude diminishes more rapidly with depth than it would in free space. This effect can be quantitatively estimated by taking a simple functional form for the attenuation,

$$B_a(z) = B_o(z)e^{-z/\sigma}, \quad (2)$$

where B_a is the actual field at the position z , B_o is the field in the absence of this effect, and σ is the skin depth. The skin depth is the distance at which the amplitude of a plane wave of electromagnetic radiation drops to $\frac{1}{e}$ of its initial value. The skin depth of the earth at our operating frequency is roughly 1,000 m (Hoekstra and McNeill 1973). For sensor depths of 1 m the exponential can be expanded to obtain

$$\frac{B_a}{B_o} = 1 - \frac{z}{\sigma} + \frac{1}{2} \left(\frac{z}{\sigma}\right)^2 \dots = 99.9\% \text{ (at } z = 1 \text{ m)}. \quad (3)$$

This energy loss due to eddy current effects is essentially constant in time, but increases with depth and will vary slightly with location. If very high resolution ($>1:10^3$) at long ranges (>1 m) is desired, a few field calibration points should provide a corrected calibration curve; otherwise the effect can be safely neglected.

Temperature

The relevant electromagnetic properties of the earth are effectively constant over the temperature range of interest. Electronic systems, however, are often susceptible to errors introduced by temperature variations. Careful design and component selection (including batteries) are mandatory. Our present drive system functions adequately, but will be modified as outlined in the section on future work.

RESULTS

Data obtained in the laboratory indicate that vertical and horizontal resolution of up to 1 mm is attainable.

The sample data in Table 2 were obtained by suspending the sensor above the drive coil and varying the separation between the two. Both coils were in air, at room temperature. The drive frequency was 298.5 ± 0.2 Hz, and the voltage was 3.000 ± 0.001 V rms. Note the distinct signal change in going from 317 to 318 mm. An average ratio is computed on the basis of five trials at each separation. This information constitutes the calibration curve for the system and is given in Figure 2.

The range is determined by the minimum detectable signal in the sensor and can be extended by increasing the drive amplitude. The vertical resolution of the system depends upon the separation and is governed by the change in B_z with

TABLE 2 Sample Data Obtained in Air.

	1.225	2.250	0.544

FIGURE 2 Calibration curve obtained in air. Curve A is the calibration curve obtained from a drive of 298.5 Hz at 3.000 V. B was obtained at a lower resonant frequency. C shows the effect of adding an iron core to the drive coil. The uncertainties in the ratio and the position are ± 0.001 and ± 0.5 mm, respectively, and cannot be resolved on this plot.

separation, $\frac{\partial B}{\partial z}$. Hence by optimally shaping the field, the region of maximum sensitivity can be adjusted to coincide with a depth of interest. The field can be modified by adding an iron core, or pole piece, to the drive coil. Figure 2 shows that by adding a laminated iron core we enhanced the sensitivity, which is helpful in probing greater depths. As the addition of the core changes the coil's inductance and therefore the resonant frequency, either the drive frequency or the timing capacitor must be adjusted before calibrating.

To examine reproducibility, we fixed the location of the sensor coil, then dismantled the drive system and reassembled it after several days. The ratio was unaltered within ± 0.001 .

The effects of soil and temperature were determined experimentally by first taking data in air at an arbitrary separation of roughly 300 mm. The sensor was then surrounded with frost-susceptible soil, including the region between it and the drive coil. The measurement was repeated in the presence of the soil. Water was then added to the soil, and data again taken. Finally, the calibration apparatus, with the wet frost-susceptible soil, was placed in a -3°C environment in the Periglacial Laboratory of the Quaternary Research Center. The soil was allowed to freeze, and the measurements were repeated. Our results were obtained at a drive of 298.5 ± 0.2 Hz and 3.000 ± 0.001 V and are summarized in Table 3.

The data taken at Z_0 show a sizable change in both signal values, but the ratio remains virtually constant. The ratio variation does not jeopardize the resolution at the 1-mm level. The utility of the calibration coil is very apparent in this sequence of measurements. We anticipated some circuitry drifts to be associated with the temperature change, and indeed the resonant frequency dropped by about 1 Hz. Furthermore, the changes in the sensor and calibration signals are consistent with a 5% increase in the magnetic field intensity. We believe that this is due to an impedance change in the RLC circuit, an idea supported by the resonance drift. A current-regulated system would avoid this problem, but in any event the ratio technique very effectively cancels it out.

FUTURE WORK

The most significant single improvement upon the present system would be the elimination of the wires through which the sensor communicates with the surface. This can be achieved using a scheme presented in Figure 3. Essentially, the battery-powered sensor would act like a transponder, transmitting information on command. The use of low power circuitry should allow sensor lifetimes of several years, if transmitting is minimized. A precision voltage reference would be buried with the sensor to provide calibration against drifts in the sensor circuitry. Additional devices, to measure temperature and pressure, for example, could be included in the sensor package.

The revised sensor would continuously monitor the local magnetic field at the drive frequency, ω_d . When the drive coil is turned on, the

TABLE 3 Soil and Temperature Effects.

Temperature (°C)	Medium	Separation	Sensor Signal (V)	Calibration Signal (V)	Signal Ratio
25	Air	Z_0	1.396	2.263	0.617

A resolution of 1 mm is readily seen.

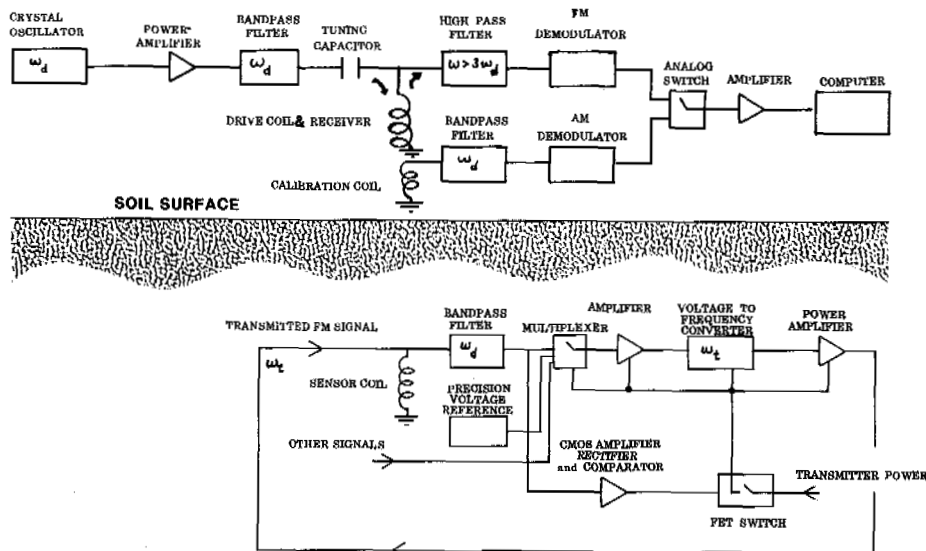

FIGURE 3 Schematic of a proposed wireless version. The underground device would consist of two sections: a stage which is always on and sensing the coil, and a transmitter which would automatically switch on when the drive coil is activated. The position information would consist of a rectified EMF that is transformed into an FM signal, with $\omega_t \gg \omega_d$. The FM signal is transmitted to the surface via the sensing coil. A multiplexer would switch between the various transducer signals and a stable reference voltage.

comparator would respond to the increased magnetic field by switching on the transmitter (the multiplexer, amplifier, voltage-to-frequency converter, and power amplifier). The multiplexer would select a signal from the sensor coil, a precision voltage reference, or one of the additional transducers for transmission at a frequency ω_t . Choosing $\omega_t \gg \omega_d$ allows decoupling between the incoming and outgoing signals, and thus the sensor coil can serve to both transmit and receive information without interference.

On the surface the drive coil would detect the frequency-modulated (FM) signal from the sensor.

The demodulated voltage should reflect the amplified transducer signal in the sensor. The buried voltage reference would provide a fixed point for calibration.

Modifications to the drive circuitry are also in order. Our present drive system functions adequately, but the voltage and frequency must be periodically trimmed by adjusting two variable resistors. A crystal-controlled oscillator with digital counters would provide a stable square wave, with better temperature stability than the present device. A current-regulated system would also be preferable to the voltage-regulated system now in use. This would provide better field amplitude

regulation.

CONCLUSION

The current system has the requisite range and resolution to be of use in a quantitative investigation of soil and rock movement in the active layer. Laboratory tests indicate that the electronics operate reliably to our lowest test temperature, -3.0°C , with no signal degradation. High-reliability integrated circuits (Mil Spec) should extend the temperature range to -55°C . Convenient calibration of the system can be performed in air. We found that introducing frost-susceptible soil (dry, wet, frozen) had no appreciable effect. Excluding the support frame, the total instrument package has a mass of 10 kg and is easily field portable.

We plan to install sensors both in sorted circles in the field and in laboratory experiments related to sorted pattern development. We welcome comments and inquiries concerning this system.

ACKNOWLEDGMENTS

Discussions with R. S. Anderson, D. B. Booth, Y. J. Brown, C. A. Gregory, and A. L. Washburn were very helpful. The facilities of the Periglacial Laboratory were invaluable in the development of the apparatus. We are particularly grateful to the Laboratory's director, B. Hallet, for his support and suggestions. Special thanks go to P. Leaming for typing the manuscript.

ZONATION AND FORMATION HISTORY OF PERMAFROST IN QILIAN MOUNTAINS OF CHINA

Guo Pengfei¹ and Cheng Guodong²

¹ 00926 Unit, Xining, Qinghai Province

² Lanzhou Institute of Glaciology and Cryopedology, Academia Sinica
People's Republic of China

Alpine permafrost underlies 91,000 km² in Qilian Shan, and its distribution shows obvious latitudinal and longitudinal zonation. The lower limit of the permafrost is at 3700-3900 m a.s.l. in the south and at 3494-3650 m in the north. As the latitude increases by 1°N, the permafrost lower limit descends 123.7 m; as the longitude increases 1°E, the permafrost lower limit descends 56.6 m. In the insular permafrost zone, the permafrost is generally 25-35 m thick, with a mean annual ground temperature of 0° to -1.5°C. In the discontinuous permafrost zone, it is 35-95 m thick and the mean annual ground temperature is -15° to -23°C. Temperature inversions, which become stronger northwards, affect permafrost distribution; a maximum thickness of 139.3 m occurs in the Mu Li and Tuo Lei Basins. Permafrost on north-facing slopes is 30-50 m thicker than on south-facing slopes. Qilian Shan has undergone several ice ages, but the existing permafrost was formed around 3000 yr B.P., because during the interglacial period of the Pleistocene and the post-glacial stage at the beginning of the Holocene temperatures were too high for permafrost preservation.

GENERAL DESCRIPTION OF PHYSIOGRAPHY

Qilian Shan is a great peripheral mountain system to the northeast of the Qinghai-Xizang Plateau. It occupies a total area of about 210,000 km², and contains seven, five, and three ranges in the western, middle, and eastern sections respectively. All these mountains range from 4000 to 4500 m, and the highest peaks are 5245 to 5826 m. There are perennial snow fields and modern glaciers in the alpine zones above 4300 to 4500 m.

Influenced by the circulation of west wind, the western part of Qilian Shan is dry. The annual rainfall is only 150 to 300 mm, the annual amount of evaporation is 1500 to 2000 mm, belonging to continental desert climate. Affected by the oceanic monsoon, are relatively humid the east and middle sections of the mountains, with an annual precipitation of 400 to 500 mm, belonging to semi-arid alpine steppe climate. Its mean annual temperatures are 0 to -3°C, the temperatures in Jiang Cang, Tuo Lei are -3.2 to -5.7°C.

Qilian Shan belongs to the high altitude periglacial zone. Various periglacial phenomena develop very well, most of them closely related in origin and development to permafrost. These phenomena are also direct indications of modern permafrost.

LAW OF ZONATION IN PERMAFROST DISTRIBUTION

The permafrost in Qilian Shan covers an area of about 91,000 km², which is 43% of

the total area of the mountains. According to the distributing state of permafrost and the area of taliks, the permafrost can be divided into two main zones: insular permafrost zone and discontinuously blocky permafrost zone (Figure 1). The area of taliks in the insular and discontinuously blocky permafrost zones is 60-80%, and 10-20% respectively.

The Changes of Permafrost Lower Limit and Zonation of the Types of Permafrost

The permafrost in Qilian Shan is of the alpine permafrost type of the middle latitudes. The elevations of its lower limit changes with the latitude and longitude, restricted by solar radiation and the types of climate. The elevations of the south boundary (lower limit) of the permafrost, extending along the southern slopes of La Ji Shan, Qinghai Nan Shan and Qaidam Shan, are 3700, 3800, 3900 m respectively. This boundary coincides with the -2°C isotherm for mean annual air temperature. The altitudes of the north boundary (lower limit) of the permafrost, along the northern slopes of Leng Long Ling, Zou Lang Nan Shan, and Dang He Nan Shan are 3494, 3550, 3650 m respectively. This boundary is identical to the -2.5°C isotherm for mean annual air temperature. The southern boundary is 206 to 250 m higher than the northern boundary. By regression analysis, the decreasing rate of the lower limit of permafrost is 123.7 m per degree of latitude from south to north. The permafrost lower limit falls with the increase of longitude from west to east, decreasing at a rate of 56.6 m per degree of longitude.

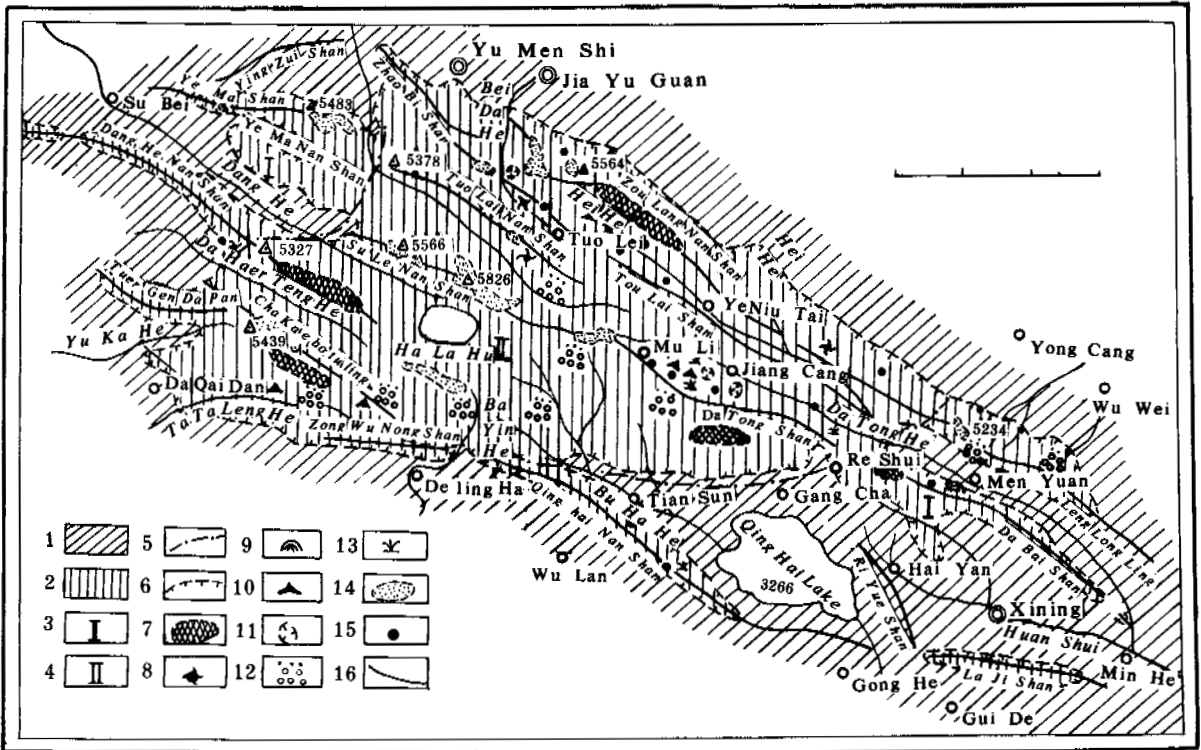

FIGURE 1 Map of permafrost distribution in Qilian Shan.

1. seasonally frozen ground; 2. permafrost; 3. insular permafrost zones; 4. discontinuously blocky permafrost zones; 5. border line between the insular and discontinuously blocky permafrost zones; 6. border line of permafrost distribution; 7. cryoplanation surface; 8. frost heaving mounds; 9. debris flow; 10. icing; 11. thermokarst depression; 12. rock stream talik; 13. grassy marsh in talik; 14. modern glaciers; 15. holes drilled in frozen ground; 16. main mountain ridge.

These changes are contrary to the law that the permafrost lower limit in Europe, America, and Tian Shan of China rises with the decrease of continentality. The restriction of regional climate conditions on the distribution of permafrost is quite apparent. Assuming that the relations between the measured heights of the zones of permafrost and glaciers are taken as the mark dividing the types of permafrost, we then plot a section (Figure 2) in accordance with the relations between Dunde, Yigelige, and Leng Long Ling glaciers and the lower limit of permafrost along 38°N from west to east. The snow line and the permafrost lower limit descend regularly with increasing precipitation from west to east. The distance between the snow line and the lower limit of permafrost is 1350 m in the west part of Qilian Shan, and is less than 1000 m in the east section. The average distance is more than 1000 m, having the characteristics of a continental climate region.

Because of the differences of climatic conditions and corresponding to the types of glaciers, the permafrost in the eastern part of Qilian Shan belongs to sub-continental type and in the western part belongs to extreme continental type (Table 1).

Changes of Zonation and Thickness of Permafrost

The thickness of permafrost in Qilian Shan varies in different places. In the insular permafrost zones, the permafrost is 25 to 35 m thick, and 1-13 m thick in some areas. The mean annual ground tem-

Type of permafrost		Extremely continental type (in west part)	Sub-continental type (in east part)
Comprehensive characteristics	Permafrost lower limit (m)	3650-3900 (north slope-south slope)	3494-3700 (north slope-south slope)
	Distance between snow line and lower limit (m)	More than 1000	Less than 1000
	Annual average temperature near permafrost lower limit (°C)	-2.5 to -3.0	-1.7 to -2.5
Permafrost features	Height of snow line (m)	4830 (Ye Ma Shan glaciers No. 12)	4600-4450 (Zou Lang Nan Shan-Leng Long Ling)
	Annual rainfall near snow line (mm)	400	600-800
	Annual average temperature along snow line (°C)	Lower than -11	Higher than -11
	Type of glaciers	Extremely continental type	Sub-continental type
Main periglacial indications	Frost weathering, debris slope, cryoplanation terraces, frost heave mounds, alpine grassy marshes	Nivation, cryoplanation terraces, rock sea, rock stream, frost heave mounds, solifluction, thaw slumping, stone ring, thaw settlement, thick-layered ground ice	
Climate features	Type of climate	Continental arid desert climate	Continental semi-arid alpine steppe climate
	Annual precipitation (mm)	150-300	400-500
Vegetation types	Semi-shrub-desert steppe	Mountain forest, shrub, steppe meadow	

perature is 0°C to -1.5°C. In discontinuous blocky permafrost zones, the thickness of permafrost is 35 to 95 m. The mean annual ground temperature is -1.5 to -2.3°C (Table 2).

It is clear that permafrost becomes thicker with the rise in altitude, in response to the vertical decreasing lapse rates (Figure 3, 4). Under the influence of the cold air draining from Qinghai-Xizang Plateau, cold air "lakes" often occur in some small basins in the middle part of the Qilian Shan, and temperature

inversions occur. The mean temperature of January in the Mu Li and Tuo Lei basins is -18 to -19.7°C respectively, these being the coldest areas in January. Permafrost in these regions is generally 50 to 95 m thick, with a maximum of 139.3 m. In addition, as the intensity of the temperature inversion becomes stronger from south to north, the permafrost thickness increases at a given altitude from south to north. The thickness of permafrost increases about 42 m in approximately 100 km at a given altitude in the middle section

of Qilian Shan. This is a special phenomenon occurring in alpine type permafrost in middle latitudes.

Another feature of the distribution of permafrost thickness is the evident lack of symmetry on the southern and northern sides of the mountains, due to the effect of the duration of the insolation on mountain slopes of different aspects. The thickness of permafrost in the south-facing slopes is 30 to 50 m thinner than that on the north-facing slopes.

Moreover, marshes that absorb solar radiation prevent permafrost from thawing. The thickness of permafrost varies significantly with the differing degree of swamping (Figure 5).

FORMATION HISTORY OF PERMAFROST

It is well-known that the prerequisite conditions for the formation of permafrost are the ancient periglacial climatic environments since the Quaternary. Glaciers and permafrost were produced under cold climatic conditions, and an important way to reveal the history of the formation of

permafrost in Qilian Shan is by means of correlations with the division of the glacial periods.

Qilian Shan has witnessed four ice ages and three interglacial periods since the Quaternary (Guo Pengfei 1980). All these can be compared with the glacial ages in the various parts of Qinghai-Xizang Plateau (Table 3). Therefore, fossil perma-

frost must have developed in Qilian Mountains in each ice age. Its area of distribution could have been considerably larger than that of the ancient glaciers. However, the climate over Qilian Shan in every interglacial period in the Quaternary was gradually becoming drier and colder from early to late Pleistocene (Yang Huiqiu and Jiang Dexin 1965). The mean annual air temperatures in the interglacial period were about 8 to 12°C higher than those of today, and the mean annual air temperatures in the hypsithermal were 3 to 5°C (Guo Xudong 1976) higher than now. Furthermore, the influence of the Himalayas, located in the southern part of Qinghai-Xizang Plateau, was not notable in changing the atmospheric circulation and the hydrothermal condition over the Plateau before the middle Pleistocene. As the mountains rose to more than 4500 m in the late Pleistocene, it demonstrates the function of "barriers". The development of glaciers and permafrost were primarily controlled by the vicissitudes of global climate, and the latitude zoning, for both Qilian Shan and the Plateau were under the influence of the Indian Ocean monsoon in early and middle Pleistocene. The ancient permafrost formed in Tuo Lai ice age in early Pleistocene and in Leng Long Ling glacial age in middle Pleistocene must have completely thawed after undergoing a rather long warm climate in Tuo Lai-Leng Long and Leng Long-Da Ban interglacial periods. A careful study should be undertaken as to whether the fossil permafrost formed in Da Ban ice age in the late Pleistocene is preserved now or not. Effected by the fluctuation of global climate controlled by solar radiation, the warm climate in Ya Li period in the southern part of the plateau was common on the whole Qinghai-Xizang Plateau, and it corresponds to the Atlantic period in Europe and the Ban Po warm period in China. The ancient permafrost formed during the Da Ban glacial age in Qilian Shan must have melted greatly or totally after experiencing the warm period.

The permafrost distributed in Qilian

Shan was then produced in the Gang Shi Ga Neoglacial event. According to Zhu Kezhen (1972), and Qin Dahe (1981), the coldest period in the last one thousand years was during the period 1620-1880 A.D., and lasting two hundred and fifty years. It was a favourable time for permafrost to develop and to be preserved. From the oscillation of radiocarbon records, the climatic fluctuations in Neoglacial periods match reasonably well in southern and northern hemispheres. Consequently, not only a great deal of glaciers developed there but also a huge amount of permafrost was formed. Thus it seems appropriate to confine the age of formation of modern permafrost in Qilian Shan in a period after the Gang Shi Ga Neoglaciation, about 3000 years B.P.

A COMPARISON OF REMOTELY SENSED SURFACE TEMPERATURE AND BIOMASS
ESTIMATES FOR AIDING EVAPOTRANSPIRATION DETERMINATION
IN CENTRAL ALASKA

Aerodynamic surface roughness, an important parameter controlling the evaporation rate, is related to the biomass. Previous work indicated that temperature variations in the Heat Capacity Mapping Mission (HCMM) satellite data were related primarily to evaporation differences for similar albedo values. LANDSAT-derived estimates of the biomass were related to HCMM-derived estimates of the surface temperature for an area of the Alaskan sub-Arctic for which contemporaneous LANDSAT and HCMM data existed. It was found that the relationship showed some scatter, the correlation coefficient being only ~.62. Thus, land cover data are not good substitutes for remotely sensed thermal infrared data in this area at this time of year, but these data have ancillary uses for situations in which high spatial resolution data are needed to improve coarse resolution thermal infrared data.

INTRODUCTION

Permafrost areas are subject to economic development that may well alter their ecological and environmental equilibria. Unlike in many non-permafrost areas, the tolerance to change is unknown and likely to be small, while the monitoring of changes is very difficult using conventional means because of the remoteness of the areas. Remote sensing techniques provide a set of methods that may allow successful environmental monitoring in these areas. Several techniques may be used: the use of visible and near infrared multispectral data, which are mainly related to vegetation type and biomass, the use of thermal data, which may be related to the evapotranspiration and the use of microwave data, which may be related to the surface roughness and the soil moisture status. The properties to which these systems are sensitive are related. However, the relationships among these properties are not always straightforward. This paper discusses the relationships that may exist, in an area of discontinuous permafrost in central Alaska, among biomass, surface temperature and albedo. Multispectral visible and near-infrared data from the Multispectral Scanner Subsystem (MSS) and a contemporaneous thermal infrared data set from the Heat Capacity Mapping Radiometer (HCRM) are employed. As is discussed, there are good physically-based reasons for thinking that these data types should be related in this area. There is an intricate relationship among vegetation, slope, soil type and presence of permafrost in the study area. For example, interior low brush, muskeg-bog areas and black spruce hardwood associations are generally found in areas that are underlain by continuous permafrost (LUPC, 1973). Bottomland spruce poplar forests are generally found in areas in which permafrost is

deep or absent (LUPC, 1973). Thus, a relationship exists between permafrost, evapotranspiration and surface temperature.

BACKGROUND

Previous work has demonstrated that the relationships among the components of the energy balance equation can be modeled using remotely sensed data, e.g. Price (1980). Gurney and Hall (1983) used an HCMM scene of central Alaska to estimate the components of the energy balance equation for 12 May 1978:

$$G = R_N + LE + H, \quad (1)$$

where G is the soil heat flux, R_N the net radiation, LE the latent heat flux and H the sensible heat flux. The HCMM data used were obtained just after the ice breakup. At this time, when the ground is wet and the air is still quite dry and cold, evapotranspiration is at or near potential. Evapotranspiration within the study area was found to vary from 2 to 5 mm day⁻¹. This agreed favorably with surface measurements of evapotranspiration taken in previous years in Arctic and Sub-Arctic areas just after the ice breakup.

The latent and sensible heat components of the surface energy balance were modeled as follows:

$$LE = -C_1 U_a (e_s - e_a) \quad (2)$$

$$H = -C_1 \gamma U_a (T_s - T_a), \quad (3)$$

where T_s is the surface temperature, T_a the air temperature, e_s the surface vapor pressure, e_a the atmospheric vapor pressure, U_a the wind speed,

and γ the psychrometric constant. The constant C_1 in Equations (2) and (3) is the bulk diffusion coefficient. This constant, C_1 , may be modeled as:

$$C_1 = \frac{\rho c_p k^2}{\gamma \ln^2 \left(\frac{z}{z_0} \right) \left(1 + \frac{r_s}{r_a} \right)}, \quad (4)$$

where ρ and c_p are the density and heat capacity of air, r_a and r_s are the aerodynamic and stomatal resistances, z is the height at which the meteorological data are measured, z_0 is the roughness length, and k is von Karman's constant (Brutsaert, 1982).

The bulk diffusion resistance C_1 is thus related to the aerodynamic surface roughness. This surface roughness is in turn related to the vegetation height and thus, at least in part, to the vegetation type (Monteith 1973).

This type of approach has, at least indirectly, been the basis of previous work, such as that of Priestley and Taylor (1972). They define an empirical parameter α that relates potential and equilibrium evaporation rates, E_p and E_e , respectively:

$$E_p = \alpha E_e. \quad (5)$$

Priestley and Taylor (1972) suggest that this parameter has a value of 1.26 for grass, a value supported by subsequent studies, as reviewed by Brutsaert (1982). Other vegetation types with different surface roughnesses yield different estimates of this parameter. For instance, McNaughton and Black (1973) found $\alpha = 1.05$ for a young 8-m-high Douglas fir forest. Thus, it may be seen that the evaporation is often related to the land cover type and, as mentioned previously, vegetation type is related to permafrost. Land cover types may be estimated from multispectral remotely sensed data, such as supplied by the LANDSAT MSS. There are thus at least two ways in which land cover type can be used to improve estimates of evaporation, both involving the use of semiempirical parameters. The surface roughness estimates z_0 (Equation 4) can be modified by the type of land cover, or the parameter α (Equation 5) can be changed. Both cases presuppose a simple relationship between biomass and the evaporation rate. This is tested here for this area.

METHOD

Each of the components of the surface energy balance (Equation 1) depends in part on the surface temperature. Gurney and Hall (1983) found that the surface temperature as estimated by the HCMR is a good indicator of evaporation, because the other parameters (such as the albedo) were similar over much of the area. It is thus of interest to compare the surface temperatures estimated by using the HCMR to the land cover types estimated from LANDSAT, and to existing vegetation maps. The temperature estimates are closely related

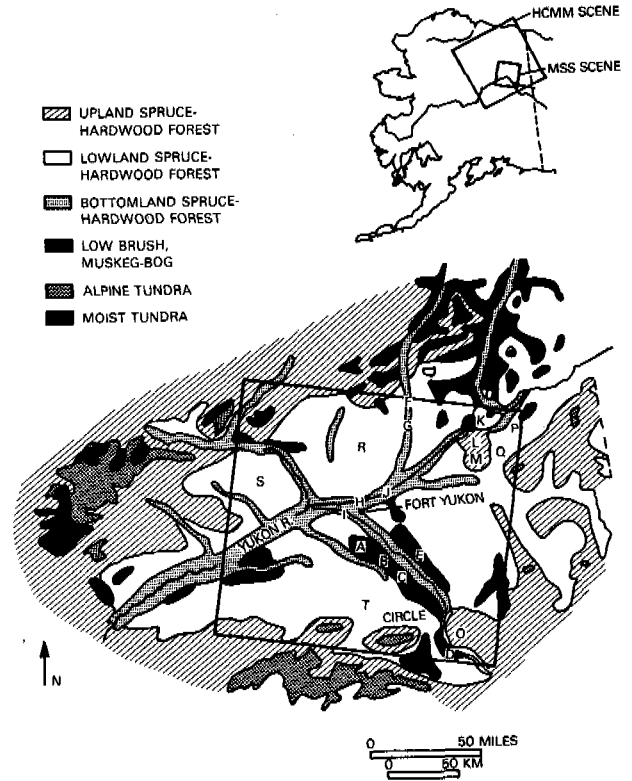

FIGURE 1 Land cover map of the Alaskan study area (after LUPC 1973), showing the major land cover groups and the locations of areas used to extract values for use in this study.

to the actual evapotranspiration, as shown by Gurney and Hall (1983). Gurney and Hall (1983) used an HCMR scene (A0016-22230-2) of the Alaskan sub-Arctic together with a model described by Camillo et al. (1983) to estimate daily evapotranspiration. This same HCMR scene was used in the present study. A LANDSAT scene (30068-20374) was acquired two hours before the HCMR scene of the same area on 12 May 1978 (see Figure 1). The two scenes were geometrically registered (digitally overlaid), as described later, and compared by using the following method.

The bulk diffusion resistance, C_1 , is related to the vegetation height and biomass. Holben et al. (1980) have shown that the normalized difference (ND) ratio obtained from MSS data, is also related to the biomass:

$$ND = \frac{R_7 - R_5}{R_7 + R_5}, \quad (6)$$

where R_5 and R_7 are the gray-level counts for LANDSAT MSS Bands 5 and 7, respectively. The

temperature for certain areas of known cover type, from a land cover survey (LUPC 1973), was then related to the ND ratio. If there is a relationship between cover type and evaporation, it should appear as a relationship between the ND ratio and the surface temperature.

DATA MANIPULATION

To use the information from the HCMM and LANDSAT data better, the two images were geometrically registered so that the HCMM transformed data lay exactly over the LANDSAT data. The LANDSAT scene was used as the base. The HCMM scene was rotated 45° so that its orientation was approximately the same as that of the LANDSAT scene. Tie points, features that were clearly identifiable in both scenes, were located within the two scenes, a procedure that required two iterations because of the different resolutions of the HCMM and LANDSAT data. A second-order polynomial was fitted to model the geometric errors, and cubic convolution resampling was performed to obtain registered data. The registration root mean square error was estimated at about 250 m, or about half an HCMM pixel. The LANDSAT data were reduced to the HCMM resolution by pixel averaging so that HCMM and LANDSAT pixels were closely overlaid in order to facilitate the extraction of surface temperatures (from HCMM) and ND ratios (from MSS) from precisely the same areas on each image.

An ND ratio image was produced by using Equation 6. This ratio was used as an estimate of the biomass to compare with the HCMM-derived estimates of surface temperature (see Figure 2). Several areas were chosen within each of four cover types, as shown in Figure 1: low brush and muskeg-bog, bottom land spruce-poplar, lowland spruce-hardwood, and upland spruce-hardwood. In each cover type, 10 x 5 pixel areas were selected and mean temperature and the ND ratios estimated. The albedos for all the areas were similar. None was in an area of high relief, and so the surface temperature should be a good indicator of the evaporation rate. The method of estimating surface temperatures from HCMM data is discussed by Gurney and Hall (1983).

RESULTS

The plot of the HCMM estimates of the surface temperature against the estimate of the biomass provided by the ND ratio is shown in Figure 2. The points are divided into the four land cover groups as discussed above. It can be seen that the relationship between temperature and the ND ratio exhibits a lot of scatter. The relationship is basically linear, with a greater surface roughness (implying a larger biomass) being related to a lower surface temperature. The correlation coefficient, r , is -0.62 , significant at the 99% level. The coefficient of determination is 0.38 and, therefore, there is a large unexplained variance, about 62%. The use of LANDSAT data alone is thus unlikely to produce satisfactory

FIGURE 2 Relationship between surface temperature, estimated by using the Heat Capacity Mapping Radiometer, and the Normalized Difference Ratio (ND, Equation 6) estimated by using LANDSAT.

estimates of the evapotranspiration either through the use of a Priestley-Taylor method, or through the estimation of surface roughness from vegetation biomass. However, the use of the thermal data can provide additional information that may be useful in land cover studies using the LANDSAT 4 Thematic Mapper. There is sufficient correlation between LANDSAT and HCMM data for the LANDSAT data to be a useful aid to interpolation in areas where there are mixed pixels on the coarser resolution HCMM or other thermal data. It has previously been shown that the HCMM data provide adequate evaporation estimates in this area for uniform pixels. However, the number of small lakes and areas of bare ground where the modeling assumptions do not hold are sufficient that many pixels of thermal data are contaminated and the model approach cannot readily be used. In these areas, LANDSAT higher spatial resolution data could allow useful evaporation data to be obtained even though the principal method based on thermal data is invalid. It would thus be of use to have suitable multispectral high spatial resolution data co-registered with the low resolution thermal data for environmental monitoring in areas of discontinuous permafrost.

ANALYSIS OF INTERACTIONS BETWEEN LINED SHAFTS,
PIPES AND THAWING PERMAFROST

I. E. Guryanov

Permafrost Institute, Siberian Branch,
Academy of Sciences, Yakutsk, USSR

Changes in the compressibility properties of permafrost materials were studied with regard to structures in the ground subject to stress-bending, e.g., shaft linings where there is an unfrozen aureole around the shaft, or pipelines built on a thawing foundation. Expressions were derived for the compressibility coefficient of thawing materials in the immediate area of contact depending on the relative thaw radius around the structure. Limits for the applicability of the calculated formulae for types of structures are indicated. Permissible approximations of the calculated models as dictated by the impact of actual uncertainties in the interaction of structure with the ground are determined.

INTRODUCTION

The aim of this paper is to describe the compressibility of thawing soil surrounding vertical structures such as shaft linings supporting surface buildings (head-frames). A similar problem can be formulated for bending of buried pipes whose design lacks distributed vertical loads along their length.

When shaft construction is carried out in permafrost regions, warm operating conditions within a shaft and head-frame give rise to the formation of a thawed zone behind the lining. When near the surface, say within a few tens of meters, there is no firm rock present and foundation curbs are not feasible. In most cases vertical loads due to the lining and head-frame can be transferred to surrounding rock only at great depth. In the lack of such transfer an analysis is to be made of longitudinal bending of the lining in a pliable ground medium, i.e. the thawed zone.

When the lining is deformed under the combined action of horizontal stress near the surface, and vertical loading from above, compression of soil surrounding the lining results from asymmetrical redistribution of soil pressure in each horizontal cross-section. The magnitude of this redistribution, restricted by actual lining deflection, is more than an order of magnitude lower than the general level of soil pressure values. Therefore, with the aid of the method of superposition, the stressed-deformed state can be interpreted as a combined result of axially symmetric rock pressure and unidirectional soil compressibility. Assuming the deformations associated with soil pressure are in equilibrium, compression due to unidirectional movement of the lining can be investigated without taking into account the stressed state that determines soil pressure.

Calculations have shown that horizontal shifts of the lining are small, within the limit of linear deformations. Accordingly, the problem of the compression of soil is formulated here in terms of the theory of elasticity, and deals with the plane

deformation of an annulus of thawing soil surrounding the lining. In this case the frozen soil surrounding the thawing zone may be assumed incompressible (Guryanov, 1976). The deformable lining is considered as a cylindrical surface subject to radial displacement (see Fig. 1).

Actual results of construction do not always correspond to expected boundary conditions for the lining-soil interface because the contribution from contact friction is largely indeterminate. To assess possible errors in design, two limiting cases are considered: complete connection of the deformable lining and thawing soil, and complete slip at the interface with separation in an extended zone.

We assume the maximum interfacial strength of the lining and surrounding soil to be equal to the shear strength of the soil which, according to current standards (SNIP, 1974), as well as L. I. Baron's investigations (Baron, 1972), is two orders of magnitude lower than the value of deformation modulus E of thawed soil:

$$\tau_c \sim 10^{-2}E$$

On the other hand, it is easy to show that for tangential stress $\tau_{r\alpha}$ the inequality

$$\tau_{r\alpha} < E \frac{u_0}{R_0}$$

is valid in the problem under consideration, where u_0 is the maximum transversal displacement of soil adjacent to the lining (horizontal displacement of a vertical structure), and R_0 is the radius of the structure.

Calculations of lining buckling for a particular problem have shown that maximum horizontal displacements do not exceed 5 mm. At $R_0 \approx 3-4$ m we have $u_0/R_0 \sim 10^{-3}$. Then, taking into account the preceding expressions we obtain

$$\tau_{r\alpha} < 10^{-1} \tau_c$$

Thus, contact tangential stress is at least an order

of magnitude lower than the limiting interfacial shearing strength, i.e. for this particular problem no slip occurs at the contact of shaft lining and surrounding soil.

In the case of a pipeline within a thawing zone having $R_0 \approx 20-30$ cm, supposed shifts are $u_0 \approx 1-2$ cm and therefore we have $u_0/R_0 \sim 10^{-1}$. Following the previous reasoning for the case of shaft lining, for pipelines we get in this case:

$$\tau_{r\alpha} \sim 10\tau_c$$

i.e. contact stress is on the average an order of magnitude larger than limiting interfacial shearing strength, and therefore there is virtually full slippage at the contact.

One therefore concludes that the two limiting cases of structural deformation within a thawed zone are potentially observable, many other cases will be intermediate.

ANALYSIS

Stresses and displacements are basic to the definition of compressibility of soil. Using the method of degenerated solutions extended to the system of differential equations of equilibrium for this problem, we apply to the soil the conditions:

$$u = u(r) \cdot u(\alpha) = u(r) \cdot \cos \alpha,$$

$$v = v(r) \cdot v(\alpha) = v(r) \cdot \sin \alpha,$$

where u, v are the radial and tangential displacements, respectively.

In the case of no slippage between the lining and soil it is necessary that $u(r) = -v(r)$ and the degenerated solution follows from the equation of equilibrium:

$$r \frac{d^2 u(r)}{dr^2} + \left(1 + \frac{1}{1-2\mu}\right) \frac{du(r)}{dr} = 0 \quad (1)$$

The condition of complete slippage, $v = 0$, occurring despite the entraining action of the deformable lining, corresponds to the condition $dv(r)/dr = 0$ at the interface. In this case the final form of the equation of equilibrium is:

$$r^2 \frac{d^2 u(r)}{dr^2} + r \frac{du(r)}{dr} - \frac{3-4\mu}{2(1-\mu)} u(r) = 0 \quad (2)$$

The solutions of equations (1) and (2) subject to the boundary conditions:

$$\begin{aligned} u(r) &= u_0 & \text{at } r &= R_0, \\ u(r) &= 0 & \text{at } r &= R \end{aligned}$$

are for equation (1):

$$u(r) = u_0 \frac{\rho^\ell - 1}{\eta^\ell - 1}; \quad \ell = \frac{1}{1-2\mu}; \quad (3)$$

and for equation (2):

$$u(r) = u_0 \frac{\eta^n (\rho^{2n} - 1)}{\rho^n (\eta^{2n} - 1)}; \quad n = \sqrt{\frac{3-4\mu}{2(1-\mu)}}; \quad (4)$$

where $\rho = R/r$, $\eta = R/R_0$ are dimensionless parameters and r, R are the coordinate direction radius of the deforming annular soil mass respectively.

Substitution of the solutions (3) and (4) into the known physical equations for stress, expressed in terms of shears, yields the following functions for normal and tangential stress within the thawed soil mass:

according to the solution (3):

$$\sigma_r = - \frac{\eta^\ell E u_0 (1-\mu) \cos \alpha}{R_0 (1+\mu) (1-2\mu)^2 (\eta^\ell - 1)}; \quad (5)$$

$$\tau_{r\alpha} = \frac{\eta^\ell E u_0 \sin \alpha}{2R_0 (1+\mu) (1-2\mu) (\eta^\ell - 1)};$$

and according to the solution (4):

$$\sigma_r = - \frac{E u_0 (1-\mu) \cos \alpha}{R_0 (1+\mu) (1-2\mu)} \left(n \frac{\eta^{2n+1}}{\eta^{2n-1}} - \frac{\mu}{1-\mu} \right); \quad (6)$$

$$\tau_{r\alpha} = - \frac{E u_0 \sin \alpha}{2R_0 (1+\mu)}.$$

Tangential stress given by the expression (6) describes the conditions of net shear in a deforming soil mass near the surface of slippage. However, this stress is not of contact but of internal nature and therefore is neglected in analyses of the compressibility of soil mass.

When a structure in contact with soil exerts a unidirectional force (case 1), the resulting compression along a circular contour is the sum of contact stresses projected onto the direction of shear, and is expressed by the function:

$$q = \oint (\sigma_r \cos \alpha - \tau_{r\alpha} \sin \alpha) R_0 d\alpha \quad (7)$$

where q is a linear load per unit of length of the structure.

According to formula (6), the maximum tensile stress on the structure-soil contact is of the order of

$$\sigma_r \sim - \frac{u_0}{R_0} E \approx -10^{-1} E$$

Since for soils the limiting tensile stress is:

$$\sigma_p \sim 10^{-1} \tau_c \sim 10^{-3} E,$$

we get

$$\sigma_r \sim 10^2 \sigma_p,$$

that is, for a design scheme without contact friction (case 2), soil resistance to separation is completely overcome. Therefore, in the expression for the compression of soil the circulation is replaced by an integral around the semicircle

defining the compression zone, and for tangential contact stress, $\tau_{r\alpha} = 0$. Ultimately we then have:

$$q = \int_0^{\pi} \sigma_r R_0 \cos \alpha \cdot d\alpha. \quad (8)$$

Taking into account the expressions (5) and (6), formulas for compression (7) and (8) take the form:

for case 1 (no slippage):

$$q = - \frac{\pi E u_0 (3-4\mu) \eta^{\ell}}{2(1+\mu)(1-2\mu)^2 (\eta^{\ell}-1)}; \quad (9)$$

for case 2 (complete slippage):

$$q = - \frac{\pi E u_0 (1-\mu)}{2(1+\mu)(1-2\mu)} \left(n \frac{\eta^{2n+1}}{\eta^{2n}-1} - \frac{\mu}{1-\mu} \right). \quad (10)$$

For an infinitesimal thickness of the thawed zone (at the start of thawing), assuming $u_0 = \xi R_0 (\eta-1)$ as $\eta \rightarrow 1$, from formulas (9) and (10) we obtain the expressions for initial compression: for no slippage:

$$q = - \frac{\pi R_0 E \xi (3-4\mu)}{2(1+\mu)(1-2\mu)}; \quad (11)$$

for complete slippage:

$$q = - \frac{\pi R_0 E \xi (1-\mu)}{2(1+\mu)(1-2\mu)} \quad (12)$$

It is evident that in the absence of friction, the initial compression according to formula (12) is equivalent to compression along one-fourth of the perimeter of the circle. In comparison with the slippage case, the initial compression in the presence of friction is greater by a factor of 2 at $\mu = 0.5$, and 3 at $\mu = 0$.

Compression of the deforming zone is conveniently expressed in the form of the Fuss-Winckler relation:

$$q = -k u_0, \quad (13)$$

where $k = mE$ is the bed coefficient (proportional to the modulus of soil deformation, E).

The bed coefficient k in formula (13) is related to the conventional expression for bed coefficient k through the relationship:

$$k = 2R_0 k',$$

since the compressibility q is distributed over the full diameter of the structure. In contrast to the ordinary bed coefficient, k' , with a dimensionality $L^{-2}MT^{-2}(N \cdot m^{-3})$, the coefficient k has a dimensionality of the deformation modulus $L^{-1}MT^{-2}(Pa)$ and is independent of the structure diameter under the assumptions since the coefficient k' is inversely proportional to the size of the lining (Gorbanov-Posadov, 1953). Accordingly, the quantity m in the expression for k is a dimensionless function of soil properties (of the coefficient of transverse deformation, μ) and of compressible zone configuration. Formulas (9) and (10) readily yield expres-

sions for m , which as $\eta \rightarrow \infty$, i.e. for unfrozen soil, have, in particular, the form: for no slippage:

$$m = \frac{\pi(3-4\mu)}{2(1+\mu)(1-2\mu)^2}; \quad (14)$$

and for complete slippage:

$$m = \frac{\pi[\sqrt{(1-\mu)(1,5-2\mu)} - \mu]}{2(1+\mu)(1-2\mu)}. \quad (15)$$

Plots of m [following formulas (9) and (10)] versus relative depth of thawing, η , are presented in Fig. 2. The figure shows that the limiting influence of boundary conditions leads to a five-fold (and more) change of the compressibility.

The obtained functions of compressibility are intended for use in a linear differential equation of fourth-order which describes the bending of structures supported by an elastic base. The characteristic polynomial involved in this equation has conjugate roots and therefore the general solution of the equation involves sine functions of depth. Therefore for different values of the bed coefficient k the half-wavelength of sinusoids of transverse shears for a structure with rigidity $E_k J$ is generally inversely proportional to the parameter $\beta = \sqrt[4]{k/4E_k J}$. Therefore a five-fold increase of k and unchanged loads increases the structure's incline by a factor of about one and a half ($\sqrt[4]{5}$). Similar results are obtained from test calculations. Consequently, in the analysis of a structure's effect on an elastic foundation, the determination of boundary conditions is considerably more important than the refinement of methods of calculation.

Fig. 2 also shows limiting values of the coefficient m for an unlimited increase of the extent of thawing. It is evident that for no slippage of the structure-soil interface and at $\mu \rightarrow 0.5$ (for incompressible soil) the compressibility (back pressure) increases without bound. In the case of complete slippage the compressibility remains a finite value, different from zero. This is an important advantage of the equation obtained here over modifications of Flaman's solutions which specify that, for an unlimited compression zone, there are large shears and therefore a zero bed coefficient.

It is interesting that formula (15) for the entire range $0 \leq \mu \leq 0.5$, up to the second significant digit, coincides with the expression:

$$m = \frac{2}{1+\mu} \quad (16)$$

We substitute (16) into the expression for the bed coefficient,

$$k = mE = \frac{2E}{1+\mu} = 4G \quad G = \frac{E}{2(1+\mu)},$$

express the compressibility through normal stress,

$$q = \sigma 2R_0$$

and, introducing these values into formula (13), we obtain:

$$\sigma = -2G \frac{u_0}{R_0} \quad (17)$$

Since for this type of stressed-deformed state the mean stress and deformation are zero, from (17) it follows that compressibility properties of a mass of unlimited size can be related only to its shape change.

If we use the solution obtained earlier for the problem (Guryanov, 1976) to estimate the value of compressibility, assuming its distribution along the arc of length $0.5 \pi R_0$, then the relevant expression for the bed coefficient

$$k = \frac{\sqrt{2} E [1 + \eta^2 (1 - 2\mu)]}{(1 + \mu)(1 - 2\mu)(\eta^2 - 1)} \quad (18)$$

has the same features as function (10), and as $\eta \rightarrow \infty$ the expression (17) also follows from (18). Equation (18) also implies the possibility of determining the bed coefficient directly from pressure test results, without using the mechanical characteristics of the soil. In particular, if the working stress σ on the pressure meter of radius R_0 refers to radial shear u_0 , the bed coefficient approximating the case of contact with slippage will then be:

$$k = \sqrt{2} \sigma \frac{R_0}{u_0} \quad (19)$$

Thus, the compressibility of thawing soils interacting with bendible structures depends on boundary conditions no less than on values of soil mechanical characteristics. For actual structures the boundary conditions are generally indeterminate and therefore calculations and design of bendible structures are advantageously done using marginal variations of their size and shears. The combination of a large diameter and small shears of the bendible structure, for example, when shaft lining is being bent, is closer to the case of contact with no slippage and requires that formulas (9) and (14) be used. The combination of a small diameter and large shears, including deformation of pipes in unfrozen soils is closer to the case of complete slippage and requires that formulas (10) and (15) be used. For intermediate cases, calculations for both limiting variant can be used to judge design feasibility.

A one-dimensional mathematical model of frost heave based upon a nodal domain integration analog is compared to data collected from a Winchendon, Mass., field site. Air and soil temperatures, pore water pressures, and ground-water level data were collected on test sections containing six different soils during the winters of 1978-1979 and 1979-1980. The soil samples were evaluated in the laboratory to determine soil moisture characteristics, hydraulic conductivity as a function of pore water tensions, density, and other parameters. The parameters were used together with assumed thermal parameters in a one-dimensional model that calculates the distributions of temperature and moisture content as well as the amount of ice segregation (vertically lumped frost heave) and thaw consolidation. Using measured air and soil surface temperatures as input data, the simulated frost heave and thaw consolidation agreed well with measured ground surface displacements that resulted from ice segregation or ice lens melting.

This paper compares measured field data of frost heave and thaw consolidation and simulated frost heave and thaw consolidations using a one-dimensional model that is being developed by USACRREL for a project funded by the Corps of Engineers, the Federal Highway Administration, and the Federal Aviation Administration (Guymon et al. 1981a). This paper reports on continued verification of the mathematical model with some of the field data collected for the tri-agency project.

Beginning in the mid-1970's with Harlan (1973) and Guymon and Luthin (1974), investigators have increasingly studied the use of mathematical models to simulate coupled heat and moisture movement in freezing and thawing soils. In the early 1980's a number of investigators proposed using such models to estimate frost heave as well. Most of these models are reviewed by Guymon et al. (1980) and Hopke (1980). Generally, models are based upon deterministic equations that describe heat and moisture transport; however, the manner of incorporating required ancillary models, i.e. those used to determine latent heat effects, hydraulic properties, and stress distribution in the freezing zone, and the manner of assembling the complex models varies widely between investigators. It is reasonable to state that agreement on either the necessary level of complexity of frost heave models or the formulation of algorithms representing processes in the freezing zone is not wide-spread. Indeed, there is still considerable controversy associated with modeling endeavors. Due to the inherent spatial variability of soil properties, deterministic models will probably never be entirely satisfactory, and we have included probabilistic features in one version of the model used herein (Guymon et al. 1981b).

Probably the best way to show the utility of deterministic mathematical models of frost heave and

the problems associated with their use is to compare results from these models with prototype field data and experimental laboratory data. We present such comparisons using a specific model that has been refined over several years.

THE NUMERICAL MODEL

The numerical model has been described elsewhere by Guymon et al. (1980, 1981a, 1981b, 1983) and Hromadka et al. (1982). Consequently, only a brief outline of the model is given here.

Table 1 presents the mathematical basis of the model. The nomenclature used in this table is defined at the end of this paper.

Phase-change processes in freezing or thawing zones are modeled by an isothermal approximation. The phase-change components for discrete times are decoupled using a simple control volume approach that accounts for the total available latent heat for freezing available water or thawing available ice. Overburden and surcharge effects are approximated by computing an equivalent positive pore water pressure, u , and adding it to simulated negative pore water pressures at discrete nodes where ice segregation is occurring. Positive pore water pressures due to consolidation are assumed to be negligible compared to overburden and surcharge stresses.

The equations of state are solved by a nodal domain integration analog (Hromadka et al. 1982), which results in a matrix system similar to the finite element system; that is, for the decoupled heat transport equation:

$$S T + C \dot{T} = F \quad (1)$$

TABLE 1 Mathematical equation describing frost heave model.

Soil region	Energy state	Liquid moisture transport	Phase change	Sensible heat transport	Ancillary relationships
Surface boundary		$\partial(u-x)/\partial x = 0$		$T_u = T(t)$	
Frozen	$T < T_f$ $u = u(\theta_n) + \delta u_o$ $\delta = \begin{cases} 1, & \theta_i > \theta_o - \theta_n \\ 0, & \theta_i < \theta_o - \theta_n \end{cases}$	$\partial(u-x)/\partial x = 0 = v$	$\frac{\partial \theta_i}{\partial t} = 0$	$\frac{\partial}{\partial x} [K_T \partial T / \partial x] = C_m \frac{\partial T}{\partial t}$	$K_H = K(u) \cdot 10^{-E\theta_i}$, $E\theta_i > 1$ $\theta_u = \theta(u)$ $v = -K_H \partial(u-x) / \partial x$
Freezing or thawing	$T = T_f$ $u(\theta_n) < u < 0$	$\frac{\partial \theta_u}{\partial t} = \frac{\partial}{\partial x} [K_H \partial(u-x) / \partial x]$	$-\frac{\rho_i}{\rho_w} \frac{\partial \theta_i}{\partial t}$ $L \frac{\rho_i}{\rho_w} \frac{\partial \theta_i}{\partial t}$	$+\frac{\partial}{\partial x} [K_T \partial T / \partial x] - C_w v \frac{\partial T}{\partial x} = C_m \frac{\partial T}{\partial t}$	$C_m = [C_i \theta_i + C_w \theta_u + C_s (1 - \theta_o)] / (1 + \theta_s)$ $K_T = [K_i \theta_i + K_w \theta_u + K_s (1 - \theta_o)] / (1 + \theta_s)$
Unfrozen	$T > T_f$ $u(\theta_n) < u < u_L$	$\frac{\partial \theta_u}{\partial t} = \frac{\partial}{\partial x} [K_H \partial(u-x) / \partial x]$	$\frac{\partial \theta_i}{\partial t} = 0$	$\frac{\partial}{\partial x} [K_T \partial T / \partial x] - C_w v \frac{\partial T}{\partial x} = C_m \frac{\partial T}{\partial t}$	$\theta_s = \theta_i - (\theta_o - \theta_u)$, $\theta_s > 0$, $\theta_u > \theta_n$ $v = \Sigma \theta_s \theta$
Column bottom boundary		$u_L = u(t)$		$T_L = T(t) > T_f$	

where S is a matrix of conductivity parameters and spatial discretization, C is a matrix of capacitance parameters, T and \dot{T} are the unknown state variable and temporal derivative vectors, and F is a vector of specified boundary conditions. The moisture transport equation reduces to an identical form.

The nodal domain integration method results in a C matrix that is also a function of a single mass lumping parameter, η ; that is, $C = C(\eta)$ where η can arbitrarily be chosen to represent various numerical analogs. For instance, if $\eta = 2$, a Galerkin finite element scheme results, or if $\eta \rightarrow \infty$, an integrated finite difference scheme results. The Galerkin finite element scheme was used in this study.

Governing equations are solved by decoupling them for discrete computational intervals and by holding each parameter constant. The solution is advanced in constant time-steps, Δt , by the Crank-Nicolson approximation. At the end of discrete time periods, nonlinear parameters are updated with ancillary relationships and secondary variables are computed. The computational technique and the sensitivity of results to the choice of numerical analog method are described in detail by Hromadka et al. (1982).

Guymon et al. (1981b, 1983) describe the verification of the model with freezing test data from laboratory soil columns, evaluate the uncertainty relating to boundary condition errors, describe modeling errors in general, and present a detailed analysis of parameter error effects.

FIELD AND LABORATORY DATA

Field data were collected at a test site in Winchendon, Massachusetts, located about 8 km (5 mi.) south of the New Hampshire border and about 32 km (20 mi.) east of the Connecticut River. The site consists of 26 asphalt concrete pavement test sections with 13 different test materials. The test sections have a 76 mm (3 in.) asphalt concrete pavement underlain by a uniformly compacted subbase

material from 0.9 to 1.5 m (3 to 5 ft) deep. Six of the test sections are included in the tri-agency study. Climatic data, ground-water levels, soil temperatures, and soil pore water pressure data were collected in the field during the 1978-1979 and 1979-1980 winters. Undisturbed and disturbed samples were obtained from the test soils and evaluated in the laboratory to determine the physical, hydraulic, and mechanical properties of the various materials. Field observations of frost heave, frost depth, and soil moisture tension were monitored for the following test materials: (a) Ikaonian silt, (b) Graves sandy silt, (c) Hart Brothers sand, (d) Sibley till, (e) Hyannis sand, and (f) dense-graded stone.

Figure 1 shows the mean daily air temperature beginning 10 December 1978 and extending through 15 March 1979. These data are determined from the average of the maximum and minimum daily temperatures taken from a thermograph. Several major freeze-thaw cycles occurred and, due to diurnal temperature variations, there were numerous diurnal freeze-thaw cycles during the winter. Table 2 presents the average monthly diurnal temperature variations.

Table 3 presents the physical data obtained in the laboratory. The soil water characteristics are represented by the equation

$$\theta = \frac{\theta_o}{A_w |u|^n + 1} \tag{2}$$

where the regression parameters A_w and n are given in Table 3. The freezing soil hydraulic conductivity factors, E, in Tables 1 and 3 were determined by calibration as described below. The E factor (Table 1) is a phenomenological parameter used to adjust unfrozen hydraulic conductivity to represent the hydraulic conductivity in the freezing zone. The version of the model used herein uses a hydraulic conductivity function in tabular form (i.e. hydraulic conductivity as a function of tension).

Sibley till	4.6	10.4	5.9	10.6	14.0	13.2	0.3	5.8	1.8	61	28	69

MODEL SIMULATION

A soil column 1 m long was assumed for all soils except Sibley till, where a 1.3 m column was used. Generally, the water table was a little over 1 m deep in all sections except the one containing Sibley till, which had a lower water table (less than 1.3 m). The soil column was divided into 50 variable-length elements ranging from 0.5 cm at the column top to 10 cm at the column bottom. A Crank-Nicolson time-step of 0.2 hr and a parameter update frequency of 1.0 hr were used. Column bottom boundary conditions were determined from recorded data. Mean daily surface temperature data or air temperature data multiplied by the Corps of Engineers *n*-factor (Berg 1974) were used for the upper boundary conditions. A sinusoidal diurnal surface temperature variation with a 7°C amplitude was used. Parameters were assumed, measured in the laboratory, or determined by calibration. Table 3 summarizes the parameters used in the simulations.

The results of simulations for the Graves sandy silt and Sibley till during the 1978-1979 winter are shown in Figures 2 and 3 along with the results when mean daily surface temperatures are used without a diurnal variation. Similar results were obtained for other soils studied. In general, errors introduced by using mean daily surface temperature were negligible. The most significant difference observed was for Graves sandy silt (Figure 2). In all cases, the use of mean daily surface temperatures approximated measured thaw penetration more accurately than the 7°C amplitude diurnal variation.

In some cases, it was difficult to predict accurately frost penetration near the end of the season. Measured frost (0°C isotherm) depths, which are subject to some error, are generally deeper than simulated with the model.

The only parameter calibrated was the freezing soil hydraulic conductivity correction factor. Adjusting other parameters, such as the soil water characteristics, might have yielded better overall

TABLE 3 Soil parameters for remolded Winchendon, Massachusetts, test site soils.

results, but this type of calibration is not a wise procedure since it may mask errors in the model. Calibration errors may stem from three sources: (1) a surface moisture flux boundary condition error, (2) the fact that soil parameters vary due to freeze/thaw cycles, and (3) use of pavement surface temperatures instead of soil surface temperatures.

Alternate freezing and thawing occurs near the soil surface in most field prototype situations. It seems appropriate that any complete model of frost heave should include analogs that account for changes in key parameters, such as a hydraulic conductivity due to freeze/thaw cycles. Neither this model nor any other currently available attempts to

FIGURE 3 Simulated frost heave, thaw consolidation, frost penetration, and thaw penetration for Sibley till, 1978-1979 (day 0 = 10 Dec 1978).

FIGURE 4 Simulated frost heave, thaw consolidation, frost penetration, and thaw penetration for Graves silty sand, 1979-1980.

FIGURE 5 Simulated frost heave, thaw consolidation, frost penetration, and thaw penetration for Sibley till, 1979-1980.

include the influence of alternate freezing and thawing.

To further test the model, and particularly the validity of calibrating the E factor, data for the 1979-1980 winter were used. Air temperature data and frost heave and frost penetration data are only available for (a) Ikaonian silt, (b) Graves sandy silt, (c) Hart Brothers sand, and (d) Sibley till.

Simulated results are compared to measured frost heave and frost penetration for Graves sandy silt and Sibley till in Figures 4 and 5. To match the measured maximum frost heave for the 1979-1980 winter more closely, the E factors are 10.3, 5.0, 9.0, and 8.5 for Ikaonian silt, Graves sandy silt, Hart brothers sand, and Sibley till, respectively. Data in Figure 4 show computed results using both E factors.

CONCLUSIONS

The proposed model can reasonably estimate field frost heave, provided accurate data on boundary conditions and parameters are available. Tests of the model were for field conditions where a number of freeze/thaw cycles occurred as well as significant diurnal temperature variations. Using measured air and soil surface temperatures as input data, the simulated frost heave and thaw consolidation agreed well with ground surface displacements resulting from ice segregation or ice lens melting.

Currently the model requires calibration to determine the E factor for each soil, the phenomenological parameter that accounts for decreased hydraulic conductivity in freezing or thawing zones. The results of the study reported here suggest that it is feasible to calibrate the model for field soils using imperfect input data; however, a long period of data is required with a number of freeze/thaw cycles.

ACKNOWLEDGMENTS

This work was sponsored by the U.S. Army Corps of Engineers, the Federal Highway Administration, and the Federal Aviation Administration. The test site at Winchendon, Massachusetts, was operated by the Massachusetts Department of Public Works. Jonathan Ingersoll and David Carbee, civil engineering technicians, were responsible for the laboratory and field investigations supporting this study.

NOMENCLATURE

T = temperature (primary state variable)
 u = pore water pressure (primary state variable)
 θ_u = volumetric unfrozen water content (secondary state variable)
 θ_i = volumetric ice content (secondary state variable)
 θ_s = volumetric segregated ice content (secondary state variable)
 x = coordinate vertically downward
 l = length of a finite element
 y = lumped total frost heave (secondary state variable)
 t = time

θ_n = unfrozen water content factor (parameter)
 θ_o = soil porosity (parameter)
 K_s = soil thermal conductivity (parameter)
 C_s = soil volumetric heat capacity (parameter)
 T_f = freezing point depression of water (parameter)
 K_H = $K_H(u)$ = hydraulic conductivity function (parameter)
 E = freezing soil hydraulic conductivity correction (parameter)
 K_i = ice thermal conductivity (specified constant)
 K_w = water thermal conductivity (specified constant)
 K_t = thermal conductivity of soil, water, ice mixture
 C_i = ice volumetric heat capacity (specified constant)
 C_w = water volumetric heat capacity (specified constant)
 C_m = volumetric heat capacity of soil, water, ice mixture
 L = bulk water volumetric latent heat coefficient (specified constant)
 ρ_i = ice density (specified constant)
 ρ_w = water density (specified constant)

Parameter refers to a measured or assumed parameter required in the model. Specific constant refers to a parameter obtained from standard tables. Variables are computed by the model.

PERMAFROST-GLACIER RELATIONSHIPS IN THE SWISS ALPS - TODAY AND IN THE PAST

Wilfried Haeberli

Versuchsanstalt für Wasserbau, Hydrologie und Glaziologie, ETH Zürich, Switzerland

A conceptual model is proposed to explain the geographical distribution of permafrost and glacier phenomena in high altitude/low latitude mountains. The concept developed shows how the vertical distance between the lower boundary of permafrost distribution and the equilibrium line on glaciers can be related to the mean annual air temperature at the equilibrium line. This temperature term strongly depends on the continentality of the climate and can be empirically linked to thermal conditions in ice and permafrost, and also to glacier activity. Conditions in the Swiss Alps both today and in the past are used to illustrate the concept and to demonstrate its use for paleoclimatic reconstructions. In the humid marginal zones of the Alps, where permafrost is restricted to rock outcrops in the accumulation area of glaciers, active, temperate glaciers are dominant; on the other hand, less active, partially cold glaciers and creep phenomena in perennially frozen sediments (such as rock glaciers and push moraines) are abundant in the sheltered interior regions today. Partially warm-based, cold glaciers of extremely low activity within continuous permafrost were typical for the coldest period of the last ice age. In agreement with palynological reconstructions, this indicates that precipitation was greatly reduced at this time.

INTRODUCTION

Glaciers are the most obvious form of ice on many high altitude/low latitude mountains and have been studied since long before the beginning of the twentieth century. However, high-mountain permafrost is a less striking feature, and research into it has only developed over the last few decades. The growing knowledge about glaciers and permafrost in the Swiss Alps now makes it possible to discuss the relationships between the two phenomena. While the vertical sequence of glacier and permafrost zones in the Alps (discussed earlier by Haeberli (1976, 1978)) mainly depends on the (mean annual) air temperature, the regional distribution of glacier and permafrost features will be shown here to depend primarily on precipitation. Both air temperature and precipitation vary not only in space but also in time, and so does the distribution pattern of permafrost and glacier ice. A greater understanding of the spatial relations between actual glaciers and existing permafrost should therefore also lead to a better interpretation of paleoclimatic conditions.

The purpose of this paper is to propose a conceptual model to explain the relationships between permafrost and glacier phenomena in the Swiss Alps. The concept developed here is mainly based upon ideas and observations by Shumskii (1964), Haeberli (1975), (1978), Barsch (1978), Gorbunov (1978), Kuhn (1980) and Shi and Li (1981).

PERMAFROST-GLACIER RELATIONSHIPS IN THE SWISS ALPS

The concept is a combined consideration of several basic permafrost and glacier phenomena, their

FIGURE 1 Schematic model of the structure of the cryosphere. Explanation in the text.

interrelationships and their variation with changes in precipitation. It is based upon a model of the cryosphere as depicted in Figure 1; the field, defined by the mean annual air temperature (i.e., "altitude" in mountain regions) and the mean annual precipitation (i.e., "continentality"), is subdivided by the equilibrium line on glaciers (mass balance = 0) and the lower boundary of discontinuous permafrost into three main zones. Zone A, above the equilibrium line, is the accumulation zone of glaciers where no sediments are deposited. Zone B, below the lower boundary of permafrost distribution, is free from permafrost. Zone C, below the equilibrium line of glaciers and above the lower boundary of permafrost distribution, is the zone in which

glacier ice can be cold and unconsolidated sediments can be in a perennially frozen state. The vertical extent of this zone C is a direct expression of precipitation - a principle now used for paleoclimatic reconstructions (Kerschner 1978, 1982, 1983, Haeberli 1982). In a maritime climate, zone C disappears because the equilibrium line descends below the lower boundary of permafrost distribution.

The vertical extent of zone C is related to the mean annual air temperature at the equilibrium line, T_E , via the air temperature gradient (assumed to be constant in this paper, viz., $0.65^\circ\text{C}/100\text{ m}$). As is the case for the mean air temperature during the ablation period, to which it is obviously correlated via precipitation, T_E is a good indicator of precipitation (cf. Ahlmann 1924, 1933, Kuhn 1980, 1982). It is this term, T_E , which may be considered as the central point of the concept, because it is not only related to precipitation, to the vertical extent of zone C (where geomorphological expressions of permafrost such as rock glaciers, push moraines or ice wedges can occur), and to thermal conditions in glacier ice and permafrost, but also to processes of mass exchange at glacier surfaces (mass balance gradient) and glacier activity (ice thickness, shear stress, glacier flow). These terms of the concept and their interrelationships are explained below.

The mean surface temperature in ice and permafrost as measured in boreholes is, on average, about $3^\circ\text{--}4^\circ\text{C}$ warmer than the mean annual air temperature at the same place (cf. data given by Haeberli 1975, 1976, Markl and Wagner 1978, Barsch et al. 1979). Because of the effect of latent heat exchange by percolating meltwater, the *firn temperature* is 0°C providing the mean annual air temperature is higher than about -8°C . Temperate *firn* bodies (within zone A) therefore occur where $T_E > -8^\circ\text{C}$ and are absent in more continental regions, whereas cold *glacier ice* (zone C) exists in regions where $T_E < -3^\circ$ to -4°C but not in regions with a more maritime climate.

As a consequence of the topographical variation of ground temperatures at a given altitude (about $\pm 3^\circ\text{C}$), the *lower boundary of discontinuous permafrost* follows the -1° to -2°C isotherm, whereas the *lower boundary of continuous permafrost* is close to the -6° to -8°C isotherm (Haeberli 1978). *Rock glaciers* are the morphological expression of creep in perennially frozen, supersaturated sediments under the influence of gravity alone (Barsch 1978, Fisch et al. 1978, Haeberli 1978). On the other hand, the deformation of such sediments through flow of (partially) cold glaciers leads to the formation of *push moraines* in the strict sense (s.s.) (Haeberli 1979). These two phenomena can be used to reconstruct the position of the lower boundary of discontinuous permafrost or the -1° to -2°C isotherm in regions or times without weather station records, if $T_E > -2^\circ\text{C}$, where zone C disappears. *Ice wedge* occurrence is limited to the continuous permafrost zone (Péwé 1966, Brown and Péwé 1973) or to regions with $T_E < -6^\circ$ to -8°C (low precipitation).

The equilibrium line on glaciers, when not di-

rectly observed in mass balance studies, is inferred from an accumulation area ratio of 0.6 to 0.7 (Gross et al. 1977). With increasing continentality, it moves to colder regions because the decreasing amount of snow accumulation can be balanced by lower amounts of melting (temperature dependent). In these colder regions (lower T_E) the amount of liquid precipitation in the lower reaches of the glacier decreases. This lowers the *mass balance gradient*, the change in snow and ice balance with altitude for a given glacier, often referred to as the "activity index" (Meier 1961). The mass balance gradient not only depends on precipitation (Schytt 1967, Kuhn 1980) and T_E but is also an expression of the mass exchange at the surface of a glacier with a given size. At the same time, it drives the mass flux within a glacier via glacier flow. The latter, involving both ice deformation and sliding at the glacier bed, depends in a nonlinear way on the *basal shear stress in a glacier* (Paterson 1981). The basal shear stress therefore varies with varying mass exchange at the glacier surface; for a given size it decreases with decreasing balance gradient (Maisch and Haeberli 1982) and decreasing T_E , at least for small or continental glaciers. It is related to glacier geometry (thickness, inclination, valley cross section) and may furnish information about glacier activity during past glaciations, even though no mass balance or flow velocity measurements are possible for the vanished glaciers.

Values for balance gradients and basal shear stresses, as quoted in this paper, are averaged over the ablation areas of the corresponding glaciers. It is for these areas only that balance gradients are more or less linear and glacier geometry (for stress calculations) is relatively well documented, both by drillings and geophysical soundings in recent glaciers (e.g., Süssstrunk 1951, Waechter 1981) and by moraines in the case of ice age glaciers (Maisch 1981). *Annual precipitation and mean annual air temperature* are long-term averages estimated from weather station records. Values for precipitation refer to a standard altitude of 2,000 m a.s.l. and can only be rough estimates. Emphasis is placed upon relative differences rather than on absolute numbers. *Permafrost* and *glaciers* are considered to be in equilibrium with climate. This is certainly a simplification, but it probably does not introduce too large an error into the overall picture. The remainder of this paper illustrates the concept outlined above and demonstrates its use for a better understanding of paleoclimatic conditions.

CONDITIONS TODAY

The Swiss Alps are characterized by a transition from maritime to continental climate without showing extreme conditions. An example of each - the "humid margin" and the "dry interior", respectively - is described here. Many regions in the Alps belong to the transitional zone (Figure 2) between the two examples. More extreme conditions can be found in other low latitude mountain chains of the world (e.g., Asia, South America).

The "humid margin" of the Alps, with an annual

FIGURE 2 Bodmergletscher near the Simplon Pass, an example from the transitional zone between the "humid margin" and the "dry interior" of the Swiss Alps. Typical phenomena discussed in the text are 1, Bergschlund; 2, accumulation area; 3, equilibrium line (accumulation equals ablation); 4, ablation zone (partially debris-covered); 5, lateral moraine of historical and postglacial advances; 6, (small) rock glaciers (creep of perennially frozen, supersaturated sediments). The arrow points to a holocene push moraine (glacially deformed frozen, supersaturated sediments) and at the same time to the north. During postglacial times, T_E was around -4°C , corresponding to an annual precipitation at 2,000 m a.s.l. of 1,000-1,500 mm.

precipitation of about 2,000 mm, is exemplified by the regions of Engelberg in central Switzerland, the upper Reuss valley in the Bernese Alps, and by wide parts of the Alps of Uri and Glarus. A surface trend analysis of snow line altitudes in the Swiss Alps (Müller et al. 1976) shows low values in the regions considered, and the equilibrium line on glaciers indeed descends below 2,600 m a.s.l. T_E is about -1° to -2.5°C , and below the bergschlund, in most cases, the glaciers are temperate throughout. Balance gradients show annual values close to 1 m/100 m (Kasser 1981, p. 123: Silvretta) and basal shear stresses in large glaciers are between 1 and 1.5 bars (Unteraargletscher, Rhonegletscher). As the equilibrium line is very close to the lower boundary of discontinuous permafrost, the presence

of permafrost is essentially limited to rock outcrops such as summits, sharp crests, and very steep walls, all within the accumulation area of glaciers. Active rock glaciers and push moraines s.s. are absent because unconsolidated sediments are not in a perennially frozen state. The firn of the accumulation area of glaciers is temperate to an altitude of about 3,500 m a.s.l., at which level the mean annual air temperature is around -8°C and permafrost starts to be continuous. The landscape above the timberline is characterized by active, temperate glaciers, nonfrozen sediments, and bedrock.

Glaciological mountain research in the western world has traditionally concentrated on this "humid margin" type of landscape in which the most spectacular glaciers are found. In the corresponding literature, low-latitude mountains are often generally assumed to be free from permafrost and to be covered with temperate glaciers only. The resulting discrepancies in the identification of rock glaciers and debris-covered glaciers has mainly evolved from this viewpoint.

The Mischabel group within the Wallis Alps or the mountains around the Engadin Valley in the Alps of Grisons are good examples of the relatively "dry interior" of the Alps. Annual precipitation is close to, or below, 1,000 mm and the equilibrium line rises to 3,000 m a.s.l. and higher. T_E is about -5° to -7°C . Between the equilibrium line and the lower boundary of discontinuous permafrost (2,400 m a.s.l.), ice temperatures are between 0°C and about -4°C , and many glaciers ending in this belt are probably frozen to their beds at the margins, as is the case for the Grubengletscher (Haeberli 1976). In the driest spots, the equilibrium line approaches the -8°C isotherm of mean annual air temperature, and here firn starts to be cold and permafrost is continuous. Balance gradients are 0.5-1 m/100 m annually and shear stresses in glaciers of considerable size are around 0.8-1.2 bars (Grubengletscher, Griesgletscher: Kasser 1981, p. 123 and author's unpublished data). Large amounts of unconsolidated sediments between the equilibrium line and the lower boundary of discontinuous permafrost are in a perennially frozen state and are supersaturated with ice. Creep of such sediments at a rate which is roughly 1 order of magnitude less than the creep of glacier ice is frequent and leads to the formation of numerous rock glaciers. Push moraines s.s. are abundant in places where partially cold glaciers and perennially frozen sediments are, or have been, in direct contact with one another (many transitions between push moraines and rock glaciers: Figure 3).

For dry, low latitude mountains of the western world there is only scant information available in this context. However, more observations are reported from Asia, where arid mountains are widespread (e.g., Krenke 1975, Gorbunow 1978, Huang et al. 1982, Cheng and Wang 1982, Huang and Sun 1982).

CONDITIONS IN THE PAST

By going back in time, we leave the world of measurements and soundings and we enter the delicate

FIGURE 3 Val Muragl, Upper Engadin Valley - an example from the "dry interior". Here 1, active rock glacier; 2, fluted ground moraine, indicating that the perennially frozen sediments were overridden by a partially cold glacier during postglacial times; 3, holocene push moraine (upslope deformation, caused by glacier flow, of perennially frozen sediments during postglacial times) with transitions to rock glacier flow; 4, late glacial lateral moraine showing signs of past permafrost creep. Arrow points to north. T_E in the region is around -5°C , corresponding to an annual precipitation at 2,000 m a.s.l. of about 800-1,000 mm.

field of estimations and analogies. Some features are nevertheless striking and therefore worthy of mention here. Since climatic conditions during *holocene time* probably did not differ much from those of the last few centuries (Patzelt 1977, Gamper and Suter 1982), they need no special attention in this paper.

The picture changes abruptly during the time of the *late-Würm glacier retreat* (10,000-15,000 years B.P., Maisch 1982). The mean annual air temperature during the Younger Dryas cold-phase (10,000-11,000 years B.P.) was lower than that of today by about 2.5° - 4°C . As outlined by Kerschner (1982, 1983), precipitation in regions of the "humid margin" described above did not differ too much from today's values but was reduced to about 60-70% of those of today in the "dry interior" (cf. Burga 1982, p. 177). Thus the climatic contrasts seem to have been considerably greater; permafrost boundaries were lower by 400 m or more, whereas the depression of the equilibrium line in the sheltered interior regions was only about 250 m or less. T_E in these interior regions was lower than today by about 1° - 2°C , shear stresses in glaciers were slightly reduced (Haeberli 1982, Maisch and Haeberli 1982), the vertical extent of zone C (Figure 1) was enhanced, permafrost phenomena such as rock glaciers were widespread (Maisch 1981), and most of the glacier tongues may have been partially cold and frozen to the bed at the margins. Less information is available at present about earlier stages of glacier retreat (Daun/Gschnitz, Pre-Bölling, 13,000-15,000 years B.P.) when a depression of the mean annual air temperatu-

re by at least 4.5° - 5°C took place, a fact which is inferred from the depression of the boundary of permafrost and rock glacier occurrence (Kerschner 1983). Shear stresses in glaciers of comparable size were definitely smaller than during postglacial times by about 0.3-0.5 bar in the interior regions. This indicates probably an even more continental climate than that of the Younger Dryas time period (Maisch and Haeberli 1982, p. 124), with even lower T_E values, lower ice temperatures, lower balance gradients, and less active glaciers. Firn or ice covered many steep slopes favourable for rock glacier formation. Since push moraines form independently of local slope conditions, through shearing at the beds of partially cold glaciers, they are probably better indicators of permafrost boundaries during this time. A distinct lack of information exists to date about glacier-permafrost relationships during earlier periods of Oldest Dryas time.

Extreme conditions must have existed during and shortly after the time of *maximum glacier advance within the Würm ice age* (about 18,000 years B.P.). Large push moraines and periglacial ice wedges are the predominant indicators of permafrost (e.g. Schindler et al. 1978, Van der Meer 1980), because only flat lowlands were free from glacier ice; rock glaciers therefore only occurred in exceptional cases (e.g., Van Husen 1981). The lower boundary of continuous permafrost reached beyond Switzerland (Kaiser 1960, Washburn 1979), whereas equilibrium lines on glaciers were around 1,000-1,500 m a.s.l. (Jäckli 1970, Keller and Krays 1980). The depression of permafrost boundaries by more than 3,000 m

corresponds to a lowering of the mean annual air temperature by at least 15°C compared to today's. These boundaries were depressed at least twice as much as the equilibrium lines on glaciers, and T_E is estimated to have been -10° to -15°C. Surface temperatures were well below 0°C, not only in the ice of the ablation areas but probably also throughout the firn of the accumulation areas. Geothermal heat flow and frictional heat production must have nevertheless led to phase equilibrium temperatures at the beds, near the fronts, of piedmont glaciers (Blatter and Haeberli, in preparation). Shear stresses in these piedmont glaciers amounted to only about 0.3-0.5 bar, a stress condition which can be more easily explained by the present concept, than by extraordinary deformation of unconsolidated, nonfrozen sediments at the glacier bed (cf. Boulton and Jones 1979, Haeberli 1981). Balance gradients and ice flow must have been at a very low level. In agreement with palynological reconstructions, precipitation must be assumed to have been in the order of 30% or less of today's values (Frenzel 1980, Haeberli 1982).

IFS AND BUTS

As is the case with every generalization, the proposed concept cannot hope to explain all the intricacies of natural phenomena. It can nevertheless be considered as a guideline for the interpretation of distribution patterns of permafrost and glaciers. These two phenomena are not only related to each other but also to climate in many ways. Thus a combined consideration of all three may furnish improved knowledge about paleoclimates and present ice conditions on earth.

ACKNOWLEDGEMENTS

Through direct contacts, many colleagues have contributed significantly to the clarity of the author's thinking. H. Röthlisberger, head of the Section for Glaciology at the Versuchsanstalt für Wasserbau, Hydrologie und Glaziologie, ETH Zürich, and P. Alean, who assisted in the preparation of the manuscript, receive my thanks in the name of all those not cited in the reference list.

STRATIGRAPHIC DISTRIBUTION OF PERIGLACIAL FEATURES INDICATIVE OF
PERMAFROST IN THE UPPER PLEISTOCENE LOESSES OF BELGIUM

Paul Haesaerts

Koninklijk Belgisch Instituut voor Natuurwetenschappen, Vautierstraat 29,
B-1040 Brussels, Belgium

Among the various types of periglacial features known within the loesses of Belgium, only ice-wedge casts and tundra gleys, mainly those associated with an ice-segregation structure, may be considered as indicative of permafrost. The distribution of those features in the upper Pleistocene loesses of Belgium implies that the most widespread episodes of permafrost formation took place at intervals, between 33,000 and 20,000 years B.P., before and during the sedimentation of the late Weichselian loess cover. Permafrost conditions did also occur at the beginning of the middle Weichselian (around 60,000 years B.P.) and during the second half of the late Weichselian (around 15,000 years B.P.).

INTRODUCTION

In Belgium, two loessic deposits, named Brabantian and Hesbayan, were recognized within the upper Pleistocene. Assigned to the late Weichselian and to the middle Weichselian respectively, they are separated by a cryoturbated soil horizon named Kesselt Soil (Gullentops 1954). This has been correlated with the cryoturbated peaty horizon of Zelzate (Flanders) dated 28,000 \pm 400 years B.P. (Paepe and Vanhoorne 1967), and subsequently used as a major marker bed for correlations with northwestern France (Paepe and Sommé 1970, Lautridou and Sommé 1974, 1981).

Considering the distribution of desert pavements and large frost wedges within the loessic deposits, those authors concluded that two major cold episodes occurred during the upper Pleistocene. The first has been placed during the beginning of the middle Weichselian, approximately around 55,000 years B.P., and the second one during the late Weichselian, in the interval between 26,000 and 14,000 years B.P. More recently, Kolstrup (1980), having reviewed the main wedge cast localities of northwestern Europe, considered that the major period of continuous permafrost occurred between 23,000 and 19,000 years B.P.

Since 1970 new data have been obtained for the upper Pleistocene loesses of Belgium, especially regarding fossil soils, periglacial features, archeology and tephrostratigraphy (Haesaerts and Van Vliet 1974, 1981, Haesaerts and de Heinzelin 1979, Haesaerts et al. 1981).

From these data it can be considered that the upper part of the Hesbayan loess sequence, as defined by Gullentops (1954), belongs to the late Weichselian, and not to the middle Weichselian as previously stated (Haesaerts et al. 1981). As a result, a new stratigraphic sequence has been developed (Figures 1 and 3) suggesting a more consistent distribution of periglacial features which could be used as markers for long distance correlations between Belgium and northwestern France.

INDICATORS OF PERMAFROST IN LOESS

Various types of periglacial features are known

within the upper Pleistocene loesses, namely involutions, large wedges (isolated or in polygons networks), small fissures (isolated or in a row), desert pavements, hummocks, tundra gleys, and solifluction structures. The genesis and the climatic environment of these features were discussed during the field meeting of the I.G.U. Commission for Periglacial Research held in Belgium and in The Netherlands in the autumn of 1978. As far as loess formations are concerned, only tundra gleys, mainly those associated with ice-segregation structures, and ice-wedge casts were considered as permafrost indicators (Haesaerts and Van Vliet 1981).

Tundra gleys

Those soils, also called "Nassboden" or "nannopodzols" (Gullentops 1954), are well represented within the upper Pleistocene loess sequence.

They usually show a light grey horizon, the thickness of which may vary from 0.1 to 0.5 m, resting in a brown-yellow iron enriched B horizon (see units H.C.6-H.C.3, Figure 3). The lower part of the greyish horizon generally presents a well developed fine foliated platy structure; downwards, this structure often abruptly grades into a more coarse lenticular to subangular blocky structure usually with iron coatings. Sometimes, a coarse prismatic structure is present, starting from the bottom of the greyish horizon.

By comparison with present-day arctic soils (Tedrow 1968), the bleaching of the upper horizon, due to a release of iron, requires moisture and a low surface pH. Considering the high permeability of the loamy or loessic sediments on which those soils developed, this process necessarily implies the presence of a permafrost underneath.

This interpretation is supported by the presence of a laminated structure across the soil profile. It has been demonstrated that the upper platy structure did originate from repeated seasonal frost, while the underlying subangular blocky structure resulted from the slow growth of ice lenses into the upper part of the permafrost (Van Vliet 1976, Haesaerts and Van Vliet 1981). Therefore the abrupt transition between both types of structure at the bottom of the iron-enriched horizon most probably corresponds to the mean position

FIGURE 1 Lithostratigraphic correlations of upper Pleistocene type-sections from Belgium. Left part of each column: lithostratigraphy; right part of each column: pedology and periglacial features. Legend : 1, loess; 2, sand; 3, colluviated sediment; 4, humic sediment; 5, peat; 6, Alfisoil (Bt horizon); 7, weakly developed Alfisoil (B horizon); 8, eluvial horizon; 9, chalk or limestone; 10, bleached or reduced sediment; 11, weakly bleached or reduced sediment; 12, iron staining; 13, radiocarbon date; 14, ice-segregation structure; 15, volcanic tuff layer; 16-17, artifacts (U.P.: upper Paleolithic; M.P.: middle Paleolithic); 18, generally occurring polygons; 19, occasional polygons; 20, isolated ice-wedge casts; 21, narrow frost-wedges in a row; 22, solifluction structures; 23-27, paleoclimatic curve based on data derived from fossil soils, periglacial features and from paleontological, palynological and sedimentological analysis: R, rigorous climate (with continuous or discontinuous permafrost); C, cold climate (without active permafrost); MC, moderately cold climate; CT, cool temperate climate; T, temperate climate.

of the permafrost table.

This type of soil profile has been usually observed on loamy sediments, in various topographical environments such as valley-floors, well drained plateaus, as well as on hill-slopes. In very dry environments, as on pure loesses, the structure is usually absent, while the upper greyish horizon may be less developed. In both situations, ice-wedge casts start from the top of the greyish horizon and confirm the relationship between tundra gley and permafrost.

Ice-wedge casts

Most of the large wedge-like structures examined by us within the upper Pleistocene loess sequence have a loessic or loamy filling. Wedges with a sandy or a gravelly infilling are also recorded but are restricted to the upper and the lower part of the sequence.

Almost all the large wedge-like structures observed within the loess possess characteristics generally attributed to ice-wedge casts (cf. Washburn 1979, Black 1976), and therefore may be considered as indicators of former permafrost conditions.

All wedges appear to be epigenetic, although in several localities a cone-in-cone superposition has been observed. In Harmignies (Haine Valley), where one of the most complete upper Pleistocene loess

sequence has been recorded (Haesaerts 1974, Haesaerts and Van Vliet 1974), at least nine generations of wedges are present (Figure 1, column 1). The distribution of the wedges, as well as the geometry of the surmounting layers, likely indicate that each generation has been filled with loess or loam before the development of the following generation.

Since the infilling of an ice-wedge by overlying sediments requests a complete melting of the ice-core as well as the degradation of the surrounding permafrost (Black 1976), each generation of ice-wedge casts corresponds to one distinct episode of permafrost development.

In Harmignies, as well as in Rocourt and in Kes-selt (Figure 1), a different type of large wedge-like structure has been observed within the late Weichselian loess cover. It results from the coalescence of several long and narrow fissures which form polygons between 0.2 to 0.5 m in diameter (see Figure 2, top of unit K.B.). Most probably originated from dessication (Black 1976), this type of structure is not indicative of permafrost. Nevertheless, in Harmignies, the narrow fissures always start from the lower part of weakly developed tundra gleys which were probably formed under permafrost conditions as suggested by the presence of occasional ice-wedge casts at this level.

FIGURE 3 Composite section of the Weichselian loess deposits of Belgium (symbols: see Figure 1)

STRATIGRAPHIC AND REGIONAL DISTRIBUTION
OF PERMAFROST INDICATORS

Figure 3 shows a lithostratigraphical sequence of the upper Pleistocene loessic deposits of Belgium. Also shown is the distribution of fossil soils, radiocarbon dates, periglacial features indicative of permafrost and proposed paleoclimatic curve. The curve is based on data derived from fossil soils, periglacial features, and from sedimentological, palynological and paleontological analysis (Haesaerts 1974, Haesaerts and Van Vliet 1981). The paleoclimatic curve fluctuates from rigorous climate (left) with discontinuous or continuous permafrost, to temperate climate (right) similar to the present-day climate of northwestern Europe.

In most of the loess sections of Belgium, the early Weichselian is poorly recorded, except at Harmignies where it is represented by two distinct loamy colluvial deposits, each having a grey-brown podzolic soil developed on top (Villers-Saint-Christain Soil and Malplaquet Soil, Figure 1, column 1). During this period, humid and rather mild climatic conditions probably prevailed; however, several colder episodes occurred as the small ice-wedge casts present in the lower part of the second colluvial deposit suggest.

During the lower part of the middle Weichselian (approximately 70,000 to 45,000 years B.P.), a first loess cover, locally preserved, was deposited under cold climatic conditions. In Harmignies, two tundra gleys are preserved in the lower part of the loess cover, the lower one, locally associated with small ice-wedge casts, being the most developed. Tundra gleys were also observed, in a similar stratigraphic context, in the Méhaigne Valley at Huccorgne (Figure 1, column 2) and in Normandy (section of Mesnil-Esnard, author's observations); this episode of permafrost development is stratigraphically placed around 60,000 years B.P.

During the central part of the middle Weichselian (approximately 45,000 to 33,000 years B.P.), mild and humid climatic conditions probably existed (Zagwijn and Paepe 1968); this period is poorly represented in the loess sequence because of the dominance of erosional processes

The main period of permafrost development undoubtedly took place during the upper part of the middle Weichselian, between 33,000 and 25,000 years B.P. In Harmignies, at least three distinct networks of ice-wedge polygons, 10 to 30 m in diameter are recorded (Figure 2, units H.C.2, H.C.4 and I.A.). The upper ice-wedge polygons (I.A.), associated with a tundra gley (H.C.6), are the most visible and were stratigraphically situated around 26,000 years B.P., just before the deposition of the late Weichselian loess cover (Figure 2, units K.A. to K.C.).

In a similar stratigraphic position, tundra gleys and large ice-wedge polygons were also recorded in most of the loess sections of Belgium and northwestern France, in plateau position as well as on valley-floor (Figure 4). From north to south, the maximum width of the ice-wedge casts varies from 1.5 to 0.1 m, while the thickness of the active layer is estimated to be between 0.8 and 0.4m.

On this basis, it is likely that around 26,000 years B.P., a continuous permafrost extended across northwestern Europe, probably up to northern Fran-

ce. Considering the present-day climatic environment necessary for ice-wedge polygons to form (Washburn 1979), one may conclude that at that time mean annual air temperatures were lower than -6°C and mean January temperatures were close to -20°C . On the other hand, the maximum width of the ice-wedge casts (1.5 m in Harmignies) suggests that permafrost was present for a considerable period of time, probably more than one thousand years.

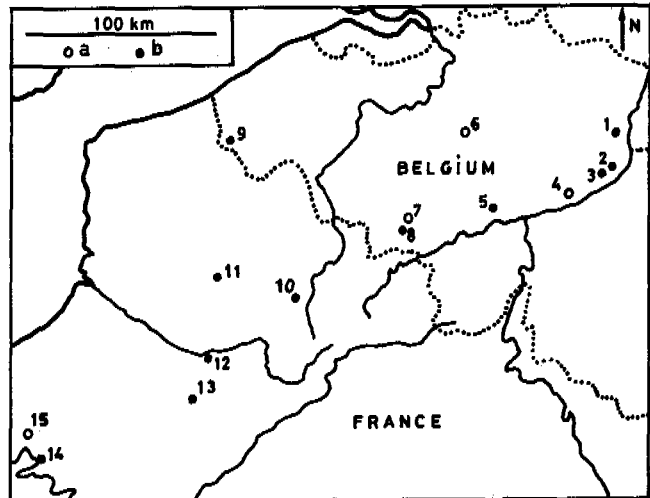

FIGURE 4 Distribution within the loess area of the permafrost indicators reported for the period 26,000–25,000 years B.P. (author's observations). Legend: a, tundra gley; b, tundra gley associated with ice-wedge polygons; 1, Kesselt; 2, Rocourt; 3, Ans; 4, Huccorgne (valley-floor); 5, Tongrinne; 6, Wezenbeek-Oppem; 7, Maisières-Canal (valley-floor); 8, Harmignies; 9, Poperinge; 10, Marcoing; 11, Beaumetz-les-Loges; 12, Corbie; 13, Sourdon; 14, Mesnil-Esnard; 15, Roumare.

During the first part of the late Weichselian (25,000 to 20,000 years B.P.), the deposition of the upper loess cover took place; permafrost recurred several times up to Normandy, as shown by the distribution of the tundra gleys within the loess cover. However, climatic conditions were dryer, as suggested by the weak development of the tundra gleys associated with narrow dessication fissures, and the rare occurrences of ice-wedge polygons.

Finally, the last important period of permafrost conditions is situated stratigraphically around 15,000 years B.P.; it is recorded on the valley-floor of the Eaine river at Maisières-Canal, near Mons, where a network of ice-wedge polygons, 10 to 20 m in diameter, is present at the base of the late Weichselian coversands (Haesaerts and de Heinzelin 1979, Haesaerts and Van Vliet 1981). Furthermore, evidences of permafrost seem also to be present within most of the Alfisols developed on top of the late Weichselian loess cover in Belgium (Van Vliet and Langhor 1981).

CONCLUSIONS

The distribution of permafrost indicators within the upper Pleistocene loess sequence of Belgium and

surrounding areas, implies that many relatively short episodes of permafrost formation occurred across Belgium and northwestern France during the Weichselian. The most widespread episodes took place at intervals, between 33,000 and 20,000 years B.P., mainly before and during the sedimentation of the late Weichselian loess cover. In Belgium and in northern France at least one episode of continuous permafrost existed around 26,000 years B.P.

Permafrost conditions did also occur at the beginning of the middle Weichselian (around 60,000 years B.P.) and during the second half of the late Weichselian (around 15,000 years B.P.). Furthermore, it seems that, at least in the loess area of Belgium, main periods of permafrost development always precede important episodes of eolian sedimentation.

PERIGLACIAL PHENOMENA IN ARID REGIONS OF IRAN

Horst Hagedorn

Geographisches Institut, Universität Würzburg
Am Hubland, D-8700 Würzburg, Federal Republic of Germany

Field work in the Shir-Kuh Mountains (el. 4,055 m) of central Iran included studies of periglacial phenomena as well as of the present and Pleistocene limits of patterned ground and the snow line.

The climate is semi-arid. Average annual precipitation is about 200 mm at 2,000 m and about 400 mm at 4,000 m. Precipitation occurs almost exclusively in winter in the form of snow. The summer months are characterized by low cloud cover, and thus high solar radiation.

All of the mountain area possesses Pleistocene glacial landforms down to 1,900 m, as well as present periglacial forms above 2,000 m. Four groups of periglacial features are distinguished:

1. On the Shir-Kuh summit plateau at 4,055 m stone circles, stone stripes and solifluction lobes occur, comparable to alpine forms. Stone circle diameters are 50 - 100 cm. Limestone frost debris is upturned and well oriented.

2. Between 3,400 and 4,000 m, smooth slopes ("Glatthänge") cut across limestone strata. Slope inclinations are between 35° and 40° . They are interpreted as periglacial forms.

3. At the foot of limestone outcrops, between 3,000 and 3,400 m, there are frequent occurrences of vegetation garlands of periglacial origin. Stone stripes are also common and extend down to 2,500 m.

4. Occurrences of patterned ground are found as low as 2,100 m. With the exception of those on very suitable substrates they appear to be convergence forms due to wetting and drying of clays and salts.

There is some evidence for progressive divergence of the snow line and the lower limit of patterned ground towards the arid zones.

INTRODUCTION

There has been a long-standing and controversial discussion on the altitudinal range and lower limit of periglacial phenomena in arid-zone mountains. One opinion, as summarized by Troll (1944, 1947), holds that the lower limit of patterned ground rises and falls in accordance with the tree line and the snow line, thus not culminating in the humid tropics, but in the arid zones of both hemispheres. This view is challenged by Hövermann (1962) who asserts that there is a general rise of the lower limit of patterned ground from the poles to the equator, and that this trend is interrupted, or even reversed, in the arid zones. Since the pattern of altitudinal limits is important for the reconstruction of paleoclimates, there is a need to settle this controversy.

Present periglacial phenomena have been reported from many areas of Iran. Hövermann (1960) attributes an altitude of 2,000 m to the lower limit of patterned ground on the dry southern flank of the Alborz Mountains whereas Bobek (1937, 1952) places the same line 1,000 m higher. Similar figures are

given for the Pleistocene depression of altitudinal limits in Iran. Bobek (1955) calculates a rather insignificant depression, interpreting this as evidence that more or less the same forces governed the arid highlands during the last glacial as today.

When members of the Department of Geography of the University of Würzburg did geomorphological fieldwork in the Shir-Kuh Mountains (Figure 1) of central Iran (elevation, 4,055 m; latitude $31^{\circ} 30'N$) from 1972 to 1977, they also collected information upon the present and Pleistocene positions of the lower limit of patterned ground and of the snow line.

GEOLOGY AND GEOMORPHOLOGY

The Shir-Kuh Mountains consist of a granite base topped by as much as 600 m of hard Cretaceous limestones and dolomites. The mountain block is tilted northward. Its sedimentary blanket covers most of the north flank, which is dissected by deep canyons. Limestone forms the highest elevations: 4,055 m at the Shir Kuh summit proper, and about 3,900 m in the Kuh-e-Barfkhaneh. Steep

FIGURE 1 Topographic map of the Shir-Kuh Mountains, central Iran, and location of the study area within Iran.

walls plunge from all sides of the summits. The transition to the granitic basement, with steep slopes 30° - 40° in angle, cuts across a series of marls and conglomerates of variable thickness. Below the base of the Cretaceous outcrops V-shaped valleys are cut into the granite. The asymmetric profile of the mountains is further emphasized by the different heights of the foreland plains. On the north side this is the Mehriz plain below 1,900 m; its bedrock deeply buried by alluvial fan deposits. The southern foreland is a wide granitic planation surface, attaining 2,400 m at the foot of the mountain.

CLIMATIC CONDITIONS

There is no weather station within the mountains. The nearest station, Yazd (Figure 2) lies at 1,200 m on the east, or lee, side of the mountains. It receives 124 mm/yr of precipitation. The mountains are likely to be less arid. Incomplete records from a former mountain station, among other evidence, suggest 200 mm for 2,000 m elevation, and further increase to around 400 mm in the summit region. The higher parts of

the mountains can thus be called semi-arid.

Most of the precipitation falls during the winter, above 2,000 m almost exclusively as snow. There is a continuous snow cover at higher elevations each year from November to April. Snow patches survive until early June: On the north side of the Kuh-e-Barfkhaneh, which means 'snow house mountain', there are perennial firn patches in protected positions at 3,300 m.

Winter snowfalls are accompanied by low temperatures (Figure 2). Even at Yazd, January nighttime temperatures frequently fall below -5°C . In the high valleys of Deh Bala and Tezerjan (2,200 - 2,500 m), ground temperatures below -15°C are not uncommon. For the development of periglacial features the beginning and end of winter are of prime importance. Alternating inroads of cold and warm air masses lead to frequent freeze-thaw cycles in areas above 2,500 m. During the winter the soil remains frozen at these altitudes, with occasional thaws on the south slopes.

The summer months, from June to September, are hot and practically precipitation-free. These are also the

months with least cloud cover, and thus with high radiation and evaporation. These conditions result in the rather high elevation of the present snow line.

FIGURE 2 Climatic diagram of Yazd, elevation 1,200 m, NE of the Shir-Kuh Mountains (Djavadi, 1966).

PERIGLACIAL FEATURES

1. SHIR-KUH SUMMIT PLATEAU (4,000 - 4,055 m)

The highest elevation of the mountains is a narrow limestone plateau bounded by steep slopes on its south, west and east sides. The rock walls themselves are almost bare. At their base is a fringe of fresh talus cones indicating rapid frost weathering of the heavily jointed limestone walls. Freeze-thaw cycles are frequent and occasionally occur during the summer months.

The dominant periglacial features at this altitude are straight, smooth slopes ("Glatthänge"), that begin at the summit plateau. On S and SW exposures they extend down to about 3,700 m. All limestone strata are uniformly cut at an angle of 35° - 40°. The debris cover is thin, but highly mobile, indicating considerable denudation. According to Klaer (1962), Schweizer (1975) and others, these smooth slopes are typical for the periglacial altitudinal zone of the winter-cold continental mountains of the Near East.

Additional periglacial features occur on the Shir-Kuh summit plateau between 4,000 and 4,055 m. These include stone circles, stone stripes, solifluction lobes, and turf garlands. All are well developed over large areas and compare well with alpine periglacial features (Hagedorn et al. 1978).

The stone circles are 70 - 100 m in diameter. Their coarse angular slabs of limestone frost debris are clearly oriented and pushed into near-vertical

positions. The average diameter of the rubble is 15 cm, that of the largest displaced slabs 25 cm. Sorting depth is 40 cm. On slopes of more than 5° the stone circles change to solifluction lobes.

Where the substrate is slightly more loamy, stone stripes a few metres in length occur on slopes of about 10° inclination. The stripes are well sorted into fine and coarse material. The latter have an average particle length of 15 cm and a sorting depth of as much as 30 cm.

The less inclined parts of the summit plateau bear a dense network of vegetation garlands. Strong root lengthening indicates that solifluction is quite efficient. The vegetation garlands are restricted to the windward side of the plateau where snow is blown off and which is thus rather dry. Stone circles concentrate in the lower lee positions and depressions. This clearly indicates the dependence of these features on moisture supply, which relates to differences of snow cover. A few snow patches survive well into summer.

2. KUH-E-BARFKHANEH (3,900 m)

The Kuh-e-Barfkhaneh is an isolated limestone mountain resting, just as the Shir-Kuh summit plateau, on granite. The less resistant marly strata of the basal Cretaceous beds are smoothly cut by slopes 30 - 40° in angle, in contrast to the limestone walls above and the densely dissected granite relief below.

In a few places at the foot of the north wall some snow survives even the hottest summer months. In August and September of 1974 and 1975 there were four perennial snow patches at 3,300 m. The largest was 100 x 30 x 5 m in dimensions and consisted of at least four annual firn layers. The snow patches are flanked by moraine ridges 7 - 10 m high which go down to the granite contact at 3,150 m, and continue into the steep ravines of the granite terrain. They can be traced to a 40 m high moraine in a bowlshaped valley at the foot of the Kuh-e-Barfkhaneh. This follows the valley down to 2,500 m and gives some impression of the remarkable Pleistocene glaciation of the mountains (Hagedorn et al. 1975).

The 30° - 40° slope of the Cretaceous base is covered by loamy debris, in some places by rockfall masses from the limestone wall. On the north side of the mountain there is always a pronounced nick between the wall and its foot, while there is a smooth transition on the south side. Especially in SW exposures periglacial smooth slopes ("Glatthänge") are inclined 35° - 40° across the limestone beds between 3,300 and 3,800 m elevation.

Smaller periglacial features, such as soil stripes and vegetation terraces, are also present. The biggest area of soil stripes lies in a SW exposure underlain by Cretaceous rocks at an elevation of 3,250 m. On an area of 3,000 m² stripes of walnut-size limestone rubble with a diameter between 2 and 3 cm alternate with the fines from the underlying basal beds. The stripes are spaced at 15 - 20 cm. Sorting depth is 20 cm; the slope is 25°. They typically bend around larger obstacles, where they get closer to each other, but never unite.

Vegetation terraces occur at the same height (3,100 - 3,300 m) on the slopes of the Cretaceous base, preferably on the sunprotected and thus more humid north side. Aside from some grass the patchy vegetation mainly consists of woody shrubs the roots of which are lengthened downslope. This indicates that considerable debris transport by solifluction still occurs at this height on slopes of 30° - 35°. Severe over-grazing by goats and innumerable goat tracks tend to obscure the periglacial component. Undamaged terraces are preserved in only a few inaccessible places.

3. "BLACK" PASS (2,650 m)

The "Black" Pass, in the western part of the mountains, owes its name to the dark schist debris covering the adjacent slopes. Patterned ground is common above 2,700 m on the east slope. Soil stripes are most frequent, with stone circles on more gentle slopes. Both forms are intermingled with dwarf shrubs.

The biggest area of soil stripes is about 15 m². The stripes are 20 - 25 cm apart; sorting depth at a slope inclination of 7° is 12 cm. All particles are oriented with their longer axes downslope. The coarser components have been pushed up subvertically. The solifluction material is splintering dark schist; the particles 3 - 10 cm long are in a matrix of silt and clay. The solifluction horizon is underlain by a reddish-brown fossil soil without any sorting. Debris accumulation on the upslope side of obstacles is evidence of rather strong solifluction. Where the debris has moved around obstacles, it has fully preserved its striped appearance, thus excluding their interpretation as mudflow deposits.

The stone circles on the almost horizontal slope terraces have a diameter of 30 cm; sorting depth is 15 cm. Up to a length of 12 cm the splintered particles are turned up and oriented tangentially. The fine-earth cores, just as in the stone circles, appear to have been squeezed up, thus resembling fine-earth buds. In summer their smooth surfaces

are dissected by small desiccation cracks.

Similar stone circles occur in other parts of the mountains at comparable altitudes, but mostly only on a suitable substrate. In most cases this is loamy moraine material, as for instance at the so-called hematite pass at 2,650 m, where polygons with a diameter of 20 cm exist on the moraine surface sloping about 2°.

Practically not patterned ground has developed on the grus-size weathering debris of the granite at comparable heights. Poorly developed forms were discovered in only one place, in a shallow depression on the "Pass to Sunij" at 2,800 m. Occasional existence of patterned ground on the slopes would be hard to prove, because of heavy disturbance of the surface by grazing goats.

4. "MARBLE PASS" (2,150 m)

The lowest occurrences of patterned ground are found at 2,000 to 2,200 m in various parts of the mountains. One such location is a broad ridge near the so-called "Marble Pass" at 2,150 m. This gently sloping ridge is covered with fine debris containing much silt. In a few places, small polygons have developed that are transformed into downslope stripes at about 5° inclination. The polygons resemble desiccation cracks. Their diameter is 15 cm, distance between stripes 10 cm, and sorting depth 5 - 7 cm. The latter is clearly visible, as the light-colored sorted soil overlies a red-brown fossil soil. The following profile is typical:

1. A more or less well structured stone pavement 2 - 3 cm thick on top; components up to 5 cm diameter still show signs of upturning and orientation;

2. underneath the pavement a stone-free vesicular layer about 2 cm thick, mostly silty with some clay;

3. occasionally a thin gypsum crust;
4. and below that crusts at 5 - 7 cm the weathered bedrock with debris-rich relicts of a fossil red-brown soil.

These observations raise the suspicion that the patterned ground near Marble Pass is not wholly a frost-dynamic feature but at least partly the result of periodic swelling and shrinking of the clays in the profile. The profile resembles those described by Cooke (1970) from the Chilean and Californian deserts. Cooke attributes the present formation of the stone pavement and the vesicular layer to swelling and shrinking of clay-rich soils (20 - 30 % clay content). He reports that stones were moved up 1 - 2 cm in only 4 - 11 cycles in laboratory tests.

ALTITUDINAL LIMITS AND PRESENT SNOWLINE

Observations suggest an approximate position of the lower limit of "true" periglacial phenomena to be around 2,500 m. Occasionally it may be as low as 2,000 m, but only on suitable loamy substrate and on northerly exposures. The limit should be higher on the south side of the mountains, but evidence is lacking, as the foreland plain rises to 2,400 m, and the granite slopes rising up to 3,000 m are unfavorable to the development of patterned ground.

All patterned ground phenomena below 2,000 m elevation are pseudoforms and not periglacial. This is especially evident where beautiful polygonal ground exists on the hard salt clays in the center of the kavirs, as in the Bafq kavr at 1,000 m. They most likely owe their existence to processes of salt solution and recrystallization together with strong evaporation.

The next question concerns the vertical range of the periglacial zone, i. e., the vertical distance between the "zonal" lower limit of patterned ground as defined by Troll (1944) and Höllermann (1967, 1972) and the present snow line. In the maps published by Bobek (1937, 1952) the present snow line west of Isfahan, at 32°30', has been drawn at 4,000 m. Only a short distance to the east the isochrone turns sharply westward, leaving an unusually steep rise of the present snow line in the study area to 4,500 or 4,600 m. This hypothetical rise of the snow line toward the arid interior of Iran was extrapolated by Bobek from his observations in the Alborz Mountains.

Assuming the "zonal" lower limit of patterned ground at 2,500 m and the present snow line at around 4,300 m the vertical extent of the periglacial zone of the Shir-Kuh Mountains would be 1,800 m. This supports Hövermann's (1960, 1962, 1972) theory of the wedgelike divergence of the snow line and the lower limit of patterned ground toward the arid zones of the earth.

The Pleistocene snow line may have been depressed by 1,000 m, since the lowest terminal moraines are at 1,900 m on the north side, and of the so-called Turkestan type, i. e., avalanche-fed. This interpretation is supported by the total absence of true cirques and the very rare occurrence of firn fields in the highest parts of the mountains (Hagedorn et al. 1975).

Since the average elevation of the valley floors is 2,500 m, and assuming that the valley glaciers were as much as 300 m thick, the Pleistocene snow line must have occurred between the ancient glacier surface at 2,800 m and the

enclosing rockwall summits at 3,800 - 4,000 m. By simply halving this interval a snow line between 3,300 and 3,400 m on the north side and between 3,700 and 3,800 m on the south side is suggested.

CONCLUSIONS

Periglacial features diminish in size with decreasing altitude in the Shir-Kuh Mountains, and at the same time become less clear. Similarly the depth of sorting diminishes. On the north side the "zonal" lower limit of periglacial phenomena lies near 2,500 m, and the "extra-zonal" lower limit of patterned ground near 2,000 m. Large-scale solifluction as a factor of slope formation does not occur below 3,000 m. The development of frost structures depends heavily on the suitability of the substrate. Loamy material on slopes of metamorphic schists or on moraines is suitable; granite grus is not suited. Exposure is not an important control over the distribution of periglacial phenomena with the exception of smooth slopes ("Glatthänge") that are best developed on south-facing slopes. Patterned ground as a convergence phenomenon exists below 2,500 m, with only a few genuine forms on highly suitable substrate. For most, a vesicular layer or salt crust indicates a nonperiglacial origin. A zone 300 - 500 m high separates "true" periglacial feature from convergence forms.

THE BREAKDOWN OF ROCK DUE TO FREEZING: A THEORETICAL MODEL

Bernard Hallet

Quaternary Research Center and Department of Geological Sciences,
University of Washington, Seattle, Washington 98195

Frost wedging -- the breakdown of rock due to freezing -- is viewed as a manifestation of slow crack propagation in rocks due to ice growth in cracks. Frost wedging is modeled through a synthesis of Gilpin's (1980a) analysis of freezing in porous media and well-established principles of fracture mechanics. The model predicts most rapid breakdown at temperatures that range from -5° to -15°C for most rocks. At higher temperatures, ice pressures sufficient to produce significant rates of crack propagation are not thermodynamically possible. At lower temperatures the rate of ice growth is greatly reduced because water mobility and, hence, the flux of water necessary to sustain crack growth decrease considerably.

The model clarifies the dependence of frost wedging on lithology, temperature, and moisture conditions. Four important rock properties figure in the analysis: pore size, permeability, average crack length, and fracture toughness. Crack growth rate has a complex dependence on temperature and is proportional to temperature gradient. The moisture content of rock can strongly affect frost wedging rates primarily by controlling the pore water pressure. Solutes are inferred to influence crack growth rates in several distinct ways.

INTRODUCTION

A number of careful studies of the breakdown of rock due to freezing have yielded considerable empirical data (Washburn 1980, McGreevy 1981, Lautridou and Ozouf 1982). However, the actual mechanisms of rock degradation, and the relative importance of lithologic, thermal, and hydraulic parameters have yet to be clearly defined. The theoretical model presented here provides considerable aid in interpreting the numerous and varied experimental results and in evaluating existing concepts of frost-induced rock breakdown. In some cases the model helps reconcile conceptual models that are in apparent conflict. Finally, the model offers guidance for future laboratory, field, and theoretical studies of frost wedging by precisely delineating the important controlling parameters.

MODEL DESCRIPTION

Frost wedging is viewed as resulting from the progressive growth of cracks that are pressurized internally by the freezing process. As in studies of frost heaving in soils (Taber 1929, Gilpin 1980a), the pressure caused by ice growth is not attributed primarily to the volumetric expansion that accompanies the water-ice phase transition. Rather, the induced pressure is assumed to arise thermodynamically because mineral surfaces effectively decrease the chemical potential of water in their close proximity (Gilpin 1979). This effect has two important and relevant consequences: (1) considerable unfrozen water persists in porous media at subzero temperatures (Taber 1929, Anderson and Morgenstern 1973, Miller 1978, Gilpin 1979), and (2) water tends to flow toward mineral

surfaces, but at equilibrium this flow is counteracted by an effective pressure increase near surfaces (Gilpin 1979, 1980b). This surface-induced increase in pressure gives rise to a "disjoining pressure" that can be related to the heave pressure in freezing soils (Gilpin 1980a). The disjoining pressure is assumed here to control the pressure generated by ice growth within rock cracks and, as such, it is a form of "crystallization pressure", as used by Taber (1929) and Robin (1978).

Analyses of the thermodynamic equilibrium between ice and water in porous media lead to a modified version of the Clausius-Clapeyron equation (Radd and Oertle 1973, Loch 1978, Gilpin 1980a). The effect of mineral surfaces on the chemical potential of water renders it possible for ice at a certain pressure to exist in contact and in thermodynamic equilibrium with water at a different pressure. When the water is hydraulically connected to a reservoir at reference pressure P_0 , the ice pressure and ice-water interface temperature at equilibrium are related by

$$v_s P_s + \frac{LT_1}{T_a} = 0, \quad (1)$$

where v_s is the specific volume of ice, L is the heat of fusion of ice, T_a ($^{\circ}\text{K}$) is effectively the freezing temperature of pure water at pressure P_0 ; P_s is the ice pressure in excess of P_0 , and T_1 is the deviation from T_a of the ice-water interface temperature. For convenience, P_0 is taken to be atmospheric; $P_0 = 10^5$ Pa and in this case, T_1 is simply the Celsius temperature.

From equation (1) it is evident that water at 0°C and atmospheric pressure can be in thermodynamic equilibrium with water in contact with ice at a pressure P_s that increases linearly with the

negative Celsius temperature at the rate of $L/(T_{av}v_s)$. This rate is $1.14 \text{ MPa } ^\circ\text{C}^{-1}$. If P_s is lower than the equilibrium value given by (1), it would be thermodynamically favorable for water to flow to the ice interface despite adverse pressure gradients. In the context of frost wedging, given sufficiently low temperatures, water would tend to flow to an ice body in a rock crack even if the pressure in the unfrozen water film between the ice and the crack wall is already high. Let us consider, for example, the ice pressure in a crack to be about 10 MPa (100 bars), a value on the order of the tensile strength of sound rock. Water flow into the crack, and hence crack expansion, would be thermodynamically favored as long as the crack temperature is below about -9°C .

The equilibrium condition (1) has been experimentally verified at temperatures down to approximately -18°C (Radd and Oertle 1973, Buil et al. 1981, Takashi et al. 1980), with heaving pressures P_s of up to 20 MPa (200 bars). It is apparent from these studies that freezing could generate pressures on the order of tens of MPa in rock pores and cracks if thermodynamic equilibrium is approached at temperatures on the order of -10°C or lower. As the tensile strength of rocks seldom exceeds 10 MPa, such frost-induced pressures in rock cracks could cause progressive crack propagation.

Crack growth depends on the magnitude (Atkinson 1982) and maintenance of pressure inside cracks. Therefore, it will be controlled both by the ice pressure and the rate of water flow necessary to maintain pressure in an expanding crack. A complex dependence can be anticipated between temperature and crack propagation rate. At very low temperatures, high pressures can be generated in cracks but crack expansion is limited because water mobility decreases sharply with decreasing temperature (Miller 1978, Gilpin 1980a). In contrast, at negative temperatures closer to 0°C , water is considerably more mobile, but pressures inside cracks are limited to low values dictated by the equilibrium condition (1).

Because of space limitations, only the simplest form of the model that contains the essential physics, including these competing effects, is presented. Ongoing work by Joseph Walder and the author has shown that the model can readily be refined and rendered more realistic.

Crack Propagation in Rocks

Modern fracture-mechanics theory focuses attention on the stress intensity factor K_I . This quantity represents the strength of the singularity in the crack-tip stress field that tends to produce opening-mode (tensile) failure (Paris and Sih 1965). For example, neglecting direct interactions between adjacent cracks and idealizing rocks as isotropic linear elastic media,

$$K_I = \left(\frac{\pi l}{2}\right)^{1/2} (P + \sigma), \quad (2)$$

where l is the length of a two-dimensional crack, P is the pressure inside the crack, and σ is the "applied" normal stress perpendicular to the crack plane (tensile stresses are positive).

In minerals and rocks under low K_I conditions, progressive crack growth--often known as stress corrosion or subcritical crack growth--occurs at rates that are sensitively dependent on K_I , and on the presence of water, water vapor, or other reactive species in the crack-tip environment (Atkinson 1982). One of the most commonly used equations to describe slow crack propagation data is Charles' power law (Atkinson 1982):

$$V_C = V_0 \exp\left(-\frac{\Delta H}{RT}\right) K_I^n, \quad (3)$$

where V_C is the crack velocity, V_0 is a proportionality factor characteristic of the material, ΔH is the activation enthalpy, R is the gas constant, and T is the absolute temperature. n is a material-dependent constant known as the stress corrosion index which is typically in the range of 40 ± 10 for rocks (Atkinson 1982), indicating an extremely sensitive dependence of crack propagation rates on the magnitude of crack loading. Equation (3) adequately describes fracture data for several types of crystalline rocks down to crack velocities of 10^{-9} m s^{-1} , and for Lac du Bonnet granite to crack velocities of $10^{-11} \text{ m s}^{-1}$.

Experimental studies of frost wedging often indicate that significant disaggregation of individual mineral grains occurs in few temperature cycles with periods ranging from hours to days. This would imply that cracks must propagate distances on the order of grain diameters, which typically range from 0.1 to 10 mm, within periods ranging from 1 to 100 days. The corresponding average crack propagation rates range from 10^{-7} to $10^{-11} \text{ m s}^{-1}$. Because the crack velocity is related to K_I raised to a high power (40 ± 10), this 4 order-of-magnitude span for inferred crack velocity collapses to a narrow range of stress intensity factors for a particular rock, with the highest value exceeding the lowest by about 50%.

For illustrative purposes, let us focus on conditions that lead to K_I values corresponding to the midrange of probable crack velocities (i.e., 10^{-9} m s^{-1}). Experimental values for K_I at these crack velocities are presented by Atkinson (1982) for several rock types. He reports approximate K_I values of 1.1, 1.5 and $2.1 \text{ MN m}^{-3/2}$ for granite, basalt, and dolerite samples, respectively. According to equation (2) with σ set at zero, these values correspond respectively to pressures P inside cracks of 28, 38, and 53 MPa for 1-mm cracks, and of 9, 12, and 17 MPa for 10-mm cracks. Thus, relatively high pressures in cracks are required to fracture crystalline rocks devoid of large fractures. Although data on relevant stress intensity factor K_I for sedimentary and metamorphic rocks are scarce, it is evident that pressures only a fraction of those necessary for crystalline rocks would suffice to crack many sedimentary and low-grade metamorphic rocks.

Significant sustained crack growth requires that pressure inside cracks be maintained by ice growth as cracks propagate. The rate of ice growth and hence of crack widening is analyzed in the next section.

Ice Growth in Rock Cracks

The model developed by Gilpin (1980a) for prediction of ice lensing and heave in soils offers a particularly suitable theoretical basis for analyzing ice growth in rocks. He derives a simple relationship between the flow rate of water and the driving potential in films of unfrozen water at ice-mineral interfaces. The water flux, which is assumed to be rate limiting, is then related to the rate of ice growth through a continuity relation. The principal governing equations will be presented here (the reader is referred to Gilpin (1979, 1980a) for the complete development). The water flow rate is proportional to the driving potential:

$$q = -k \frac{v_s d}{v_l dx} \left(P_s + \frac{LT_1}{v_s T_a} \right), \quad (4)$$

where k is the hydraulic permeability, v_s and v_l are the specific volumes of the solid and liquid phases, and x is the distance normal to the ice lens (perpendicular to the crack). As can be seen from equations (4) and (1), water flow vanishes when thermodynamic equilibrium is established, that is, when $P_s = -LT_1/v_s T_a$. It should also be noted that, in the driving potential term, the effects of both pressure and temperature are likely to be important. For example, a pressure difference of 1 MPa in ice is equivalent to a temperature difference of 0.88°C as far as the potential for driving water flow is concerned.

The mobility of water is a complicated function of temperature because it appears to be largely dictated by the permeability of a partially frozen zone on the warmer side of an ice-filled crack (Figure 1). After a detailed analysis, Gilpin (1980a) showed that the permeability of the partially frozen fringe in non-colloidal soils can be approximated adequately by

$$k_f = k_l (-T_1 + T_f)^{-2} \quad (5)$$

Figure 1 Schematic diagram of ice (oblique stripe pattern) in a rock crack with an intervening water film. Wavy lines represent paths of water flow necessary for sustained ice and crack growth.

where k_l is a constant dependent on grain size (Gilpin 1980a, Figure 5). T_f , the temperature depression required to form ice in soil pores, is inversely related to pore radius (Gilpin 1980a, equation 18). On the basis of equations (4) and (5), together with conservation of mass, Gilpin (1980a) derived his equation (25) for the rate of heave or ice growth as a function of the effective hydraulic resistance provided by the frozen fringe and by thin water films that envelop growing ice lenses.

For the frost-wedging problem, water influx is simply related to the volume increase of cracks, the shape of which is dictated by the effective internal pressure ($P + \sigma$) and crack length. To streamline this analysis, however, shape will be taken as invariant by fixing the crack aspect ratio A (crack width/length). This simplification is appropriate for increments of crack growth that are small relative to crack length. The rate of ice growth can then be simply related to the crack propagation rate V_c :

$$V_c = \frac{v_s^2 k_l}{v_l g A (T_f - T_1)^3} \frac{dT}{dx} (P_1 - P_c - \frac{T_1 L}{v_s T_a}), \quad (6)$$

where g is acceleration due to gravity, dT/dx is the temperature gradient, P_c is the pressure exerted on crack walls by ice via the intervening water film and P_1 is the pore water pressure outside the frozen fringe. Equation (6) is derived directly from Gilpin's (1980a) equation (25) by assuming that the hydraulic resistance at ice bodies is negligible relative to that of the frozen fringe. This assumption is likely to be valid in rocks for freezing in cracks that are large relative to the spacing of pores and intragranular cracks. Implicit in equation (6) is the hydraulic resistance of the frozen fringe; it scales with the inverse of k_f , approximated by equation (5), and with fringe thickness a , which depends on the temperature gradient: $a \approx (T_f - T_1)/(dT/dx)$.

The rate of crack propagation, V_c , can be obtained simply from equation (6) by selecting values for the pressure P_c inside cracks that correspond to the broad V_c range of interest for particular rock types, as discussed above. Alternatively, to avoid selecting a fixed value of P_c , the fracture equations (2) and (3) can be combined and solved simultaneously with equation (6) to calculate both V_c and P_c .

RESULTS

From the form of equation (6) it is apparent that crack growth occurs only when

$$-\frac{T_1 L}{v_s T_a} + P_1 > P_c \quad (7)$$

For negligible pore pressures P_1 , T_1 must be less than $v_s T_a P_c / L$. For example, for values of P_c around 10 MPa, crack growth could only occur at temperatures T_1 below about -9°C. As the temperature drops below this critical value, V_c first increases steeply but soon falls off because of a rapid decrease in permeability, which scales roughly as T_1^{-3} . This dependence on T_1 arises from equation (6) because, as seen in the numerical example below, the contribution of T_f is often

insignificant relative to that of T_1 . It is also apparent that V_c is directly proportional to the temperature gradient, which controls the thickness of the frozen fringe and, hence, of the effective rock permeability.

A calculation of crack-propagation rate as a function of temperature illustrates many of these relationships quantitatively. The results shown in Figure 2 were obtained using reasonable values for the variable physical parameters: k_1 was taken to be $10^{-13} \text{ m s}^{-1} \text{ } ^\circ\text{C}^2$ because, at 1°C below the freezing temperature T_f , it corresponds to a permeability of about $10^{-13} \text{ m s}^{-1}$, a reasonable value for sound crystalline rocks. The crack length l was assumed to be 100 times its width w , corresponding to $A = 0.01$. The temperature gradient in the frozen fringe was taken to be 3°C m^{-1} and the freezing point depression T_f related to pore size was taken to be -1°C . This T_f corresponds to pores $0.1 \mu\text{m}$ in diameter given an ice-water interfacial energy of 0.03 N m^{-1} (Gilpin 1980a, equation 18). Crack propagation rates were calculated for internal crack pressures P_c of 5 MPa (appropriate for relatively weak sedimentary rocks) and 10 MPa (for granites). The pore pressure P_1 outside the frozen fringe was assumed negligible.

Although V_c values are rather poorly defined primarily because of uncertainties in k_1 and P_c , the form of the temperature dependence of V_c shown in Figure 2 is not expected to vary appreciably. Thus it is evident that frost-induced cracking of rock is expected to occur only below a critical temperature and that cracking is fastest at a

slightly lower temperature. Below this the rapid decrease in permeability causes the crack growth rate to diminish with temperature because water flux becomes severely limiting.

DISCUSSION

The analysis shows that freezing can generate sufficient pressure in rock cracks to cause significant cracking over a time scale of interest. It is emphasized that cracks are assumed to be pressurized internally by ice with an intervening film of water. As only water contacts crack walls in the model, this mechanism could be viewed as a form of hydration cracking, which has been perceived by others (e.g., White 1976) as being in direct conflict with frost-shattering concepts. Similarly, the distinction emphasized by Hudec (1974) between "frost sensitive" rocks and "sorption sensitive" rocks now appears largely arbitrary because, according to the model presented here, both "sensitivities" result directly from the reduction of the chemical potential of vicinal water due to mineral surfaces. The thermodynamic properties that are fundamental to the model constitute common ground for a number of apparently distinct frost shattering hypotheses. As a result, this model effectively unifies several hypotheses that commonly figure under separate headings: crystallization pressure, capillarity, and ordered water (Washburn 1980, McGreevy 1981).

The principal implications of the model are subdivided into the effects of lithology, temperature, moisture, and solutes on frost wedging.

Lithologic Controls

Susceptibility to frost wedging is generally recognized to be sensitively dependent on lithology. This is to be expected because lithologic characteristics figure in the analysis of crack-growth rates in several ways: (1) pore size affects the temperature T_f at which ice forms in pores; (2) intrinsic permeability controls water mobility at subfreezing temperatures through k_1 ; (3) the relevant stress intensity factor K_I of the rock, together with crack geometry A , dictate the value of P_c . These parameters all correspond to rock properties known experimentally to influence the frost susceptibility of rock (Lautridou and Ozouf 1982).

For example, rapid frost wedging in shales and argillites probably results from low K_I values, high permeability at subfreezing temperatures because of high unfrozen water content--a characteristic of frost sensitive rocks (McGreevy 1981)--, and long narrow cracks--often present in rocks with well-developed fissility. In contrast, dolerite with fracture properties similar to those reported by Atkinson (1982 and above) would be very resistant to frost wedging unless long, pre-existing cracks could be exploited.

Figure 2 Rate of crack propagation as a function of temperature T_1 and ice pressure P_c in cracks. Crack growth is most rapid at temperatures slightly lower than that at which ice under pressure P_c is in thermodynamic equilibrium with water at atmospheric pressure. For lower temperatures, water mobility is so low that ice growth is severely limited by water flux. $P_c = 5$ and 10 MPa are generally appropriate values for sedimentary rocks and for plutonic rocks, respectively.

Thermal Regime

It is clear from equation (6) and Figure 2 that frost-induced breakdown of rock is not expected to occur at appreciable rates at temperatures warmer than a critical subzero value. The instantaneous rate of frost wedging is expected to be highest at a temperature, T_* , slightly below the critical value. The ratio T_*/P_c is approximately 1.3°C/MPa for negligible T_f .

The lack of consensus about thermal conditions that are most favorable for frost wedging (Washburn 1980, McGreevy 1981) is not surprising in view of the complex dependence of crack-propagation rate on both temperature and lithology, as illustrated in Figure 2. The results, however, are compatible with frost wedging being most active in areas where temperatures are substantially below 0°C but not at the extremes found, for example, in Antarctica.

Other aspects of the thermal regime often reported to favor frost wedging, including frequency of freeze-thaw cycles, rate of cooling, minimum temperature, and duration of cold period, can be interpreted with new insight gained from the model. Both the rate of cooling and the cycle frequency affect V_c by controlling temperature gradients dT/dx . The lowest temperatures attained can play a critical role in frost wedging of sound crystalline rock with small cracks that only propagate when stressed highly. The duration of the cold period is clearly important because crack propagation is proportional to time.

Moisture Controls

High initial moisture content and ample water supply are commonly recognized to favor frost wedging (Mellor 1973, McGreevy 1981, White 1976). The effect of moisture content in unsaturated rock cannot be analyzed explicitly in this simple model, which parallels Gilpin's (1980a) heave model for saturated porous media. However, the model presented here does provide considerable guidance for a qualitative assessment of moisture effects. As water freezes in rock pores, the total volume of water in rock expands by about 9%. In saturated rocks freezing results in expulsion of water ahead of the freezing front as long as crack expansion is insufficient to accommodate the volume increase due to the ice-water transition. This expulsion of water, which is characteristic of ice lensing under high confining pressure (Gilpin 1980a), will increase the pore pressure P_1 . It is evident from equation (6) that increasing P_1 directly increases the crack-propagation rate, and can cause significant cracking at temperatures above those required when $P_1 = 0$. In fact, if P_1 is sufficiently high ($P_1 > P_c$), hydrofractures may form in rock regardless of temperature. This situation is most likely to occur when rock fragments are frozen from all sides, as may be common for talus. Highest pressures would be reached, and hence cracking would be most likely, in the central portion of rocks with high water contents. Such an effect may underlie a causative relationship between the size of rock fragments and climatic variables.

Solute Effects

Current models of freezing in porous media (Miller 1978, Gilpin 1980a) have been developed for pure water systems. Although it is beyond the scope of this paper to treat solutes quantitatively, several observations can help us understand why solutes greatly accelerate the breakdown of rock under freezing conditions in some experiments (White 1976, Williams and Robinson 1981) and have the opposite effect in other experiments (McGreevy 1982).

Solutes are anticipated to affect frost wedging in several ways: 1) the freezing temperature T_f is lowered, thereby increasing the unfrozen water content and water mobility at subfreezing temperatures in accord with the known effect of solutes on phase-equilibria in frozen soils (Anderson and Morgenstern 1973); (2) T_f and the chemical potential of water near freezing interfaces would be selectively lowered by the interfacial solute buildup that results as growing ice preferentially rejects solutes; and (3) the relevant stress-intensity factor K_I , and hence P_c , required to cause particular crack-growth rates may be reduced substantially by high-solute concentrations in cracks (Atkinson 1982). The lowering of T_f effectively shifts the curves in Figure 2 to lower temperatures; this can either increase or decrease frost-wedging rates depending on whether the dominant experimental temperatures are below or above the temperature T_* at which cracking is fastest. The interfacial lowering of the chemical potential would tend to speed up crack growth by increasing water transport to freezing interfaces. This effect is likely to be important for low solute concentrations because, at concentrations approaching the saturation value, the interfacial solute buildup cannot develop fully, as the solute concentration cannot appreciably exceed the eutectic concentration. This is in accord with McGreevy's (1982) experimental finding that for each salt solution the greatest frost-induced damage was associated with the most dilute solutions used. In contrast, however, Williams and Robinson (1981) found that frost wedging in rocks containing saturated salt solutions was considerably more rapid than in the same rock containing water. This result may reflect a strong influence of solute concentration in the vicinity of crack tips on crack-propagation rates. Such an influence is evident in stress corrosion experiments on sandstones in which crack propagation rates increased by an order of magnitude as the NaCl concentration of pore fluids was increased above 0.1 M (D. M. Johnson, personal communication 1983).

CONCLUSIONS

The simple model developed here for frost-induced breakdown of rocks provides considerable guidance in interpreting the large existing data base obtained through laboratory and field studies. Lithology and temperature take on multiple but clearly defined roles in the analysis. The results of the model provide guidelines for future laboratory and field studies and motivate

complementary theoretical treatments. Analyses of pore pressure and solute distribution in porous media undergoing freezing would be particularly helpful for improved understanding of the breakdown of rock under such conditions. Some of these analyses are currently underway.

ACKNOWLEDGMENTS

It is a sincere pleasure to acknowledge E. C. Gregory, A. J. Heyneman, and C. W. Stubbs for their truly outstanding assistance without which this paper would not have been completed. I also wish to thank R. S. Anderson for help with numerical analyses, and J. S. Walder and W. M. Bruner for detailed discussions of frost wedging and rock fracture. Critical comments on the manuscript by R. S. Anderson, D. B. Booth, W. M. Bruner, M. P. Muir, M. Sharp, J. S. Walder, and A. L. Washburn are much appreciated. D. L. Gardner and P. S. Leaming's help in preparing the manuscript is acknowledged. This study was supported by NSF grant (EAR 81-09308).

ALASKA HIGHWAY GAS PIPELINE PROJECT (YUKON) SECTION
THAW SETTLEMENT DESIGN APPROACH

A. J. Hanna¹, R. J. Saunders¹, G. N. Lem¹ and L. E. Carlson²

¹Hardy Associates (1978) Ltd., Calgary, Alberta, Canada T2E 6J5

²Foothills Pipe Lines (Yukon) Ltd., Calgary, Alberta, Canada T2P 2V7

The Alaska Highway Gas Pipeline will traverse permafrost terrain for much of the route through the Yukon Territory. In the predominantly frozen ground, the pipeline will operate in the "cold" mode. Where the terrain is predominantly unfrozen, the pipe will operate in the "warm" mode requiring mitigative design for thaw settlement in some frozen terrains.

The results of the thaw settlement tests carried out for the project are presented as well as other data available in the literature. Statistical methods were used to arrive at correlations between thaw settlement and moisture content or density. The thaw settlement predictions were based on a computerized Borehole Data Bank containing simplified borehole logs and a computerized thaw settlement program.

The thaw settlement predictions were applied to the pipeline design by assuming that the predicted thaw settlement could occur as a differential settlement over a relatively short length of pipe. The various mitigative designs are presented.

INTRODUCTION

The Alaska Highway Gas Pipeline has been proposed to transport gas from the Prudhoe Bay area on the north shore of Alaska, USA, across Alaska through northwestern Canada to the southern states. Figure 1 shows the Yukon section of the proposed route. The 1.2 m diameter pipeline will traverse permafrost terrain for much of the route through the state of Alaska and the Yukon Territory. The pipeline will be operated continuously at temperatures below 0° C for the entire portion within Alaska and for the first 214 km into the Yukon Territory. Compressor Station 313 at KP 214 is the last point of cold flow, just northwest of Kluane Lake (see Figure 1). The remaining portion of the line is proposed to be operated in a warm mode. Between Kluane Lake and Whitehorse, a high percentage of the route is underlain by permafrost. If significant amounts of excess ice are present in the ground, the thawing created by the warm pipe would cause thaw settlement beneath the pipe over a period of time and lead to possible pipeline stability problems.

This paper summarizes the various components of the thaw settlement design process that were undertaken for the Yukon portion of the pipeline route. These are as follows:

1. investigation of extent and conditions of permafrost along route;
2. assembly of test data and compilation into basic soil groups;
3. establishing thaw settlement correlations;
4. prediction of thaw depths and resulting settlement; and
5. application of the predicted thaw settlements to design.

FIGURE 1 The Alaska Highway Gas Pipeline route through Yukon.

EXTENT AND CONDITIONS OF PERMAFROST

Extensive programs of terrain analysis, field reconnaissance, geophysical surveys, and borehole drilling have been carried out in the Yukon. Particular attention was paid to delineating permafrost and determining its properties where present. The extent of permafrost in the warmflow portion of the route is summarized in Table 1 according to different physiographic regions established as part of the overall terrain assessment for the route. Based on airphoto interpretation and considerable borehole data, terrain

analysis has made possible the delineation of the potentially ice-rich terrain units along the route. The extent of ice-rich terrain is also given in Table 1.

TABLE 1 Extent of Permafrost South of Kluane Lake.

Physiographic Regions (KP Range)*	Length of Region (km)	Percentage Permafrost	Percentage Ice-Rich Permafrost
226.3-314.5	88.2	46.9	24.3
314.5-439.0	124.5	19.6	13.3
439.0-549.6	110.6	16.9	11.1
549.6-662.0	112.4	18.5	13.4
662.0-769.1	107.1	3.6	0.5
769.1-829.5	60.4	3.1	3.1
226.3-829.5	603.2	18.3	11.2

*KP is the distance in km from the Alaska-Yukon border.

THAW SETTLEMENT TEST DATA

Project Test Data

A total of 185 thaw settlement tests have been performed on frozen core samples obtained during the various drilling programs along the route since 1976. Particular emphasis has been made to define the thaw settlement characteristics for soils with relatively low ice contents.

The development of the basic thaw settlement test has been outlined in Watson et al. (1973). The general test procedure consists of thawing a frozen core under some nominal (5 kPa) pressure, and then two or more subsequent load increments (e.g., 40 and 80 kPa) are applied. This test procedure permits a distinction between the settlement due to thawing of the excess ice alone, from that of the additional settlement attributable to an increase in pressure, as illustrated in Figure 2 (after Watson et al. 1973).

Moisture content and frozen bulk density tests were carried out on the test specimens to permit a correlation between thaw settlement and these more readily available soil properties.

Other Available Thaw Settlement Data

Two main sources of additional thaw settlement data have been used: Mackenzie Valley, N.W.T., data presented by McRoberts et al. (1978) and Alaskan data published by Luscher and Afifi (1973).

The Mackenzie Valley data were compared with the South Yukon data. All the data from the two sources were plotted separately, and a visual

FIGURE 2 Typical thaw settlement test result.

comparison was made for each of the soil types represented. The test data for peats differed very considerably, and so the Mackenzie Valley data for peat have not been used. The other soil types were found to compare favorably.

The test data for gravels presented by Luscher and Afifi (1973) represent the only major source of data on granular soil, and therefore, no real comparison with Yukon gravels is possible.

THAW SETTLEMENT CORRELATIONS

Some of the earliest analysis of thaw settlement was carried out by Tsytoovich and Sumgin (1937). More recent works include Morgenstern and Nixon (1971), and Crory (1973). In basic form (Figure 2) the thaw strain under any given pressure is expressed by:

$$\epsilon_p = A_0 + m_v \cdot p \quad (1)$$

where ϵ_p is thaw strain at pressure, p ; A_0 is initial thaw strain at zero overburden pressure; p is the effective pressure (kPa); and m_v is the coefficient of compressibility (1/kPa).

For the purposes of thaw settlement evaluation over the pipeline route, the thaw strain at a representative effective pressure of 50 kPa has been taken. This pressure conservatively represents the insitu effective pressure in the upper layers of the thaw bulb where most of the thaw settlement occurs. The actual pressure selected is not very critical for general route evaluation, as the major component of the thaw strain value is the initial thaw value, A_0 .

Figure 3 shows a typical data plot. Because there is the possibility of error or random variation in both the thaw strain value measured and the moisture content or bulk density determined for each test, there exists a joint probability distribution. Two "best fit" lines have been obtained by linear regression, considering each variable errorfree, respectively, as illustrated in Figure 3. The best estimate of the true correlation lies between these two lines (Lyon, 1970).

FIGURE 3 Establishing thaw strain-moisture correlation.

FIGURE 6 Thaw strain-moisture correlation for gravel.

FIGURE 4 Thaw strain-moisture correlation for peat.

FIGURE 7 Thaw strain-moisture correlation for low plastic fine-grained soils.

FIGURE 5 Thaw strain-moisture correlation for organic silt.

FIGURE 8 Thaw strain-moisture correlation for high plastic soils.

The actual correlations have been obtained as follows:

- For the upper thaw settlement range, the correlation has been defined to provide a thaw strain of 1.0 when the sample becomes pure ice (volumetric moisture content 100%; or frozen bulk density of 917 kg/m^3). This upper limit thaw settlement is joined to the intersection of the two regression lines (see Figure 3).
- The lower portion of the correlation is taken as the bisector of the two regression lines, below the point of intersection.

The thaw strain value ϵ_{50} , at 50 kPa, has been obtained from all the available test data. (The strain at a minimum pressure of 100 kPa is presented for the gravels by Luscher and Afifi (1973).) Based on the visual comparisons of all data, basic soil groups were selected, i.e., peat, organic silts, gravels, non to low plastic silts and clays, and medium to high plastic silts and clays. All of the thaw strain values are presented with respect to volumetric moisture content of the soil groups in Figures 4-8. Volumetric water content was chosen as a dependent variable rather than the more usual gravimetric water content, as the full range of volumetric water content is confined between 0 and 100%. The thaw strain versus frozen bulk density is presented in Figure 9 for the low plastic fine-grained soils only.

FIGURE 9 Thaw strain-density correlation for low plastic fine-grained soils.

The established thaw strain correlations for the various soil types are shown in Figures 4-9. In the case of the low plastic fine-grained soils (Figure 7), the moisture content (37% by vol.) for which zero thaw settlement was indicated by the bisector appeared too high. It was judged that the moistures and density corresponding to zero thaw strain should be:

- moisture content (dry wt.) = 17.0%; (volumetric) = 31.3%
- frozen bulk density = 2165 kg/m^3

and the lower portion of the correlation for these low plastic soils was modified accordingly.

THAW SETTLEMENT PREDICTIONS

Geothermal Predictions

Thermal simulations of the ground thawing induced by a noninsulated warm buried pipeline were carried out using a computerized geothermal model (Hwang, 1976). Several different pipe temperatures and soil conditions were considered. This study provides the ultimate depth or zone of soil that may eventually be thawed by the operation of the warm pipe. These predicted thaw depths (see Figure 10) have been used for selecting the base of the thaw bulb for thaw settlement calculations. This is primarily dependent on soil type and water content, as these influence the thermal properties.

FIGURE 10 Predicted (30 year) thaw depths below the ground surface.

Thaw Settlement Program

A computer program was developed to calculate thaw settlement for both the pipe and the right-of-way (ROW). A brief flow chart in Figure 11

illustrates the major steps in the program. The settlement can be calculated for each individual borehole and for any given depth range by defining the depths to the top and bottom of the thaw zone.

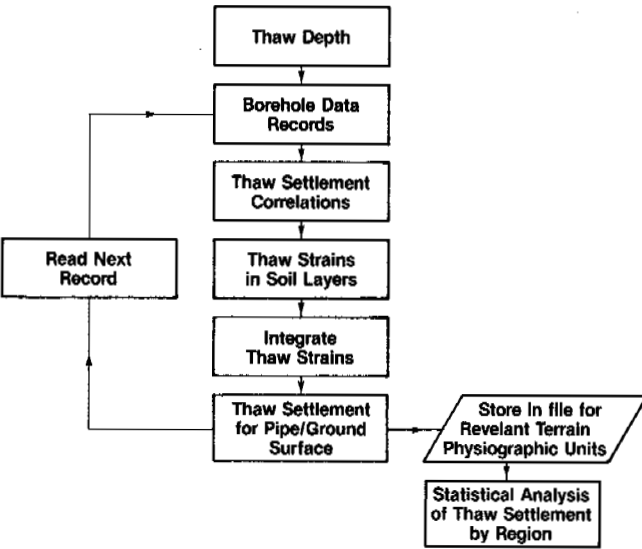

FIGURE 11 Conceptual flow chart for thaw settlement calculations.

The actual thaw settlement calculation was carried out for each individual borehole, layer by layer, using the data stored in a borehole data bank which listed up to eight layers per borehole with moisture and density data. Over 1,000 borehole records were available for this area of the pipeline in the South Yukon, and these were stored on floppy discs and accessed by a Hewlett Packard HP-9845 minicomputer. The layer settlements were then summed to provide the total settlement prediction for the thaw zone defined. The thaw strain values of the individual layers were obtained from the moisture content correlation in preference to the density correlation because moisture data were more abundant.

The mean thaw settlement was calculated for each borehole as

$$S_B = \sum (x_i)(\epsilon_i) \quad (2)$$

where S_B is the mean borehole settlement; x_i is the thickness of soil layer i and ϵ_i is the mean thaw strain for the layer, obtained from the correlations.

The standard deviation in the above settlement value was calculated based on the standard error for each soil layer and the layer thickness as follows:

$$\sigma_B = \sqrt{\sigma_1^2 + \sigma_2^2 + \dots + \sigma_8^2} \quad (3)$$

where $\sigma_1 = (x_1)(s_1)$ etc. and σ_B is the individual borehole standard deviation; x_1 is the thickness of layer one; and s_1 is the standard error in the mean thaw strain for layer one.

For most design purposes it was required to evaluate the thaw settlement potential for a given terrain unit by examining all the boreholes in that terrain unit. Therefore, the mean value of settlement, \bar{S} , for a terrain unit with M boreholes is:

$$\bar{S} = \frac{1}{M} \{ (S_B)_1 + (S_B)_2 + \dots + (S_B)_M \} \quad (4)$$

and the overall standard deviation, $\bar{\sigma}$, for the terrain unit is:

$$\bar{\sigma} = \frac{1}{M} \sqrt{(\sigma_B)_1^2 + (\sigma_B)_2^2 + \dots + (\sigma_B)_M^2} \quad (5)$$

For any required confidence level, the thaw settlement can then be stated as

$$S \pm \bar{S} + (Z_c)(\bar{\sigma}) \quad (6)$$

where Z_c is the number of standard deviations for a given confidence level.

$Z_c = 0.0$ for 50%; 1.04 for 85%; and 2.33 for 99% confidence level, using a one-sided test.

While these statistically determined data for terrain units provided the major input into final thaw settlement design, thaw settlement prediction for individual boreholes were also used for certain isolated areas.

DESIGN PROCESS

A design confidence level of 85% was adopted for the project. The appropriate predicted thaw settlements were compared to the allowable thaw settlements developed by pipe stress analyses. To arrive at the allowable thaw settlement, it was assumed that the considered settlement could occur suddenly in a stepwise fashion across an interface. This interface could occur anywhere within the terrain unit under consideration (see Johnson et al. 1982). The basic model analyzed is shown in Figure 12. The analysis was performed using a

FIGURE 12 Differential thaw settlement at a transition.

commercially available structural pipe stress model (PIPLIN-III, Structural Software Development, Inc., 1981). The allowable thaw settlement was predicted based on established project pipe strain criteria and was dependent

largely on the bearing strength of the soil beneath the pipe on the thaw-stable side and the weight of backfill on the pipe on the settling side.

The detailed design of the pipeline has been carried out for two "warm-flow" construction sections. On a kilometer-by-kilometer basis the predicted and allowable settlements were compared considering first of all a standard depth of burial (pipe invert approximately 2 m below original grade). Where the predicted settlement exceeded the allowable settlement, the design proceeded toward selecting one of the alternate design modes to mitigate the thaw settlement problem.

Mitigative Design Modes

The first option was to bury the pipe deeper. This mode was particularly appropriate where icy surface soils extended to depths greater than standard pipe burial depth, but were underlain at reasonable depth by dense, thaw-stable soil types. The practical limits to the depth of ditch are normally 3.5 to 4 m, though in special situations up to 5 or even 6 m was considered. Where icy soils extended to depths greater than this, for significant lengths of pipeline, a combination of deep burial with a foamed bedding material was considered. The purpose of the foam (polyurethane was to provide, in effect, a weaker bearing support on the thaw-stable side of the basic model (Figure 12). The allowable settlement could be effectively increased by the amount the foam could compress.

In particularly ice-rich terrain units, such as lacustrine silts and clays and organic deposits, the design selected was invariably an above-grade mode. The concrete-restrained mode evolved during the design process as the preferred above-grade design mode. In this mode, the pipe was essentially placed on an insulated gravel pad laid on the cleared ROW, and specially designed, insulated concrete weights placed over the pipe (see Figure 13). Further details of this design mode are presented by Carlson and Butterwick (1983).

Another special design considered was a buried insulated pipe. This mode was only considered where an above-grade mode would otherwise intersect a highway, and a buried crossing of the highway is required.

VESICLES IN THIN SECTIONS OF PERIGLACIAL SOILS FROM NORTH AND SOUTH NORWAY

Charles Harris

Department of Geology, University College Cardiff, Cardiff CF1 1XL, U.K.

Micromorphological investigations of silty sand soils from a solifluction slope in Okstindan, North Norway, revealed vesicles apparently identical to those encountered in samples from the centers of sorted circles at Gråsubreen, Jotunheimen, Norway. Vesicles appeared in thin section as smooth-walled spherical voids. Walls were clean with no evidence of illuvial silt linings. Other elements of the micromorphology were disrupted by vesicles, including silt coatings on sand grains and silt droplet fabrics. On the basis of simple laboratory experimentation and field observation it was concluded that vesicles resulted from the following conditions: (1) low initial bulk densities during thaw of ice-rich soils; (2) high moisture contents, but air present in larger pores; (3) disturbance of the sensitive soil due to thaw-consolidation, or to the process of sampling. Disturbance caused repacking of grains, reduction in void ratio, increase in pore water pressures and liquefaction. Air in larger voids and pores became bubbles, forming the vesicles observed in thin section.

INTRODUCTION

There have been a number of reports of arctic and alpine soils containing spherical bubble pores or vesicles in their upper layers. The occurrence of vesicles has, for instance, been recorded in the Mesters Vig area of Greenland (Ugolini 1966), the islands of the Canadian High Arctic (Bunting and Jackson 1970, Bunting and Fedoroff 1974, Bunting 1977), Spitzbergen (Chandler 1972), Elephant Island, South Shetlands (O'Brien et al. 1979), northern Norway (Harris 1977, Harris and Ellis 1980) and South-east Iceland (Romans, Robertson and Dent 1980). Vesicles are commonly developed in areas of patterned ground such as sorted and nonsorted circles and gelifluction lobes and terraces where soils are immature, either due to environmental factors or recent exposure of the surface to pedogenesis, and where soils are wet, at least during the thaw period.

In this paper vesicles are described from a soil developed on the tread of a turf-banked solifluction lobe in Okstindan, North Norway, and from the fine-grained centre of a sorted circle below the glacier Gråsubreen in Veodalen, Jotunheimen, southern Norway (Figure 1). On the basis of field observations and simple laboratory experimentation a mechanism of vesicle formation is proposed.

SITE DESCRIPTION

In Okstindan solifluction lobes are developed on an east-facing slope of gradient 5° - 15° an altitude of around 710m, some 2km to the east of the outlet glacier Austre Okstindbreen (Figure 1a). Mean annual temperatures are approximately -0.5°C (Harris 1982), and annual freezing has been measured to depths in excess of 1.5m (Harris 1974). Permafrost is absent. At Gråsubreen in the Jotunheim, sorted circles some 3m in diameter are present at an altitude of around 1,860m immedi-

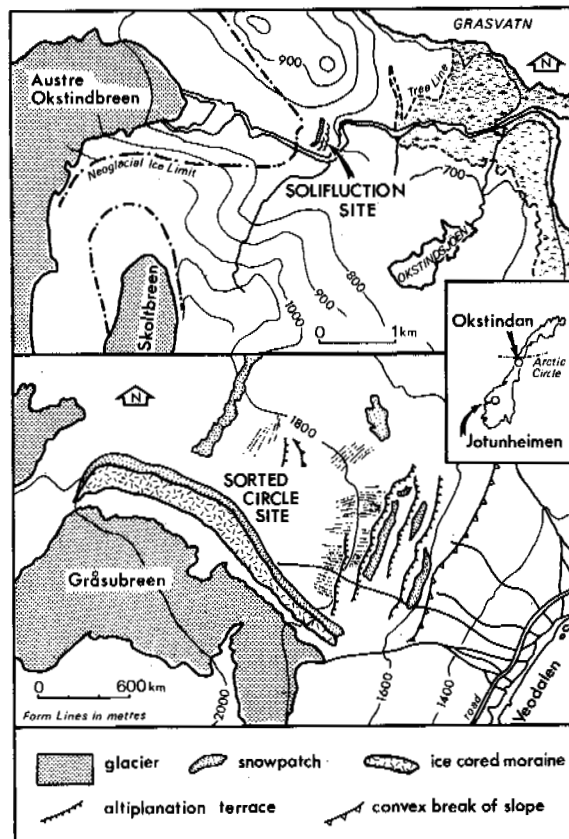

FIGURE 1 (a) Location map Okstindan (b) Location map Gråsubreen

ately in front of a large ice-cored (Østrem 1964, 1965) terminal moraine (Figure 1b). The circles consist of central islands of fines, surrounded by concentrations of coarse clasts. The coarser margins form an irregular polygonal network which grades laterally into stripes where the gradient increases. Mean annual temperature was estimated as approximately -5°C from the analysis of Green and Harding (1980). It is not known if permafrost is present at this site; none was encountered during sampling, but soil waterlogging prevented deep excavation. At both sites moisture contents were high during sampling, water being supplied by late snow patches immediately upslope in both cases.

MATERIALS AND METHODS

Silty sand tills deposited by the last major Scandinavian glaciation form the substrate at both the Okstindan and the Jotunheim sites, the tills being derived from mica schists and pyroxene granulite gneiss respectively. Grain-size determinations (Figure 2) show both soils to be frost susceptible. Liquid limits and plasticity indices are low (Okstindan site 27% and 5%, respectively; Jotunheimen site 24% and 1%, respectively) and shear strength determination for samples from the Okstindan solifluction slope revealed a peak angle of friction of 35° , with residual angle of friction between 29° and 33° , the cohesion intercept being zero in both cases (Harris 1977). Similar shear strength parameters are to be anticipated for the sorted circle site in view of its similarity in texture and Atterberg properties to the Okstindan soils. Both sites, therefore have nonplastic frictional soils whose consistency is likely to be sensitive to relatively small variations in moisture status. Unit weights for the Okstindan soil are relatively low, with an average of 1.58Mgm^{-3} (Harris 1977).

FIGURE 2 Grain size distributions with envelopes of soils susceptible to bubble pore formation

Pedological descriptions of profiles on the Okstindan turf-banked solifluction lobes were given by Harris and Ellis (1980). The thin sections

reported here are from the upper part of the slope (profile 1, Harris and Ellis 1980), where late lying snow restricts vegetation to mosses, with some *Salix herbacea* and *Carex bigelowii*. Pedogenesis is limited to a 3cm thick A_h horizon which merges into the underlying silty sand soliflucted till. At the Gråsubreen site the vegetation is largely mosses and lichens, and the pedological soil consists of a black organic crust up to 2cm thick above the frost-sorted till substrate.

Undisturbed samples were collected in 6cm^2 , 4cm deep open plastic boxes. At the solifluction site two samples were taken from three depths, 2-8cm (nominally 5cm), 22-28cm (nominally 25cm) and 47-53cm (nominally 50cm), and at the sorted circles three samples were collected from the centre of a circle at depths of 5-11cm, soil saturation preventing deeper sampling. Following impregnation, vertical and horizontal thin sections were prepared for microscopic investigation.

VESICLES

At both sites rounded bubble-like pores formed prominent elements of the soil micromorphology (Figure 3). Vesicles were most numerous in the near-surface samples from Okstindan, were less numerous at 25cm, and were not observed in samples from 50cm depth. Samples taken from the center of the Jotunheim sorted circle showed a similar frequency to the near-surface samples in Okstindan. One hundred vesicles were measured for each sample, and results are summarized in Table 1.

TABLE 1 Dimensions of Vesicular Pores

	Okstindan 5cm depth	Okstindan 25cm depth	Jotunheimen sorted circle
mean diameter (μm)	664	390	772
maximum diameter (μm)	4000	1000	2600

At both sites vesicles were simple smooth-walled voids, approximately spherical in shape. Walls were clean with no evidence of illuvial silt linings. These pores appeared to resemble closely the bubbly pores in soils from Elephant Island, South Shetland Islands, and Iceland, described by O'Brien et al. (1979). Other elements of the micromorphology were disrupted by vesicles, including silt coatings on sand grains and lenticular concentrations of silt ("silt droplets", Romans and Robertson 1974) (Figure 3). Clearly the vesicles formed more recently than the grain coatings and silt droplets. Only one generation of vesicles was present, and they had not persisted long enough to acquire illuvial linings.

EXPERIMENTALLY PRODUCED VESICLES

During sampling at Gråsubreen, one undisturbed sample was accidentally shaken out of its container

and disturbed. Examination of this disturbed sample showed clearly visible bubbly pores, and further pores were found in a wet bulk sample taken by trowel. The possibility arose, therefore, that vesicles observed in thin section did not result directly from the soil freezing process as suggested by Fitzpatrick (1956), but rather from consolidation of the soil under wet conditions following thaw. A simple laboratory experiment tested this hypothesis.

Soil from the Gråsubreen sorted circles was placed in a plastic box 6cm square and 8cm high. The soil was lightly compacted and then thoroughly wetted. The specimen was placed with its base immersed in

a reservoir of water, and then frozen from the surface downwards. Ice segregation during freezing gave an excess water content in the frozen soil of 0.3cm^3 per cm^3 soil. Following freezing the specimen was allowed to thaw from the surface downwards, this being associated with consolidation and the shedding of excess water. The surface was then pressed firmly downwards with a rubber piston. Consolidation led to expulsion of excess water at the surface, and the specimen was transformed into a very viscous slurry. The sample was then air dried for one week, oven dried for 24 hours, and impregnated with resin prior to the preparation of vertical and horizontal thin sections. These revealed abundant vesicles, impossible to differentiate under the microscope from those observed in the field samples (Figure 3(h)). The experimentally produced vesicles had a maximum diameter of $2500\mu\text{m}$, and mean diameter $552\mu\text{m}$. This experiment was repeated using soil from the Okstindan site and again vesicles identical in form to those in the field samples were produced. A duplicate control specimen was prepared, using Okstindan soil, but not frozen or compacted. No vesicles were observed in thin sections of this control specimen. Finally, dry Okstindan soil was mixed with water to form a paste, placed in the specimen container and compacted with the rubber piston. Liquification and expulsion of water resulted, and when the dried specimen was broken open abundant vesicles up to 3.6mm diameter were found.

DISCUSSION

It is unlikely that the vesicles observed following the freezing experiments could have formed during the freezing process in the way proposed by Fitzpatrick (1956), since identical vesicles were produced simply by compacting a wet soil specimen, with no prior freezing. The specimens were also not subjected to rapid drying, such as that which generated vesicles in Devon Island, N.W.T., Canada (Bunting 1977), and initial wetting did not generate air bubbles in the control specimen, as was described by Chaplow (1974) and Romanov (1974). Bunting (1977, p.94) describes vesicular pores in the fine centres of sorted circles as "presumably best related to ejection of moisture and air migration under the stress of cryoturbation". In the experiment described here it seems likely that the observed vesicles developed due to the stresses applied during and after the thawing stage of cryoturbation rather than during the freezing stage.

The results of these simple laboratory experiments suggest the following sequence of vesicle formation:

- (1) low bulk density immediately following thaw due to incomplete consolidation. The volumes of the Gråsubreen and Okstindan soil specimens increased by 37.5% and 11.25% respectively due to ice segregation during freezing;
- (2) some drainage of excess water immediately following thaw, and prior to compaction, allowing air to enter the larger pores;
- (3) compaction under wet conditions leading to a thixotropic reaction as pore space was reduced, excess water expelled, and pore pressures consequently increased. The soil became a viscous

slurry, and pores containing air became bubbles, forming the vesicles observed in thin sections.

The vesicles observed in the field samples are considered to have developed by a very similar process.

Winter freezing in Okstindan is associated with considerable frost heave due to ice segregation (Harris 1972). At the Gråsubreen sorted circle site frost heaving in winter is suggested by the lenticular concentrations of silt observed in thin sections, considered to mark the former locations of ice lenses (Harris and Ellis 1980), and by the ice segregation observed in the laboratory experiment using soil from the Gråsubreen site. The unit weight determinations for the Okstindan site confirmed relatively low values following spring thaw, and Williams (1959) also reported low unit weights immediately following thaw in a soliflucted till in Rondane, Norway, with subsequent increase through the following summer.

During the thaw period moisture contents were high at both field sites, so that any disturbance of the low density soils, either naturally due to consolidation of the thawing soil, or due to the soil sampling procedure, was likely to cause liquefaction as grains resettled into a denser packing, reducing the void ratio and increasing pore pressures as excess pore water was expelled. Harris (1972) recorded settlement of the soil surface at the Okstindan site of up to 8.8cm during the summer thaw of 1971. Air-filled pores would, under these conditions become bubbles. Chaplow (1974) explained bubble voids in borehole samples of sand from the Lar Dam in northern Iran as resulting from liquefaction of partially saturated sand during sampling, and used the grading envelope for soils susceptible to flow slides of Andresen and Bjerrum (1968) as a guide to soils liable to develop bubble structures. The soils at both Norwegian sites described in this paper fall within the Chaplow/Andresen and Bjerrum range of grading curves (Figure 2). Chaplow found that bubble pores developed when the degree of saturation in the initial sample was in excess of 75%, but that as saturation approached 100% the lack of soil air prevented bubble formation.

The fresh appearance of the vesicles described in this paper, their lack of illuvial silt linings, and the absence of traces of former vesicles in the soil micromorphology suggests either that they do not survive from one season to the next, or that they arose purely as a result of disturbance during sampling and did not form under natural conditions. However, at the Okstindan site at least, thaw consolidation has been shown to occur, so that here conditions conducive to vesicle formation are provided naturally.

CONCLUSIONS

On the basis of field observations and simple experimentation the vesicles described in this paper are considered to result from thawing of ice-rich silty sand soils with low liquid limits and plasticity indices. Thaw-consolidation leads to thixotropic behaviour as excess water is expelled, and air present in voids or larger pores becomes bubbles. It is clear that any soil susceptible to liquefaction could form vesicles as a

result of consolidation under appropriate moisture conditions. The thawing of ice-rich soils provides particularly favourable conditions for vesicle formation, so that many micromorphological studies of periglacial soils have reported their presence. They are unlikely to greatly affect the hydraulic conductivity of the soil during thaw, for apart from being air-filled, they do not form an inter-connecting system of voids.

The presence of bubble pores or vesicles in soils from periglacial patterned ground may therefore indicate that liquefaction occurs during the thaw period. Such liquefaction is likely to form an important component in the process of formation of the patterned ground itself, especially sorted and nonsorted circles, and solifluction lobes and terraces.

COMPARISON OF THE CLIMATIC AND GEOMORPHIC METHODS OF PREDICTING
PERMAFROST DISTRIBUTION IN WESTERN YUKON TERRITORY

Stuart A. Harris

Department of Geography, University of Calgary, Calgary, Alberta, Canada T2N 1N4.

Drilling and ground temperature measurements along the Dempster Highway demonstrate that continuous permafrost is at least twice as extensive in Western Yukon Territory as previously shown on maps. An extensive belt occurs in the foothills below the St. Elias Range west of Destruction Bay, while continuous permafrost extends south to the North Fork Pass along the Dempster Highway. Between the zones of continuous permafrost are areas of discontinuous permafrost in lowland areas, with 30-80% of the landscape underlain by permafrost. The climatic predictive method is reasonably successful at predicting the permafrost distribution on small scale maps but tends to slightly underpredict the distribution in montane valleys. Cold air drainage is widespread and very marked in these areas, and may cause the anomalies. Groundwater movement is undoubtedly also important locally. The geomorphic method based on the distribution of zonal permafrost landforms is of little use in mapping the permafrost boundaries. It was the evidence used to augment the sparse ground-temperature data available to previous workers.

INTRODUCTION

Permafrost is a temperature condition of the ground where it remains below 0°C for more than 2 years. These conditions can be found occupying some very extensive areas of Canada, Alaska, the USSR, and China, and mapping them presents a considerable problem. Direct methods involving measuring ground temperatures are expensive and time-consuming, and so there is a great need for indirect methods of prediction.

In 1981, a climatic method of mapping or predicting was described based on a correlation between freezing and thawing indices, calculated from daily air temperatures, and the distribution of permafrost zones in areas of low winter snowfall (Harris, 1981). The method is potentially useful where sufficient climatic data are available from representative sites.

Subsequently, it has been shown that there is a general correlation between active zonal permafrost landforms (as defined by Tricart and Cailleux, 1950) and the freezing and thawing indices in areas of low winter snowfall (Harris, 1982a). Since many of these landforms, e.g., ice wedges and pingos, can be identified on aerial photographs taken at suitable scales, it would seem that this method involving photo-interpretation could have considerable value for small scale mapping, if it works adequately.

Recent work in determining the permafrost conditions along the proposed Alcan Gas pipeline route in southern Yukon Territory (courtesy of John Elwood and Doug Fisher, Foothills Pipe Lines (Yukon), Ltd.) and along the Dempster Highway, provides good control for the western Yukon. The purpose of this paper is to compare the actual permafrost distribution in Western Yukon Territory, as determined by drilling and ground temperature measurements, with the predictions based on the climatic and landform methods. This provides a good test of the adequacy of these two methods for prediction of permafrost in constructing small-scale maps.

METHODS USED

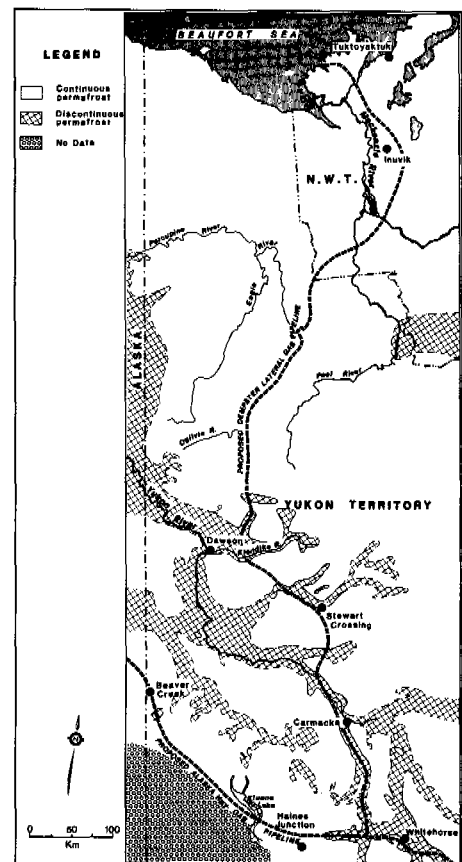

FIGURE 1 Actual distribution of permafrost in the western Yukon Territory based on ground temperature data from our 175 thermistor strings along the proposed Alcan and Dempster/Klondike pipeline routes (data courtesy of John Elwood and Doug Fisher, Foothills Pipelines (Yukon), Ltd.).

The data on permafrost conditions derived from over 50 thermistor cables along the Alcan route west of Whitehorse were used to identify and map the permafrost distribution along the Alcan route in southwest Yukon Territory (Figure 1). The data from the 125 thermistor strings emplaced between Whitehorse and Inuvik along the Klondike and Dempster highways were examined and used. Some extra readings were obtained by the writer from six key cables to check the results. Areas of continuous permafrost (defined as greater than 80% of the thermistor strings in an area proving permafrost) were separated from those with discontinuous or sporadic permafrost and mapped on 1:50,000 scale topographic maps. The boundary was then extrapolated throughout the western Yukon Territory and the adjacent portions of the Northwest Territories, using the topography, vegetation, aspect and active permafrost landforms (e.g. pingos, palsas) as a guide.

The available climatic data for the same area were examined and it was found that the number of Class A weather stations had increased substantially in 1974. All 30 stations showed under 50 cm mean winter snow covers. A check was therefore made to select two subsequent years (post-1974) for which the freezing and thawing indices were close to the long term means of four typical older weather stations. The means for 1975 and 1876 gave roughly comparable results, bearing in mind the rather wide range of individual values from year to year.

The mean daily temperatures ($^{\circ}\text{C}$) for the year for a given weather station provide the basis for calculation of the freezing index (sum of the negative values) and the thawing index (sum of the positive values). In this way, the freezing and thawing indices for all the Class A weather stations in western Yukon and the adjacent portions of the Northwest Territories for 1975 and 1976 were calculated and averaged. The results (Appendix A) were plotted on a freeze-thaw index diagram and then classified into continuous and discontinuous permafrost by the climatic method (Harris 1981). To provide extra detail, the discontinuous permafrost sector was subdivided into five equal parts (DA, DB, DC, DD, and DE) as in Figure 2. This gave greater precision to mapping the climatic zonation at the margin of the area of continuous permafrost. The latitude, longitude, and altitude of each station were used to check the homogeneity of the climatic parameters within the area, and to establish the relationship of altitude to the indices.

The distribution of landforms usually regarded as being related to permafrost conditions in the western Yukon Territory and adjacent portions of the Northwest Territories is indicated in Figure 3. Considerable detail was found in Zoltai and Tarnocai (1975) and in Hughes (1969), while other information is given in Klassen (1979). The data have been augmented by field observations and study of the aerial photographs. The occurrences of most zonal permafrost landforms were mapped for the western Yukon, although the rock glaciers were omitted since a conclusive separation of tongue-shaped and lobate forms is difficult, while too little information is available concerning which are active and which are fossil.

FIGURE 2 Mean annual freezing and thawing indices for 1975 and 1976 for the Class A weather stations in western Yukon Territory and the adjacent areas of the Northwest Territories, plotted on a freeze-thaw index diagram. Also shown are the boundaries of continuous, discontinuous and sporadic permafrost in areas of low winter snow cover. Note the way most stations from the central Yukon Plateau plot near the boundary between continuous and discontinuous permafrost. To provide closer resolution of climate in the discontinuous zone, it is divided into five equal parts labeled DA-DE (warmest).

RESULTS

The data on permafrost distribution based on the boreholes were compiled in Figure 1, and the boundaries extrapolated through the remaining portions of the western Yukon Territory. The results indicate a far larger area of continuous permafrost than previously indicated, except by Brown (1967a). A check with the drill hole logs for sites where no ground temperature cables were installed suggested that the results are correct. In view of the large number of thermistor cables (over 175) and the backup data from over 200 drill hole logs without ground temperature cables, the results should be far more accurate than the maps produced previously (e.g. Brown 1967a, 1978; Washburn 1979), which were based on measurements of about a dozen ground temperature cables, data from mines, and on landforms.

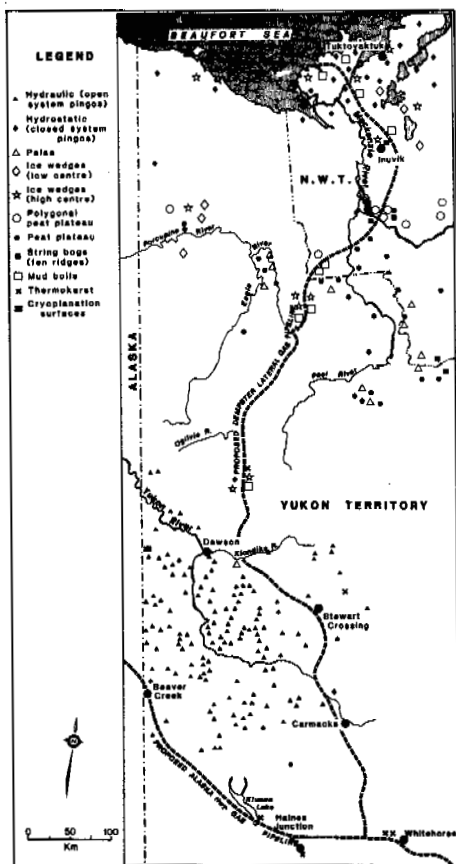

FIGURE 3 Distribution of landforms usually regarded as being related to permafrost conditions in the western Yukon Territory and adjacent portions of the Northwest Territories, based on Zoltai and Tarnocai (1975), Hughes (1969), Klassen (1979), and observations by the author. Rock glaciers are omitted, since their degree of current activity is unknown and their origin in many cases is open to question.

Comparison of the Actual Distribution of Permafrost with that Predicted by the Climatic Method

Figure 4 shows the results of (1), calculating the mean freezing and thawing indices for 1975-1976 for the class A weather stations, (2), using these to classify the stations into predicted continuous permafrost or predicted discontinuous permafrost using Figure 2, and (3), then plotting the results on a map of the western Yukon Territory. Boundaries were then interpolated and extrapolated using the topography as a guide. It was assumed that permafrost was more widespread at higher elevations, i.e., no cold air drainage occurred. The boundaries between the predicted continuous and discontinuous permafrost zones show considerable similarity to those in Figure 1.

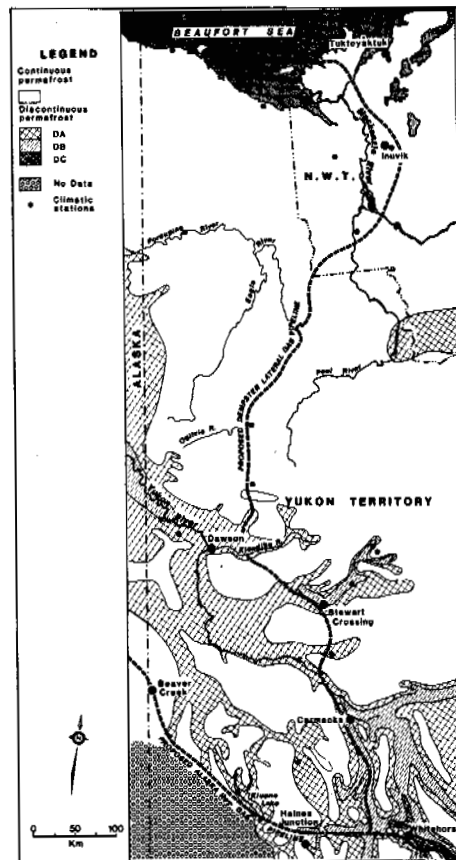

FIGURE 4 Predicted permafrost distribution using the climatic method (see Harris, 1971a). The discontinuous permafrost zone is subdivided into five equal parts as in Figure 2, but only three are found in the area. Note the similarity to Figure 1, apart from underprediction in the valleys below mountain ranges.

Thus, in general, the method of climatic prediction described in 1981 seems to work quite well, even though it disagrees with the maps of permafrost published previously (e.g. Washburn, 1979 Figure 3.3; Brown, 1978).

In detail, there are noticeable differences between Figures 1 and 4. From the Alaska border (Snag) to the west end of Kluane Lake (Burwash Landing), along the Alaska Highway, the actual distribution of continuous permafrost is more extensive than would be expected by the results of the climatic method. The same results apply in south-central Yukon. Since this is also the zone of maximum frequency of forest fires, it is probable that the distribution of permafrost in southwest Yukon is in equilibrium with its climatic environment. Disturbance and removal of vegetation would have caused the development of a

new thermal profile in the ground, in equilibrium with present-day conditions. Maximum permafrost thickness is commonly about 22 m. Again, the presence of permafrost and active thermokarst subsidence at Haines Junction in an area which was under Neoglacial Lake Alsek in the mid-late nineteenth century (Clague and Rampton, 1982) indicates that permafrost is actively forming in this century. In order to try to determine the cause of these differences, a series of extra checks were used.

Differences of grain size and lithology are known to correlate with different thermal properties (conductivity and diffusivity) (Johnston, 1981). This is a major cause of variations in thickness of permafrost, and can also determine its presence or absence in areas of discontinuous permafrost. However examination of the textures of the materials encountered in the boreholes indicates that there are two main materials present, viz.: river gravels and loess-derived silts (apart from one sample of till), based on the data in Klohn Leonoff Consultants, Ltd., 1979. Both gravels and silts occur in the floors and sides of the valley, so the materials are too homogeneous for this to be the explanation of the differences in Figures 1 and 4.

shows the results of plotting the mean freezing and thawing indices for 1975 and 1976 for the weather stations in western Yukon and the adjacent parts of the Northwest Territories against latitude. The r value will be extremely small when the regression line is nearly parallel to an axis, due to the high sensitivity of the factor. As demonstrated on the Medicine Hat/Inuvik traverse, an abrupt change in trend of the thawing and freezing indices occurs in the vicinity of Old Crow and it appears to be present on both sides of the Richardson Mountains. However, south of there, the trend for the thawing index is fairly continuous and indicates a constant relation of index to latitude right up to the foot of the St. Elias Range. This fits with previous work on the climate of southwest Yukon where Taylor-Barge (1969) has claimed that there is an abrupt change in climate between the Maritime influence of the north Pacific Ocean and the more continental interior of Yukon, which lies along the continental divide.

The freezing indices show a break in trend just north of Dawson. The change is marked and corresponds to the transition from dominantly tundra to dominantly forest. Freezing index increases more rapidly with increasing latitude under tundra vegetation. Figure 5 also shows that while the data for the thawing indices fall close to the trend line, those for the freezing index show rather more scatter. This suggests that there could be something complicating the microclimate in winter.

Harris (1982b) has shown that pronounced but sporadic cold air drainage can occur at the latitude of Fort Nelson along the valleys leading from the higher mountains. This can become extremely important in areas where the discontinuous and sporadic permafrost zones lie in the area where the cold air drainage occurs, e.g. east of Steamboat Mountain (west of Fort Nelson, B.C.).

FIGURE 5 Variation of mean freezing and thawing indices for 1975 and 1976 with latitude of the weather stations in western Yukon Territory and the adjacent portions of the Northwest Territories.

Another possible cause could be heterogeneity of the climate across the region. Both freezing and thawing indices may show abrupt change in their trends across a part of a continent, e.g., from Medicine Hat to Inuvik (Harris, 1981). Figure 5

FIGURE 6 Variation of mean freezing and thawing indices for 1975 and 1976 with altitude of the weather stations in western Yukon Territory and the adjacent portions of the Northwest Territories.

Figure 6 shows the results of plotting all the mean freezing and thawing indices for the same stations for 1975 and 1976 against altitude of the climatic station. The thawing index shows a pattern decreasing with altitude. The only exceptions to the trend lie below 350 m and represent the stations along the Arctic coast and the Mackenzie valley.

The trend of the freezing indices is quite different from that found at lower latitudes (see for example Figure 8 in Harris, 1981) in that the index decreases with altitude. There is considerable scatter, but above 700 m altitude, the rate of change is a mere 200 C°days/yr every 600 m. At lower elevations it is over 100°C days/yr every 100 m. This indicates that the winter air temperatures below about 700 m above mean sea level are considerably colder than those at higher elevations. This is consistent with the presence of cold air drainage occurring throughout the region especially during the long, cold winter nights (Marcus, 1974, Harris, 1982b).

The effects of this process on mean annual air temperatures near Stewart Crossing-Keno Hill and Dawson City and vicinity are shown in Figure 7. In both cases, the highest stations have the lowest freezing indices. The effects of the cold air drainage are so great that they even cause a reversal of the direction of the normal lapse rate at lower elevations based on mean annual temperatures (Figure 8), indicating the influence of a strong persistent winter inversion.

FIGURE 7 Changes in mean freezing (open circles) and thawing indices (solid circles) with altitude around Dawson City and at Keno Hill for 1975 and 1976.

The fact that both the freezing index and the thawing index decrease with altitude (Figure 7) makes detailed prediction of the presence or absence of continuous permafrost by climatic parameters in the Yukon Territory particularly hazardous. Re-examination of Figure 2 shows that the stations from the Yukon Interior Basin, i.e. south of Dawson City, lie straddling the boundary between the discontinuous and continuous permafrost zones. This means that any local microclimatic modifications to the temperature regime such as variations in thickness of snow cover and zones of groundwater movement can have a profound effect on the distribution of permafrost. Cold air drainage

may cause such a modification and would appear to be a probable contributing factor for the differences between the actual distribution of permafrost (Figure 1) and those predicted by using freezing and thawing indices (Figure 4). The effect of snow cover variability is minimized by the method, but the effects of zones of groundwater movement are obviously also considerable.

FIGURE 8 Change in mean annual air temperature for 1975 and 1976 with altitude for Class A weather stations around Dawson City and Keno Hill. Note the reversed slope of the lapse rate at lower elevations.

Comparison of the Actual Distribution of Permafrost with that Predicted Using Zonal Permafrost Landforms

Figure 3 shows the distribution of zonal permafrost landforms in western Yukon Territory and in the adjacent portions of the Northwest Territories. When it is compared with the actual distribution of permafrost in Figure 1, it becomes clear that only the major areas of continuous permafrost can be recognized using the variety and frequency of the landforms. Even then, it is only the areas with considerable ground ice that exhibit marked varieties and abundances of zonal permafrost landforms. The better drained alpine permafrost in the central Yukon Plateau lacks appreciable diagnostic permafrost landforms.

The area with both continuous and discontinuous permafrost present shows scattered zonal geomorphic features, mainly pingos, but these are inadequate for mapping the boundary between them. They merely suggest the presence of scattered permafrost throughout the area, which is very different to the actual distribution (see Figure 1).

CONCLUSIONS

Data from thermistor strings in boreholes along the proposed pipeline routes show that permafrost is much more widespread in western Yukon Territory than previously suspected (Figure 1). Continuous permafrost extends throughout the region, although discontinuous permafrost is found in the lower parts of the Yukon River valley and again near Whitehorse.

It is clear from a comparison of Figures 1 and 4

that the climatic method using freezing and thawing indices for weather stations in areas of low winter snowfall works fairly well in predicting the distribution of present day permafrost on small scale maps. However, in southern Yukon, variations in soil moisture and snow cover, and the presence of localized cold air drainage in winter probably cause an extension of the zone of continuous permafrost downslope into valleys below high mountains, e.g. along the foot of the St. Elias range from Snag to Burwash Landing.

As can be seen in Figure 2, the climate of the western Yukon Interior Basin is borderline between continuous and discontinuous permafrost. This explains why the prediction of permafrost is so difficult here. Both the freezing index and the thawing index decrease with altitude, unlike the situation in areas without appreciable cold air drainage, so that the vertical zonation of permafrost is weaker.

The geomorphic method of predicting permafrost works well for the zone of icy continuous permafrost in the north and also for showing that scattered permafrost occurs throughout the area. However, it fails to provide enough data for mapping the boundary between continuous and discontinuous permafrost and also fails to separate dry, well drained continuous permafrost from areas with sporadic icy permafrost. Thus the climatic predictive method is far superior.

THE ORIENTATION AND EVOLUTION OF THAW LAKES,
SOUTHWEST BANKS ISLAND, CANADIAN ARCTIC

D. G. Harry¹ and H. M. French²

Canada K1N 6N5

On southwest Banks Island, the melt-out of ice within unconsolidated permafrost sediments has resulted in the formation of numerous thaw lakes. A majority of basins are oriented perpendicular to prevailing winds and possess a D-shaped outline which is in equilibrium with wind-generated geomorphic processes. In particular, a strong relationship exists between lake morphology and the storm wind regime during the summer period of open water conditions. Thaw lakes in this area cannot be interpreted within the traditional "thaw lake cycle" and appear to represent quasi-equilibrium landforms. Shoreline erosion results in asymmetrical expansion rather than a lateral migration of the basin. Lake drainage occurs primarily by catastrophic outflow, following basin capture or truncation by coastal retreat.

INTRODUCTION

Thaw lakes develop by thermokarst subsidence of ice-rich permafrost. Their widespread occurrence has been reported from lowland tundra regions of Alaska, Siberia, and Arctic Canada (e.g., Sellmann et al. 1975, Tomirdiario and Ryabchun 1978, Bird 1967 pp. 211-216). The conditions under which they evolve are, however, poorly understood and many of the questions raised by Black (1969), in a review of the early literature on the subject, remain unanswered. In particular, the common development of a preferred long axis orientation, first described in North America by Black and Barksdale (1949), is still open to interpretation (e.g., Carson and Hussey 1960, 1962, Rex 1961, Mackay 1956, 1957). Since the development of a preferred orientation is not restricted to thaw lakes (Kaczorowski 1977, Price 1968), it follows that the presence of permafrost serves only to modify the action of essentially azonal processes.

This paper describes the evolution of oriented thaw lakes within the Sachs and Kellett drainage basins of southwest Banks Island (Figure 1). Observations of contemporary lakes and drained lake basins in this area permit an evaluation of the traditional "cycle" of thaw lake evolution (Britton 1967). An alternative model is proposed, based upon the identification of an equilibrium basin morphology which develops in response to currently active lacustrine processes.

LAKE DISTRIBUTION

High concentrations of lakes occur in two major areas of southwest Banks Island. Southeast of Sachs Harbour, the Sachs River lowlands are characterized by a number of large lakes, greater than 1.0 km in diameter, together with numerous smaller tundra ponds (Figure 2). Most of this area has a lake cover in excess of 20%, rising in some places to over 50%. North of Sachs Harbour, lake cover exceeds 20% in parts of the Kellett River valley,

with highest concentrations occurring on low terraces above the present floodplain. Numerous small ponds occupy low-centered polygon sites, while larger lakes have formed apparently by basin coalescence following breaching of the polygon ramparts (Figure 3).

Both areas are underlain by outwash sediments, deposited when the late-Pleistocene ice margin lay to the east of Sachs Harbour (Vincent 1982). Permafrost is continuous on Banks Island and probably extends to depths in excess of 500 m (Taylor et al. 1982); however, it is likely that open taliks exist beneath the larger lakes and principal river channels in the Sachs River lowlands (Harry 1982). The surficial sediments are ice-rich, and are characterized by the development of multiple ice-wedge systems (French et al. 1982).

ORIGIN AND AGE

The coastal truncation of thaw lakes in the Sachs River lowlands enables stratigraphic studies to be undertaken of their age and evolution. A thermokarst origin is indicated by the vertical compression of stratigraphic units beneath many basins and by the reduced ice content of the sediments (French and Harry in press). Typically, sediments beneath drained lake basins contain 40-50% less excess ice than equivalent materials outside the basins. Ground ice may constitute nearly 60% by volume of the upper 8.0 m of permafrost in this area, and thawing of this material would result in subsidence of at least 3.0 m. This is consistent with stratigraphic observations beneath drained basins, which suggest an average thaw settlement of 5.0-6.0 m.

Several radiocarbon age determinations relate to the age of thaw lake initiation in the Sachs River lowlands. Organic material collected from the basal horizon of lacustrine sediments beneath one drained basin yields a ¹⁴C date of 8560 ± 210 years B.P. (GSC-3292). At a second locality, a ¹⁴C date of 8280 ± 140 year B.P. (GSC-2246) has

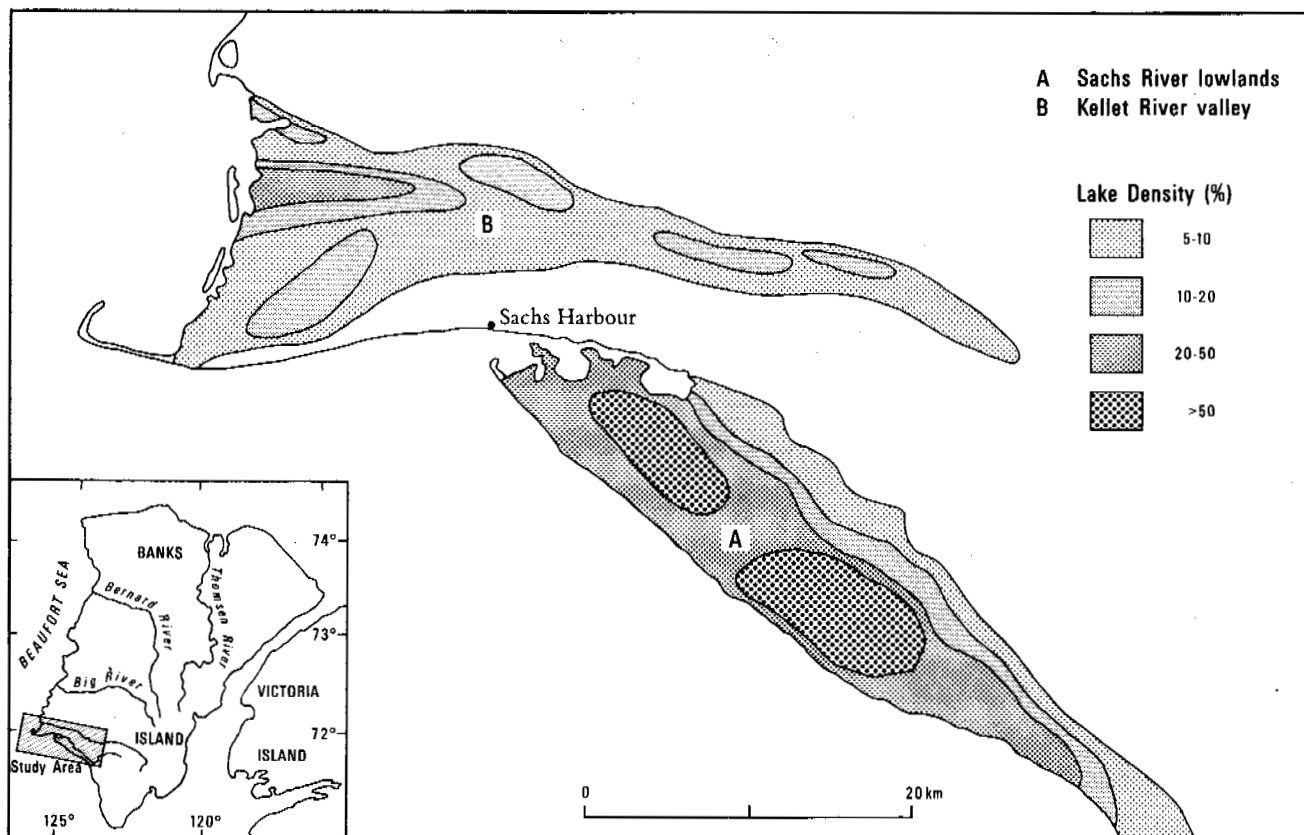

FIGURE 1 Location map of southwest Banks Island, showing distribution of thaw lakes. Density is expressed as percentage lake cover per 25 km².

been obtained from peat underlying lacustrine material (Vincent 1980). Third, blocks of fibrous organic material, contained within silts beneath a lake basin 4.0 km west of Sachs Harbour, yield a ¹⁴C date of 9490 ± 80 years B.P. (GSC-2364). These dates suggest that many lakes were initiated approximately 8000-9000 years B.P. This period corresponds to an early phase of the mid-Holocene climatic optimum, during which warmer air temperatures may have triggered the melt-out of ground ice.

The age of thaw lake development in the Kellett River valley has not yet been determined. However, the observed influence of ice wedge polygons on basin location suggests that lakes in this area may have been initiated during a period of cold climate conditions. At that time, the formation of a polygon network on the terrace surface would have facilitated the ponding of water bodies and the initiation of self-sustaining thermokarst.

EQUILIBRIUM MORPHOLOGY

Many thaw lakes possess an equilibrium shape which, in its simplest form, is expressed as a preferred long-axis orientation (e.g., Carson and Hussey 1962, Mackay 1956). Random sampling from 1:60,000 scale air photographs indicates that 84% of lakes in the Sachs River lowlands and 97% of

lakes in the Kellett River valley have a measurable long-axis orientation (defined by a length-width ratio greater than 1.1). Mean lake elongation is 1.53 in the Sachs River lowlands, as compared to 1.92 in the Kellett River valley. This disparity is partly accounted for by the prevalence of basins in the latter area which have coalesced in the direction of elongation. Lake orientation patterns are similar in the two areas, with a major northeast-southwest component and a minor perpendicular component (Figure 4). Lakes in the Kellett River valley display a particularly strong preferred orientation, with approximately 60% of long axes possessing azimuths between 230° and 240°.

Detailed morphological analysis was based on the identification of commonly occurring lake shape categories. These were defined as circle, oval, ellipse, and rectangle. A D-shaped class was added to describe highly asymmetrical elliptical lakes, and a "complex" category was established to include irregular or multiple basins. Lake shape in each area was determined by visual comparison of these standard categories to 100 lake outlines randomly sampled from 1:60,000 scale air photographs. In the Sachs River lowlands, elliptical or D-shaped morphological types are most common (Table 1). In the Kellett River valley, morphology is frequently complex, reflecting the high percentage of coalescent basins. However, over 50% of lakes possess a D-shaped element.

FIGURE 2 Typical thaw lake terrain in the Sachs River lowlands. Note the D-shaped morphology of many lakes and the numerous drained basins. Detail of the outlet channel at locality A is shown in Figure 7. Lake B drained catastrophically in January 1977.

FIGURE 3 Thaw lakes developed on terraces of the Kellett River. Note occurrence of small lakes within ice-wedge polygons and larger basins which have coalesced along a northeast-southwest axis.

TABLE 1 Lake Shape Classification, Southwest Banks Island

Basin Morphology (%)	Kellett River Valley (%)	Sachs River Lowlands (%)	Total (%)
D-shape	52.0	22.0	37.0
Complex	18.0	17.0	17.5
Ellipse	4.0	30.0	17.0
Rectangle	18.0	12.0	15.0
Oval	6.0	13.0	9.5
Circle	2.0	6.0	4.0
Total	100.0	100.0	100.0

Under equilibrium geomorphic conditions, it is probable that a lake basin developed upon a homogeneous surface will possess an outline consisting of a number of smoothly curved bays. This form should be widespread and developed upon a range of surficial materials. On southwest Banks Island, lakes of the D-shaped category most consistently satisfy these criteria. The D-shape is, in fact, curvilinear; the "straight" segment forms approximately half of an extremely flattened ellipse, while the opposing "bow" segment forms a broad semi-ellipse or semicircle. Morphometric analysis of D-shaped lakes of varying size in the Kellett River valley indicates only slight variation from the mean shape shown in Figure 5a. It is suggested, therefore, that this shape represents the equilibrium form of thaw lakes on southwest Banks Island.

Many lakes are oriented perpendicular to the prevailing wind direction during the July-September period of open water (see Figure 4). Directional wind data recorded at the Sachs Harbour meteorological station between 1971 and 1977 display a bimodal frequency distribution, dominated by northerly and southeasterly components. The mean long-axis orientation of lakes bisects the vector resultants of this opposed wind regime. In particular, the long axes of D-shaped lakes, which extend parallel to the "straight" shoreline segment, have an orientation almost exactly perpendicular to the northwest and southeast wind resultants. Similar relationships between lake orientation and wind direction exist elsewhere, especially in parts of northern Alaska and the Mackenzie Delta.

These observations suggest that an understanding of equilibrium lake morphology may be based on models of wind-generated wave and current distributions as first proposed by Livingstone (1954) and Rex (1961). It has been shown that the equilibrium form of a shoreline developed in unconsolidated sediment is a cycloid, within which erosion is greatest in zones oriented at 50° to wave approach (Bruun 1953). Mackay (1963 pp. 46-55) described a simple process-response model of lake morphology, based on the assumption that winds from each compass point tend to develop cycloidal bays. In this way, equilibrium morphology may be regarded as the integrated form of a number of cycloids of different size.

This model was applied to thaw lake morphology

FIGURE 4 Thaw lake orientation, southwest Banks Island. Sample size for each area is 100; R_1 and R_2 are opposed vector resultants of the summer storm wind regime at Sachs Harbour.

on southwest Banks Island, using seasonal wind data from Sachs Harbour. Predicted lake morphology is elliptical, with a length-width ratio of 1.23 and a long-axis azimuth of approximately 247° . Although this provides a reasonable first approximation to observed lake morphology, a closer correspondence is obtained when storm wind data are used. Storm events are defined, following McCann (1972), as periods during which hourly wind speed is 20 kn (37 km/h) or more for at least three consecutive hours. In this case, the model predicts a D-shaped lake, with a length-width ratio of 1.54 and a long-axis azimuth of approximately 237° (Figure 5b). The significantly better fit suggests that storm events play a major role in shoreline evolution.

Field observations of thaw lakes in the Kellett River valley tend to support this model. Shoreline characteristics may be interpreted with respect to the inferred pattern of wind-generated littoral drift. At the northeast and southwest corners, where maximum rates of littoral drift are expected to occur, shoreline morphology is predominantly erosional. The 10-50 cm high shoreline bluff is undercut and terrace gravels are exposed in the lake bottom. By contrast, the "straight" shoreline corresponds to a zone of minimum littoral drift and is characterized by broad, low-angle depositional flats. Shoreline morphology is therefore consistent with the energy environments predicted by Rex's (1961) model of lake circulation.

LAKE DRAINAGE

Many lake basins, especially within the Sachs River lowlands, are either partly or completely drained. Two models of lake drainage may be

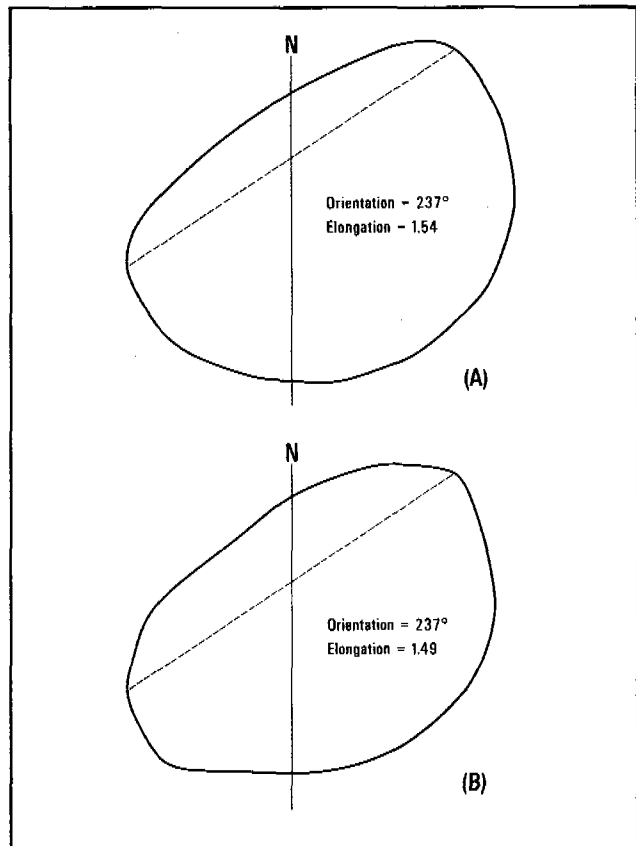

FIGURE 5 Thaw lake morphology, southwest Banks Island. (a) Observed morphology, based on analysis of five D-shaped lakes in the Kellett River valley. (b) Predicted morphology, based on calculation of equilibrium bays related to the summer storm wind regime at Sachs Harbour.

considered. The first consists of gradual infilling and segmentation (e.g., Kaczorowki 1977 p. 111), while the second consists of catastrophic outflow, following lake tapping or truncation by coastal retreat (e.g., Mackay 1979 p. 31, Walker 1979, Weller and Derksen 1979). On southwest Banks Island, evidence points strongly to the importance of the catastrophic outflow model.

Catastrophic lake drainage in the Sachs River lowlands has occurred as a result of tapping by headward erosion of streams along ice wedges, coalescence with a basin at a lower elevation, or coastal retreat (Figure 6). Once flow is initiated through the new outlet, drainage may be extremely rapid, resulting in the formation of box-canyon outlet channels. These are characterized by steep lateral bluffs and flat floors, which may be incised into the former lake bed (Figure 7).

Under certain circumstances, buried ice bodies may provide subsurface outlets for lake drainage. For example, one lake located approximately 40 km southeast of Sachs Harbour (see Figure 2, Lake B) experienced catastrophic subterranean drainage in January 1977 (David Nasogaluak, personal communication). While this may be common in areas of thin or discontinuous permafrost, resulting in the

FIGURE 6 Drained basin truncated by sea cliffs, approximately 30 km southeast of Sachs Harbour. Note the deep gully eroded during lake drainage.

FIGURE 7 Box canyon drainage channel, eroded into the lake floor following basin capture (see Figure 2, locality A). Note figures for scale.

formation of thaw sinks (Hopkins 1949, Tedrow 1969), it is rarely reported from regions underlain by thick, continuous permafrost. This lake lies within an area of morainic topography, attributed to the Sand Hills Readvance (Vincent 1982), part of which may be ice-cored (Harry 1982 pp. 88-99). It is possible, therefore, that lake drainage resulted from thermal contraction cracking, allowing water to escape into an ice cave.

DISCUSSION AND CONCLUSIONS

The concept of a thaw lake cycle, consisting of sequential stages of initiation, expansion and drainage is well established (e.g., Billings and Peterson 1980, Britton 1966, Everett 1981, Tedrow 1969). The results of this study suggest, however, that such models are by no means universally applicable. A number of alternative models of thaw lake development are possible, reflecting a delicate equilibrium between process, materials, and morphology.

On southwest Banks Island, thaw lakes appear to have originated either by melt-out of ground ice

during a mid-Holocene period of climatic amelioration, or by ponding within ice-wedge polygons developed under cold climate conditions. In the absence of topographic control, subsequent lake expansion is strongly influenced by wind-related patterns of wave and current erosion. This results in the development of a preferred long-axis orientation and D-shaped equilibrium morphology. The sensitivity of this process is demonstrated by the relative rarity of oriented lakes elsewhere on Banks Island. The development of preferred orientation appears dependent on an opposed summer wind regime, unmodified by local topographic effects.

It has been suggested that the processes responsible for thaw lake orientation may also result in migration of the lake basin across the tundra surface (e.g., Tedrow 1969, Tomirdiario and Ryabchun 1978). No geomorphic or stratigraphic evidence for this is found on southwest Banks Island. Wind-generated patterns of shoreline erosion result in asymmetrical expansion, to form D-shaped lakes, rather than causing an overall translocation of the basin. Oriented thaw lakes in this area appear, therefore, to represent quasi-equilibrium landscape elements.

ACKNOWLEDGMENTS

Geomorphological investigations on Banks Island are being supported by the Natural Sciences and Engineering Research Council (Grant A8367), the Polar Continental Shelf Project, Department of Energy, Mines and Resources (Project 34-73), and the University of Ottawa Northern Research Group.

RELATIONSHIPS BETWEEN ESTIMATED MEAN ANNUAL AIR AND
PERMAFROST TEMPERATURES IN NORTH-CENTRAL ALASKA

R. K. Haugen¹, S. I. Outcalt², and J. C. Harle³

¹U.S. Army Cold Regions Research and Engineering Laboratory
Hanover, New Hampshire 03755 USA

²Department of Geological Sciences, University of Michigan,
Ann Arbor, Michigan 48109 USA

³Alaska Pipeline Service Company, Anchorage, Alaska 99512 USA

Mean annual air temperatures (MAAT) are estimated for a transect from central to northern Alaska. The estimated MAAT are compared to mean annual ground temperatures (MAGT) representative of upper permafrost temperatures. The estimation of MAAT for the remote and topographically complex transect area was based on trend surface estimates of numerous short-term (1-7 years) temperature records obtained from climatic stations operated by research projects and longer records from existing National Weather Service stations. The standard error of the estimated MAAT falls within a degree (C) of observed MAAT for stations with long-term records. The MAGT are based on subsurface thermistor measurements made at construction sites and are therefore from disturbed terrain, but data were selected to minimize the effects of disturbance. MAGT measurements ranged from -7.5°C in the north to -0.7°C near Fairbanks. Predicted MAAT ranged from -11.5°C at Prudhoe Bay to -4.5°C in the Fairbanks area. A simple regression relationship showed MAGT to average 3.6°C higher than MAAT. This study suggests that, based on estimated MAAT and MAGT values, the boundary between the zones of continuous and discontinuous permafrost is located at or slightly north of the continental divide at Atigun Pass.

Our understanding of the relationships of permafrost distribution and air temperature in central and northern Alaska is limited by the lack of available direct observations. For the most part, permafrost temperature observations have been confined to populated areas in interior Alaska and in the northern coastal regions. Similarly, long-term observations of air temperature are scarce, and are mostly representative of populated lowland or coastal areas.

Beginning in 1975, climatic data were collected at sites along the route of the Trans-Alaska Pipeline System extending from the Yukon River to the Arctic Ocean. These measurements, together with data from additional remote upland sites in interior Alaska, have been summarized (Haugen 1982) and provide a data base from which mean air temperature values can be established for this poorly known climatic region of north-central Alaska.

Following construction of the Trans-Alaska Pipeline, thermistor strings were installed at selected locations along the pipeline to monitor the performance of its engineering structures. These sites are located in both discontinuous and continuous permafrost zones (Ferrians 1965). Most of these temperature measurements were associated with thermal disturbances. Only a few of the subsurface thermistor arrays were judged to be sufficiently free of the influence of the pipeline or its associated structures to provide subsurface temperatures for comparison with the regional air temperature data. The objectives of this paper are to present a method of estimating air temperature values for a region of diverse terrain and climate

and to examine the relationship of mean annual air temperature to ground temperature measurements.

REGIONAL CLIMATE

The Alaskan interior is a zone of temperature extremes and of relatively high precipitation compared to the Arctic (Bowling 1979). During the summer, storms track through the region from the south or southwest. Most summer precipitation is of the convective type and is widely scattered and variable in amount. During the winter, the interior is dominated by relatively dry Continental Polar air masses, and sinking cold air creates high atmospheric pressure. Occasionally, maritime air intrudes into the area from the west or southwest, causing major snowstorms and, rarely, winter rain. The alpine areas within the interior typically have less extreme temperatures but higher precipitation than the forested areas at lower elevations.

North of the continental divide is a region of extremely low winter temperatures, low summer temperatures, and relatively low precipitation. Unlike the continental interior, this is a region where wind is a major environmental factor throughout much of the year. Although winds rarely exceed 17 m/s on the Arctic Coastal Plain, calms are also rare.

Average annual air temperatures range from -11.5°C at Prudhoe Bay to -3.5°C at Fairbanks. The temperatures are some of the most extreme encountered on the North American continent. Extremely low temperatures (<-50°C) recorded at valley

stations in the southern foothills of the Brooks Range (e.g. Prospect, Coldfoot, Dietrich) are the result of inversions of the vertical temperature profile, caused by cold air draining downslope. The higher elevations, represented by Gobbler's Knob, Chandalar Shelf, and Atigun Pass, are above the average height of the inversion and have higher average winter temperatures. The lower summer temperatures at the high-elevation sites reflect a normal decrease of temperature with elevation. At least half the stations have summer maximum temperatures over 30°C for an annual range of more than 80°C.

APPROACH TO ESTIMATING TEMPERATURES

The successful estimation of air temperatures over an area of complex topography requires (1) a method for filling in short gaps in the data base which occur at many of the remote sites, (2) a procedure for adjustment of a short record (in this case, 2 to 7 years) to standard 30-year normal values, and (3) the development and testing of methods for extrapolating site-specific air temperature data to locations with differing elevations and ultimately differing slopes and exposures. The initial effort was to estimate mean monthly air temperatures and freezing and thawing degree-day accumulations for the Arctic Slope (Haugen 1982). Although that area is not topographically complex, the sparsity of inland stations created problems. However, simple regression analysis, utilizing distance from the ocean, or multiple regression, using latitude, longitude, and elevation as independent variables, proved reasonably successful for this region. The technique was less successful for the topographically complex areas of central Alaska, primarily because of the lack of data. The present approach treats a 600 x 800 km area extending northward from the latitude of Fairbanks to the Arctic Ocean (SW corner 64.0°N, 158.0°W).

Air Temperature

The stations used in this analysis (Figure 1) were operated by the National Weather Service and

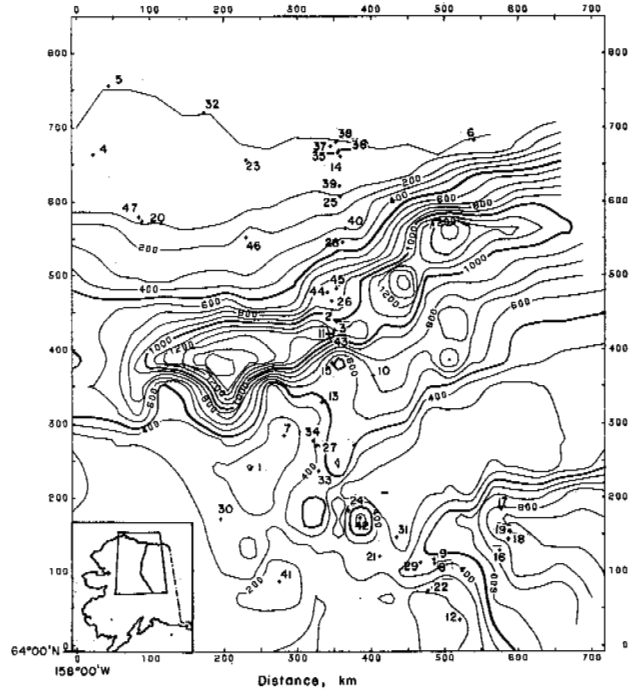

FIGURE 1 Topography of study area. Distance from point of grid origin at 64°N, 158°W used to determine temperature values (Equations 1 and 2). Numbers are keyed to station data, Table 2.

CRREL. Most of the remote stations began operation in 1975 or 1976 and have continued at least intermittently since then. Fewer data were collected in the winter than in the summer because of the difficulty of servicing the instruments in winter. It was decided that the existing data base could be most effectively utilized for comparison with permafrost temperatures by considering only the warmest month (TMAX) and the coldest month (TMIN). TMAX and TMIN are not always for the same month each year. The determination of mean annual temperature is based on the sum of TMAX + TMIN divided by 2 for the period of station record. A comparison of MAAT

TABLE 1 Comparison of mean annual air temperatures based on long-term records and short-term coldest and warmest month.

Period of record	Barrow 1941-70	Barter Island 1948-70	Bettles 1952-70	Fairbanks 1941-70
Long-term average of 12 months	-12.6	-12.7	-5.9	-3.5
1975-81 average of TMAX-TMIN month	-11.7	-12.0	-5.6	-3.8

Grid origin: 64.00°N, 158.00°W

derived in this manner with MAAT calculated in the usual manner, based on the mean of 12-monthly temperatures for stations with available records, is shown in Table 1. The differences in MAAT according to the two methods are usually less than 1°C. TMIN temperatures during the 1975-1981 period were 1.7°-3.1°C higher than long-term mean temperatures calculated in the same fashion (i.e. based on the coldest month each year). TMAX temperatures were all less than 1°C higher in this comparison.

At least one year of TMIN data was available at 32 stations and TMAX was available at 47 stations (Table 2). Matrices by location consist of maximum (TMAX) and minimum (TMIN) mean monthly temperatures for each year. Missing values are computed accord-

ing to the average of departures from the regional climate for those years when data does exist. The matrix has the following form:

	1975	1976	...	1981	Departures for all years
Allakaket	T(1,1)			T(1,NK)	D(1)
.					
.		T(L,K)			D(L)
.					
Umiat	T(NL,1)			T(NL,NK)	D(NL)
Regional means	C(1)	C(K)		C(NK)	

FIGURE 2 Cold month air temperature map. Shaded areas represent elevations above climatic data sample population.

FIGURE 3 Warm month temperature map. Shaded areas as in Figure 2.

The row index is L , representing the location, and the column is K , representing the year. The mean monthly temperature of the region during a given year is the mean value of the entries in each column excluding the missing matrix element. Thus, there is for each year a mean value in what might be termed the regional climate vector $C(K)$. The average deviation $D(L)$ at a climate station is the mean value of $[T(L,K) - C(K)]$ for each station, again excluding the missing entries in the matrix. When replacing a missing entry in the matrix, the best estimate would be the sum of the monthly mean climate for the region $C(K)$ and the average value of the difference between that station value and the regional climate mean when those data were available. The replacement of a missing matrix element is then $T(L,K) + C(K) + D(L)$.

A stepwise regression model is used to predict $TMIN$ and $TMAX$ values for any location in the geographic grid. The model that best fitted the data is described by Equations 1 and 2,

$$TMIN = -22.3 - 0.303 \cdot 10^{-1}Y + 0.283 \cdot 10^{-4}Y^2 + 0.752 \cdot 10^{-5}Z^2$$

$$R^2=0.65 \text{ SE} = 2.7^\circ\text{C} \quad (1)$$

$$TMAX = 12.9 + 0.265 \cdot 10^{-1}Y - 0.346 \cdot 10^{-2}Z - 0.494 \cdot 10^{-4}Y^2$$

$$R^2=0.83 \text{ SE} = 1.3^\circ\text{C} \quad (2)$$

where Y is the distance north (km), Z is the elevation (m), and SE is the standard error of estimate. Distance east was not statistically significant in this model. Elevations within the study area are shown in Figure 1. A spatial representation of the $TMIN$ and $TMAX$ equations is shown in Figures 2 and 3, respectively. Large variations of $TMIN$ and $TMAX$ over the short distances shown in these figures (e.g. the Fairbanks area) are due to elevation differences and should be viewed in comparison with the topographic map (Figure 1).

Ground Temperature

Temperatures representative of the upper permafrost were obtained from thermistors installed at locations between the Tanana River and the vicinity of Prudhoe Bay. These temperature sites were designed to monitor the performance of the oil pipeline and its associated structures in areas of ice-rich permafrost. The thermistor locations utilized in this analysis were selected to minimize the effects of surface disturbance or of the pipeline itself. Unfortunately temperature data are not yet available from areas adjacent to the pipeline route in essentially undisturbed areas. Therefore, the data used probably differ from data for the adjacent undisturbed ground. Temperatures obtained near the buried hot pipeline or near vertical support members (VSM's) that were artificially cooled by thermopiles were not used. At some of the sites with thermopiles, two thermistor strings were installed, one near the VSM and the other some distance (1-10 m) away. In these cases, the temperatures at a distance from the VSM were used.

The depths of the subsurface observations used varied from a minimum of 3.5 m in the north to about 16 m at some of the southern sites. Most temperature observations were obtained bimonthly over a period of 2 or 3 years. For each site, the maximum

RESULTS AND DISCUSSION

and minimum temperatures recorded by the deepest thermistor over the entire observation period were averaged to obtain the mean value. The first-year data were not used, to avoid the thermal effects associated with installation. Snow depth was recorded at the time of observation but was not considered in this study.

FIGURE 4 Mean annual air temperature (MAAT) map. Shaded areas as in Figure 2.

FIGURE 5 Mean annual ground temperature (MAGT) map. Shaded areas as in Figure 2.

Mean annual air temperatures were estimated for locations where permafrost temperatures were available along the pipeline transect. This was done by averaging the TMAX and TMIN values obtained from Equations 1 and 2 for the distance north of $64^{\circ}50'N$ latitude and the elevation of the site. The geographic distribution of estimated MAAT in the study area is shown in Figure 4. A simple regression relationship $Y = 1.25 + 0.71X$ between MAAT (X) and the upper permafrost temperature (Y) based on the data shown in Figure 4 indicates an average temperature difference of $3.6^{\circ}C$ and a coefficient of determination (r^2) of 0.85. This difference falls within the range of 1° to $5.5^{\circ}C$ (average $3.3^{\circ}C$) generally assumed between air and upper permafrost mean annual temperature (Brown and Péwé 1973, Hydrological Atlas of Canada 1978, Plate 32). The mapped values of MAGT are shown in Figure 5. A profile showing the relationship from Fairbanks to Prudhoe Bay is shown in Figure 6.

Subsurface temperature data available for the higher elevations in the Brooks Range were influenced by the buried pipeline: they were above freezing. Therefore, normal temperature measurements from Chandalar Shelf and Atigun Pass were not used in the predictive MAGT equation. Existing maps show the transition from discontinuous to continuous permafrost (>90% on an area basis) south of the continental divide (Ferrians 1965, Brown and Péwé 1973). Recent observations from borings suggest this line more properly belongs in the vicinity of the continental divide (Kreig and Reger 1982). The MAAT isotherm delineating these two zones is in the range of $-7^{\circ}C$ (Ferrians 1965) to $-8.5^{\circ}C$ (Brown and Péwé 1973), which corresponds to an approximate subsurface permafrost temperature of $-4^{\circ}C$ to $-5^{\circ}C$. Using Equations 1 and 2, we find an estimated MAAT for Atigun Pass of $-6.3^{\circ}C$ and, applying the simple regression relationship, we obtain a mean annual ground temperature of $-2.7^{\circ}C$. Chandalar Shelf, just to the south of Atigun Pass at an elevation of 1000 m, indicates a MAAT of $-5.2^{\circ}C$ and MAGT of $-1.6^{\circ}C$. This study indicates the position of the $-8.5^{\circ}C$ MAAT isotherm at or slightly north of the continental divide, as shown in Figure 4.

Several other permafrost temperature observations from comparably shallow depths are available

FIGURE 6 Comparison of MAAT, MAGT, and estimated MAGT in profile from Fairbanks to Prudhoe Bay.

for comparison with our approach. At Deadhorse, a MAGT of -8.5°C was obtained over 5 years at 23 m (J. Brown, personal communication), and at Ivotuk, 240 km west of Toolik, a MAGT of -4.7°C was obtained at 7 m (Kachadoorian and Crory 1983). Utilizing the procedures described in this study, we obtain estimated MAGT of -7.9°C for Deadhorse and -3.3°C for Ivotuk. Both of these estimates are on the warm side, probably reflecting the effects of disturbance on our ground temperature data set.

Measurements of permafrost temperatures in undisturbed terrain are rare except for sites along the Arctic Ocean (Lachenbruch et al. 1982) or in some populated areas in the interior (Brown and Péwé 1973). Observed upper permafrost temperatures along the Arctic Coast range from -8.5°C to -10.9°C and increase to -6.5°C near Umiat (Brown and Péwé 1973). South of the Brooks Range, permafrost temperatures approach 0°C near Fairbanks. The thickness of the permafrost also decreases southward. Osterkamp and Payne (1981) illustrated this thinning of the ice-rich permafrost between Prudhoe Bay, where it exceeds 600 m, and the Brooks Range, where it becomes less than 200 m thick.

This analysis is intended to provide a broad regional perspective for the relationship of MAAT and MAGT. Direct observations of both values are for the most part lacking in this remote and topographically complex portion of Alaska. Although the MAAT is calculated based on somewhat sparse data and the upper permafrost temperatures are obtained from a disturbed surface environment, we believe that the relationships described are regionally representative. It is possible that using freezing and thawing degree-days to describe air temperatures in relation to permafrost distribution will provide greater precision (e.g. Harris and Brown 1982). However, the approach taken here (the average of $T_{\text{MAX}} + T_{\text{MIN}}$) is appropriate for comparison with the available MAGT data and with previous mapping of the region. As more air and ground temperature data become available, these relationships can be further refined.

ACKNOWLEDGMENTS

Collection and analysis of the climatic data were performed under projects of the U. S. Army Corps of Engineers Cold Regions Research and Engineering Laboratory and were partially supported by funding from the U. S. Geological Survey and the U. S. Department of Energy. The ground temperature data were made available through the courtesy of the Alyeska Pipeline Service Company.

Embankment settlements have presented a long-term track maintenance problem where the Hudson Bay Railway crosses extensive peatlands of northern Manitoba. Localized zones of settlement, termed sinkholes, typically consist of short sections of track that settle about 100 mm each summer. Field studies have verified that subsidence is caused by thaw at the unstable transition between unfrozen fen and permafrost-cored peat plateaus. In 1978, five test sections were constructed on the railway to study techniques for stabilizing the roadbed by stopping permafrost degradation. A total of 40 two-phase heat pipes were installed along the toe of the embankment at four of the sites. Ground temperatures, track movements and surface settlements were monitored from October 1978 through March 1982. A well-defined ground cooling trend was evident at all of the test sites and settlements were substantially reduced after the first year of operation. The research program successfully demonstrated that heat pipes provide a viable means of arresting localized thaw settlement for embankments constructed on peatlands where permafrost is warm and discontinuous.

INTRODUCTION

The Hudson Bay Railway was the first major transportation facility to be built in the permafrost region of Canada. The line provides a shipping route for prairie grain to port facilities located on Hudson Bay at Churchill, Manitoba. The railway runs northeast for 820 km from The Pas to Churchill, along the route shown in Figure 1. During construction, isolated permafrost bodies were observed in peat bogs as far south as Wabowden. The size and frequency of permafrost islands increased as the line advanced toward the north and east.

Track and roadway subsidence, experienced during and immediately following construction, was a precursor to long-term behavior of the roadbed. The most common manifestations of track settlement have been termed sinkholes by Canadian National Railway (CNR) maintenance personnel. Sinkholes consist of short sections of track that typically experience 100 to 150 mm of settlement during a two-month period at the end of summer. These seasonal sags caused by thaw and compression of permafrost soils in the subgrade necessitate frequent track lifting and bank widening. Maintenance records confirm that the sinkholes recur at approximately the same locations year after year.

This paper describes a track stabilization research program undertaken between 1976 and 1982. The aim of the program was to develop practical means for eliminating or reducing the extent of sinkhole development. Tangible benefits to the railway would include reduced operating restrictions, improved safety, and a reduction in track maintenance costs.

REGIONAL ENVIRONMENT

The route north of the Nelson River crossing, at Gillam, lies within the Hudson Bay Lowland

FIGURE 1 Location map, Manitoba Canada.

physiographic region. The topography is subdued, with a maximum elevation about 150 m above mean sea level. The climate varies mainly with latitude but is modified to some degree by the presence of Hudson Bay. The continental climate results in long cold winters and short summers that can be quite warm. Mean annual air temperatures for Churchill and Gillam are -7.1°C and -4.5°C , respectively. Prevailing wind directions are westerly to northwesterly. Between Gillam and Churchill the railway trends in a northerly

direction; therefore, drifting results in snow accumulation on either side of the embankment.

Throughout the Hudson Bay Lowland limestone and dolomite bedrock is overlain by a thick sequence of quaternary sediments. Between Gillam and Churchill, the thickness of quaternary sediments ranges from 10 to 50 m. Bedrock outcrops are confined to valleys of deeply incised rivers.

During the Wisconsin glacial maximum, ice occupied the Hudson Bay basin. As the ice retreated, the Tyrell Sea penetrated to the east well beyond the shore of the present bay (Dyke et al. 1982). Glacial retreat was followed by isostatic uplift that eventually forced the Tyrell Sea to retreat toward the present-day shoreline. This retreat exposed a flat plain with a few till-cored knolls protruding above a veneer of fine-grained marine and lacustrine sediments. The climatic and drainage conditions prevailing since deglaciation have resulted in the accumulation of substantial thicknesses of peat throughout the entire lowland. This area exists today as one of the most extensive uninterrupted peatlands in the world.

The internal structure of frozen peat landforms suggests that most of the peat in northern Canada was deposited in a permafrost-free environment (Zoltai and Tarnocai 1975). Permafrost found in peat landforms near the southern boundary of the Hudson Bay Lowlands may be only 600 years old, having been initiated by a brief period of cooler climate at that time (Thie 1974). Once permafrost aggradation has been initiated in peat-covered soil, growth of ice lenses elevates the ground surface, permitting the new plant species to establish. Domed or elevated surfaces then continue to provide the particular thermal characteristics and microclimate required to sustain permafrost (Brown 1968). Most of the relief displayed by frozen peat landforms can be attributed to the formation of ice lenses in the mineral soil beneath the peat (Salmi 1968). Proprietary studies of ground ice distribution conducted adjacent to the railway, along a proposed route for the Polar Gas pipeline, supports this hypothesis.

The terms palsa and peat plateau have been adopted to refer to these elevated landforms. Peat plateaus are the common landforms within the study region, where more than 50% of the area is underlain by permafrost. They plateaus assume a wide range of lateral dimensions and are typically surrounded by unfrozen, water-saturated fens in which ponds and streams are common. The fens are invariably wet and are predominated by marsh sedges and thin non-Sphagnum mosses. Conversely, peat plateaus usually have a dry surface and are covered with dense to scattered stands of Black Spruce trees. The ground has a thick forest peat cover consisting of Sphagnum mosses and lichens. The peripheries of frozen peat landforms show a distinct response to regional drainage, being molded smooth by the slow flow of ground and surface water in the adjacent fens.

The dimensions of peat plateaus are controlled by climatic conditions, drainage, and local relief. Although they appear to be stable, they respond to both natural and artificial disturbances. Permafrost aggradation and degradation processes can exist simultaneously according to Thie (1974), so the isolated melting of frozen peat landforms does not necessarily reflect a climatic warming trend.

CONSTRUCTION HISTORY

Construction of the Hudson Bay Railway began at The Pas, Manitoba in 1910. The fact that much of this rail line would be built across permafrost terrain was not readily appreciated. Procedures that evolved for coping with the permafrost terrain are described in an historic paper by Charles (1959). Demands on manpower and material imposed by World War I resulted in the project being suspended in 1917. By that time, track had been laid to the Limestone River (north of Gillam), and the right-of-way had been cleared from the end of track all the way to Port Nelson on Hudson Bay. Considerable civil works associated with port development at the mouth of the Nelson River had also been undertaken. For a variety of technical and political reasons, a controversy erupted regarding the selection of Port Nelson as the terminus for the railway. When construction resumed in 1927, the port location had been changed to Churchill, following recommendations of the Palmer Royal Commission.

The first step in resuming construction was to rehabilitate approximately 320 km of track that had been laid and abandoned 10 years previously. Many embankments and cuts had experienced substantial settlement: ponded water was found lying across the right-of-way in many places, leaving the track and ties suspended in the air. Surveys were conducted to provide a more effective basis for planning drainage, which led to the construction of offtake and parallel ditches in advance of placing the roadbed. However, within the study region shown in Figure 1, the topography is so subdued that it is not feasible to maintain effective drainage control along the right-of-way (J. L. Charles, personal communication, 1978).

Route reconnaissance for the line between the Limestone River and Churchill was carried out on foot during winter. Charles (1959) reports that testholes dug by hand in frozen ground, encountered up to 5.5 m of organics that were usually ice-rich. Recognizing the increasing amount of permafrost encountered north of the Nelson River, it was decided to build the remaining railway almost entirely as an embankment, keeping cuts to a minimum. Initial grading was restricted to that required to permit track to be laid, but occasional cutting into high relief peat plateaus could not be avoided. These cuts were made by using picks and shovels to excavate the frozen peat. The peat was transported by wheelbarrows to adjacent fens where it was used as fill. Track laid on the frozen peat was lifted through train-hauled sand and gravel that originated from offline borrow pits. Figure 2 provides a typical aerial view of the Hudson Bay railway traversing fens and peat plateaus within the test area. The track reached Churchill in March 1929 and has been maintained and operated continuously for more than 50 years.

SINKHOLE DEVELOPMENT

A geotechnical investigation was conducted in 1976, comprising field observations plus drilling and sampling at selected sites. The program's objective was to develop an understanding of the thaw-subsidence mechanism and to rationalize the

FIGURE 2 Hudson Bay Railway crossing peatlands.

distribution of sinkholes along the railway. Abundant segregated ground ice was identified in the peat and mineral soil substrate at each of the sites drilled. Thermistor cables installed in boreholes indicated that maximum ground temperatures within permafrost in the vicinity of Gillam ranged from -0.4°C to 0°C . Field observations supplemented with analysis of the borehole data verified that localized subsidence or sinkhole formation is due to thaw-settlement of the embankment at the transition zone between the nonpermafrost fen and the peat plateau. Track settlement at a typical sinkhole site is shown in Figure 3.

FIGURE 3 Typical sinkhole.

Very little track maintenance has been required on the central portions of peat plateaus. Between the fen and the thermally-stable portion of the peat plateau, however, the track is often bordered by a hummocky actively slumping remnant of the former plateau. These areas of degraded permafrost are usually occupied by thaw ponds 1.5 to 3 m deep.

The hypothesis that was derived to explain development of the sinkholes is illustrated in Figure 4. The rail grade shown in the figure, passes from a substantial embankment across the fen to a small embankment or perhaps a cut across the top of the peat plateau. Disturbance develops at the point where the grade first contacts the boundary of the peat plateau. As small amounts of permafrost degradation accumulate, a transition zone develops and permafrost thaw proceeds along the shoulders before thaw and accompanying settlement occur beneath the railway embankment proper. Gradual degradation along both toes of the embank-

FIGURE 4 Sinkhole development model.

ment eventually coalesce, resulting in a localized sag in the embankment. These sinkholes migrate very slowly along the track into the peat plateau from the original fen-plateau boundary. From year to year, maintenance crews have perceived that settlements recur at the same location, thus leading to the descriptive term sinkhole.

Initiation of permafrost degradation at the transition zone is closely linked to the very warm ground temperatures that are present at the periphery of a peat plateau and the high unfrozen water content of the clayey soils involved in thaw. The degradation is sustained and often accelerated by ponded water and by detrimental snow-drifting patterns. The implication of the thaw-subsidence hypothesis described above is that sinkholes will require maintenance in perpetuity unless progressive lateral shifting of the transition zone can be stopped.

Several alternative remedial measures were proposed and then tested by geothermal simulation to determine their long-term affect. Two-dimensional finite element analyses were first used to investigate the existing section without remedial measures. Formulation and verification of the computer program has been described by Hwang (1976). The simulation predicted an average lateral thaw rate of about 60 mm per year, which reflects a low net positive heat flux into the frozen ground supporting the embankment. To arrest or reverse this process requires that winter heat extraction be increased or that summer heat input be decreased. Embankment modifications that were assessed by further numerical simulation included flattening sideslopes to 6H:1V to limit snow drift accumulation, application of synthetic board insulation on or in the embankment slopes, and insertion of heat pipes into the thawing foundation soils.

Analytical studies of various mitigative measures indicated that a passive system, such as insulation or slope flattening, would probably not be sufficient to stabilize thaw in the fen-plateau transition. However, heat pipes would increase the

net heat withdrawal during the winter months by about 25%, and therefore looked promising as a stabilization technique. It was anticipated that cooling beneath the track structure could be achieved with a row of heat pipes installed parallel to the toe of the embankment.

STABILIZATION TEST PROGRAM

A grade stabilization test program was planned to determine the field effectiveness of heat pipes acting both alone and in combination with other measures, such as slope flattening and surface insulation. Five test sites were selected on the basis of their similarity and conformance to a simple and symmetrical pattern of permafrost degradation at the fen-plateau transition. All of the sites were located on the Herchmer Subdivision north of Gillam, Manitoba (Figure 1). This route segment was judged to have the greatest frequency of sinkholes displaying significant settlement magnitudes. The test sites were numbered from north to south and were referenced to railway mileposts. Configurations adopted for the various test sites are summarized in Table 1.

TABLE 1 Test Site Configurations

Site No.	Mile-post	Side-slopes (H:V)	Wood Chip Insulation	Heat Pipes	
				Number	SPACING
1	368.8	2:1	yes	10	4 m
2	368.8	6:1	yes	0	
3	365.4	2:1	yes	12	4 m
4	363.0	2:1	no	8	4 m
5	340.7	2:1	yes	10	3 m

Model 800 Cryo-Anchor heat pipes, manufactured by the McDonnell Douglas Astronautics Co., were selected for the test program. These two-phase heat pipes afforded a proven history of use on the Trans Alaska Pipeline Project (Heuer 1979) and were also used previously to stabilize a settling foundation on thawing permafrost (Hayley 1982). The units were chosen because of their robust nature and familiarity with their thermal performance characteristics.

A total of 40 units was purchased for installation at 4 of the 5 test sites. The units were 51 mm in diameter and 9.1 m long, with 1.8-m-long extruded aluminum radiator segments. The number of heat pipes installed at each site varied from 8 to 12, as indicated in Table 1. The units were evenly distributed along opposite sides of the track near the embankment toe. Spacing between adjacent heat pipes was 4 m, except for the most southerly site, where the spacing was decreased to 3 m. At 3 of the heat pipe sites, a 150 mm thick layer of wood chips was spread over the embankment sideslopes to provide an insulating cover over the gravel surface. The single site without heat pipes had embankment slopes that were groomed to 6H:1V, then covered with wood chip insulation.

Test site construction and heat pipe installation took place in October 1978. The units were installed in boreholes drilled with a rotary drill rig and grouted into place with a neat cement grout. The extruded aluminum radiator fins were installed on the heat pipes after the borehole grout had set. A typical completed test site is shown in Figure 5.

FIGURE 5 Typical test site.

During the construction period, the following instrumentation was installed at each site: 7 thermistor cables, 1 deep benchmark, 10 surface settlement plates, stations for repeated top-of-rail surveys, and 10 snow depth gauges.

Test site performance was monitored for a 3.5-year period. Elevation surveys were repeated at approximately 2 month intervals throughout the 3 thawing seasons. Ground temperature measurements were obtained at 2-month intervals throughout the year with additional readings during the fall freeze-up period.

PERFORMANCE SUMMARY

Meteorological data for both Churchill and Gillam indicated a slight annual warming trend over the 3.5-year monitoring period. The warming resulted chiefly from warmer winters, as reflected by a decrease in air freezing index. Despite this warming trend, the installation of heat pipes has brought about general cooling in the transition zone between the fen and peat plateau. In all cases, track settlement has been substantially reduced. Little, if any, cooling was observed in connection with the flattened sideslopes at Site 2.

Data from two of the thermistor cables installed at Site 3 are shown in Figure 6. The location of the cables relative to the track and the heat pipe array is shown in Figure 7. The data illustrates the modest cooling trend that is typical below the track centerline at all of the transition zone sites where heat pipes were installed. The extent of cooling recorded over the 3.5-year period ranged from 0.3 C° at Site 3 to 0.5 C° at Site 5. The thermistor cable located between adjacent heat pipes shows a stronger cooling trend with a notable decrease in winter ground temperature minima from year to year. This behavior reflects the decrease in latent heat extraction required to fully freeze the soil between heat pipes during successive winters.

FIGURE 6 Ground temperature variations, Site 3.

FIGURE 7 Thermistor cable location plan, Site 3.

The performance of individual heat pipes has been evaluated by back analyses of the soil temperature records at the midpoint between adjacent units. The two-dimensional finite-element model described previously (Hwang 1976) was used to predict radial freezing about a vertical line heat sink. The program was modified to allow analyses using polar coordinates to represent cylindrical freezing about a vertical axis of symmetry. Seasonal heat flux from the ground surface was also taken into account in the analyses, with input based on meteorological data from Gillam.

A comparison between predicted and measured ground temperatures at an initially unfrozen location between heat pipes (Site 1) is shown in Figure 8. The predictions have been developed for average winter wind speeds of 5 and 15 km per hour using thermal performance data provided by the manufacturer. The predicted and observed ground temperatures at the depth shown in Figure 8 match very well for wind speeds in the order of 15 km per hour. For the design wind speed of 5 km per hour, the measured maximum summer temperature is cooler than predictions by about 0.2 C°. The excellent overall comparison confirms the reliability of the performance criterion used for the design. The heat pipes have, in fact, performed somewhat better than anticipated.

There have been only minor differences between thermal effects achieved at 3- and 4-m spacings with heat pipes placed along either side of the embankment. A 1-m decrease in spacing does result

in quicker freezeback between the heat pipes, but even at 4-m spacings the frost cylinders converge after 2 to 3 years of operation.

Top-of-rail elevation surveys did not provide useful quantitative data pertaining to grade settlements. Periodic resurfacing of the tracks resulted in disparities that could not be adequately evaluated. Settlement plates embedded in the embankment sideslopes within the heat pipe array show negligible settlements. Maximum reported settlements were on the order of 50 mm in 3 years, and these were generally located at the extreme fen end of the test sections. These settlements could be attributed to compression of peat due to placement of new fill. Elevation readings from the most southerly test site show slight heave of the embankment as permafrost conditions have been reestablished in the foundation soils.

CONCLUSIONS AND FUTURE APPLICATIONS

Stabilization of the transition zone by heat pipes has been successful at all of the test sites where the technique was used. This conclusion has been confirmed by operating and maintenance crews who have been pleased with track stability during the monitoring period. The use of sideslope flattening has also been moderately successful during the short period of observation. However, passive methods of stabilization, such as bank widening and slope flattening, are considered to be much less effective than active heat removal. Adverse weather conditions, such as successive years with warmer-than-average temperatures, could initiate irreversible thaw settlements.

The heat pipe array adopted for the test sites appears to be a near optimal configuration. Long-term stabilization has been achieved with a spacing of 4 m. Although the 3-m spacing results in more rapid freezeback, significant improvements in performance have not been realized with the closer spacing. The axisymmetric geothermal simulator provides a useful technique for investigating heat pipe effectiveness and spacing at locations outside the immediate test area.

FIGURE 8 Comparison of measured and computed ground temperatures midway between heat pipes.

Heat pipes installed in ground that is presently frozen do not appear to enhance the stabilization process; therefore, accurate definition of the transition zone is a critical component in future large-scale applications of this technique. The total number of heat pipes required to stabilize a localized sinkhole could conceivably be reduced to 4 or 6 if the transition zone can be predefined by geophysical techniques.

Insulating the fill by placing wood chips on the ground surface around the heat pipes improved performance of the test sections only marginally. This minimal improvement in net heat extraction does not appear to justify the difficulties associated with transport and hand placement of surface insulation.

Development of a fully rail-mounted operation has been recommended for future installation of heat pipes to stabilize the railway grade. They could be inserted into a predrilled hole that is sized to ensure a tight fit, thus eliminating the requirements for backfill or grout. The entire operation could be accomplished with either a mobile crane or a crane mounted on a flatbed car. Such an installation technique would be highly efficient in a region where access is available only along the railway. Working from the rails would also minimize handling and placement of additional granular fill in a region where haul distances in excess of 100 km are common.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the support of a number of agencies and individuals who contributed to the program. The early investigative studies on Hudson Bay Railway were funded jointly by the Transportation Development Agency and the Canadian National Railways. Test installation and monitoring were funded by the Prairie Branch Line Rehabilitation Program, administered by Transport Canada. Field support logistics, surveying, and monitoring were provided by CNR from The Pas, Manitoba. Valuable assistance with administering the program was provided by D. J. Horbay of CNR, Saskatoon. The two-dimensional thermal analyses was conducted by D. C. Cathro and Dr. C. T. Hwang of EBA Engineering Consultants Ltd., Edmonton. The

Cryo-Anchor heat pipes were supplied and installed by Mobile Augers and Research Ltd. of Edmonton. They also provided valuable assistance with planning and executing the field program.

BUILDING FOUNDATIONS ON PERMAFROST

He Changgeng

The Third Survey and Design Institute of the Ministry of Railways
People's Republic of China

To examine the applicability of various foundations to cold regions, the massive concrete foundation, earth-padded ventilation foundation, reinforced concrete strip foundation, and column and pile foundations were tested at Zhaohui and Jingtao field stations in northeast China, where the mean annual air temperatures are -5° and -5° to -6°C , respectively. The ground temperature fields, thawing settlement, and tangential frost-heaving forces of subsoils were measured from 1972 through 1980. Test results showed that the distribution of ground temperature beneath structures depends upon the type of foundation, and that the thawing depth under foundations is governed by the building's heating system. The formation of cracks in buildings not only depends upon the settlement of foundations, but is also influenced by air temperature. In designing the ground floor of buildings, thermodynamic calculations must be made according to the type of foundation.

Since the type of foundation is not suitable to the floor which settles at thawing and expands at freezing, buildings on permafrost have often sustained damage. In order to study such damage, we have tested buildings on five types of foundations at Zhaohui and Jingtao, where the natural conditions are as follows.

1. Zhaohui Station: mean annual air temperature is about -5°C , original permafrost table 1.6 m. The ground has a pine and birch forest with some moss. Underneath is a peat layer 0.15 m thick, with a sandy loam soil having a 10-25% crushed stone content and 10-80% ice content with a thickness of 4.7-7.3 m. Further down, a sandy pebble layer has thickness of 3.5-5.0 m. Further down is a tuff weathering layer. Constant annual ground temperature is -1.1°C .

2. Jingtao Station: mean annual air temperature is -5 - -6°C original permafrost table 0.4 - 1.0 m. Ground surface has grass mould and moss, with some pine and birch trees. Peat layer is 0.3 - 0.5 m thick, content of ice 65%, ice layer containing soil is about 1.0 m, with ice amounting to 70-80%. Sandy loam soil mixed with gravel is about 1.4 m thick, ice content 20-35%. Pebbles and grit about 4.5 m thick, containing 20-30% ice. Constant annual ground temperature is -2 to -3°C .

The tests began respectively in 1972 and 1976, and on the basis of observations over 5-8 years, we have obtained sufficient data on the thawed settlement and heave of foundation soils ground temperatures, tangential frost heaving forces, as follows.

ZHAOHUI STATION

Explosively Enlarging Pile Foundation of this type of foundation five test buildings were

built, using different methods to treat three artificial heat sources (fire stove, space-heated wall, and heated brick bed). When heat from the three sources was suspended on posts or beams, depth of thaw in October each year reached 2.9 m at the maximum, as shown in Fig. 1. The bigger end of the pile foundation is 1.0 m below the thawing plate. Maximum temperature at the bigger end is -0.6°C . At this time, the compressive strength of permafrost is $\sigma = 40\text{t/m}^2$, the stress of pile foundation is:

(1) load bearing capacity

$$P = A \sigma = (0.4 \text{ m})^2 \pi \times 40\text{t/m}^2 = 20.1 \text{ t}$$

FIGURE 1 Temperature at maximum depth of thaw in subsoil under explosively enlarging pile foundation (3 heat sources on stilts), October 1975.

FIGURE 2 Maximum and minimum temperatures explosively enlarging pile foundation (3 heat sources on stilts).

(2) N (weight carried) + G (dead weight of Pile) = $16.3^t < 20.1^t$

When freezing recurs in winter, pile foundations are also subjected to tangential frost heaving forces. By actual measurement of a 0 - 0.8m section, the tangential frost heaving force $15^t/m^2$. Over 2.0 m it was measured as $15^t/m^2$; under 2 m as $1/3$ of $15^t/m^2$. Temperature at the pile foundation is shown in Figure 2.

(3) Frost pulling force $T = \sum_{i=1}^n A_{ui} \tau_i = 0.3^m \pi (2^m \times 15^t/m^2 + 0.9^m \times 5^t/m^2) = 32.5^t$

(4) Antifrost pulling force $T = N+G + \sum_{i=1}^n F_{mi} t_i = 16.3^t + 0.8^m \pi \times 1.1^m \times 6^t/m^2 = 32.8^t$

On the basis of a number of observations, maximum foundation subsidence difference is 8 mm, without exceeding the specified value of 10.8 mm. However, a crack has occurred, though this does not affect usage. The big-headed pile has the effect of reactive force on frost heaving, and thus increases the stability of the pile, making it quite safe. But since the floor is built directly on the ground surface, which freezes again in winter, mean floor temperature is only about $5.0^{\circ}C$ despite the insulation layer laid on room floor. It is unfit as living quarters.

In similar buildings with heat from stove and heated wall built on stilts, maximum depth of thaw is 3.6 m, the differential in value of foundation settlement is 11 mm, which is in excess of the specified value 6.8 mm, thus producing many cracks.

In houses on the work site with all three heat sources not on stilts, the foot of the northwest wall is filled with a pile of slag for heat insulation. Maximum depth of thaw of the subsoil is 5.7 m, exceeding the pile depth and forming a stable melting plate. The amount of thawing and settlement is 120 mm. The freezeback in winter is faster at the two ends and slow in the middle, thus again causing inhomogeneous freezing expansion, with more cracks in the wall of the house.

From the above-mentioned variations in ground temperature, it may be seen that artificial heat sources on stilts is one of the methods of reducing the depth of thaw. The reason why the depth of thaw is not great is the settlement of subsoil, and beneath the foundation beam crevices are formed resulting in a semiventilated foundation. In winter most of the foundation is frozen, while in summer the depth of thaw is shallow. This type of foundation is stable.

Open Cased Foundation

It is solid as one body with great rigidity, and may rise and fall with the expansion and settlement of the subsoil. It is better adapted to the thawing settlement and freezing expansion of the subsoil. Its maximum depth of thaw is 7.0 m as shown in Figure 3.

In winter, when freezeback occurs, the depth is only 2.1 m, the width of freezeback toward the

FIGURE 3 Temperature distribution at maximum depth of thaw in subsoil under open-cased foundation.

FIGURE 4 Minimum temperature distribution in subsoil under open-cased foundation.

center of the room is 0.3 m, as shown in Figure 4. In the most severe cold room temperature is only 12.6°C , while the floor still retains 8.6°C . It is feasible, therefore, to maintain room floor temperature by the use of thawed subsoil, without ventilation.

The subsoil of this foundation has a maximum settlement as much as 300 mm, while the two ends settle only to a depth of 150-180 mm. In winter, the two ends are entirely frozen and heaved. The inhomogeneous value of settlement and expansion of the foundation at the east and is 100 mm, which is 9 times in excess of the specified value of 10 mm, thus resulting in more cracks at both ends. Some cracks are big enough for the wind to blow through and therefore need repairs. In the mid-section, the depth of thaw is greater but more homogeneous, with a settlement differential of 11 mm, which is in close proximity to the specified maximum value. It has fewer cracks. From this it is seen that to control cracks, the settlement differential value must be controlled.

Soil Filling Cycle-Beam Foundation:

Subsoil filled with sandy gravel with soil has a large amount of stored heat thus deepening the natural permafrost table. With heating provided in the room, the depth of thaw gradually increases. After the station room had been in use for seven years, the depth of thaw reached

9 m, and began to be stabilized. The reason for the greater depth of thaw, apart from the heat provided, is mainly because soil filling on the south is 4 m high, while the three slopes on the east, south and west are all exposed to sunshine. So the subsoil absorbs more heat and thawing becomes deeper. Freezeback in winter is also deeper: 6.0 m under the north wall, and 4.2 m under the south wall. It is evident that the thermal effect of sunshine is considerable. Because the filling soil has a low water content and better conditions for drainage, the extent of settlement is not appreciable, so the room has only two small cracks.

JINGTAO PERMAFROST EXPERIMENT STATION

Built on Stilts Embedded Pile Foundation

This type of foundation is similar to the explosively enlarging pile foundation in nature and condition under stress. After five years of observation, it is found that changes in freezing and thawing in the subsoil are essentially the same each year. Thawing begins at the end of April and reaches in September the maximum depth of thaw of 2.1 m. At this time temperature in the subsoil is -1.4°C , as shown in Figure 5. In October ground surface begins freezing and by January of next year is completely frozen. Temperature of the subsoil in February is -1.4°C , in April -2.8°C , as shown in Figure 6. But when soil temperature drops to -1.8°C , there is some slight freezing expansion. Hence there is a 0-6 mm deformation of the foundation caused by freezing expansion, and also an inhomogeneous deformation of 9 mm, which is less than the specified 13.6 mm. Theoretically, there should be no cracks, but in practice there are several vertical cracks. This is a result of the common effect of freez-

FIGURE 5. Temperature distribution at maximum depth of thaw in subsoil under built-on-stilts ventilation foundation, September 1979.

Figure 6 Maximum and minimum temperatures in subsoil under built-on-stilts ventilation foundation.

ing expansion and stress of temperature differential (air temperature difference 34 to -48°C) Usage is not affected.

From Figure 6, it may be seen that there are drastic changes in ground temperature. In this case is the deformation of foundation caused by the tangential frost force? By actual measurement of six foundation piles is obtained the tangential frost force $\tau_i = 13t/m^2$.

Then,

$$(1) \text{ Frost pulling force } \tau = \sum_{i=1}^n A_{ui} \tau_i = 0.2m \times 4 \times 2.1m \times 13t/m^2 = 21.8t$$

$$(2) \text{ Antifrost pulling force } T = \sum_{i=1}^n F_{mi} t_i + N + G = 1.1m \times 4 \times 1.6m \times 7t/m^2 + 16.7t = 66t > 21.8t$$

It is evident that deformation of the foundation is not due to the effect of tangential frost force. Where possible, the depth of foundation with ventilation on stilts should be further increased, or heat insulation measures be adopted, so that changes in subsoil temperature may not exceed 1.0°C. In short, it is feasible to use embedded pile foundation with ventilation on stilts for buildings in large areas of continuous permafrost soil.

It may be seen from Figure 5 that the foundation pile has moved 0.8 m toward the center of the room, while ground temperature of subsoil in the south drops about 0.2°C, which is favorable to the load bearing capacity of the foundation. If the apron slope at foot of the south wall is made to extend out from the

pile it will not only avoid damage from freeze or thaw of subsoil, and also reduce the depth of thaw of subsoil beneath the outer wall.

Drilled and Backfilled Pile Foundations

Two test houses were built on this type of foundation. The foundation pile penetrates the thawing plate, using the freezing force of permafrost for bearing load and anti-frost pulling. In order to reduce the depth of thaw, the outdoor height differential for residence is 1.1 m, that for dormitory is 0.5 m, for the purpose of comparing the effect. After five years of usage, the maximum depth of subsoil is: counting from the outdoor ground surface, 2.0 m for residence, as shown in Figure 7, and 2.0 m for dormitory. The two houses have different height differentials, but the depth of thaw is the same. The main reason is that constant annual ground temperature of the dormitory (-3°C) is 1.0°C lower than that of the residence (-2°C).

Like houses built on the explosively enlarging pile foundation, it too has a ventilation path under the floor beam, so the floor temperature in the room is only 5 to 8°C in the coldest weather.

This load bearing capacity of the drilled and backfield piles, on the basis of ground temperature around the pile as shown in Figure 8,

FIGURE 7 Temperature distribution at maximum depth of thaw in subsoil under drilling and filling pile foundation, October 1979.

FIGURE 8 Maximum and minimum temperatures at surrounding depth of thaw under drilling and filling pile foundation.

is calculated as follows:

$$(1) \text{ Load bearing capacity } P = \sum_{i=1}^n A_{mi} S_i +$$

$$A \bar{B} = 0.26\pi (1.0\text{m} \times 3\text{t/m}^2 + 2.0\text{m} \times 8.5\text{t/m}^2 + 1.4\text{m} \times 14\text{t/m}^2) + (0.13\text{m})^2 \pi \times 140\text{t/m}^2 = 39.7\text{t}$$

$$(2) \text{ Load and dead weight of pile } N + G = 21.2\text{t}$$

$$\text{Degree of safety} = 39.7\text{t} / 21.2\text{t} = 1.87$$

$$(3) \text{ Antifrost pulling force } T = \sum_{i=1}^n A_{mi} S_i + N + G =$$

$$0.26\pi (1.0\text{m} \times 3\text{t/m}^2 + 2.0\text{m} \times 8.5\text{t/m}^2 + 1.4\text{m} \times 14\text{t/m}^2) + 9.3\text{t} = 32.4\text{t} + 9.3\text{t} = 41.7\text{t}$$

$$(4) \text{ Frost pulling force } \mathcal{Z} = \sum_{i=1}^n A_{ui} \mathcal{Z}_i =$$

$$0.26\pi \times 2\text{m} \times 20.5\text{t/m}^2 = 33.5\text{t}$$

$$\text{Overall safety margin} = 41.7\text{t} / 33.5\text{t} = 1.24$$

Note: $\mathcal{Z}_i = 20.5\text{t/m}^2$ is actually measured value without calculation of individual layers.

Where: \bar{B} — Compressive strength of permafrost soil (t/m^2)
 A — Cross section of pile end (m^2)
 N — Load on pile (t)
 G — Dead weight of pile (including the weight of soil around the pile)(t)

A_{ui} — circumferential area of foundation pile in "i" seasonal frozen soil layer (m^2)

\mathcal{Z}_i — tangential frost heaving force around pile in "i" seasonal frozen soil layer (t/m^2)

F_{mi} — circumferential area of soil column on the pile end in "i" permafrost soil layer (m^2)

t_i — Tangential heaving force in "i" permafrost soil layer (t/m^2)

n — number of permafrost soil layers.

A_{mi} — circumferential area of pile in "i" permafrost soil layer (m^2)

S_i — Tangential heaving force of "i" permafrost soil layer (t/m^2)

It is known from this calculation that both the load bearing capacity and antifrost pulling force of the pile are adequate. However, there is still some deformation of the foundation, maximum settlement differential being 8 mm, which is in excess of the permissible value 6.8 mm. Hence there are cracks in the houses. The cracks were found after construction, and they expand and contract with changes in air temperature. It is evident that the stress of temperature differential also has some effect. Besides, there may also be some creep effect produced by permafrost under stress.

From the above analysis and discussions, it may be said that tests on all five types of foundations are basically successful. Each of these, however, has its own optimum conditions for adaptation.

1. Explosively enlarging pile and prefabricated embedded pile: In both cases, the depth of embedment is limited by manual construction, generally to the extent of about 4 m. Therefore, these are suitable for foundations of buildings with underflow ventilation and without heating. Moreover, the maximum subsoil temperature should conform with the requirement for sandy soil at -0.3°C and clayey loam at -0.5°C .

2. Filling pile foundation: This has a greater adaptability and may be used as the foundation for various buildings on different types of permafrost soil. However, permafrost clayey loam with a temperature higher than -0.5°C should not be used because of inadequate load-bearing capacity.

3. Open cased foundation: This is built in the strata of ground surface and easy to construct. It is closely integrated with the subsoil, with a greater depth of thaw. The temperature of the floor is high and suitable for living quarters. But it has a greater settlement and cracks are liable to occur. So

it is suitable for buildings with small areas such as 60m². Preferably, building site should be permafrost soil with negligible settlement at thawing and clayey loam at a temperature over -0.5°C.

4. Soil filling cycle-beam foundation:

Filling is costly and not easy to ram down, so it is unsuitable for use in ordinary cases. Where production requires, besides having it rammed down, it is necessary to have the height of filling soil plus the depth of natural table greater than the building's maximum depth of

thaw, in order to ensure the stability of this type of foundation.

Pile foundations are better types of foundation for buildings on permafrost soil, but because in most cases there are air gaps beneath the subsoil beam thus forming ventilation paths, the temperature of room floor is reduced in winter to the extent that it is uninhabitable. It is recommended, therefore, that buildings on pile foundation, whether ventilated or not, should be built on stilts and provided with ground surface heat insulation in order to make them habitable.

PROBLEMS IN THE CARTOGRAPHY OF GROUND ICE: A PILOT PROJECT FOR NORTHWESTERN CANADA

J.A. Heginbottom

Geological Survey of Canada, Ottawa, Canada, K1A 0E8

A new permafrost map of Canada is being proposed, emphasizing the occurrence and distribution of ground ice. The key element is the extreme variability of ground ice both horizontally and with depth. Problems include the development of a suitable classification scheme and the quality and variability of the source data. Previous work on ground ice classification and mapping is reviewed and a new, morphological classification of ground ice bodies is proposed. The main classes are: ice crystals in voids, equidimensional ice masses, layers or sheets of ice (horizontal, vertical, diagonal) and networks of segregated ice. These classes are subdivided on the basis of the regularity of the shapes of ice masses and whether their occurrences are simple or multiple. A qualitative classification of the amount of ground ice is proposed: low, moderate, high, very high and extreme. Selected geomorphic features, such as pingos, will be shown by symbols. A pilot study map of northwestern Canada, using these classifications is being prepared.

INTRODUCTION

Permafrost is a ubiquitous phenomenon in northern Canada and, as such, is of concern in many aspects of life and in most engineering activities in the area. The engineering problems arise not so much because of the low ground temperature, but because most or all of the water in the ground is in the form of ice. The difficulties are compounded because the ice is unevenly distributed in the ground, commonly occurs in quantities in excess of the void volume, and often exists in large, relatively pure bodies. These attributes result in a soil-ice-water system that is sensitive to disturbance and which has physical properties highly variable over short distances.

Although the existence of permafrost has been known for centuries, the serious engineering problems caused by its existence have been recognized only in the last 50 years. In North America, Muller's (1947) book was a key document in drawing the attention of scientists and engineers to the challenge of permafrost. In Canada, military construction activities gave a number of engineers firsthand experience in coping with permafrost.

Recognizing this, the National Research Council of Canada undertook, in the 1950s and 60s, a survey of permafrost in Canada. This program resulted in a series of reports describing permafrost conditions (e.g. Brown, 1964, 1965 and 1968), and culminated in a map of permafrost in Canada (Brown, 1967).

This map, and the many other maps of permafrost in Canada and North America published in the last 70 years, all have one major deficiency from the perspective of geologists and engineers: they contain essentially no data on the occurrence or distribution of ground ice. Permafrost is largely treated as a climatic phenomenon. The very definition of permafrost, strictly on the basis of temperature, reinforces this approach. And yet, it is the ground ice component of the permafrost that is of most concern to many northern engineering projects.

OCCURRENCE OF GROUND ICE

Ground ice occurs in a variety of forms and a wide range of quantities. At one extreme, ice can comprise 50-70% by volume of the upper 2-3 m of the permafrost over broad areas (J. Brown 1967, Pollard and French 1980). Locally ground ice can exceed 90% of the volume of the ground (Rampton and Mackay 1971). In other areas permafrost contains essentially no ground ice and is termed "dry permafrost". In addition to this gross variability, detailed work along exposures and by means of borings indicates that there is considerable local variation in the distribution of ground ice on a metre-by-metre scale (Heginbottom and Kurfurst 1975). This variability makes the compilation of a ground ice map difficult. Other problems are the selection of a suitable ground ice classification, the availability and the quality of source data and the cartographic difficulties of displaying a complex three-dimensional phenomenon on a map.

Vertical Variability of Ground Ice Conditions

There are relatively few published descriptions of the variation in ground ice content with respect to depth. Examples of two are shown in Figure 1; others from the Mackenzie Delta area have been published by Mackay (1972a, 1973) and Williams (1968). Rampton and Mackay (1971) also analysed the proportion of drill holes which encountered massive ground ice or icy sediments in Richards Island, Tuktoyaktuk Peninsula and adjacent areas, while for the Mackenzie Valley, Heginbottom and Kurfurst (1975) presented detailed borehole logs of ground ice from seven specific localities. The depths of the boreholes described in these sources range from as little as 1 m to over 40 m.

In extreme cases, the ground can consist of essentially pure ice for thickness of over 30 m (Mackay 1973) and the depth to the top of such massive ground ice can be as great as 45 m, although it is commonly less than 20 m (Mackay 1972a, 1973). The profiles shown in Figure 1 seem to be generally representative of the distribution

FIGURE 1a

FIGURE 1 Examples of the distribution of ice content with depth for sites in the continuous permafrost zone of Canada. (a) Melville Island, N.W.T. (Stangl et al. 1982). A generalized profile for soils developed on rocks of Mesozoic and Paleozoic age. (b) Richards Island, N.W.T. (Pollard and French 1980). Note: the curve is a visual best fit and not calculated.

of ground ice in soil profiles. The highest ice contents occur at the top of the permafrost profile. The general downward decrease in ice contents is punctuated by local increases, commonly at stratigraphic breaks. Similar observations have been reported from northern Alaska (J. Brown 1967).

Horizontal Variability of Ground Ice Conditions

Information on the horizontal variability of ground ice contents is available locally at either large or small scales and in the form of both plans and profiles. At the large scale, the existence of individual masses of ground ice or, in the discontinuous permafrost zone, of distinct bodies of frozen ground have been described by several workers. Examples from the continuous permafrost zone of Canada are mainly from the western arctic region (Figure 2).

For the zone of discontinuous permafrost, site investigations at Thompson, Manitoba (Johnston et al. 1963), and at Dawson, Yukon Territory (EBA 1977), showed how the existence of frozen ground and ground ice varied on metre-by-metre scale. Both plans and trench profiles are in these reports.

On the broad or regional scale, Mackay (1966) has presented a map of the types of ground ice found in the Mackenzie Delta and on Tuktoyaktuk Peninsula. Other than this example, most reports for Canada are in the form of incidental reports in regional descriptions (e.g. Brown 1972) or annotations to surficial geology maps (e.g. Rampton 1981).

FIGURE 1b

THE CLASSIFICATION OF GROUND ICE

The attributes of ground ice that are of most importance in the compilation of the proposed map are the quantity of ice present and its form. Published classifications do not emphasize either of these characteristics. Those of Shumskii (1959) and Mackay (1966, 1972a) emphasize the genesis of the underground ice rather than its form, while the commonly used engineering classification (Pihlainen and Johnston 1963) is designed to facilitate the production of standardized descriptions of permafrost and ground ice conditions. It does not provide a classification scheme for ground ice. Accordingly a new, simple morphological classification has been developed (Table 1). All of Mackay's (1972a) genetic classes can be related to members of this new classification.

Descriptions of the quantity of ground ice are commonly provided in general terms such as low, moderate and high or unsaturated, saturated and excess. In some cases, percentage values of total moisture content, ice content or excess ice content, on either a gravimetric or a volumetric basis are quoted, often as a range of values. Few sources include both. One is the series of Terrain Classification and Sensitivity Maps of the Mackenzie Valley and Delta regions produced by the Geological Survey of Canada in the early 1970s (e.g. Monroe 1972). The following correlations are used by Monroe for segregated ice by volume.

- very high: 75 or 80%
- high : 40, 50 or 60%
- moderate : 10 or 20%

While these correlations do not lead directly to an acceptable classification, they do indicate the approximate relationship between descriptive and quantitative estimates of ground ice occurrence.

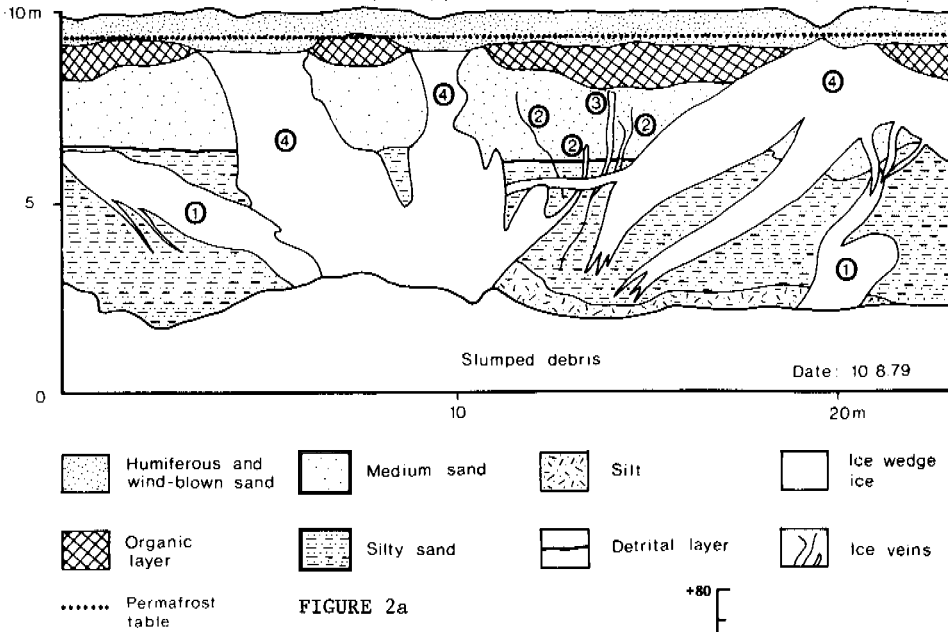

FIGURE 2a

FIGURE 2 Examples of short range horizontal variability of ice content in the continuous permafrost zone of Canada. (a) Ground ice bodies exposed in coastal bluffs, southern Banks Island, N.W.T. (French et al. 1982). (b) Massive ground ice body plotted from seismic shot hole logs, near Tuktoyaktuk, N.W.T. (Mackay 1973).

The classification now proposed is given in Table 2.

A special problem arises in the case of permafrost beneath the bed of the sea. The permafrost conditions of the Beaufort Sea are becoming known in some detail (Hunter et al. 1978; Mackay 1972b) and several instances of sub-seabottom ground ice have been recorded from boreholes. There is, however, a major terminological problem (van Everdingen 1976), as the presence of seawater with a temperature below 0°C means that the standard definition of permafrost, strictly on the basis of temperature, is not easily applicable. Scientists working in the Beaufort Sea area have been using terms such as ice-bearing permafrost, ice-bonded permafrost and even acoustical permafrost. At this time it is not known if the classifications proposed in Tables 1 and 2 can be applied to sub-seabottom ground ice or if new ones will have to be developed.

MAPPING OF GROUND ICE

There are few published maps showing the occurrence of ground ice in Canada. Mackay (1966) presented a map of types of ground ice in the Mackenzie Delta and Tuktoyaktuk Peninsula areas. Other than this, only maps of pingo distribution have been published (e.g. Mackay 1962; Hughes 1969). In Alaska, the general distribution of ice wedges has been mapped (Péwé 1965) as has the distribution of pingos (Holmes et al. 1965).

For the USSR, the distribution of a wider range of ground ice related features has been depicted, though on small scale maps. These include maps of the general distribution of injection ice and repeated-wedge ice (Shumskii and Vtyurin 1966), of polygons with ice wedges (Popov et al. 1966), of pingos (Frenzel 1967, in Washburn 1980), and of ice wedges (Vtyurin 1975, in J. Brown and Grave 1979). There are also three maps by Vtyurin (1973) showing (i) the total visible ice content

FIGURE 2b

of the permafrost in the USSR, (ii) three-dimensional macro ice content of the permafrost, as derived from multiwedge ice and (iii) the total amount of visible ice in the upper layers of permafrost. General geocryological maps for Central Siberia (Fotiev, et al. 1973), Yakutia (Melnikov 1966), the Yamal-Gydan area (Yunak 1979) and northeastern USSR (Vtyurin 1980) include some information on the broad distribution of several ground ice related features: injection ice, segregation ice, wedge ice and pingos.

Other published work on the quantity and distribution of ground ice includes estimates on the total quantity of ground ice in specific areas (e.g. J. Brown 1967, Pollard and French 1980), statements of the principles of compiling ice content maps (Lur'e 1972, Trofimov and Badu 1976, Gavrilov and Kondrat'yeva 1978 and Cheng 1981), and regional descriptions of the occurrence of ground ice (e.g. Rampton and Mackay 1971).

PROPOSED METHODOLOGY FOR COMPILING A NEW PERMAFROST MAP OF CANADA

The compilation of a new permafrost and ground ice map of Canada at a scale of 1:5 million is

TABLE 1 Morphologic Classification of Ground Ice

	Forms of occurrence of ground ice bodies	Genetic classes of Mackay (1972a)
1	Individual crystals or small groups of crystals in voids	1 Open cavity ice 5 Closed cavity ice 10 Pore ice
2	Equidimensional masses of ice	
a	- Irregular in shape	
b	- Regular in shape	9 Pingo ice
3	Layers or sheets of ice, more or less continuous	
a	- Horizontal or sub-horizontal layers	7 Aggradational ice
(i)	- Single layer	8 Sill ice
(ii)	- Multiple layers	6 Epigenetic ice
b	- Vertical or sub-vertical layers	2 Single vein ice 3 Wedge ice
(i)	- Single layer	4 Tension crack ice
(ii)	- Multiple layers	
c	- Diagonal layers	
4	Network of segregated ice surrounding masses of soil	

proposed. In preparation for this, a pilot study at a scale of 1:1 million is being undertaken to test the ground ice classifications (Tables 1 and 2) data sources, and map legend and to devise appropriate cartographic techniques for presenting the information.

The area of the pilot study is outlined in Figure 3. It comprises the Yukon, the lower Mackenzie River Valley and part of the Beaufort Sea. This region was selected for the pilot study because: (1) It includes areas of continuous permafrost, and both widespread and sporadic discontinuous permafrost; (2) There is a large body of subsurface borehole data available, resulting from petroleum exploration activities, pipeline proposals and highway construction; (3) It includes the northern end of the Canadian Cordillera, where alpine permafrost occurs; (4) It includes the southern Beaufort Sea, where sub-sea-bottom permafrost occurs; and (5) Recent surficial geology and terrain maps, which include information on permafrost and ground ice conditions, are available for over two thirds of the map area.

Although the topography and Quaternary history of this region are complex, with mountains, plateaus and valleys, and both glaciated and unglaciated areas, they are relatively well known. A wide range of ground ice conditions occur within the map area, including the possibility of relic permafrost in the unglaciated area.

The primary data sources of the pilot study are surficial geology and terrain maps produced by the Geological Survey of Canada over the last 15 years. These maps are available at scales of 1:100 000 to 1:250 000. They include conventional surficial

geology maps, terrain inventory maps and terrain sensitivity maps. The map legends include information on permafrost and ground ice conditions, keyed to the main map units. Much of this information has been derived from borehole data, which are from a variety of sources. Most of the boreholes were drilled as either shot holes for petroleum exploration by seismic methods or for geotechnical investigations for pipeline or other construction projects. Less detailed surficial geology, Quaternary geology and bedrock geology maps are available for the remainder of the area. While few or no ground ice data are directly available on these maps, they do give some information on environmental conditions.

In the southern Beaufort Sea area, the primary data sources are geophysical interpretations of marine seismic data collected for petroleum exploration, geocryological and geotechnical purposes.

The primary data sources for both the pilot study map and the final, Canada-wide map provide information on soils, geology and permafrost conditions to a variable depth, generally not greater than 10 m. Since the ground ice conditions in these near surface materials are of greatest consequence for geotechnical purposes, it is proposed to restrict the mapped information to the upper 10 m of ground.

The map legend used for the pilot study is based on the classifications presented in Tables 1 and 2. The compilation approach is to use map units defined on the basis of surface geology, and to label them according to known ground ice conditions. This requires a considerable amount of interpretation and extrapolation in many areas. Nonetheless, it is the only approach currently practicable. Ground ice conditions are shown by using colour for the amount or quantity of ice and a pattern or combination of patterns for its form. In addition, selected geomorphic features, such as pingos, are shown by means of symbols. For the final map of Canada any or all of these elements may be modified.

TABLE 2 Quantitative classification of Ground Ice

Descriptive Term	Equivalent segregated ice content (% by volume)
Extreme	80-100
Very high	60-80
High	40-60
Moderate	20-40
Low	0-20

Any comments, suggestions or information which may assist in the preparation of the final map will be gratefully received by the author.

ACKNOWLEDGMENTS

Thanks are due to Drs. J. Brown, J.G. Fyles, S.A. Harris, J.R. Mackay, T.L. Péwé and

A.L. Washburn for helpful discussions. O.J. Ferrians, Jr., H.M. French, D.A. St-Onge and J.S. Scott kindly read and commented upon the paper. The valuable comments of an anonymous reviewer are gratefully acknowledged.

DESIGN OF BURIED SEAFLOOR PIPELINES FOR PERMAFROST THAW SETTLEMENT

C. E. Heuer, J. B. Caldwell, and B. Zamsky
Exxon Production Research Company, Houston, Texas 77001 USA

Computer simulations were performed to model the mechanical and thermal behavior of pipelines buried in the seafloor above ice-bonded permafrost. Conditions typical of the Alaskan Beaufort Sea were used, and the study was directed at water depths greater than 2 m (6 ft). Maximum pipe diameter, operating temperature, and cover depth considered were 61 cm (24 in.), 93°C (200°F), and 3.0 m (10 ft), respectively. A few cases considered two parallel pipelines instead of a single isolated pipeline. Allowable permafrost settlement was determined by modeling the mechanical interaction between the pipeline and settling soil. If the top of ice-bonded permafrost was within about 9 m (30 ft) of the seafloor, then the allowable permafrost settlement was only about 0.3 m (1 ft). However, the allowable settlement increased rapidly as the depth to ice-bonded permafrost increased. For example, doubling the depth to ice-bonded permafrost more than tripled the allowable settlement. The soil thermal regime was modeled to develop guidelines for preventing excessive thaw and settlement. Where the ice-bonded permafrost was below a depth of about 27 m (90 ft), thaw was acceptable for all situations considered. For ice-bonded permafrost depths of about 14-27 m (45-90 ft), insulation was used to limit thaw. If the ice-bonded permafrost was at a depth less than about 14 m, then restrictions on operating temperature or changes in burial geometry were sometimes also necessary. These guidelines can change depending on the specific application but are useful for planning future studies. Salt transfer in the thawed soil was identified as a significant factor in calculating thaw depth because it controls the permafrost thawing temperature.

INTRODUCTION

Within a few years, construction to develop petroleum resources beneath the Alaskan Beaufort Sea could begin, and pipelines buried in the seafloor are likely to be an integral part of any such development. As has been done for exploration, man-made islands will probably be used as platforms for drilling, but they may also serve as locations for large processing facilities. Inter-island pipelines may be needed to connect satellite drilling islands to a central processing island, and island-to-shore pipelines may be needed to deliver the oil and gas to large-diameter onshore trunk lines for transportation to markets. Ice-bonded permafrost is known to be present throughout the potential development areas, and the pipelines may operate at temperatures as high as 93°C (200°F). Therefore, differential settlement due to thawing of permafrost is an important design consideration.

Permafrost thaw settlement has previously been addressed for onshore pipelines, but for offshore pipelines there are three significant differences. First, water depth exerts a controlling influence on seafloor temperature, and even for depths as low as 1 m, the mean annual seafloor temperature is much warmer than the nearby onshore surface temperature. Second, for water depths greater than about 2 m there is no active layer, and the top of ice-bonded permafrost can be tens of meters below the seafloor. The upper layer of thawed soil provides a thermal and mechanical buffer between the pipeline and the ice-bonded permafrost. Finally, pore water salinity decreases the permafrost thawing temperature and makes the frozen soil thermal properties highly temperature dependent. Computer simulations were conducted to study the effects of these differences and other parameters for water depths greater than 2 m. The simulations modeled both the soil thawing and the mechanical interaction between a

pipeline and settling soil.

The following assumptions were made in performing the simulations: (1) The design life is 30 years. (2) Differential settlement is the only permafrost-related design problem. (3) Thaw of ice-bonded permafrost is acceptable as long as it does not lead to excessive pipe deformation. (4) The allowable longitudinal compressive or tensile strain is 0.5%, which allows some inelastic pipe deformation. (5) Mapping small areas of ice-rich soil along an entire pipeline route may not be practical, so the worst case length of ice-rich soil is used. (6) A design value for permafrost thaw strain can be developed by testing and correlating a large number of seafloor samples. (7) Maximum differential settlement equals total settlement. (8) Settlement occurs simultaneously with thawing. (9) The thermal and mechanical aspects of the problem can be uncoupled, since allowable settlement is relatively small. (10) Seismic loads may be important in some situations but are not included in this analysis. Additional work may allow relaxation of some of the more restrictive assumptions such as 5 and 7.

The mechanical simulations are described first, and then the thermal simulations are covered. This order is used because the mechanical simulations establish the limits on thaw depth.

MECHANICAL SIMULATIONS

The pipeline mechanical simulations were performed using an earlier version of a commercially available program for two-dimensional stress and deformation analysis of pipelines (Price et al. 1982). The program considers soil settlement, thermal expansion, internal pressure, gravity loads, longitudinal soil friction, and soil deformation. The latter is modeled as a Winkler foundation. Nonlinear effects include inelastic pipe

deformation, large pipe displacements, and bilinear soil springs. The program has been used since 1972 in the design of major pipeline projects.

The geometry used to determine soil settlement is shown in Figure 1. This geometry is considered conservative because it assumes that the settled region is infinitely wide perpendicular to the longitudinal axis of the pipeline. Actually, the width is determined by the width of the thaw bulb and can be about the same as the length of the settled region parallel to the pipeline. The resulting three-dimensional settlement would lead to smaller vertical displacement.

FIGURE 1 Soil settlement geometry.

The soil settlement profile was based on a stochastic model for cohesionless soil (Attewell 1977), which compared well with measured surface settlement above a deformed tunnel. The general shape of the vertical displacement is shown in Figure 2. The hyperbolic tangent function given in Figure 2 is a very close approximation to the results from the stochastic model and is more convenient to use. This function implicitly requires that the volume of settlement directly below the pipe equal the volume of permafrost settlement. This is conservative because in the real case, the former is likely to be smaller than the latter.

FIGURE 2 Vertical soil displacement.

By assuming an incompressible soil and small strain, the corresponding longitudinal soil displacement can be calculated, and the general shape is shown in Figure 3. In the past, longitudinal displacement has not been

FIGURE 3 Longitudinal soil displacement.

considered. However, for the settlement of deep permafrost, the resulting longitudinal force on the pipeline can be significant.

Figures 1-3 assume that thaw-stable and thaw-unstable soil have the same friction angle, but the thaw-stable soil is likely to have a much higher friction angle. This is because of its higher density. To accommodate the change in friction angle, the following mixing and smoothing functions

$$M = \left\{ \tanh \left[\frac{2(2x + W)}{L_U + L_S} \right] - \tanh \left[\frac{2(2x - W)}{L_U + L_S} \right] \right\} / 2$$

$$F_C = M \cdot F_U + (1 - M) F_S$$

were developed. Although arbitrary, they provide for a smooth transition between stable and unstable soil. Subscripts c, s, and u are for composite, stable, and unstable, and F represents either the vertical or the longitudinal displacement functions in Figures 2 and 3. Note that M approaches a maximum value not greater than one as x approaches zero, and that M approaches zero as the absolute value of x increases.

The thaw-stable soil could have smaller latent heat and higher thermal conductivity than the thaw-unstable soil. This would cause the thaw depth in the unstable soil to increase toward the boundary with the stable soil. In view of other uncertainties, modeling this effect was not considered necessary.

Support, uplift and downdrag, and longitudinal soil springs were used to model the force applied to the pipeline when it moved downward, upward, and axially relative to the soil. For each type of spring, the force increased linearly with displacement up to a yield displacement. Above the yield displacement, the force was constant at its ultimate value. The spring constants along with other soil mechanical parameters are given in Table 1 (Bowles 1977, Price et al. 1982).

The pipe steel grade was assumed to be X-65, with the following piecewise-linear stress-strain relation: 0 GPa at 0% strain, 0.36 GPa (52 ksi) at 0.18%, 0.45 GPa (65 ksi) at 0.5%, 0.48 GPa (70 ksi) at 0.8%, and 0.52 GPa (75 ksi) at 3%. Pipeline outside diameters of 30 cm (12 in.) and 61 cm (24 in.) were used with corresponding wall thicknesses of 1.11 cm (0.437 in.) and 1.43 cm (0.563 in.). Cover depth was either 0.9 or 3.0 m (3 or 10 ft).

The gravity load on the pipeline was independent of displacement. It consisted of the buoyant weight of the soil directly above the pipeline plus the buoyant weight of the pipe, insulation, concrete coating, and oil line

fill. To determine the buoyant weight of the pipe, a 0.318 cm (0.125 in.) corrosion allowance was added to the wall thickness. The insulation thickness was 15.2 cm (6 in.), and the concrete thickness was 10.2 cm (4.0 in.) for the 30 cm pipe, and 14.0 cm (5.5 in.) for the 61 cm pipe. The possible increase in overburden pressure due to infilling of a seafloor settlement depression was not modeled.

The pipeline operating pressure was assumed to be 9.31 MPa (1,350 psi), and the installation temperature was assumed to be -1.1°C (30°F). The latter was used to calculate the force due to thermal expansion.

The length of pipeline modeled was over 900 m (3,000 ft). One end was at the midpoint of the settled region. Both ends were restrained in rotation and longitudinal displacement. Before any loads were applied, the pipeline was assumed to be horizontal and stress free. Residual stresses from laying or pressure testing were not considered.

Pipeline diameter, operating temperature, cover depth, and depth to top of ice-bonded permafrost were found to be the major variables controlling allowable permafrost settlement. Friction angle, pipe wall thickness, and soil spring constants were of lesser importance.

Several simulations were needed to determine allowable settlement for a given set of input parameters. For each set, both the depth and the width of the settled region in Figure 1 were varied until two conditions were satisfied: $\epsilon = 0.5\%$ and $\partial\epsilon/\partial W = 0$, where ϵ is longitudinal strain and W is the width of the settled region. The second condition means that the worst-case value of W was always used.

Figure 4 illustrates the results from a typical series

FIGURE 4 Pipe strain.

of simulations. For low values of W , the pipeline does not follow the shape of the soil and partially spans the settled region. As W increases, the pipe touches down on the soil in the middle of the settled region, and the soil starts to support the pipe sagbend. In Figure 4, the zero slope condition occurs just as the sagbend touches the soil. Consistent with this behavior, the maximum compressive strain occurs at the top of the sagbend for low values of W , but it occurs at the bottom of the overbend for large values of W . Note that the value of W at the design point is only about 12 m (40 ft).

Figure 5 is a plot of allowable permafrost settlement versus depth to top of ice-bonded permafrost for two cover depths, 0.9 and 3.0 m, and two pipeline diameters 30 and 61 cm. The pipe temperature was 66°C (150°F). For shallow ice-bonded permafrost, the allowable settlement is only 0.1-0.4 m (0.4-1.4 ft). The allowable settlement increases rapidly as the depth to ice-bonded permafrost increases because the soil settlement is spread over a longer interval.

FIGURE 5 Allowable permafrost settlement.

The allowable settlement for the 30 cm pipeline is initially less than that for the 61 cm pipeline. The smaller-diameter pipeline has a lower section modulus, reducing the length of the settled region the pipeline can span. However, for greater depth to ice-bonded permafrost, the smaller pipeline can more easily conform to the shape of the settlement profile.

For both pipe diameters, the allowable settlement is always less for the deeper depth of cover. The

FIGURE 6 Allowable permafrost settlement.

difference increases with increasing depth to ice-bonded permafrost. The greater overburden pressure makes the pipeline follow the settlement profile more closely.

The pipeline operating temperature strongly affects the allowable permafrost settlement. This is shown in Figure 6 for a pipeline diameter of 61 cm. Decreasing the operating temperature from 66°C (150°F) to 10°C (50°F) increases the allowable settlement by a factor of almost 3 for a cover depth of 0.9 m and by a factor of about 2 for a cover depth of 3.0 m. At 10°C and 0.9 m cover, the allowable settlement is controlled by tensile rather than compressive strain.

Figures 5 and 6 are plots of allowable permafrost settlement. To couple these results to the thermal simulations, the allowable settlement must be divided by the design thaw strain.

THERMAL SIMULATIONS

The pipeline thermal simulations were performed using a computer program which models transient, two-dimensional conduction with change of phase (Wheeler 1978). Since 1969, the program has been used to solve a variety of permafrost heat transfer problems and has been compared against analytical solutions, laboratory data, field tests, and other programs.

Some representative soil thermal properties are shown in Figures 7 and 8. The frozen and thawed dry densities were calculated to be consistent with the assumed thaw strain. The values of thawed conductivity

and heat capacity were calculated using standard correlations (Kersten 1949) and were not adjusted to account for changes in geometry due to settlement. The corresponding frozen values and latent heat were modified to account for unfrozen moisture due to both salinity (Ono 1975) and specific surface area (McGaw and Tice 1976). In Figure 7, the jump in conductivity for a thawing temperature of -0.3°C (31.5°F) is due to the step increase in dry density upon thawing. The conductivity of the pipe insulation was 0.035 W/m-°C (0.02 Btu/hr-ft-°F).

Both single and dual pipelines were modeled. When two pipelines were modeled, they had identical dimensions and temperatures. Separation between the pipelines was measured from centerline to centerline.

The finite element grid was rectangular with a width of about 30 m (100 ft) and a depth of about 45 m (150 ft). The top boundary was the seafloor. The right boundary was a plane of symmetry. For a single pipeline, it passed through the pipe centerline. For dual pipelines, it passed midway between the two centerlines. The bottom and left boundaries were far away from the pipeline. The pipeline and insulation were represented by concentric polygons determined by the assumed pipe diameter and insulation thickness. The concrete coating was not explicitly modeled because its conductivity is similar to thawed soil. The cover depth and depth to top of ice-bonded permafrost were used as shown in Figure 1.

The boundary condition at the seafloor was a heat transfer coefficient and a constant seawater temperature. The pipe was a constant temperature boundary. The side and bottom boundaries were adiabatic. The initial temperature was equal to the seawater temperature at the seafloor. It linearly decreased down to the top of the ice-bonded permafrost. There the temperature was equal to the thawing temperature based on the overlying thawed soil salinity. At greater depths, the temperature linearly decreased according to the specified geothermal gradient. All the simulations were run for 30 years.

A sensitivity study determined the possible changes in thaw depth due to variations in the input data. The parameters considered are listed in Table 2, along with the input values used and the corresponding calculated thaw depths. The parameters are listed in order of decreasing variation in thaw depth. They were varied one at a time, while all of the other parameters were set equal to their base case values. The base case

1. Thawed salinity used to determine initial temperature distribution only (slow salt transfer).
2. Thawed salinity used to determine initial temperature distribution and thawing temperature (fast salt transfer).
3. Underlined values are base case conditions.
4. All thaw depths are relative to the top of ice-bonded permafrost.

values are underlined in the table. All the input values were considered possible, but the base case was selected as a typical design situation.

The parameters can be divided into two classes, those that describe environmental conditions and those that describe the pipeline. Only limited control over the environmental parameters is possible when the pipeline route is being selected. The results of the sensitivity study indicate that the primary objectives during route selection should be to minimize thawed soil salinity and permafrost thaw strain and to maximize depth to top of ice-bonded permafrost.

Once the route is selected, the pipeline parameters can be adjusted to control thaw depth. These include insulation thickness, pipe separation, pipe temperature, depth of cover, and pipe diameter. Increasing the first two and decreasing the last three decreases thaw depth. Fortunately, most of these parameters are high on the list in Table 2, so significant control over thaw depth is potentially possible. However, other nonthermal considerations may also affect these parameters.

Thawing temperature is the second most important parameter in Table 2. It is controlled by the rate of salt transfer through thawed soil, which cannot yet be accurately predicted. However, two limiting cases can be considered. "Slow" salt transfer means that the salinity on both sides of the thaw front is equal to the initial ice-bonded permafrost salinity. The thawing temperature is therefore determined by the ice-bonded salinity. "Fast" salt transfer means that the salinity above the thaw front equals the initial thawed soil salinity. In this case, there is a sharp change in salinity at the thaw front. The higher salinity now determines the thawing temperature.

Fast and slow are relative to the thaw front velocity. Based on the allowable permafrost settlement, the allowable thaw front velocity is on the order of 0.1 m/yr, which is an order of magnitude faster than the typical natural ice-bonded permafrost degradation rate of 0.01 m/yr or less. However, the salt transfer rate could be faster than the natural degradation rate. The pore water velocity above the thaw front should provide an upper bound on the salt transfer rate. Field work by Harrison and Osterkamp (1982) for relatively coarse-grained soil indicates that the pore water velocity is probably faster than 0.01 m/yr and may be faster than 0.1 m/yr. The velocity is likely to be lower in fine-grained soil. Although very limited, the available data indicate that there are likely to be areas where the pore water velocity is close to the thaw front velocity. Therefore, the thawing temperature could be below that based on the ice-bonded permafrost salinity. This, in turn, could significantly increase thaw depth.

Decreasing the thawing temperature can increase thaw depth for several reasons: (1) Relative to the thaw front, the seafloor can be a heat source rather than a heat sink. (2) The difference between the pipe temperature and the thawing temperature is increased. (3) The sensible heat input to the thawed soil for a given thaw depth is reduced.

Changes in thaw strain have little effect on thaw depth but have a very big effect on allowable thaw. Doubling the thaw strain from 15 to 30% decreases thaw depth by only about 4%. However, it halves the allowable thaw depth. Therefore, the worst case for thaw settlement occurs for the highest thaw strain, which corresponds to the lowest thaw depth.

An interesting phenomenon occurs when both the overlying thawed soil salinity and the salt transfer rate increase. The former decreases thaw, and the latter

increases thaw. However, for the cases modeled (see bottom line in Table 2), the two effects are offsetting because there is essentially no net change in thaw. This may not be universally true.

METHODS TO LIMIT THAW AND SETTLEMENT

Pipeline insulation is considered the primary method for limiting thaw, so Figures 9 and 10 were developed to help determine where and how much insulation is needed. Figure 9 shows the required depth to the top of ice-bonded permafrost as a function of pipe temperature with no insulation. Figure 10 shows the required insulation thickness as a function of pipe temperature for 9.1 m (30 ft) to top of ice-bonded permafrost. In both figures, the pipe diameter is 61 cm, and the cover depth is 3.0 m. Curves are given for fast and slow salt migration. Other conditions are the same as the base case in Table 2. Above the curves, the permafrost settlement is less than allowable, while below the curves, the settlement is more than allowable.

Figures 9 and 10 were obtained by first plotting allowable thaw depth from the mechanical simulations and predicted thaw depth from the thermal simulations versus pipe temperature. The points of intersection for common conditions were then used to plot the curves in the figures.

The curves in Figure 9 have relatively flat slopes. This means that a small increase in depth to top of ice-bonded permafrost allows a big increase in pipe temperature. For example, if the ice-bonded permafrost is

FIGURE 9 Required depth to ice-bonded permafrost.

FIGURE 10 Required insulation thickness.

at 9.1 m, the maximum allowable pipeline temperature is 16°C (60°F) with slow salt transfer. If the depth to ice-bonded permafrost is doubled to 18 m (60 ft), then the allowable pipeline temperature increases by more than a factor of 4 to 81°C (178°F). For fast salt transfer, the required depths to top of ice-bonded permafrost are 2-4 m (7-13 ft) deeper.

If the permafrost is too shallow for a given pipeline temperature, then as shown in Figure 10, insulation can be used to reduce thaw depth to an allowable value. The slopes of the curves in this figure are relatively steep. Therefore, small changes in pipeline temperature lead to large increases in required insulation thickness. There is a strong dependence on salt transfer rate. For 15.2 cm (6 in.) of insulation and slow salt transfer, the maximum allowable pipeline temperature is 76°C (168°F). However, for fast salt transfer, the allowable pipeline temperature is only 26°C (78°F).

CONCLUSIONS

Calculation procedures were developed for design of warm pipelines buried in the seafloor above ice-bonded permafrost. Based on relatively limited results, the following guidelines were developed considering a maximum pipe diameter of 61 cm (24 in.), a maximum pipe temperature of 93°C (200°F), a maximum cover depth of 3.0 m (10 ft), a maximum of two pipelines along the same route, and a salt transfer rate intermediate between fast and slow. Where the depth to ice-bonded permafrost is greater than about 27 m (90 ft), no mitigation is needed to reduce thaw. If the depth to ice-bonded permafrost is about 14-27 m (45-90 ft), insulation can be used to limit thaw. For depths less than about 14 m, additional measures to limit thaw may also be required. Possible options are reducing cover depth, reducing pipe temperature, or increasing separation between multiple pipelines. Another option, reducing pipe diameter, will decrease thaw depth, but may also decrease allowable thaw.

These guidelines can be used to develop a preliminary assessment of thaw settlement problems for future applications. However, they are probably overly conservative for some areas of the Beaufort Sea. For example, in the Prudhoe Bay area and further to the east, there is frequently a relatively dense gravel layer at depth. The gravel has a very low thaw strain, and thawing of the gravel would cause little settlement. However, this type of layered soil profile was not considered in developing the guidelines.

There are several areas where additional work is needed to improve the existing design procedure: (1) A quantitative model for salt transfer is needed to evaluate the dependence of thawing temperature on thaw rate. (2) Insulation has never been used for permafrost protection of seafloor pipelines. The potential problems of mechanical damage and moisture absorption must be addressed to ensure long-term reliability of the insulation system. (3) The settlement profile used is reasonable but based on limited information. Model tests and more detailed computer simulations of soil deformation are needed to confirm the adequacy of the current profile. (4) More field data are needed on permafrost thaw strain. Since allowable thaw is inversely proportional to thaw strain, small decreases in strain can lead to much larger increases in allowable thaw. (5) Deformation of the insulation system and concrete coating was not considered in the mechanical simulations, but their de-

formation may impose a lower limit on allowable settlement. Simulations of the pipe, insulation, and concrete composite are needed. (6) The limit on pipe strain was developed for large diameter, onshore pipelines. The limit should be checked for smaller diameter, offshore pipelines.

The above guidelines are not applicable for water depths less than 2 m. Here the ice-bonded permafrost can be only a meter or so below the seafloor, but the mean annual seafloor temperature can still be close to the permafrost thawing temperature. This combination of very shallow permafrost and warm surface temperature makes burial in the seafloor much more difficult. With additional mitigation, such as overexcavation and backfill with thaw-stable soil, seafloor burial may be possible. Other, more thermally effective methods of avoiding settlement are burying well-insulated pipelines above sea level in a causeway or elevating the pipelines on pier supported trusses. These last two methods can totally prevent thaw of seafloor permafrost.

THAW SETTLEMENT AND GROUND TEMPERATURE MODEL FOR HIGHWAY DESIGN IN PERMAFROST AREAS

Eldo E. Hildebrand

Department of Civil Engineering, University of Waterloo,
Waterloo, Ontario, Canada N2L 3G1

Highway roughness produced by the differential settlements of thawing permafrost is probably the major problem for highway engineers in permafrost regions. A one-dimensional finite element model was developed to estimate thaw depths and subsequent settlements of an embankment on permafrost terrain. The computer program accepts basic soil parameters in an interactive manner making its use relatively simple. Soil parameters input to the model are limited to test results normally available to the highway engineer and thermal properties that may be measured or estimated from suitable correlations. Climate data may be input as daily or monthly air temperatures along with suitable n -factors. Results have been compared with theoretical calculations and several measured temperatures under insulated and uninsulated road test sections. Comparisons indicated that the model is capable of giving very good results under a variety of conditions provided that accurate estimates of dry densities and water contents can be obtained.

INTRODUCTION

A one-dimensional finite element model was developed to estimate thaw depths and resulting settlements of a road embankment on permafrost terrain. The computer program was written in a manner allowing the required soil parameters to be supplied in an interactive mode for relative ease of use. The model is intended to form part of a system to estimate highway roughness resulting from the thaw of underlying permafrost, thus performing a vital role in a pavement management system in permafrost areas. This paper will describe the development of the model, some of its features, and results obtained in a comparison with measured soil temperatures.

The number and types of parameters required to define each soil layer were purposely limited to recognize the minimal test data usually available to a highway engineer. Estimates of frozen and thawed thermal conductivities are required, along with the dry density, water contents (initial frozen and final thawed water content), specific heat capacity of the soil matrix, and parameters to define the unfrozen water content. Thaw settlement is estimated from changes in the water content after thawing. Climate data are limited to daily or monthly air temperatures and the n -factors for thawing and freezing (dependent on local climate and/or highway surface). The rationale for a model requiring minimal input data was to provide a tool for design rather than research.

Many mathematical models have been developed to estimate freeze or thaw depths within layered soil systems (Kawasaki et al, 1982). A number of analytical solutions have evolved from Neumann's original work in the late nineteenth century. However, all of the analytical solutions have limitations in their treatment of material properties and boundary conditions. More recent devel-

opments in numerical modeling have produced a range of mathematical models for soil temperature using either finite difference or finite element methods for discretization of the continuous domain. The finite difference approach is conceptually easier but generally less flexible than the finite element method. Finite elements were used in this study because the flexibility of the method made variations in grid spacing and possible expansion to two dimensions relatively straightforward.

A relatively simple one-dimensional finite element model for soil thawing/freezing is described in this paper. HIFIEL (HIGHWAY FINITE ELEMENT) was designed to handle large numbers of data points along the alignment of a highway. Variations in temperature within each element are considered linear in space and nonlinear with quadratic variation in the time dimension. A simple approach to thaw settlement has been used with volume changes based on changing of water content after the initial thaw of an ice-rich soil and the change of state from ice to water or vice versa. Heat transfer is by conduction alone with no allowance for heat loss or gain by migrating water. Theoretical justification for this neglect of convective heat transport was established by Nixon (1975) using an analytical solution for one dimensional thaw consolidation. The mathematical structure of HIFIEL and a comparison with measurements at an Alaskan test site are described in this paper.

STRUCTURE OF THE MODEL

In general, the one-dimensional heat-flow problem in a soil considering only conduction is defined by the differential equation:

$$C \frac{\partial T}{\partial t} - k \frac{\partial^2 T}{\partial x^2} = 0 \quad (1)$$

where C is the volumetric heat capacity, T is the temperature, t is time, k is the thermal conductivity, and x is depth (positive downwards). An analytical solution to the soil freezing/thawing problem derived by Neumann in the nineteenth century has proven useful as a standard against which other methods are evaluated. However, limitations in boundary conditions, initial temperature profiles, and soil homogeneity have made Neumann's approach unrealistic for all but the most simple soil freezing/thawing problems.

Finite Element Formulation

The finite element method was chosen for the research upon which this paper is based to solve the differential equation in a piece-wise manner throughout a portion of the seminfinite half space of a layered soil system. A one-dimensional linear element was used in the space domain with element size increasing with depth to reduce computational costs. A tridiagonal matrix representing the soil system resulted from the use of Galerkin's version of the method of weighted residuals. Since the thermal properties of the elements are dependent on temperature, a new set of equations is solved for each time step using a solver specifically developed for tridiagonal matrices. The nonlinear heat-flow problem is thus solved as a linear problem with continually varying thermal properties.

The nonlinear component introduced by the variation in material thermal properties with temperature requires either an iterative solution procedure, extremely small time steps, or a three-time-level scheme to ensure accurate results. A three-time-level scheme suggested by Goodrich (1980) was used in the final model after some attempts with other methods. This three-time-level scheme is a straightforward application of the Galerkin weighted residual procedure using quadratic Lagrange polynomials as shape functions. Using fixed time steps the final system of equations for solution developed by Goodrich (1980) reduces to:

$$[C] \cdot \left[\{T\}^{m-1} - 4\{T\}^m + 3\{T\}^{m+1} \right] + \frac{2\Delta t}{5} \cdot [K] \\ [-\{T\}^{m-1} + 2\{T\}^m + 4\{T\}^{m+1}] = 0, \quad (2)$$

where $[C]$ is the heat capacity matrix, $[K]$ is the heat conductance matrix, Δt is the time step, and $\{T\}$ is the appropriate temperature vector at time $m-1$, m , and $m+1$. In this particular application, the heat capacity matrix is evaluated for the transition from $\{T\}^{m-1}$ to $\{T\}^m$ and $[K]$ is based on the average temperature during the same time step. The temperatures are known or assumed for the first two time levels leaving only $\{T\}^{m+1}$ to be calculated within a tridiagonal system of equations. This procedure has resulted in a reasonably efficient algorithm that has produced good results with time steps as large as three days.

Unfrozen Water Content and Latent Heat

The most critical component of any predictor of freeze/thaw depths in a soil system is the consideration of soil moisture freezing or thawing since the ice and water contents are major factors in the variation of the soil thermal properties. A number of researchers have investigated the factors related to the unfrozen water content of saturated frozen soils (Anderson et al. 1973, Dillon et al. 1966, Tice et al. 1978) and found that fine-grained soils generally have appreciable unfrozen water contents at temperatures as low as -10°C . The neglect of this unfrozen water when considering permafrost at temperatures near 0°C will lead to substantial errors in latent heat calculations. To avoid these errors, a simple method of estimating unfrozen water based on the work of Anderson et al. (1973) has been incorporated in the latent heat calculations.

Latent heat is considered within the model as a component in the apparent specific heat capacity. The apparent specific heat calculation is based on one of two procedures depending on whether an element has changed temperature more than $.00001^\circ\text{C}$ during the previous time step. When the temperature change is negligible, the heat capacity is evaluated at the particular temperature based on the slope of the curve shown in Figure 1. However, when the temperature change has been substantial, the heat capacity is evaluated based on the same curve using an apparent heat capacity as required to get from a temperature T_{n-1} to temperature T_n . The alpha and beta values shown in Figure 1 are taken from the work by Anderson et al. (1973). To avoid the difficulty of $W_u \rightarrow \infty$ as $T \rightarrow 0^\circ\text{C}$, the unfrozen water content curve was linearized from -0.5°C to 0°C as shown in Figure 1. In the case of a coarse-grained soil with negligible unfrozen water content below 0°C , the alpha and beta values are fixed such that virtually all of the water changes state in the linear 0.5°C range. This last approach is typical of most freezing/thawing models that consider some range of temperature for the change of state.

One assumption that presents some difficulty within the model is that the apparent specific heat capacity between two time levels t_{n-1} and t_n is constant from t_n to t_{n+1} (the time level that is solved for in each step). This assumption is not generally true. However, it does represent a convenient means of linearizing a nonlinear problem that would otherwise require a more costly algorithm for solution. Within a range of time step sizes from 0.5 to 5 days, the error caused by this assumption seems to be reasonably manageable.

Figure 2 illustrates the variation in the simulated temperature at mid-depth of a 2.0-m-thick soil system subjected to a sudden increase in surface temperature from -10° to 0°C with various sizes of time steps. The temperatures in Figure 2 represent the system after 60 days with the bottom boundary specified as a temperature gradient of $.05^\circ\text{C}/\text{m}$ (increasing with depth). The maximum temperature difference from 0.5-day steps to 5-day steps is only 0.129°C which represents a difference in actual heat content of 0.365 kJ/kg

for the soil used. Sudden large temperature changes do cause some oscillations. However, as indicated by Goodrich (1980), the quadratic Galerekin time-stepping scheme seems to dampen the oscillations quickly even in large time steps.

Climate Data

One of the primary requirements to drive any soil thermal model is some set of climate data for the time period under consideration. While there are a number of microclimatic models available, a simple model based on the usual n-factor ratio of surface indices to air temperature indices was chosen. This method allows air temperatures to be factored up or down as required to reflect local characteristics or surface conditions. Data requirements are thus minimized while maintaining a reasonable estimate of the surface energy balance. Nfactors have been estimated for several surface types with asphalt pavement ranging from 0.29 to 1.0 for the freezing n-factor and 1.4 to 2.3 for the thawing n-factor (Goodrich and Gold 1981). A specific site near Chitina, Alaska, gave values of 0.86 to 1.18 and 1.58 to 1.66 for the same two factors during three freezing seasons and two thawing seasons (Esch and Livingston 1978). It was thought that estimates of air temperatures and surface n-factors would be available for most northern locations, while more detailed climate information may be unavailable.

Thaw Settlement

The model was altered slightly to provide a means of estimating the settlement if the thaw front advanced beyond the permafrost table. The model was intended for use with relatively light long-term loadings from embankments 1.5 to about 6.0 m high. Various researchers have found that under loadings of less than 100 kN/m (\approx 6-m embankment), 80 to 90% of the thaw settlement occurs almost instantly as a function of a thaw settlement parameter (Watson et al.1973). The use of a model involving only the instantaneous settlement upon thawing avoids many complications induced by consideration of the consolidation.

The development of the entire model was based on the use of parameters that would normally be measured by a highway engineer. An attempt was made to retain this principle in the thaw settlement portion. McHattie (personal communication 1981) suggested that a practical estimate of thaw settlement could be obtained from estimates of soil water content before and after thawing. An assumption is made that soils undergoing thaw settlement are saturated, so that a void ratio can be estimated based on the water content and the dry density. This information is used by the model to calculate changes in element lengths based on a new void ratio after initial thaw. Once an element has thawed, it will maintain a constant water content and only change size as the water freezes and thaws with the seasons. No attempt was made to account for the water expelled when settlement occurs, nor is the heat in the migrating water considered. Portions of the one-dimensional grid simply expand and contract as elements freeze and thaw. Changes in the geometry

allow for the effect of a heat source or disturbance moving closer to the original permafrost table as thaw settlement occurs. When the water content after thawing can be easily established, the model will provide a good estimate of the settlement. The model is not intended for use in situations where rapid thawing from an unusual heat source may cause excess pore pressure leading to possible stability problems, and it is also not intended to model thaw consolidation under loadings greater than 100 kN/m².

VERIFICATION

Analytical Versus Numerical Solution

At each stage of development, the subroutines within the Fortran algorithm were checked for their theoretical accuracy, until finally the entire structure required verification. As an initial check of the model performance, the thaw depth of a hypothetical soil structure was evaluated using HIFIEL and the Berggren equation under similar conditions. The soil properties are summarized in Table 1. The temperature at the surface was raised from -10° to $+5^{\circ}\text{C}$ during the first 30 days, and then the surface temperature was held constant at $+5^{\circ}\text{C}$ for the remaining 330 days. Calculations for the equivalent Berggren solution used an average conductivity of $2.5 \text{ W/m}^{\circ}\text{C}$ and only 335 days to account for an equivalent 1,675 C degree days. The results of the two simulations are illustrated in Figure 3, with thaw depth plotted against the square root of time. Nearly identical results appear at the end of the time period, with the numerical model predicting 1.44 m of thaw versus 1.45 m for the analytical procedure. Although the result is encouraging, there are some differences that need explanation.

TABLE 1 - Soil Properties for Simulation Check

Soil:	Fairbank Silt
Unfrozen water parameters:	$\alpha = .0481$ $\beta = -0.326$
Water content:	0.55
Dry density:	1.20 t/m^3
Conductivity thawed:	$2.0 \text{ W/m}\cdot\text{K}$
Conductivity frozen:	$3.10 \text{ W/m}\cdot\text{K}$
Soil matrix heat capacity:	$.710 \text{ kJ/kg}\cdot\text{K}$
Initial temperature:	-10°C
Depth of soil:	10 m

First, the initial start of the simulation using finite elements gradually approached the assumed step surface temperature of $+5^{\circ}\text{C}$ during the first 30 days. It is apparent from Figure 3 that this difference due to the startup diminishes after the 100 days as the simulated thaw depth approaches proportionality to the square root of time.

A second contribution to the difference may be the consideration of unfrozen water within the numerical model. The thaw depth has been defined strictly as the point at which the temperature is the 0°C isotherm. The Berggren solution is based partially on the assumption that all water changes state at 0°C . When unfrozen water is allowed to

exist below 0°C, there must be some variation from an analytical solution that freezes water at 0°C. The temperature prediction seemed to match the frost depth reasonably well, but further comparison with measured temperatures in other situations seemed necessary.

Chitina Test-Site Comparison

A road section was constructed near Chitina, Alaska, in 1969, to evaluate the performance of embankment insulation and provide needed data concerning the thermal regime under uninsulated road sections. Data from this test site were made available by the Research Section of the Alaska Department of Transportation and Public Facilities (Esch 1972, and personal communications, 1981). The site included a fill section with 5 cm and 10 cm of insulation, uninsulated fill sections, and a cut section. All of the sections were instrumented with a variety of thermocouple strings, including an undisturbed site nearby and a weather station. Data are available from the site for a period of time from October 1969 to the present. However, only three years of data have been used for a verification of the model's accuracy.

Comparisons were made of the model output and the measured temperatures for three different locations under the pavement centerline. The material properties for each location are listed in Table 2. Temperature measurements were made at monthly intervals throughout most of the time period. The results of the simulations and the measured temperatures for the same dates are shown in Figures 4 through 12. The best match between the measured data and the simulations occurred for the section with 10 cm of insulation (thermocouple

3), while in the section with 5 cm of insulation (thermocouple 4) it is apparent that the insulation is approximately 20 cm deeper than Table 2 suggests. The effect of the different thicknesses of insulation is very clear in both the measured temperatures and the simulated temperatures. It appears that over the long term the model may be predicting a cooling trend since all three simulations have colder than measured values at the maximum depth on 25 September, 1972. However, it is difficult to conclude anything from the differences since they are generally less than 0.75°C. Other large differences in the upper layers may have been caused by poor estimates of water content and conductivity. In general the correlation between measured and simulated temperatures appears quite good with no major anomalies except in the extreme upper layers.

For a complete check of the model performance the settlements predicted over a period of time should be matched to those measured at the site. Unfortunately, there were insufficient data at the time of the writing of this paper to make a realistic test of this section of the model. Accurate measurements of the water content of the subgrade soil before thawing and after thaw consolidation are required as input parameters. Settlement of the road has been measured at the site, and a reasonable estimate of the after-thaw water content was used for the uninsulated fill section in an attempt to evaluate the thaw settlement. The measured settlement between 14 July, 1971 and 18 September, 1972 was 0.1 m, while the model predicted 0.126 m during the same time period. While the results cannot be used as a measure of the model's accuracy, they do indicate that reasonable settlement estimates can be expected with the proper soil parameters.

TABLE 2 Layer Properties at Chitina Test Site Used in Simulation

Thermocouple String No.	Material	Thickness (m)	Dry Density (T/m ³)	Water Content	Conductivity		Soil Specific Heat Capacity (kJ/kgK)	Unfrozen Water

CONCLUSIONS

The model presented in this paper can be used to give estimates of road surface settlements for a variety of designs over permafrost subgrades. It is relatively easy to use with a minimum of soil parameters required as input, and it can include insulating layers or peat material without any special considerations. Thermal modeling has been conducted using a one-dimensional two-node element, but it could be expanded to two dimensions with some increased calculation costs and complexity of the program.

As a design tool for highway engineering, HIFIEL performs as well or better than the currently used modified Berggren equation. In its current form, thermal estimates can be made for a variety of alternative designs in a particular site without great cost (10-year simulation for 15-m depth using 5-day time steps required 96 seconds of CPU time using an IBM 4341). Using a gradient boundary at the bottom of the layers allows long-term warming of the permafrost to be considered in areas where there is potential for complete thaw of the permafrost.

APPROXIMATE SOLUTIONS FOR MILLER'S THEORY OF SECONDARY HEAVE

John T. Holden

Department of Theoretical Mechanics
University of Nottingham, Nottingham, NG7 2RD, England

Quasi-static approximations for the temperature and pore water pressure profiles are used to describe the one-dimensional freezing of a saturated noncolloidal soil. Using the energy and mass conservation equations the problem is reduced to the solution of two ordinary differential equations. The theory includes a criterion for the initiation of lenses and a simple numerical procedure is used to describe the growth of a lens, the frozen fringe and the initiation of a new lens. Some numerical results are given that are in general qualitative agreement with other studies.

INTRODUCTION

The phenomenon of frost heave has received considerable attention in recent years and various theories and mathematical models have been devised. Theories based on a capillary theory of ice lens growth for non-colloidal soils began with the work of Everett (1961). The earlier models are often termed primary heaving models since they predict the formation of ice lenses at the freezing front, whereas it is found that ice lenses normally form within the already frozen soil. To describe this phenomenon a rigid-ice model of secondary heave was conceived and developed by Miller (1972, 1977, 1978). Miller's model proposed that an ice lens grows behind the freezing front, so that there is a zone of partially frozen soil in front of a lens. This theory is able to predict much higher heaving pressures than the primary models, and it contains a mechanism for the initiation of new lenses in the partially frozen region. The model has been quantified by O'Neill and Miller (1982), wherein the governing partial differential equations are given together with some numerical results. In addition, Miller and Koslow (1980) have examined the predictions of the model when the temperature and water pressure fields are stationary.
