Abstract

An integrative analysis of rock glacier kinematics and ice content is presented using photogrammetric analyses and different geophysical techniques. The studied rock glacier system is situated in the eastern Swiss Alps, and comprises forms of different activity. Geophysical surveys (electrical resistivity measurements, refraction seismics) have been performed on one active rock glacier, an inactive one, as well as on a relict part underlying the active rock glacier. The highest resistivity values representing ice rich permafrost were obtained on the active rock glacier. The inactive and relict parts showed lower resistivity values. The results of the Electrical Resistivity Tomography (ERT) correspond well with the results of the seismic survey. Based on streamline interpolations, the active rock glacier is estimated to be min. 4 to 5 ka old, assuming a constant creep rate. Ground surface temperatures on this rock glacier vary strongly between years, mainly in response to the prevalent atmospheric conditions (air temperature, snow cover); this is also reflected in the year-to-year fluctuations of active layer thickness visible in the geophysical soundings.

Keywords: geophysics; ground surface temperatures; kinematics; photogrammetry; rock glaciers; Swiss Alps.

Introduction

Rock glaciers are complex morphological structures and can exhibit a large variability concerning kinematics, subsurface properties like ice content and porosity, and genesis. They are usually divided into three classes concerning their ice content and kinematics: (1) active (supersaturated with ice and creeping), (2) inactive (degrading ice and/or almost no creeping) and (3) relict (free of ice, no creeping).

In this contribution an integrative analysis of rock glacier kinematics and geophysical surveying is presented using photogrammetric analyses and different geophysical techniques. The study site is a complex, multi-unit rock glacier system in the eastern Swiss Alps. The objective of the study is (a) to link the kinematic behaviour to the subsurface properties and their temporal evolution, and (b) to get insights into the reaction of such a multi-unit rock glacier system to climate forcing. For this purpose, geophysical monitoring profiles have been installed for periodic measurements of electrical resistivity and seismic P-wave velocity in addition to ground surface temperature monitoring and kinematic velocity measurements. The presented rock glacier system is composed of active, inactive, and relict rock glacier bodies of similar nature and settings (e.g., headwall geology, cleavage, weathering conditions, slope angle, regional climate), thus enabling the simultaneous investigation of different forms that differ, most probably, mostly in their temporal history.

Geographic Setting

The Gianda Grischa rock glacier system is situated on the western slopes of Piz Julier (3384 m a.s.l.) in a side valley of Julier Pass, eastern Swiss Alps. The rock glacier system consists of three individual landforms (Fig. 1): (A) a W-exposed active rock glacier, overlaying (B) an older, possibly relict part, and (C) a W- to SW-oriented inactive rock glacier.

The active rock glacier (A) is c. 1000 m long and between 170 and 390 m wide and is situated between 2540 and 2800 m a.s.l. This rock glacier exhibits a flat root zone separated from its moderately inclined tongue by a steep slope. While the flatter areas show some ridges and furrows, such structures are absent in the steep slope. Of the possibly relict part (B), underlying the active rock glacier, only the tongue is visible, which is c. 100 m long and 100 m wide. The surface of this part is composed of small rocks and pebbles overgrown by vegetation (alpine grasses, dwarf willows, etc.). The inactive rock glacier (C) is 780 m long and 300 m wide; its surface consists of a very coarse top layer and shows a conspicuous ridge-and-furrow topography.

The area was covered by a small mountain glacier during the Egesen stage of the Younger Dryas cold phase. In the subsequent warming periods, this glacier decayed. During the Little Ice Age the catchment area of the currently active rock glacier (A) was already free of surface ice, while the

(A) active rock glacier, overlaying (B), an older, possibly relict part, (C) inactive rock glacier. Black-and-white aerial photograph from swisstopo, 11. 8. 1998, Flight-line 152, Image-No. 4647.

root zone of the presently inactive rock glacier (C) was still covered by a small cirque glacier. Today, both cirques are free of surface ice except for some small pluriannual ice patches.

Methods

Velocity measurements and streamline calculations

Using photogrammetrically derived digital elevation models and scanned aerial photography, ortho-images with 0.2 m resolution were computed digitally. From these digital ortho-images, horizontal surface displacements were derived using an image correlation technique described in detail in Kääb & Vollmer (2000). The age structure of the rock glacier surface was assessed from streamlines interpolated from the obtained surface velocity field. Assuming steady-state conditions, these streamlines represent the trajectories of specific particles on the surface and can thus be used to obtain rock glacier age estimates (for more details, cf. Kääb et al. 1998). The actual advance rate can be considerably smaller than the surface velocity, and therefore, surface ages obtained on the base of surface velocity streamline interpolations constitute a minimum age. Kääb (2005) derived empirical values of rock glacier advance rates and found that the total age of the considered rock glaciers is 2–5 times higher than the minimum age obtained for the surface.

Ground surface temperature measurements

Miniature temperature datalogger devices have been installed at six locations on rock glaciers (A) and (B) in summer 2005. One of these loggers had to be moved to a new location in 2006, and two additional loggers were installed in 2006 and 2007, respectively. Six of the loggers record the ground surface temperature (GST) at shallow depths, two loggers measure GST in air voids of the coarse blocky layer; all loggers measure in a 2h-interval. The thermistor used is a TMC-1T with a temperature range of -29°C to +39°C, with an accuracy given by the manufacturer of better than 0.25°C (cf. Hoelzle et al. 1999 for an in-depth discussion of the applied devices).

Geoelectrical techniques

Geoelectrical sounding techniques are based on the electrical resistivity differences between different subsurface materials. For a given frequency, resistivity depends mainly on the material type and the unfrozen water content of the sample (Hoekstra & McNeill 1973). Resistivity values for mountain permafrost targets can be very high and can vary over a wide range from 1–10 kOhm.m to a few MOhm.m (e.g., Haeberli & Vonder Mühll 1996). The method has been successfully applied to detect and characterize different permafrost structures in mountain terrain in various studies (e.g., Ishikawa et al. 2001, Isaksen et al. 2002, Hauck & Vonder Mühll 2003, Marescot et al. 2003).

Depending on the lateral heterogeneity and the target depth, one-dimensional (1D) vertical electrical soundings (VES) or two-dimensional (2D) electrical resistivity tomography (ERT) surveys can be conducted. For monitoring purposes, ERT measurements are repeated at certain time intervals using a permanently installed electrode array. This fixed-electrode array effectively filters resistivity variations due to variable electrode contacts or geological background variations, as mainly temporal resistivity changes are determined.

In our study, we used an "OYO McOhm" instrument for VES and a "SYSCAL Junior Switch system (IRIS)" as well as a "Geotom (Geolog)" instrument for ERT measurements. Electrode spacing of the initial surveys was 5 m, for the monitoring surveys 2 m spacing was employed in order to achieve a better resolution within the active layer. ERT data sets were inverted using the software package RES2DINV (Loke & Barker 1995). Further details on particularities of geoelectric applications in mountain permafrost are, for example, given in Kneisel & Hauck (2008).

Refraction seismics

Seismic investigations are based on different velocities of acoustic waves in subsurface materials. Energy from the seismic source is transported in waves and both reflected and refracted at interfaces. Refraction seismics concentrates on the first arrivals of the signal. The method is well suited to determine the presence or absence of ice, particularly in loose sediments. Differences in seismic velocities occur between frozen and non-frozen areas: permafrost is usually indicated by higher values, due to interstitial ice. Typical seismic velocity values for unfrozen loose sediments are lower than 1500 m s^{-1}, but can reach up to almost 4000 m s^{-1}, when icebound (Maurer & Hauck 2007).

In this study, a 12-channel "Geometrics Seismograph" equipment with a sledge-hammer as source was applied. Geophone spacing was 10 m, with six shot points.

Results and Discussion

Kinematics and age estimates

Horizontal average annual surface velocities were determined photogrammetrically between 1971 and 1998 (Fig. 2a). During the 27 years under observation, the active rock glacier crept downslope with an average velocity of approximately 0.4 to 0.5 ma^{-1}, reaching maximum velocities of up to 1 ma^{-1}. Compared to other rock glaciers in the region, Gianda Grischa is deforming at a considerable rate (e.g., Murtèl rock glacier: v_{max} = 0.2 ma^{-1}, Muragl rock glacier: v_{max} = 0.5 ma^{-1}, cf. Kääb 2005). Both the inactive rock glacier and the possibly relict part showed no statistically significant movement in the period 1971–1998.

More recent velocity measurements are not available yet, but are envisaged in the near future, in order to relate the kinematics to the results of the ongoing measurements of thermal and geophysical properties.

Rock glaciers are formed by the continuous deformation of ice-rich debris material, with the result that the age of the surface becomes greater along the flowlines from their root zone to their front. Minimum surface age estimates obtained from photogrammetric streamline interpolations are in the order of 4 to 5 ka (Fig. 2b). Both frontal lobes of the spatulate tongue seem to be of comparable age and lie on the overridden, older tongue which shows no movement.

Considering that such surface ages constitute a minimum age and that the total age of the rock glacier can be up to 2–5 times higher than the minimum age obtained for its surface (see above, section 'Methods') implies that this rock glacier presumably began to evolve during the early Holocene (for a more detailed discussion cf. Frauenfelder et al. 2005).

Ground surface temperature

Mean annual air temperature (MAAT) at the front of the rock glacier, at an altitude of 2540 m a.s.l., is approximately -1.1°C, as derived by Hoelzle & Gruber (2008). Ground surface temperature (GST) measurements are ongoing since autumn 2005 at different sites at altitudes between 2586 and 2640 m a.s.l. Mean annual GST on the active rock glacier was between -1.0 and -2.1°C at five out of seven sites during 2005–2006. During 2006–2007 MAGST was negative at one out of six sites (Table 1).

These year-to-year fluctuations are in good agreement with the prevalent atmospheric conditions (air temperature, snow cover) in the area. The MAAT measured at the nearby Murtèl-Corvatsch station showed a very cold winter 2005/2006, contrasted by a very warm winter 2006/2007 (Fig. 3).

Snow cover conditions (thickness and duration), both influencing the ground thermal regime, were normal during winter 2005/2006 as compared to the existing measurements since 1972. In contrast to this, snow cover thickness during winter 2006/2007 was the thinnest ever recorded in the last 35 years. Under normal conditions, winter 2006/2007 would have been one of the coldest recorded, due to the lacking isolation of the snow cover. However, winter 2006/2007 was characterized by a record warm period, lasting from September 2006 until May 2007. This fact is well represented

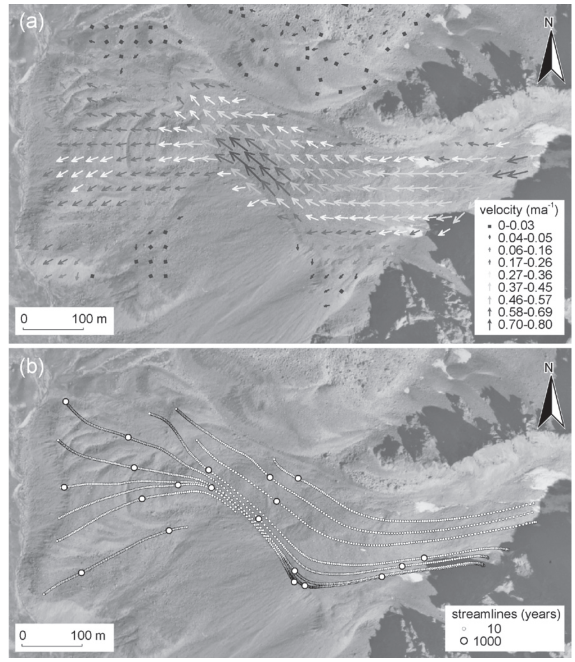

Figure 2. Photogrammetrical measurements on the Gianda Grischa rock glacier system: (a) Horizontal average annual surface velocities between 1971 and 1998; (b) Streamline calculations. Black-and-white aerial photograph from swisstopo, 11. 8. 1998, Flight-line 152, Image-No. 4647.

in the MAGST measured on the rock glacier (Fig. 3).

As the measurements show, winter 2006–2007 was characterised by warm air temperatures, combined with thin snow cover. Although the thin snow cover allowed a certain amount of ground cooling and thereby partly outbalanced the influence of the warm air temperatures, the overall result of these atmospheric conditions was considerably "warm" GSTs on the rock glacier.

Geophysical subsurface characterisation

ERT surveys have been performed on both the active (A) and the inactive (C) rock glacier, as well as on the possibly relict part (B) underlying the active rock glacier. As a complementary method, seismic surveys have been

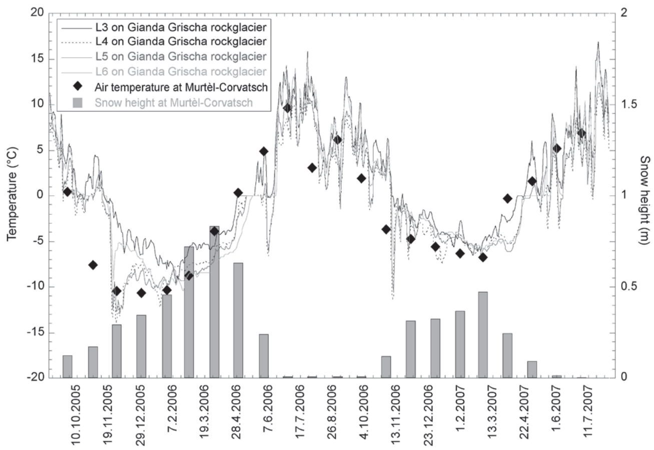

Figure 3. Ground surface temperatures (GSTs) in the period 2005–2007 as measured continuously at four locations on the active rock glacier, and air temperature and snow depth measurements from the nearby Murtèl-Corvatsch weather station.

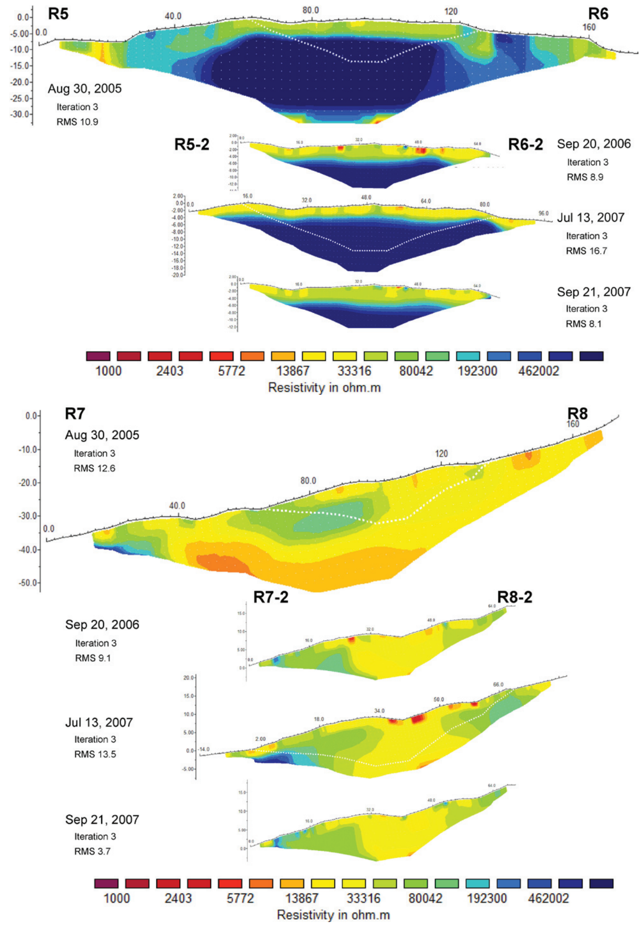

Figure 4. Results of the Electrical resistivity tomography (ERT) measurements: (top) Transversal profile on the active rock glacier (profile line R5–R6); (bottom) longitudinal profile over the edge of the active rock glacier onto the underlying, older (possibly relict) part (profile line R7–R8). R#-numbers refer to the measurements in 2005 (5 m spacing), R#-2-numbers refer to the monitoring profiles from 2006 and 2007 (2 m spacing).

conducted on the active and relict part. The aim was to confirm or contradict the geomorphological and kinematic evidence and to roughly estimate the ice content in the different rock glaciers.

On the active rock glacier (A) the active layer is comparably thick with about 4–5 m (in September, Fig. 4, top) and resistivity values between 30 and 50 kOhm.m. The maximum investigation depth is c. 30 m (obtained with a 5 m spacing profile in August 2005). From this profile a lense-shaped structure is visible with maximum values between c. 200 and >500 kOhm.m. The lateral extent of this high resistive anomaly coincides with the morphological and kinematic evidence for recent high activity. Beneath the maximum, resistivities decrease again indicating a decreasing ice content below 20–25 m depth. Even though this latter interpretation is supported by an additional ERT profile along the rock glaciers flowline (not shown here) and by the VES results (Fig. 5, Table 2), this result remains uncertain, as the reliability of the ERT profiles decreases with depth due to the high resistivity and the limited penetration depth (cf. Hauck & Vonder Mühll 2003, Marescot et al. 2003).

The corresponding seismic results show a similar active layer depth (August measurement) and a high velocity layer below the active layer, with maximum velocities between 2500–4000 ms^{-1} (Fig. 6), indicating the possibility of a significant ice layer, the velocity of ice being 3500 ms^{-1}. Both measurements are in good accordance with evidence from comparable blocky rock glaciers (e.g., rock glacier Murtèl, Maurer & Hauck 2007) and strongly suggest the presence of ice-rich permafrost or even massive ice cores. The depth of the bedrock could not be estimated conclusively.

Measurements on the inactive rock glacier (C, not shown here) and on the possibly relict part (B, Fig. 4, bottom) show significantly lower, but still comparably high resistivity values around c. 50 kOhm.m.

Although the inactive rock glacier showed no statistically significant movement in the period 1971–1998, the results of the ERT survey may indicate the presence of strongly degraded subsurface ice with higher amounts of unfrozen water which no longer has the appearance of one massive and supersaturated ice core. The resistivity values of this inactive rock glacier correspond well with the ERT results from other permafrost landforms with less (but still significant) ice content (cf. Hilbich et al. 2008b). The same is true for the older part, underlying the active rock glacier, which was mapped as relict due to its geomorphological habitus (lateral and frontal sides with low slope angles, collapsed inner structure, considerably dense vegetation cover) and the absence of measurable movement.

On the other hand, the lack of seasonal changes in most parts of the profile may indicate an absence of significant ground ice, as this would lead to, for example, a significant deepening of the surficial unfrozen layer between July and September.

Similarly, the observed seismic velocities are lower than in the active rock glacier, but still high enough to indicate possible ice occurrences. The depth of the relict part of the rock glacier is estimated around 25 m. At shallower depths, the comparatively small P-wave velocities suggest air-filled

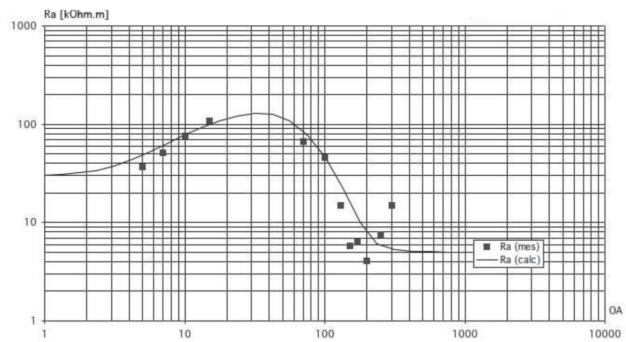

Figure 5. Sounding curve of the one-dimensional sounding (1D) on the active rock glacier (A in Fig. 1).

voids or cavities not only on the inactive and relict rock glacier, but also on the margins of the active one (Fig. 6). As these voids can cause equally high resistivities as massive ground ice, some heterogeneity concerning the ice content on the active rock glacier can, therefore, not be excluded.

The VES results confirm the general findings from the active rock glacier with a 4 m thick active layer (30–65 kOhm.m) and an approximately 20 m thick permafrost layer below (> 250 kOhm.m). Below this layer, the presence of two increasingly apparent resistivity measurements may indicate the bedrock layer or a possible further relict permafrost occurrence some 50–60 m below the surface, which was shielded from atmospheric conditions by the overlying, presently active rock glacier. Even though geomorphic evidence of a relict rock glacier below at least parts of the active rock glacier (cf. above) may argue for the latter, the geophysical evidence is too scarce to allow a reliable interpretation.

Geophysical monitoring

Two profiles were chosen as future monitoring profiles: R/S5–6 on the active rock glacier and R/S7–8 on the possibly relict part (cf. Fig. 1). To better resolve the active layer and the upper part of the permafrost, where seasonal and long-term changes will be largest, a reduced electrode spacing of 2 m was chosen. Up to now, measurements were conducted on September 20, 2006, July 13, 2007, and September 21, 2007. Due to the use of a different ERT instrument in July 2007, these measurements have slightly larger penetration depths.

For the active rock glacier profile the ERT monitoring results show a significant increase in the thickness of the unfrozen layer (low resistivity values) from July to September 2007. A similar thickening, but much smaller, can be seen from September 2006 to September 2007, indicating warmer subsurface conditions in 2007 than in 2006, which is also confirmed by the MAGST measurements (see above). In contrast to this, no such effects can be found on the possibly relict part. Differences can be seen in the lower part of the slope, where the profile nears the active rock glacier, but a clear seasonal increase of the unfrozen layer thickness as well as an interannual signal are missing. From this finding may be deduced that the ice content is low or absent in most of profile R7–8, as a significant ice content would lead to seasonal resistivity contrasts near the interface between

Table 2. Apparent resistivities and thickness of the layers in the 1D model, as shown in Figure 5.

Layer	Resistivity [kOhm.m]	Thickness [m]
1	30–65	3–5
2	>250	20 (–40)
3	5–10	∞

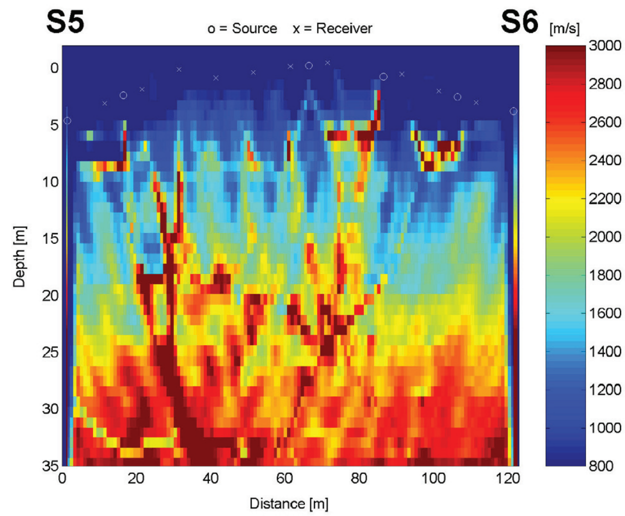

Figure 6. Results of the refraction seismics measurements on the active rock glacier (profile line S5–S6).

the active layer and the permafrost body (cf. Hauck 2002, Kneisel 2006, Hilbich et al. 2008a). This is further supported by the very small vertical resistivity gradient throughout most parts of the profile. An exception may be the lowest part of the profile, where the resistivity increases strongly with depth.

Conclusions and Perspectives

The present study shows that a sound combination of different photogrammetrical, geophysical, and meteorological methods can reveal new insights about individual rock glaciers or even complex rock glacier systems. Photo-grammetrical measurements (velocity, streamlines) help to identify moving and non-moving parts and allow age constraints to be derived. Geophysical surveys give insights into the composition and about the ice content of the studied features. Ground surface temperature measurements and additional meteorological data (such as air temperature, snow cover thickness and duration from nearby meteorological stations) give further information that helps to better understand observed kinematic behaviour, such as, short-term velocity changes as recently reported from many Alpine rock glaciers (e.g., Ikeda et al. 2003, Lambiel & Delaloye 2004, Roer et al. 2005).

In summary, our data show a connection between lower resistivities, larger unfrozen water content, and higher MAGST, with higher creep velocity and vice-versa. More extensive and repeated monitoring is necessary, however, to reliably link the kinematic behaviour to the thermal and subsurface properties.

Once longer time-series of such combined measurements are available, this data will help to explain climate forcing impacts on mountain permafrost, such as the above mentioned observed recent increase in rock glacier velocity. The presented monitoring approach will then enable the assessment of future changes of rock glacier dynamics and their causes in the atmosphere and the subsurface. These data can be used as much needed input and forcing variables in permafrost evolution models.

Acknowledgments

Abstract

We deployed a deep permafrost observatory in a borehole at the High Lake Project Site (67°22′N, 110°50′W), Nunavut, Canada with the aims of (1) investigating the physical and chemical limitations on microbial life within such environments, (2) developing life-detecting technologies for the exploration of life on Mars, and (3) constraining the hydrological and thermal parameters relevant to the evolution of permafrost and groundwater flow in these environments. The High Lake Project Site is located in an Archean mafic volcanic belt, with permafrost extending down to 458±5 m depth. The borehole, drilled to a total depth of 480 m, provides multifunctional monitoring capability: subpermafrost geochemical sampling, thermal profile, and estimation of hydraulic and thermal formation properties. The primary sampling objectives are delineating salinity gradients, gas concentration, pH, pe, microbial abundance, community structure, and activity, as well as isolating pristine subpermafrost brine for future studies. A multimode fiber-optic cable, along with a heat-trace cable, was installed to perform distributed temperature-perturbation sensor (DTPS) measurements along the entire length of the borehole. Following successful installation of the borehole observatory, we acquired a thermal perturbation dataset and obtained estimates for formation thermal conductivity and heat flux.

Keywords: borehole observatory; climate change; geothermal profile; microbial sampling; permafrost instrumentation; permafrost thickness.

Introduction

Given that global climate models predict the greatest increases in temperature at arctic latitudes, permafrost is increasingly looked upon as a harbinger of climate change (Anisimov et al. 2007). Borehole thermal profiles provide information on past ground-surface temperature histories (GSTH) not available from atmospheric temperature records collected prior to the twentieth century (Lachenbruch & Marshall 1986, Harris & Chapman 1997). To invert thermal profile data for estimating GSTH, thermal properties need to be constrained. Prior studies have either used laboratory measurements performed on drill cores or cutting fragments, or have used estimates based on lithologic descriptions (Taylor et al. 2006, Majorowicz & Safanda 2001).

Understanding a permafrost site's hydrogeological and thermal conditions is important for predicting the destabilization of permafrost by construction activities, assessing mine inflows, contaminant transport risks, and for the design of tailing and waste rock impoundments (Harris 1986). Given that the economic activities in arctic Canada are predominantly (diamond and metal) mining, as well as oil and gas exploration and production, engineering the necessary infrastructure and assessing the impact that infrastructure has on the natural environment requires understanding both present site conditions and evolving climatic conditions.

In the summer of 2007 we installed a multifunctional borehole observatory at the High Lake Project Site (67°22′N, 110°50′W), in Nunavut Territories, Canada, with the aim of acquiring a broad spectrum of environmental data. Within the permafrost, a distributed thermal perturbation sensor (DTPS) was used to measure the thermal profile; based on these temperature data, we can estimate formation thermal conductivity. Beneath a pneumatic packer located above the base of the permafrost, a U-tube geochemical sampling system acquired fluid samples for delineating gas concentration, pH, pe, microbial abundance, and community structure and

activity, as well as isolating pristine subpermafrost brine for future studies (Freifeld et al. 2005). A pressure-temperature sensor collocated with the U-tube sampling inlet facilitated estimation of hydraulic conductivity.

This paper presents the thermal and hydrologic data collected following installation of the U-tube and DTPS and contains a preliminary interpretation of these data. One of the unique results of our field program was our method of using *in situ* data to estimate formation thermal conductivity with high spatial resolution. This approach—resulting in better estimates of formation thermal conductivity, as contrasted to using laboratory derived values—can reduce uncertainty in prediction of GSTH when inverting borehole temperature measurements.

High Lake Site and Observatory Description

Site description

The High Lake Project Site, shown in Figure 1, is located in an Archaen Mafic volcanic belt, with permafrost extending down to 460 m on a mining exploratory lease originally purchased by Wolden Resources and currently operated by Zinifex Canada Inc. All of the work was conducted within a 75 mm diameter borehole, designated HL03-28. HL03-28 was initially drilled in 2003 to a length of 335 m (depth 304 m) as part of Wolfden Resource's characterization of base metals for potential economic extraction from the High Lake volcanogenic massive sulfide deposit. In July 2006, our project team cored continuously to lengthen HL03-28 to 535 m. After removing an ice blockage that formed in the borehole during the previous season, we installed a permanent borehole observatory.

Borehole observatory

The High Lake borehole observatory targeted both the permafrost region for geothermal investigation and the subpermafrost formation for estimation of hydrologic properties and collection of fluid samples. The instrumentation at the bottom of the borehole, consisting of a pneumatic packer, a U-tube sampling system with a sample fluid reservoir, and a pressure-temperature sensor, are collectively referred to as the bottom hole assembly (BHA). The fluid, electrical, and fiber-optic lines running between the BHA and the surface are referred to as the deployment string.

Figure 2(a) shows a schematic of the High Lake BHA. With an overall length of 14.9 m, the BHA is composed of (from top to bottom) a fluid reservoir for packer inflation, a pneumatic packer (Baski Model MD18, Denver, CO, USA), a sample fluid collection reservoir, a pressure-temperature sensor (In-situ Level Troll 500, Fort Collins, CO, USA) and a U-tube inlet composed of a 40 μm sintered stainless steel filter and a check valve.

Prior to deployment of the BHA, the fluid reservoir was filled with 3 lL of propylene glycol. Propylene glycol was chosen because of its low freezing point and its inability to permeate through the rubber packer gland. To inflate the packer, we applied a N_2 head to the reservoir (using a 6.4 mm stainless steel tube), forcing the fluid into the packer and inflating the packer gland. The central mandrel of the packer served as a conduit for transport of sampled fluid and electrical signals between the surface and the BHA.

A traditional U-tube sampler, as shown in Figure 2(b), is composed of a looped tube, forming a "U" that is open to the formation via a check valve. To recover a sample, compressed N_2 gas, applied to the drive leg, forces the check valve to close, and fluid is transported up the sample leg to the surface. At High Lake, the inlet filter and check valve were both located beneath a 7 lL sample collection reservoir. Using a small, 6.4 mm-diameter inner tube terminating 10 cm from the bottom of the sample collection reservoir (to form a sample leg), the outer large diameter cylinder served the function of the traditional U-tube drive
independent sample lines that ran up to the surface.

The DTPS deployed at High Lake consisted of an HDPE jacketed multimode fiber-optic cable that runs from the top of the packer fluid reservoir up to a Distributed Temperature Sensor (DTS; Agilent Technologies Manufacturing GmbH & Co. KG, Model N4385A, Böblingen, Germany) located at

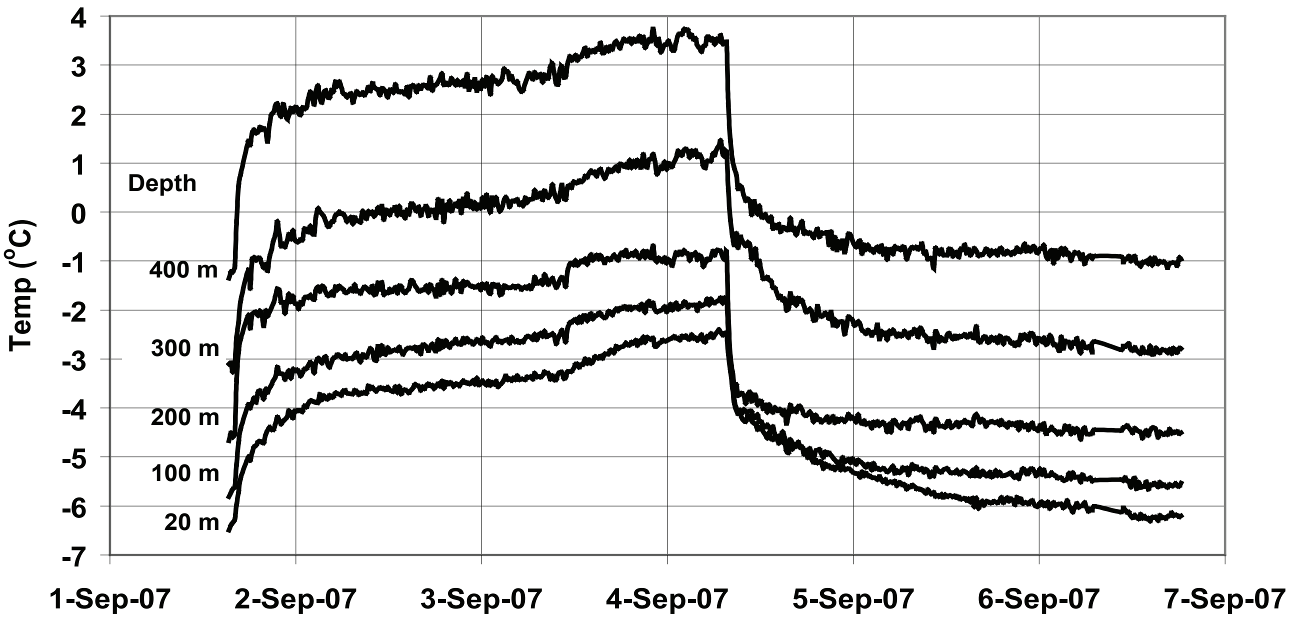

Figure 3. High Lake thermal profiles acquired using a distributed temperature sensor. Heating was initially conducted at a rate of 16.8 W/m for 43 hours, followed by heating at 20.5 W/m for 21 hours. Following the geothermal gradient, the thermal profiles go from coolest (shallowest) to warmest (deepest).

the surface. The DTS uses a laser backscattering technique to measure temperature with a 1 m spatial resolution along the length of the fiber. An overview of the DTS technology as applied to environmental monitoring can be found in Selker et al. (2006). Parallel to the fiber-optic cable is a two-conductor 14 AWG direct burial (outdoor) cable shorted at the bottom, which provides uniform heating along the length of the well when current is applied.

Following the wellbore completion process, the temperature was allowed to equilibrate for 1 month before thermal data were collected. To conduct the DTPS measurement, we first acquired a baseline thermal profile. While energizing the heater cable, additional thermal profiles were obtained at 15-minute intervals to record the thermal transient during heating. After 64 hours of monitoring the heating, the generator was turned off, and cooling was monitored for an additional 58 hours. Figure 3 shows a limited subset of the hundreds of thermal transients recorded.

Results

Fluid sampling

Immediately after deployment of the borehole observatory, the U-tube was operated five times over a span of three days, recovering a total of approximately 60 lL. Although samples were still contaminated with $CaCl_2$ saturated drilling fluids used during the removal of the ice plug a few days earlier, the salinity declined five-fold with the purging of wellbore fluids. The sampling lines eventually froze, despite the fact that heat was being applied at a rate of 20 W/m in an attempt to keep the sample lines flowing. The thermal data (discussed later in detail) show borehole temperatures approaching –7°C and moderate to high formation thermal conductivity, indicating the potential for rapid heat loss of the sampling system. In retrospect, an insulated hose encompassing both the sampling lines and the heat-trace cable would have ensured the continued operation of the sampling system.

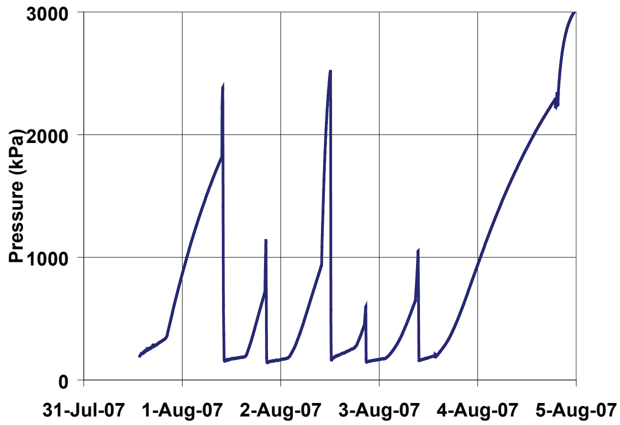
Hydraulic conductivity

During operation of the U-tube sampling system, the bottomhole pressure was continuously recorded using a pressure/temperature sensor located near the inlet of the U-tube sampling system (Fig. 4). The U-tube sampling event corresponds to a sharp increase in pressure (over several minutes) immediately followed by a rapid decrease in pressure, as the compressed gas is vented from the sampling tubing. As fluid reenters the borehole, the downhole pressure rebounds. As shown in Figure 4(b), the increase in pressure occurs in two distinct phases: (1) a slow pressure increase immediately after sampling and venting of the sample lines, which corresponds to filling of the downhole sample reservoir, and (2) a quicker increase, which corresponds to filling of the small-diameter sampling lines that run up to the surface.

To estimate the hydraulic conductivity of the formation beneath the packer, we apply Thiem's Equation. Assuming a homogeneous confined radial aquifer, the hydraulic conductivity is:

$$K = \frac{Q}{2\pi\left(h(r) - H\right)L} \ln \frac{r}{R} \tag{1}$$

where Q is the volumetric flux into the borehole, L the length of the packed-off interval, r the radius of the well, R the radius to a fictitious constant head boundary (assumed to be 2 m), and $h(r)$ (determined in the next section to be 349 m H_2O) and H are the heads at these two locations.



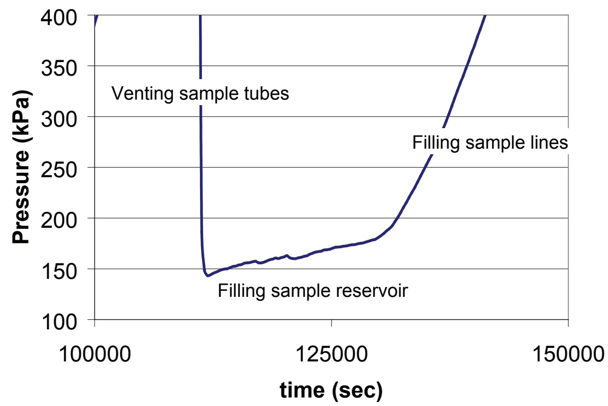


Figure 4. (a) Pressure response during U-tube sampling events as measured near the U-tube inlet. (b) Following acquisition of a U-tube sample and sample line N_2 gas venting, the pressure rebounds slowly as the sample reservoir fills, followed by a quicker rebound during filling of the small diameter sample lines.

To apply Thiem's equation, which requires steady-state conditions, we assume that the head H within the sample reservoir represents a pseudo-steady head of 18 m (Figure 4b)—justified because the change in head (3 m over several hours) is small compared to $h(r)–H$. Q, is assumed equal to the flux into the sample reservoir, determined as the product of the change in the fluid height within the sample reservoir (per unit time) and the reservoir's cross-sectional area.

Given the geometry of the High Lake borehole, the hydraulic conductivity K is estimated to be 2.3×10^{-11} m/s. This exceptionally small conductivity is typical of unfractured igneous rocks.

Permafrost thickness and hydrostatic head

Our results provide the best measured thickness of permafrost in this region, as other nearby estimates by the Geological Survey of Canada are from much shallower boreholes (e.g., Taylor et al. 1998). A linear extrapolation through the lower 120 m of fiber-optic temperature sensor data, with the addition of the discrete data point measured by the Level Troll pressure-temperature sensor (Figure 5), indicates that the base of the permafrost is at 458±5 m, where the depth uncertainty is based upon propagating a temperature error of ±0.1°C into the depth estimate. A small correction (+0.025°C) has been applied to account for the thermal perturbation created near the base of the well during the wellbore completion process, following the method suggested by Lachenbruch & Brewer (1958). By plotting the temperatures measured after wellbore completion as a function of $Log_e(t/(t\text{-}s))$, where t is the time elapsed since wellbore completion and s is the duration of the thermal perturbation (assumed to be 1.25 days), we correct for the effect of cooler water being introduced deeper in the borehole during the completion process (Figure 6).

The steady-state subpermafrost hydrostatic pressure can also be estimated by plotting pressure as a function of $Log_e(t/(t\text{-}s))$—referred to as a Horner Plot in well test literature. Using the pressure data from the Level Troll pressure-temperature sensor, we determined the hydrostatic pressure at a depth of 430 mbgs to be 3420 kPa. This is equivalent to a freshwater head of 349 m or a water table at 81 mbgs.

Thermal perturbation measurements

The DTPS experiment was conducted over a span of five days, with 63 hours of heating and 58 hours of cooling (Figs. 3, 5). To interpret the acquired thermal transients, we used a one-dimensional radial model explicitly incorporating the fluid-filled borehole and steel casing, surrounded by rock with homogeneous thermal properties, to invert cooling data. The formation of ice, which was observed to occur at depths shallower than 30 mbgs during cooling (as indicated by the thermal transients remaining stable near the freezing point of the borehole fluid [–4.5°C] for several hours), was not explicitly incorporated, but will be in future analyses. Heating data are not used, because small variations in spatial distance between the fiber-optic cable and the heating cable create large differences in temperatures. During cooling, however, conduction of heat tends to homogenize temperatures near the wellbore, making the simulations insensitive to the exact separation between the heating cable and monitoring fiber.

Figure 7 shows modeled cooling transients as a function of rock thermal conductivity, with data shown for selected depths. The model data are shown as lines and the measurements are shown as points. Using the one-dimensional radial model to invert the DTPS data, thermal conductivity is estimated along the wellbore with a spatial resolution equivalent to the 1 m resolution of the DTS (Fig. 8). The results shown in Figure 8 are consistent with the borehole lithology and literature values (Clauser & Huenges 1995), in which lower thermal conductivity felsic metavolcanic strata overly mafic metavolcanic strata. The exceedingly high thermal conductivities are attributed to zones in which the core was observed to consist of at least 50% pyrite.

Heat flux

Using the baseline temperature profile (Fig. 5) and the thermal conductivity profile (Fig. 8), the vertical heat flux

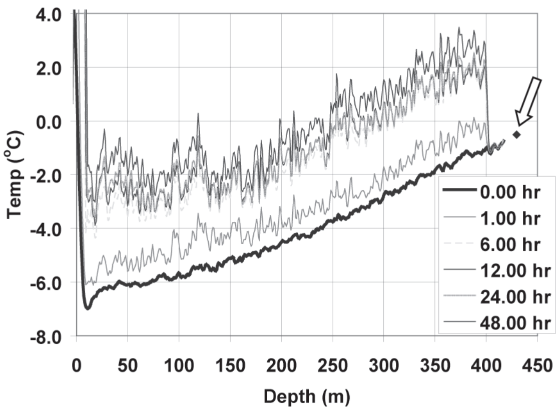

Figure 5. Thermal profiles acquired using a DTS. The lowest profile is the baseline prior to heating and cooling. The arrow points to a temperature measurement provided by the downhole Level Troll pressure-temperature sensor.

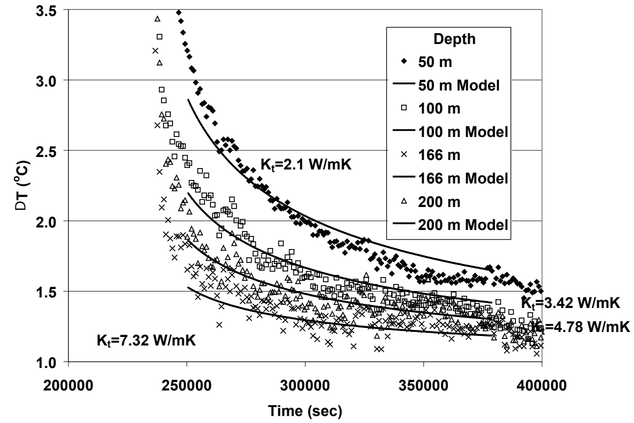

Figure 7. One-dimensional thermal simulations of DTPS testing showing modeled cooling transients along with select measurements. Time is measured from start of heating.

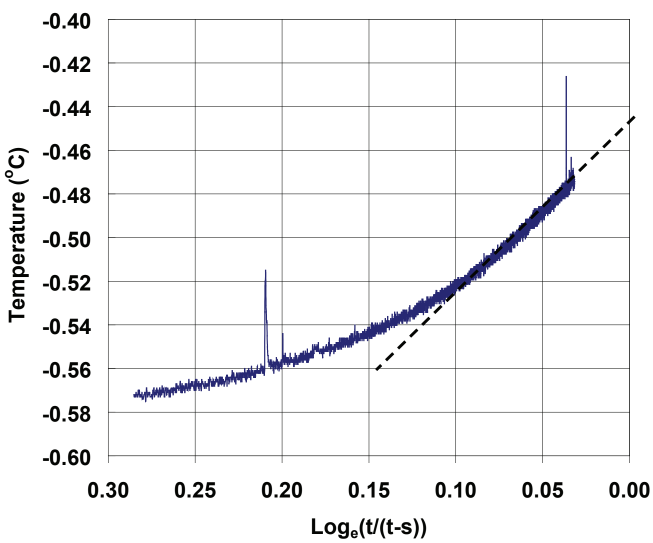

Figure 6. Temperatures measured in HL03-28 at a depth of 430 m following the wellbore completion process, as suggested by Lachenbruch & Brewer (1959) to determine undisturbed conditions. The temperatures extrapolated along the dotted line indicate the well is still 0.025°C cooler than at equilibrium.

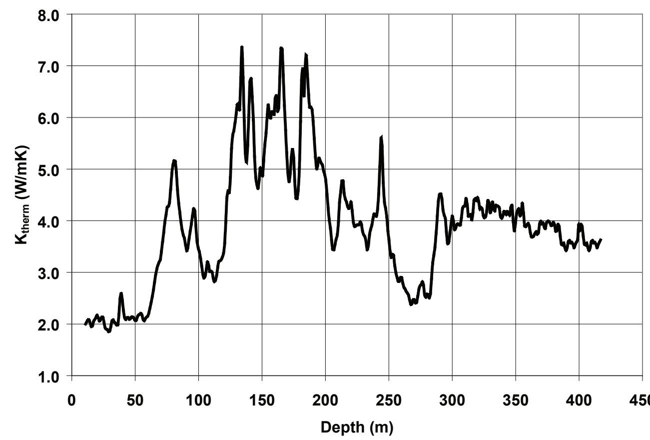

Figure 8. Thermal conductivity as a function of depth using a 1-D model to invert DTPS data. The results are consistent with lithology, in which shallow tuffs are underlain by ore-bearing mafic intrusives.

can be estimated in the vicinity of the wellbore. Using averaged values for thermal conductivity within the felsic metavolcanic units at a depth of 50 to 100 m, we estimate a heat flux of 30 mW/m^2, whereas at a depth between 300 and 400 m, the heat flux is much greater, 70 mW/m^2. The value of 70 mW/m^2 is considerably greater than the average value of 46±6 mW/m^2 reported for two wells 320 km south of High Lake by Mareschal et al. (2004) at Lac du Gras, Nunuvut, Canada. It is also greater than the value of 54.1 mW/m^2 estimated by inversion of thermobarometric data by Russell & Kopylova (1999) at the Jericho Kimberlite Pipes located 230 km southwest of High Lake. The much higher heat flow at High Lake can probably be attributed to the effect of the massive volcaniclastic sulphide deposit that can act as a conduit for conduction of heat to the surface.

The reduction in the estimated heat flux observed at the shallower depths (50 m to 100 m) at HL03-28 is consistent with other studies investigating GSTH. This change in heat flux is apparent in Superior Province temperature logs (Shen & Beck 1992), temperature logs from three borehole in northern Québec (Chouinard et al. 2007), and also in temperature profiles reported in the Canadian Arctic Archipelago (Taylor et al. 2006). However, without more detailed information on the three-dimensional shape of the High Lake ore body, which could influence lateral heat flux, and/or the regional history of snow cover, which would impact vertical heat flux (Stieglitz et al. 2003), it is impossible to know how much of the observed warming can be attributed solely to changes in GSTH.

Conclusions

We have deployed a multifunctional borehole observatory at the High Lake Project Site, which includes a bottomhole assembly for subpermafrost geochemical sampling using a

U-tube sampler located beneath a packer, and a pressure/temperature sensor for monitoring hydrologic conditions. The deployment lines contained a distributed thermal perturbation measurement system, consisting of a fiber-optic cable for distributed temperature measurements, and a heat trace cable to uniformly heat the wellbore.

Given the interest in using borehole temperature profiles as an indicator of paleoclimate, we have demonstrated a methodology for using the DTPS data for estimating formation thermal conductivity as a function of depth with meter-scale resolution. Having *in situ* estimates for thermal properties can reduce uncertainty in inverting borehole temperature profiles, leading to more accurate delineations of ground surface temperature history (GSTH). Future work using the High Lake data set will estimate the GSTH using the detailed thermal conductivity profile and the measured baseline temperature profile.

The Permafrost Legacy of Siemon W. Muller

Hugh M French
10945 Marti Lane, North Saanich, British Columbia, Canada
Frederick E. Nelson
Department of Geography, University of Delaware, USA

Abstract

Siemon W. Muller's contribution to permafrost engineering in North America is widely recognized. His status in this field derives from a 1943 US Army engineering manual, compiled from translated Soviet literature and prepared to alleviate problems experienced during construction of the Alcan (Alaska) Highway. Muller's status in permafrost science is derived from the same source, but in this context his contribution is less well defined. A previously unpublished manuscript by Muller, drafted prior to 1963, could have made a contribution to permafrost *science* as significant as his earlier effort was to permafrost *engineering*. It would also have encouraged development of a holistic approach to geocryology in North America, similar to that developed in Russia and China, as opposed to the dualism that evolved between permafrost science and permafrost engineering in the mid-century North American literature.

Keywords: geocryology; history of science; North America; permafrost engineering; permafrost science.

Introduction

Siemon W. Muller is generally regarded as the "father" of permafrost studies in North America. Muller used the term *permafrost*, which he apparently calqued from Russian (Kabakchi & Butters 1989, French & Nelson 2008), to describe the perennially frozen and often ice-rich terrain encountered during construction of the Alcan (Alaska) Highway in 1942–43. He documented the engineering problems associated with construction in ice-rich permafrost terrain in a US Army handbook, first printed in 1943 and subsequently declassified and printed in book form in 1947 (Muller 1943, 1947). This book formed the framework for North American permafrost engineering over the next two decades.

Less clear is Muller's legacy as regards permafrost science in North America. A monograph by Stephen Taber (1943), published virtually simultaneously, provided a more thorough discussion of the genesis and evolution of perennially frozen ground in Alaska. The present paper draws upon a previously unpublished manuscript completed by 1963 (French & Nelson 2008) and speculates about how Muller's contribution to permafrost science might have been enhanced if this manuscript had been published at that time. The near-complete manuscript was found in 1996 in his files.

The Man

Of critical significance to Muller's permafrost legacy was his Russian heritage. He was born in Blagoveshchensk, eastern Russia, near the border of Manchuria. He left Russia shortly after the Russian revolution and moved to the US in 1921. His fluency in Russian allowed him to introduce Russian permafrost knowledge into North America at a time when few North American scientists were fluent in Russian and there were few contacts between Soviet and North American scientists.

Contrary to what one might expect, permafrost was a distinctly subsidiary interest for Muller, and he never contributed to its primary literature. The central focus of his research was the Triassic paleontology and stratigraphy of western Nevada. His teaching responsibilities at Stanford University, where he studied and worked for more than 40 years, included courses in historical geology, paleontology, stratigraphy, and the geology of California.

During the 1930s, Muller developed a close collaboration with the USGS geologist Henry Ferguson. They worked together on the geology of western Nevada, and Muller assumed a part-time affiliation with the USGS. Muller's knowledge of stratigraphy, structural geology, and field methods, combined with his knowledge of Russian, explains why he was approached by the US Army in 1942 to give geological advice during construction of the Alcan Highway. The outstanding merit of the 1943 US Army handbook was its accurate, well-organized summary of early Russian permafrost literature. This allowed others to solve the many permafrost engineering problems encountered in wartime projects in Alaska and northern Canada.

Upon his return to academia in 1945, Muller resumed his teaching responsibilities and collaborative research with Henry Ferguson. He also began teaching a course on permafrost. His only graduate student to concentrate on permafrost was Troy Péwé (PhD Stanford, 1953) but others, such as Lou deGoes and some USGS staff at Menlo Park, probably attended his classes. Muller published virtually nothing on permafrost during the remainder of his career. The unpublished book manuscript referred to above appears to have been his only attempt to add to the permafrost literature. We can only speculate about the reasons why he did not bring the book to publication (see French & Nelson 2008).

The Growth of Geocryology in the USSR

The occurrence of perennially frozen ground in northern North America had been known in general terms for more than a century by the time of Muller's 1943 report (e.g., Leffingwell 1919; see French 2003, 29–34). By the early 1930s the extent of frozen ground in both Alaska and northern Canada was reasonably well known. However, a detailed understanding of the permafrost terrain of central Alaska was still lacking.

By contrast, the Russian experience with frozen ground was far more extensive (see Shiklomanov 2005). This was because an Institute of Permafrost had been established in Yakutsk by the USSR Academy of Sciences in 1939. Also, the movement of population, often penal in nature, to the more remote parts of Siberia had begun. The boreal forest was being removed and agriculture started. Russian-language texts soon summarized extensive knowledge about permafrost (e.g., Sumgin 1927, 1937), and the first edition of what was to become the standard Russian text on permafrost for the next 25 years, *Obshcheye Merzlotovedeniya (General Permafrostology*), was published in 1940 (Sumgin et. al. 1940). By the late 1950s, a major publication by the V.A. Obruchev Institute of Permafrost Studies, Moscow, entitled *Osnovy geokriologii (merzlotevedeniya) (Principles of Geocryology*) (Shvetsov & Dostovalov 1959) had appeared. This text was divided into two volumes: Part I – General Geocryology and Part II – Engineering Geocryology. The science and engineering aspects of permafrost were explicitly linked in one discipline: geocryology. A similar approach to geocryology developed later in China (Academia Sinica 1975, Zhou et al. 2000).

The Emergence of Permafrost Science and Permafrost Engineering in North America

In North America, the most significant early advances in understanding permafrost phenomena were made in a series of laboratory experiments by Stephen Taber, an American engineer. In a number of papers published between 1916 and 1930, he examined the mechanics of frost action and the process by which ice segregates in freezing soil (Taber 1929, 1930). These were seminal contributions, soon followed by Swedish studies of frost heaving, especially as they applied to roads and buildings, and then by Japanese military engineers in Manchuria during the Second World War (see Sugaya 1956). It was in a similar context that Muller became involved, in 1942–43, in construction of the Alcan Highway (Fig. 1).

In the same year that Muller's US Army handbook appeared, Stephen Taber published a monograph-length paper summarizing available knowledge on perennially frozen ground in Alaska (Taber 1943). This paper describes the climatic and vegetation conditions associated with perennially frozen ground and related geomorphological processes, including freezing and thawing, frost heaving, and mass wasting. It also discusses the Quaternary-age gravels and silts that overlie bedrock in Alaska, their frozen nature, and the occurrence of ground ice, both in bedrock and surficial sediments. Finally, a sequence of Pleistocene events is set out, involving successive periods of sediment deposition, deep freezing, deep thawing and erosion, and refreezing.

Taber's 1943 monograph, rather than Muller's, might more properly be regarded as the beginning of modern permafrost science in North America. Not only does it discuss the conditions associated with permafrost occurrence (as does Muller's), but also it considers the Pleistocene history and origin of permafrost and ground ice as mentioned above. These became central themes in permafrost science in North America in the second half of the 20th century. Examples are T.L. Péwé's Pleistocene and Quaternary geology work in Alaska, J.R. Mackay's permafrost and ground-ice-related studies in the western Canadian Arctic, and A.L. Washburn's concern for solifluction and mass-wasting processes. It is significant that Taber used the term "perennially frozen ground" and made no mention of either "permanently frozen ground" or "permafrost." The latter were the two terms used by Muller in his 1943 manual. Permafrost is now, of course, generally referred to as being "perennially" rather than "permanently" frozen ground.

Muller's primary concerns in his 1943 manual were the geotechnical and engineering problems associated with ice-rich permafrost terrain. His admirably explicit treatment

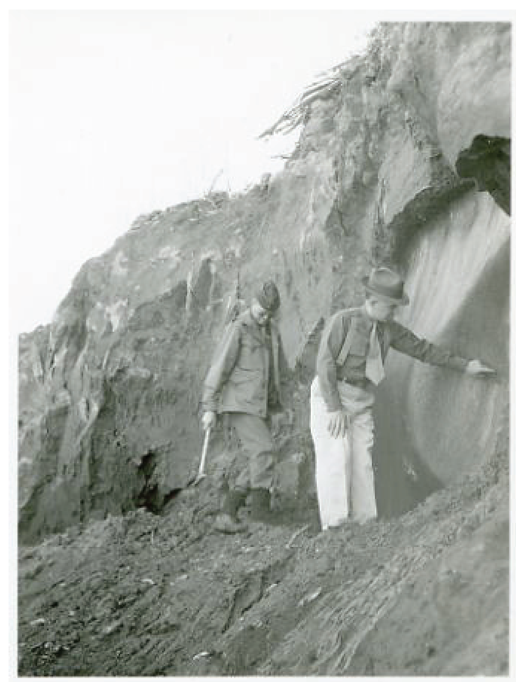

Figure 1. Photo of Siemon Muller in 1944, near Fairbanks, Alaska, with Roy Earling, President of the U.S. Smelting, Refining, and Mining Company, and Fairbanks Exploration Company. Muller is wearing the clothes of a US Army officer, but with no insignia or rank; he was a civilian. The sediments that enclose the ice wedges are part of the Goldstream Formation of Wisconsinan age (~120,000 to 10,000 years ago). The upper 1.5 m (above the ice wedges) is Holocene-age sediment (Ready Bullion Formation). Caption details supplied by T.L. Péwé, December 1996. Source of photo: unknown.

of these issues promoted the formation of governmental research agencies involved with cold regions geotechnical engineering in both the US and Canada (e.g., the Snow, Ice and Permafrost Research Establishment [SIPRE], later to become the Cold Regions Research and Engineering Laboratory [CRREL], in Hanover, New Hampshire, and the Division of Building Research [DBR], National Research Council of Canada [NRCC], in Ottawa, Ontario); and the emergence of professional groups such as the Technical Committee on Cold Regions Engineering (TCCRE) of the American Society of Civil Engineers (ASCE), the Cold Regions Engineering Division of the Canadian Society of Civil Engineering (CSCE), and the Cold Regions Geotechnology Division of the Canadian Geotechnical Society (CGS).

The Muller and Taber publications of 1943 are complementary. Symbolically, they mark the beginning of a dualism that continues in North America between the literature of permafrost science and permafrost engineering. Attempts were initially made to bridge the divide, as personified by the close collaboration between Roger Brown and Hank Johnston at the NRCC (e.g., Brown & Johnston 1964, Johnston et al. 1963), and various USGS reports on permafrost terrain problems in Alaska (e.g., Hopkins et al. 1955, Lachenbruch 1962, Ferrians et al. 1969). However, it is fair to conclude that cold regions engineering soon developed as a separate discipline, only to be reunited with permafrost science every five or ten years at the international permafrost conferences.

"Frozen in Time" – The 1963 Manuscript

Muller's previously unpublished manuscript (French & Nelson 2008) indicates that he was acutely aware of the imbalance between permafrost science and permafrost engineering in his 1943 monograph. It is clear that in the 15 years following his return to academia in 1945, he closely followed the permafrost literature in both North America and the USSR. Not only did he attempt to update the North American engineering practices described in his 1943 manual, but also he attempted to incorporate Russian understanding of permafrost science. Several examples can be offered.

First, Muller was aware of the importance of the unusual permafrost conditions that characterize the base of the active layer and the top of permafrost. This is why he used the term *active zone* rather than the more conventional term *active layer* that dominated the North American literature. The evolution of his ideas concerning near-surface permafrost terrain is illustrated in Figures 2 and 3, where Muller's 1943 diagram is compared with a reworked version in the later manuscript. In Figure 3b Muller indicates that the active zone is composed of two layers: a near-surface layer that freezes and thaws annually and a lower layer ("pereletok") that might remain frozen in certain years of cooler summers and thawed in others of warmer summers. This reflected the Russian permafrost literature. Nearly 30 years were to pass

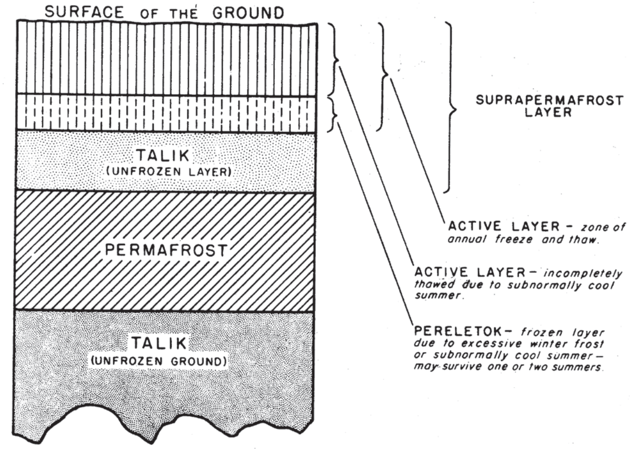

Figure 2. Muller's 1943 Figure 5, entitled "Diagram showing the different layers in the permafrost area."

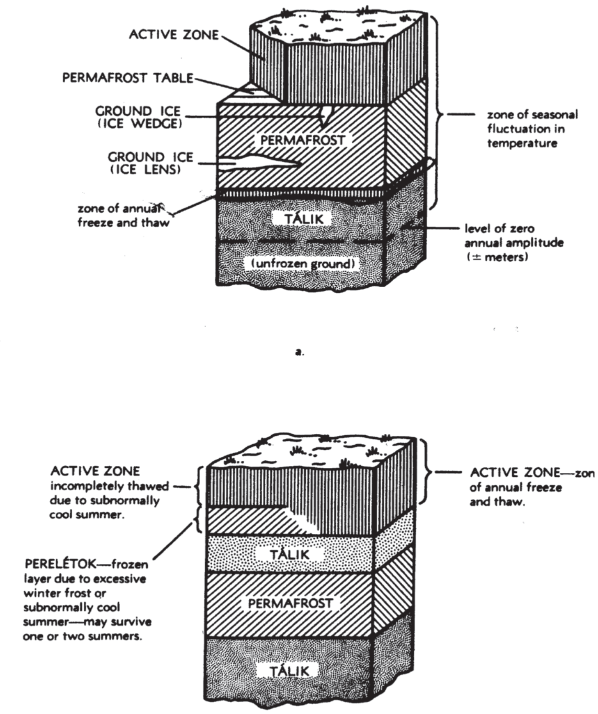

Figure 3. The 1963 manuscript's Figure 1, entitled "Diagrams of profiles with permafrost."

before a three-layer concept of the active layer-permafrost interface was formally introduced into the North American literature (Shur 1988, Shur et al. 2005). This ice-rich zone has been termed the *transient layer*.

It is now clear that the depth of the active layer fluctuates on both yearly and decadal time scales. It promotes an ice-rich layer (or "zone") at the active layer-permafrost interface. Current global warming concerns also focus attention upon this ice-rich layer; for example, it is central to the second phase of the Circumpolar Active Layer Monitoring (CALM II) program (Nelson et al. 2004).

Second, Muller understood the complex role played by vegetation over permafrost distribution and nature. Even before 1943, there was a large Russian literature available on

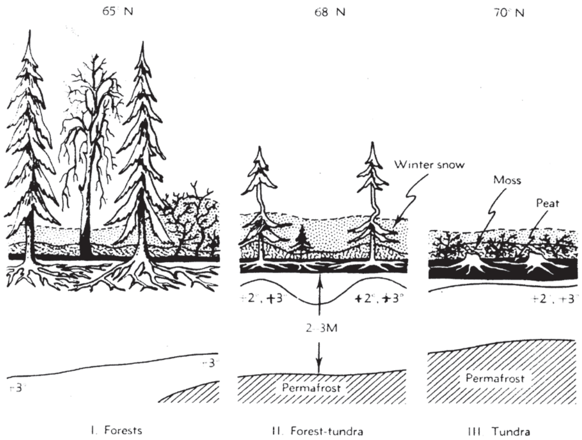

Figure 4. The 1963 manuscript's Figure 47, entitled "The combined effect of moss, peat, and snow on the distribution of roots and on the summer ground temperatures in forests, forest-tundra, and tundra, at latitudes of 65ºN, 68ºN and 70ºN."

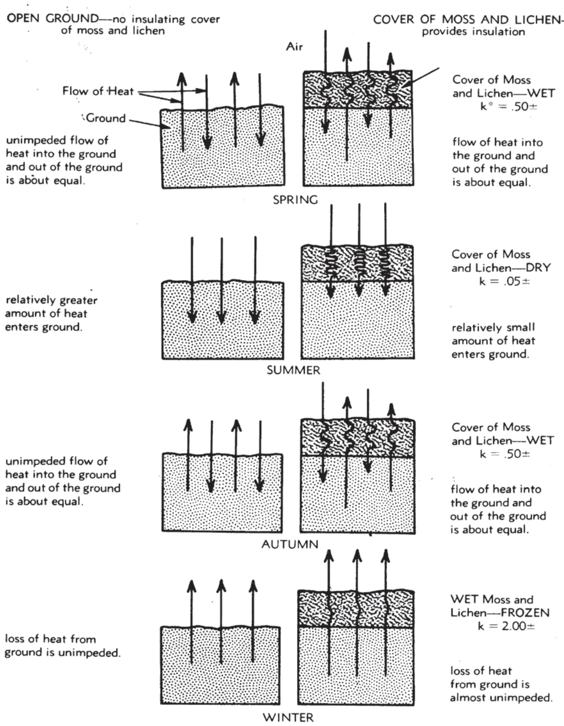

Figure 5. The 1963 manuscript's Figure 4, entitled "Flow of heat between air and ground in tundra country."

this topic (e.g., Sumgin et al. 1940, Tyrtikov 1956). Muller relied heavily on a text by A.A. Grigor'yev (1956) describing the vegetation of the Russian subarctic and tundra. For example, an elegant figure summarizes the effects of moss, peat, and snow on vegetation in the forest, forest-tundra, and tundra at latitudes of 65°, 68°, and 70°N (Fig. 4). It was not until after Muller had drafted his manuscript, and translations of the 1959 *Principles of Geocryology* had appeared, that North American permafrost scientists began to appreciate the importance of vegetation (e.g., Brown 1966, 1970).

The importance ascribed by Muller to the influence of vegetation was also a precursor to modern studies of permafrost, ground climate, and the "n-factor" (e.g., Lunardini 1978, Klene et al. 2001). For example, Figure 5 summarizes his discussion of the effects of soil thermal conductivity (k) upon heat flow in "open ground" (i.e., tundra with no insulating cover of moss and lichen) and in terrain where a cover of moss and lichen provides insulation.

Third, Muller expanded the treatment of ground ice in his 1943 manual by discussing ground ice in the context of cryostructures and cryotextures. This Russian approach (Vtyurin 1965) was far more advanced than the descriptive classification used in North America at the time (e.g., Pihlainen & Johnston 1963), since it inferred genesis and implied permafrost history. The cryostratigraphic approach to permafrost history only developed in North America three decades later (e.g., Mackay 1974, Burn et al. 1986, Murton & French 1993).

In other ways, too, Muller was ahead of his time. For example, he used some of the "cryo" terminology of K. Bryan (1946). At the time, this was largely rejected by the academic community. He thereby avoided the semantic pitfalls associated with the terms *frozen* and *unfrozen*, an ambiguity that continued into the 1990s (Burn 1998). Also, in his discussion of "cryogenic" weathering, he relied on Soviet literature that preceded later research, demonstrating the existence of microbiological processes at sub-zero temperatures (e.g., Gilichinsky et al. 1995).

Finally, many engineering concepts in the earlier text were upgraded to incorporate advances in the 1950s. For example, the manuscript reveals that Muller clearly understood the significance of moisture migration in freezing soils and its relevance to frost heave and ice segregation. Following recent Soviet work (Bozhenova 1957), Muller illustrated how moisture migrates in freezing soils (Fig. 6). Although this was confirmed by the subsequent work of E. Penner (1959), it was not until 20 years later that its geomorphological significance was recognized (e.g., Cheng 1983, Mackay 1983).

One of the last meetings Muller attended before his death in 1970 was a USGS seminar dealing with the Alaska North Slope. When Muller raised a concern about the engineering planning of the proposed pipeline, the USGS scientist A.H. Lachenbruch (1970, J5) responded that "substantial unsolved problems have received remarkably little attention." One is tempted to speculate about the impact Muller's then-unpublished text might have had on the subsequent construction of the TAPS Pipeline later in that decade.

Conclusions

Muller's pioneering status in North American permafrost engineering is well deserved. Viewed from the privileged position of hindsight, however, one can argue that his 1943 monograph neglected permafrost science. Undoubtedly, the realities of wartime explain this.

Muller's "lost" manuscript was an attempt to rectify this deficiency, but unfortunately and for unknown reasons, he abandoned his nearly completed project, never to return to it.

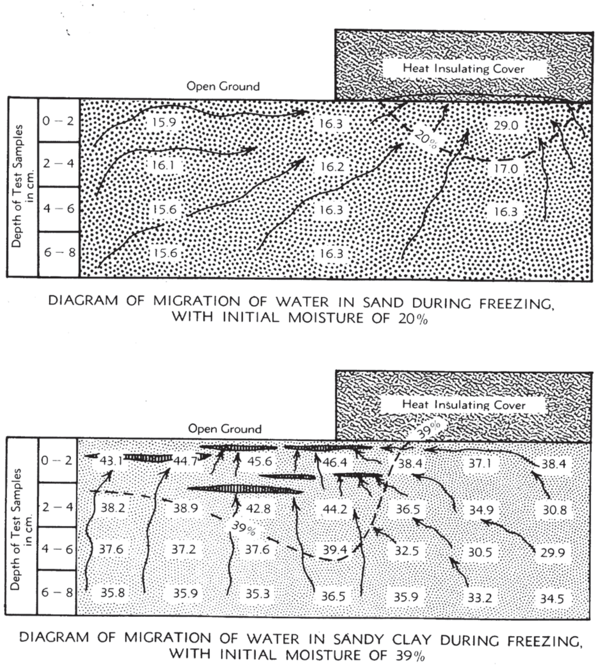

Figure 6. The lower two diagrams of the 1963 manuscript's Figure 13, entitled "Diagrams of migration of water in sand (sandy clay) during freezing with initial moisture contents of 13%, 20%, and 39%."

Muller's manuscript, if published in 1963 at the time of the First International Conference on Permafrost, would have advanced permafrost science in North America in the same way that his 1943 US Army handbook became a benchmark for permafrost engineering in North America. It contained concepts and information that would have advanced permafrost science in North America by at least two decades. But even more important, by integrating permafrost science with permafrost engineering, Muller would have promoted a holistic approach to geocryology in North America. This would have made the study of permafrost in North American more similar to the discipline of geocryology that developed in both Russia and China.

Acknowledgments

HMF acknowledges the late Troy L. Péwé, who instilled in him an appreciation of the legacy of Siemon Muller and who passed to him, in 1995, many of Muller's books, papers and photographs. Jerry Brown and an anonymous reviewer provided helpful comments on the manuscript

Abstract

The active layer thickness (ALT) in tundra ecosystems of North Yakutia is controlled by soil texture. Normal thaw depth in zonal soils of sandy tundra are about 50–105 cm, while in soils of loamy tundra it is 35–70 cm. In the intrazonal ecosystems, the seasonal thaw depth is smaller than in complementary zonal ecosystems. Studies in the Kolyma Lowland show that the ALT pattern is subject to climatic zonality. ALT reaches 27–37 cm in the Arctic tundra subzone; in the Typical tundra it is 41–42 cm, and 43–49 cm in the Southern tundra. In the Northern taiga, the thaw depth under positive microrelief elements varies between 43 and 90 cm in loamy soils and between 65 and 120 cm in sandy soils. According to our data, the active layer in Yana-Indigirka and Kolyma Lowlands experienced a progressive thickening over the 2000–2006 period.

Keywords: active layer; climate; permafrost; Russia; soils.

Introduction

The monitoring of the active layer thickness (ALT) plays an important role in global permafrost observation efforts. During the 1996–2006 period, extensive active-layer field observations were conducted in North Yakutia under the auspices of the international Circumpolar Active Layer Monitoring (CALM) program (Brown et al. 2000). An analysis of empirical data and previously published information (e.g., Karavaeva 1969, Garagulya et al. 1970, Savvinov 1976, Soloviev 1978, Elovskaya et al. 1979, Perfilieva et al. 1991) have revealed spatial and temporal patterns of seasonal thaw for one of the least investigated regions. Special emphasis was placed on analysis of the active layer response to changing air temperature attributable to climate variability and change.

Analysis, conducted in permafrost regions of West Siberia, indicates pronounced deepening of seasonal thaw over the decades (Moskalenko 2001, Melnikov et al. 2004, Pavlov et al. 2004). No long-term measurements of the active layer depth are known from North Yakutia. In this paper we investigate the spatial and temporal ALT trends for North Yakutia and its relation to landscape and climatic variables. Due to the lack of adequate long-term empirical information, this study is focused primarily on recent changes in the active-layer thickness.

Study Area

The study was conducted primarily in the tundra zone of North Yakutia and Northern taiga subzone of the Lowlands (Fig. 1). The observational sites were selected to represent characteristic landscapes of both bioclimatic zones.

The tundra zone of Yakutia occupies the coast and islands of East-Siberian and Laptev seas and extends to 250–300 km inland. Based on climatological and geobotanical criterion, it is subdivided into Arctic, Typical, and Southern tundra subzones. The territory is largely underlain by ice-rich loamy sediments of the Late Pleistocene yedoma formation, which was subject to extensive thermokarst and thermoerosion processes since the Holocene optimum. The topography is represented by alternating yedoma uplands and thermokarst depressions (alases). Upland surfaces are covered by low shrub/sedge/green moss, sedge/green moss/dryas, or green moss/osier associations, and characterized by zonal Cryozem or Gleyzem (*Glacic Haploturbels, Typic Haploturbels,* and *Typic Umbriturbels*) soils. The microrelief is represented by frost mounds. Alases are predominantly occupied by polygonized bogs. A few areas in the tundra zone are underlain by well-drained sand deposits covered by low shrub/lichen and green moss/low shrub/lichen associations with Podbur (*Spodic Psammoturbels*) soil representing a zonal soil type. The microrelief is characterized by frost mounds and hummocks.

The sites representative of the Northern taiga are underlain by loam and sands. Vegetation is characterized by larch forest with the low shrub/lichen, lichen/green moss, and low shrub/green moss/lichen associations often growing under shrub storey. Cryogenic microrelief is less expressed in Northern taiga than in tundra. Flood-plain landscapes are spotty and include drained river banks and different types of bogs. Sedge/green moss/willow and *calamagrostis* associations are found near the river channels. Frost mounds are abundant and pronounced, and they are associated with the Alluvial soddy gleyic (*Typic Umbriturbels*) soils. There is a huge variety of flood-plain bogs.

The climate of Yakutia's tundra zone is severe and strongly continental. The mean annual air temperature in tundra zone varies between -11.5°C and -15.0°C. The mean

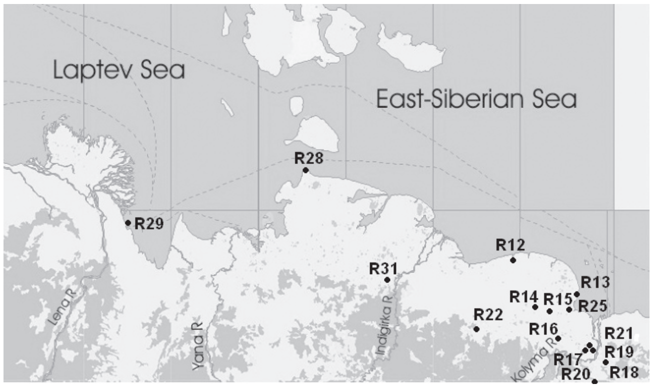

Figure 1. Map of the North Yakutia lowland with the CALM-site locations: R12 - Bolshaya Kuropatochya River (plakor and slope); R13 - Malyi Chukochiy Cape (plakor and alas); R14 - Bolshaya Chukochya River; R15 - Malaya Konkovaya River (plakor and alas); R16 - Segodnya Pingo; R17 - Akhmelo Channel; R18 - Mountain Rodinka; R19 - Glukhoe Lake; R20 - Malchikovskaya Channel; R21 - Akhmelo Lake; R22 - Alazeya River; R25 - Yakutskoe Lake; R28 - Svyatoy Nos Cape; R29 - Bykovsky Cape (plakor and alas); R31 - Allaiha River.

air temperature in January is -29.0°C to -37.5°C. The mean July air temperature varies between 2.5°C and 5.0°C in Arctic tundra and between 6.5°C and 11.5°C in Typical and Southern tundra.

The area is underlain by continuous low-temperature permafrost that is 500–650 m thick. The coldest permafrost (-10°C to -12°C) is found in the yedoma uplands of the tundra zone. Alases and areas underlain by sand are characterized by higher permafrost temperatures (-8°C to -10°C). The permafrost temperature of the Northern taiga varies within a -5°C to -8°C range and can be warmer near large streams.

Observational Program

An array of 19 active layer monitoring sites was established following standardized CALM procedure (Brown et al. 2000) in the following North Yakutian subregions: Bykovskii Peninsula, Yana-Indigirka Lowland, and Kolyma Lowland (Fig. 1). Sixteen sites are located in tundra, while the remaining three sites are situated in the Northern taiga zone. Each site consists of a regular 1 ha grid. ALT observations are carried out by graduated metal rode at 10 m interval, yielding 121 point measurements per each site. The points were arrayed with 10 m spacing in aligned rows. A set of supplementary sites of variable sizes was established in landscapes under-represented by the primary CALM sites. A detailed description of sites and observation methodology is provided in Fyodorov-Davydov et al. (2004).

Spatial Controls of Active Layer Thickness at Different Scales

The thickest active-layer of 110–125 cm was found in sandy dunes, while minimum ALT (15–30 cm) was observed at sphagnum- and/or grass/green moss-covered polygonized bogs and palsas, underlain by peat soils.

In zonal tundra, ALT usually corresponds well to soil texture. Mean multi-year ALT values for sandy Podbur soils are about 50–105 cm, with maximum recorded thaw depth reaching 120–150 cm. Loamy Cryozem and Gleyzem soils are characterized by 35–70 cm ALT with the maximum reaching 75–80 cm (Table 1).

Observations in the Kolyma Lowland, the region with the highest number of sites, showed that ALT generally corresponds to climatic zonality. For similar yedoma watersheds with zonal tundra vegetation, frost mound microrelief, and Cryozem soils, the mean multi-year ALT values increase from north to the south (Table 2). The typical ALT value for northern-most Arctic tundra is about 27–37 cm, followed by 41–42 cm in Typical tundra and 43–49 cm in southern most Southern tundra. Microtopographically, the zonal ALT pattern is better expressed for frost mounds than intermound depressions. The overall ALT difference between Northern and Southern tundra locations is about 12–22 cm. ALT difference within frost mounds increases to 30 cm, and decreases to 10–13 cm for intermound depressions (Table 3).

Sandy tundra soils are located predominantly in the northeast of the Kolyma Lowland (so called Khallerchinskaya tundra) and distributed in a narrow latitude belt within the Southern tundra subzone. Due to meridian distribution of the sandy soil, the ALT there differs more than in loamy soils characteristic of yedoma landscapes (Table 4). For instance, on the sandy sites with zonal vegetation, the ALT within the mounds increased to 35–53 cm from north to the south (1.7–2.0 times), and to 18–41 cm (1.4–1.8 times) for intermound depressions. ALT in polygonal crack areas does not express any latitudinal zonality.

The mean ALT generally increases along the tundra-taiga direction (Table 2). However, the spatial heterogeneity of landscapes also increases from north to south as the timber stand, soil and vegetation types, slope angles, and exposure play a more pronounced role. Within the Northern taiga subzone, the ALT for loamy soils ranges between 43 and 91 cm (Table 3) and between 65 and 119 cm for sandy soils (Table 4). At the same time, at the zonal boundary, the ALT in the forests is thinner than in tundra. Trees (larch) decrease the soil temperature by (a) shading ground surface; (b) creating a shielding effect through their horizontal root systems; (c) creating an additional organic soil horizon (forest litter); (d) promoting the wide occurrence of mosses; and (e) significantly delaying snow melt. As a result, in the northeast of Kolyma Lowland, the mean ALT in sandy soils of Northern taiga (R19) was up to 5–15 cm less than in its tundra analogue (R21).

The differences of seasonal thaw depth between intrazonal landscapes are determined by soil moisture and the presence and thickness of peat horizons in the soil profile. Along streams, alluvial soddy gleyic soils of riverbanks thaw to 35–90 cm, alluvial peat-gley soils of the central part of the floodplain active layer extend to 20–50 cm. In thermokarst depressions (alases), Gleyzem soils of well drained sites thaw to 25–55 cm, and the ALT at polygonized bogs with Peat-Gleyzem soils is 10–35 cm. Since the bogs are more

frequent and extensive in flood plains and alases than in well-drained areas, the mean ALT values are significantly lower compared to adjacent zonal ecosystems. In the sandy Khallerchinskaya tundra, the ALT depends on the thickness and composition of soil organic horizons. In polygonized bogs this corresponds to different stages of bog formation. For younger bogs, ALT varies from 47–55 cm, 18–27 cm in later stages of bog development and peat formation, and 33–60 cm in bogs characterized by the peat degradation stage. Mean ALT at the standard 100x100 m R16 site, covering the different stages of polygonized bogs, was about 1.5 times less than in the microplakor with zonal sandy soil, and about 2.2 times less than at the analogous R21 site characterized by a zonal landscape of sandy tundra.

Temporal Active Layer Dynamics

Annual ALT observations indicate a pronounced thickening of the active layer over 2000-2005 for both zonal and intrazonal soils of the Kolyma Lowland. This period was characterized by high summer temperatures. Based on observations at the Chersky Meteorological Station, the mean summer air temperatures over the 2000–2005 period were 11.3°C-13.7°C, a significant increase compared to the 1998–1999 minimum of 8.3°C-9.8°C. Due to warming, 10 of 12 sites demonstrated an ALT increase (r=0.67-0.96, n=10). In 2003, the thickening of the active layer became evident at all tundra (R13, R14, R21, R22, and R25) and Northern taiga (R18 and R19) zonal ecosystems, as well as at the majority of intrazonal landscapes including flood plains (R17), alases (R13A), and polygonized bogs (R16).

The maximum increase in ALT was observed in sandy Podbur soils and varies from 32 cm (40% from the multi-year mean) in taiga (R19, Fig. 2A), up to 40 cm (44%) in tundra (R21, Fig. 2B). An extremely high increase of 26 cm (65%) was found in the polygonized bogs of the Khallerchinskaya tundra (R16, Fig. 2C), where the relative increase of ALT was higher than at the zonal sites. The greatest ALT sensitivity to the increase of summer temperatures was realized at sites characterized by more advanced stages of bog development and covered by green moss and green moss/lichen/sedges. For these sites, a comparison with ALT data from the mid-1990s indicates an ALT increase of 11–18 cm, or 27%–51%, from the multi-year mean. By contrast, at the younger bogs covered with sedge/sphagnum, the ALT increase did not exceed 3%.

For loamy cryosol soils within the tundra zone, the relative ALT increase is reduced from north (Typical tundra) to south (Southern tundra).

At the upland site of the East Siberian Sea coast (R13), the ALT has increased by 13 cm (33%) (Fig. 2D), in the mid-stream of Bolshaya Chukochya River (R14) by 10 cm (24%) (Fig. 2E), and in the similar landscape at the tundra/taiga boundary (R22) by only 7 cm (14%) (Fig. 2F). In the

Legend: 1 - top of a hillock (microplakor), hummocks on the surface of mounds; 2 - top of a hillock, between hummocks in the limits of mounds; 3 - top of a hillock, between mounds; 4 - slope of a hillock (microslope), hummocks on the surface of mounds; 5 - slope of a hillock, between hummocks in the limits of mounds; 6 - slope of a hillock, between mounds; 7 - microdepression, bare spot medallions; 8 - microdepression, ridges surrounding spot medallions.

Northern taiga subzone (R18), ALT increased by 13 cm (17%) (Fig. 2G).

An even greater thaw increase of 32 cm (80%) (Fig. 2H) was observed at the other northern site (R25), located on a steep (20°–25°) southeast slope, where the ice-rich layer common to yedoma is absent.

Low summer temperatures in 2006 (10.5°C) led to a relative decrease in ALT (3%–36%) from the multi-year mean. However, ALT has never reached the level of cold of the 1998–1999 years (Fig. 2).

An increase of ALT during the investigation period was also observed at the nearby Yana-Indigirka Lowland. In 2004–2006, the mean ALT increased from 38 to 44 cm at the upland site of Typical tundra subzone (R31). On the Bykovskiy Peninsula site (R29), no significant ALT changes were obtained in either upland yedoma or alas landscapes.

The longest ALT record is available for a site established near Akhmelo Lake. Figure 3 shows temporal ALT variability at the Akhmelo site for different landscape elements over the 1989–2006 period. In 1991, the ALT reached 93–115 cm under different landscape elements in response to a high mean summer air temperature of 14.9°C.

In the mid-1990s, the active layer thinned to 74–98 cm, and beginning in 2002, ALT began to increase. In 2004–2005, the majority of the landscape elements exceeded the 1991 ALT level by 4 to 14 cm. Based on the long-term record presented in Figure 3, we can assume that the progressive increase in ALT observed over the Kolyma and Yana-Indigirka Lowlands is not attributable to irreversible global change processes, but rather show a thermal maximum of a century-scale cycle of unknown period.

Conclusions

1. The ALT in the tundra zone of North Yakutia varies significantly depending on soil texture. The mean multi-year ALT values within the positive microrelief elements are 50–105 cm for sandy Podbur soils and 35–70 cm for loamy Cryozem and Gleyzem soils.

2. The distribution of ALT in yedoma uplands and slopes is strongly influenced by climatic zonality (subzonality), which is more pronounced within positive microrelief elements than within depressions.

3. In general, the soils of flood plains, thermokarst depressions (alases), and polygonized bogs have thinner ALT than soils of corresponding zonal ecosystems. The difference in ALT between intrazonal landscapes is determined by soil moisture and thickness of peat horizons in the soil profiles.

4. The majority of soils at Northeast of Yakutia (Kolyma and Yana-Indigirka Lowlands) experienced a pronounced (14%–80%) increase in ALT over the 2000–2006 period.

Abstract

The so-called fretted terrain at the Martian dichotomy boundary exhibits a variety of creep-related morphologies generally known as lobate debris aprons and lineated valley fills. These features usually occur along troughs and circumferentially to remnant massifs. We here report on investigations of debris aprons and adjacent terrain in the Tempe Terra/Mareotis Fossae region and provide observational evidence for several phases and mechanisms of debris supply at remnant massifs comprising rock fall and large-scale landsliding and terminating with deposition and disintegration of a widespread surficial mantling deposit. The mantling deposit disintegrates by processes similar to thermokarstic degradation as indicated by heavily dissected areas and characteristic shallow and aligned circular depressions. Comparisons of theoretically derived cross-section profiles to topographic measurements along and across lineated-valley fill units, as well as lobate debris aprons, provide additional clues that such creep-related landforms are currently degrading,. It is also shown that a considerable volume of debris/ice is transported along the intra-highland valleys. Such processes might even be active today, as geomorphologic features appear pristine, and crater-size frequency measurements yield ages in the range of 50–100 Ma only. Such observations confirm modeling results of the stability of ground ice on Mars. Various phases of emplacement and degradation confirm theories about cyclic re-deposition of volatiles caused by the changes of the configuration of orbital parameters of Mars.

Keywords: climate; Mars; periglacial; planetary permafrost; rock glaciers.

Introduction

A variety of landforms indicates the possible existence of past or present ice in the near subsurface of Mars (Sharp 1973, Carr 1977 Rossbacher & Judson 1981, Lucchitta 1981). Among the most prominent ice-related features are lobate debris aprons. They have been interpreted to be a mixture of rock particles and ice (Squyres 1978, 1979) analogous to terrestrial rock glaciers, i.e., debris transport systems comprising a mixture of rock fragments and segregational and/or interstitial ice (Barsch 1996). The analogy between terrestrial rock glaciers and Martian lobate debris aprons is mainly based on (a) their lobate shape, (b) the cross-sectional convex-upward profile, (c) characteristic sets of ridges and furrows, and (d) their relationship to adjacent regions indicative of permafrost-related morphologies. Lobate debris aprons have been observed primarily along steep escarpments near the dichotomy boundary (Squyres 1978, 1979, Mangold 2001) and the large impact basin of Hellas Planitia (Squyres 1979, Crown et al. 2002). Rock glaciers are sensitive indicators for the climatic environment during their formation and are thought to be possible large and accessible water reservoirs (Whalley & Azizi 2003). Morphologies of lobate debris aprons in Tempe Terra are similar to terrestrial talus rock glaciers (Whalley 1992, Barsch 1996) which are usually derived from footslope debris situated underneath steep wall-rock of mountainous permafrost environments.

Settings and Observations

The Tempe Terra/Mareotis Fossae region (Fig. 1) is located between 270°E–294°E and 46°N–54°N and is characterized by the steep dichotomy escarpment and the so-called fretted terrain (Sharp 1973) which separates the study area into the southern highland assemblages and a region known as the northern lowland plains. Young surficial deposits interpreted as features related to creep of ice and debris (Squyres 1978, 1979) and mapped as Amazonian surficial units by Scott & Tanaka (1986) fill broad fretted channels of the heavily deformed Noachian highlands, extend from the dichotomy escarpment in northern direction, and are located circumferentially to knobs and remnants of the Noachian basement. The north-south extent of the fretted terrain in our study area varies between 60 km to 170 km. The undissected upland has an elevation of -2700 m at 294°E and about 0 m at 280°E. The lowland has its highest elevations also in the western part of the study area and slopes gently (~0.1°) towards NE, reaching minimum elevations of -4500 m at the eastern border of the study area. Elevation difference between uplands and lowlands decreases from 3000 m to 1500 m.

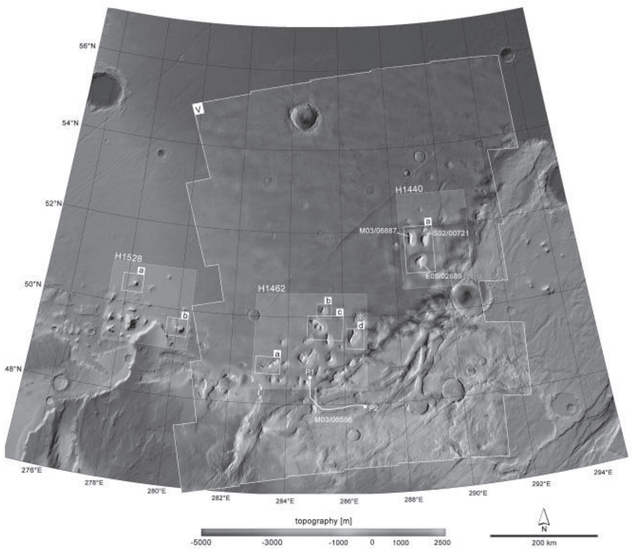

Figure 1. Study area in the Tempe Terra/Mareotis Fossae region as represented by the Viking global image mosaic (MDIM-2.1) superimposed on MOLA (MEGDR) topographic data and location of image scenes discussed in the text; [V] manually processed medium-resolution Viking image mosaic; H1528, H1462, H1440 refer to HRSC image numbers discussed in the text; lettered boxes and white outlines refer to sub-scenes depicted from HRSC image data; individual MOC scenes used in this study are labeled accordingly; P1-P2: topographic profile discussed in the text.

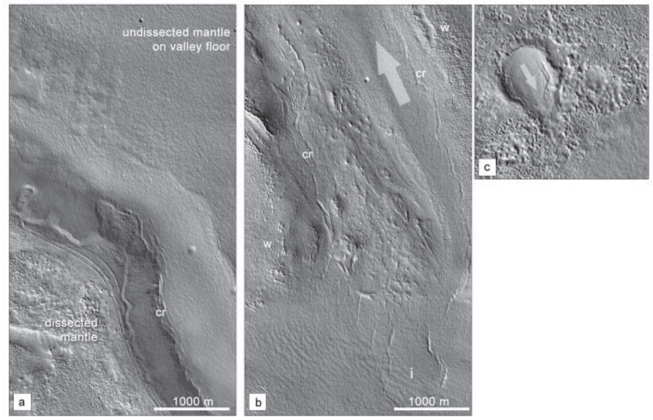

Figure 2. MOC sample scenes of the dichotomy boundary. (a) fretted channel floor (right) and wall (lower left). A mantling deposit is intact on the valley floor, but heavily degraded on the uplands. Crevasses [cr] on the floor of the fretted channels are characteristic of creep and flow of ice and debris. Parallel thin ridges 15–20 m wide run at constant elevations along the upper channel wall. (b) Floor of a fretted channel is covered by a mantling deposit. Crevasses [cr] are situated near the channel walls [w]. They also outline an impact crater completely buried by the mantle [i]. (c) Impact crater filled by mantling deposit. The mantle seems to have flowed out of the crater, scale is 1000 m across.

This difference is slightly less than that reported from the dichotomy boundary on the eastern hemisphere of Mars, i.e., Deuteronilus, Protonilus and Nilosyrtis Mensae, with 2-6 km. Highlands have a generally flat surface, sloping at an angle of less than 0.1° when measured perpendicular to the dichotomy boundary. The surfaces of very large upland segments bounded by fretted channel have larger slopes toward the lowlands (1–2°) and might be tilted as blocks. Such fretted channels have steep walls and flat floors (Squyres 1978), the latter of which are often characterized by so-called “lineated valley fill” (Squyres 1978, 1979}, which is interpreted as material comparable to that of lobate debris aprons but confined to the valley extent. In the study area, fretted valleys have uniform widths of 5–10 km and constant depths of a few hundred meters. The morphologic boundary between highland and lowland areas is characterized by two and sometimes three distinct components: (a) a steep upper slope, i.e., the wall-rock, (b) an intermediate shallow-sloped unit with downslope facing striae, and (c) the highly textured apron (Carr 2001). An intermediate unit is only rarely observed at isolated remnants. At a few sample locations we measured the angles of intermediate units (6°–8°) and angles of debris aprons (2°–4°).

Mantling deposit

A mantling deposit can be observed at scarps and channels near the dichotomy boundary (Fig. 2) as well as around isolated remnant massifs and aprons (Fig. 3) that are located in the lowlands. The deposit does not show any preference to geographical or topographic location, thus, covering all parts of the study area. This observation is based on high-resolution image data (1.5–12 m/pixel) taken with the Mars Orbiter Camera (MOC) that clearly show surfaces at the dichotomy boundary that are covered by that deposit. The mantling deposit is often degraded by erosion, resulting in surfaces whose texture are highly variable, ranging from smooth over stippled, pitted, or knobby to heavily etched. In some places the mantling is completely removed. The disintegration process seems to be controlled by slope aspect, the southern (sun-lit) slopes being more affected than northern slopes.

On the floors of some fretted channels we identify crevasse-like features (Fig. 2). Their specific geometry resembles that of terrestrial chevron crevasses in glaciers, (e.g., Benn & Evans 2003, Menzies 2002). Lineations correspond to longitudinal or transversal lineations and are frequently observed at terrestrial features indicative of creep of ice and debris. Such lineations can be observed at small scales as illustrated in Figure 2. Other lineations are formed by ridges that are thin (15–20 m wide) and extend at approximate constant elevations along upper channel walls; they seem to be genetically connected to the mantling deposit (Fig. 2a). A thick mantling is also observed in a number of image scenes covering the remnant massifs of the Tempe Terra lowland: as seen in Figure 3a, the surface of three debris aprons (A-C) appears relatively smooth although different sets of transversal ridges on the apron can still be observed. The crest of remnant A is characterized by a scalloped and fretted depression (d) and sets of elliptical and aligned shallow depressions on the eastern slope which have a dimension of few tens of meters. Both the crest depression as well as the slope depressions are located in a mantling deposit and

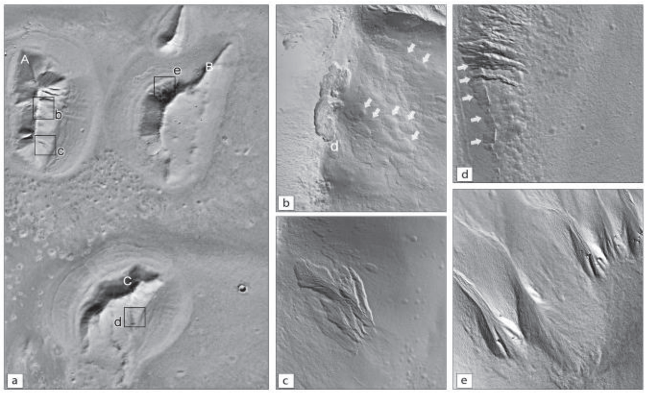

Figure 3. Sample scenes of HRSC in orbit 1440 covering the easternmost study area. Labeled black boxes in (a) refer to MOC sample scenes (b-e). All scenes show indications for the disintegration of a thick mantling deposit. (b) Unusual scalloped depression at remnant crest and elliptical depressions at eastern wall (arrows). (c) Overlapping gullied slide flows. (d) Small slide flows incised into the footslope talus of remnant C. All incision start at the boundary (arrows) between talus and debris apron and are located in a mantling deposit. (e) Slide flows incised into surficial mantling deposit of remnant B.

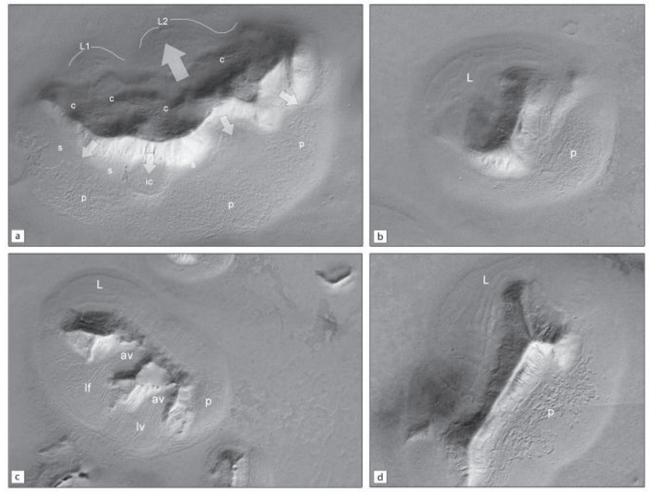

Figure 4. Sample scenes of HRSC in orbit 1462 covering the central lowlands of Tempe Terra. (a) Arcuate remnant massif characterized by an inclined surface tilting towards northern direction; two main directions of transport are observed: large lobes form in northern direction [L1-L2], large coherent debris masses with a pitted surface [p] advance in southern direction. An impact crater [ic] has been completely filled by erosional debris. The talus shows a generally smooth surface texture [s]. Arcuate and sub-parallel furrows on remnant indicate extensional flow [c]. (b) Small isolated remnant knob located northeast of remnant shown in (c); northern apron texture is characterized by ridges and furrows [L], southern apron has a pitted appearance [p]. (c) Alcoves [ac] are incised into remnant massif forming Accumulation zones of debris that is subsequently transported downslope as seen in longitudinal surface lineations. (d) Elongated remnant massif with well-defined crest exhibits transversal ridges and furrows [L] on northern apron and a pitted surface [p] on southern apron. Note also, all aprons are comparable in size when related to the remnant massif.

are indicative of material removal. Mantling-related mass-wasting features are shown in 3c–e where gullied slide flows initiate instantaneously somewhere at the mid-slope, overlap partly and produce faint terminal depositional fans (Fig. 3c, d) that are indicative of dry mass-wasting processes.

As seen in Figure 3d, gullied slide flows can be related to a boundary where the remnant talus abuts the mantling deposit. While the northern sets of slide flows are deeply incised and well expressed, the southern are shallower (Fig 3e).

Disintegration texture

Many debris aprons in Tempe Terra are characterized by surface textures indicative of disintegration of either the surficial mantling deposit or the main debris/ice body. As shown in Figure 4, a slightly northwards inclined and elongated remnant shows a well-pronounced debris apron emerging near the foot of a remnant. While the northern debris apron is characterized by at least two large lobes with transversal ridges (L1–L2), the southern apron is more homogeneously developed with a highly pitted surface texture (p). Below the southern scarp, talus forms as expressed by a relatively smooth texture (s). Eroded remnant material has filled an old impact crater (ic). The southern scarp of the remnant is relatively steep when compared to the northern remnant slope. Flow ridges (c) indicate that material is eroded as coherent sheet and thus contributes to the development of the northern apron. Arrangements of transversal ridges and furrows located on a northern apron and a pitted surface texture located on the southern apron is observed in the scenes depicted in Figures 4b, d. In Figure 4b, the shapes of the remnant massif and debris apron are more circular and the remnant slope angles are approximately comparable in the north and south. However, the northern remnant slopes is composed of a single large bowl-shaped depression in which material is collected from the wall-rock and subsequently transported downslope towards the plains. In Figure 4d, the pitted surface in the south has not reached the terminal area of the apron but is restricted to the remnant footslope. Figure 4c shows well-expressed alcoves (av) at the southwestern remnant slopes and longitudinal sets of furrows and ridges (lf, lv) in the direction of maximum slope gradient. The pitted surface texture seen in Figures 4a, b and d is here restricted to a small area of the southeastern debris apron (p) while lobes (L) are again restricted to the northern apron. In the westernmost region of the Tempe Terra study area, remnants and aprons are developed slightly differently when compared to those in the central and easternmost areas. Northern apron slopes show a ridge-and-furrow texture but it extends asymmetrically farther away from its source. Contrasting to this, the remnant in Figures 5b–b′ is heavily dissected by alcoves and cirque-like features. Towards the north, longitudinal and transversal ridges and furrows prevail while towards the south aprons merge with the apron of the dichotomy escarpment and show sets of depressions at various sizes. For few aprons crater-size measurements could be obtained to derive ages (Fig. 6). Elliptical depressions indicate deformation of impact craters after apron emplacement. In order to obtain the last

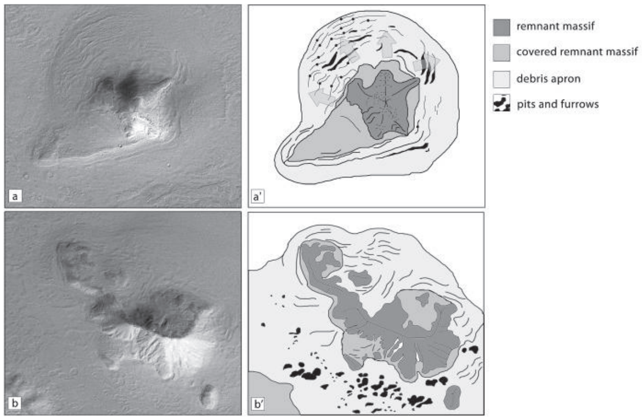

Figure 5. Sample scenes of HRSC in orbit 1528 and schematic maps covering lobate debris aprons of the westernmost study area. Labeled boxes refer to labels in Figure 1; [a–a′] isolated small remnant massif with circumferential lobate debris apron, northern apron shows pattern of ridges and valleys characteristic of compressional flow (ridges) and extensional flow (furrows); [b–b′] flow lineations at debris apron are in longitudinal configuration below alcove depression facing northeast and in transversal configuration under remnant scarp. Southern apron is characterized by pitted texture indicative of degradation.

resurfacing period only fresh-appearing craters have been mapped. Measurements provided ages in the range of 0.01 to 0.05 Ga which is consistent with data obtained from other debris apron (Squyres 1978, Mangold 2003, Berman et al. 2003, Head 2005, Li 2005, van Gasselt 2007).

Geomorphometry

Lobate debris aprons were digitized using a common GIS environment (Fig. 7). We derived geographic coordinates, topographic elevations, lengths, areas and volumes and made simplifications with respect to the (a) base of the debris apron, which was assumed to be horizontal and flat (Barsch 1996), and (b) to the volume of that part of the remnant massif located below its visible extent, i.e., covered by apron debris. In plan view, the remnants north of the dichotomy boundary in Tempe Terra have a more or less irregular polygonal shape and a rugged top, in contrast to the more flat-topped mesas of the type locations in Elysium or Arabia Terra (Mangold & Allemand 2001). The cross-sectional shapes of the aprons are convex upward and steepening towards the terminus of the apron (Fig. 8). The length of debris aprons varies between 1.4 km to 6.3 km averaging at ~4.0 km in northern direction and ~3.5 km in southern direction. The average lengths of aprons are significantly less than values provided by Mangold (2001) with 10.8 to 33 km, and also less than those given by Carr (2001) and Colaprete & Jakosky (1998) with 15 km. Thicknesses of (upper) remnant massifs in Tempe Terra range from ~20 m to ~1100 m. The thickness of aprons varies between ~70 m and ~600 m under the assumption of a flat base. Minimum thickness values are lower than those given by Mangold (2001) (276 m) for the Deuteronilus area, maximum values are about the same. Volumes of debris aprons at Tempe Terra range from <10 km³ to ~300 km³ with a mean surface

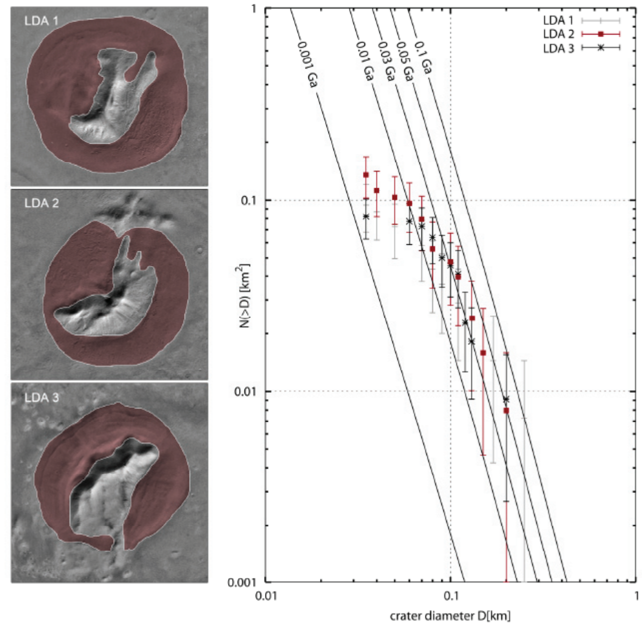

Figure 6. Ages derived for debris-apron surfaces of the central and eastern part of the study area. Stair-stepped distribution indicates multiple episodes of erosional activity, derivation of isochrones (in Ga) are based on Hartmann and Neukum (2001) with the polynomial production function coefficients by Ivanov (2001); for a discussion on errors, see Neukum et al. (2004).

area of ~282 km² (Fig. 7). The remnants have a mean size of ~115 km² (15 to >1000 km²) and a mean volume of ~21 km³ (<5 to 200 km³). As Barsch (1996) summarizes, there might be a close relationship between the source area of debris production and the surface area of a (terrestrial) rock glacier at the footslope with values between 1:1.36 to 1:4.4 (Wahrhaftig & Cox 1959, Barsch 1977, Gorbunov 1983). From 27 observations at Tempe Terra we obtain a factor of 2 for the remnant size when compared to the area occupied by the debris apron. Mangold (2001) calculated the basal shear stress and obtained values in the range of σ = 34–108 kPa for the Deuteronilus/Protonilus Mensae areas. These values are lower than photoclinometrically derived values by Squyres (1978). For the Tempe Terra region we obtain values between 6.7–82.4 kPa for average apron lengths, with an average of ~38 kPa. The calculated values are not consistent with basal shear stresses given for terrestrial rock glaciers by Whalley (1992) with 100–300 kPa. This may indicate an ice content which is higher (Hauber et al. 2007) than typically considered for rock glaciers or very low strain rates due to a low shear stress. Inactive rock glaciers tend to have generally lower slopes as either debris material was eroded or volatiles were removed, subsequently causing thermokarstic degradation of the rock-glacier surface (Barsch 1996, Ikeda & Matsuoka 2002, Berthling et al. 1998).

Discussion and Conclusions

Image data provide observational evidence for the existence of a widespread mantling deposit in the Tempe Terra/Mareotis Fossae region which covers not only debris

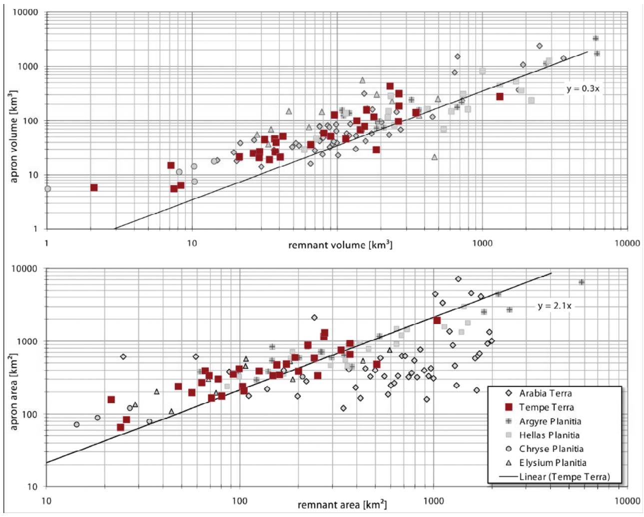

Figure 7. Plot of derived ratios between volumes (a) and areas (b) of remnant massifs and debris aprons as indicator for the degradational state. Values of Tempe Terra massifs and debris aprons (dark squares) are approximated by linear fit.

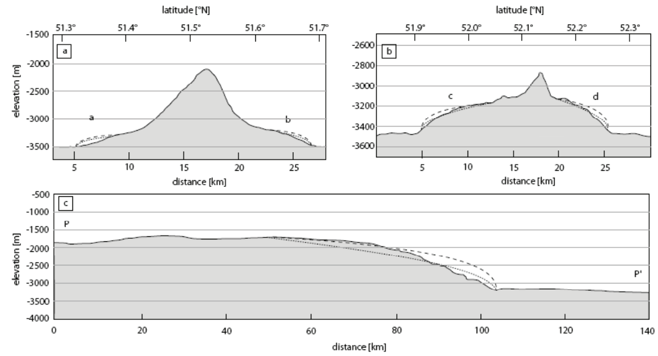

Figure 8. MOLA-based topographic profiles across debris aprons (a, b) and along fretted channel (c) and theoretic profiles of debris aprons obtained from equation derived by Paterson (2001).

aprons of the lowlands but also the escarpment of the Martian dichotomy boundary. At the dichotomy escarpment this mantling deposit shows several characteristics of creep and deformation as well as for processes of disintegration similar to thermokarstic degradation of ice-rich surface materials. Indicators for the mobility of that mantling deposit are found at various locations.

We confirm the presence of a mantle at latitudes higher than ~30–50° as inferred from global-scale roughness maps (Kreslavsky 2000) and directly observed in MOC images (Carr 2001, Malin 2001). Flow lineations on debris aprons resemble closely features known from terrestrial rock glaciers comprising various sets of transversal and longitudinal ridges and furrows indicative of differential movements controlled by subsurface topography. At several locations in Tempe Terra, southward-facing debris aprons show a pitted surface texture that is interpreted as indicators for thermokarstic degeneration and loss of volatiles subsequently leading to collapse and formation of shallow depressions or pits. Their restricted extent suggests control by sun-irradiation (Rossi et al. 2008). Shallow depressions form primarily in mantling material covering remnant massifs whereas pits and furrows are more often observed on the debris-apron surface. Degradation of surfaces is also confirmed by observations of theoretically derived cross-profiles of debris aprons and lineated valley fill units. Both creep-related landforms show an unsatisfactory fit to the model curve. The convex-upward shape of lineated valley fill at the entrance of fretted channels shows not only debris transport perpendicular to valleys walls but also in parallel direction. This furthermore indicates that flow lineations seen in lineated valley fill deposits are not only caused by compression but also by the downslope movement along the valley. It is suggested that the main processes of landsliding and rockfall had come to an end and that subsequent deposition of a mantling deposit caused smoothing of the underlying topography and allowed formation of such slides and gullied flows. Resurfacing ages of 0.01 to 0.05 Ga are consistent with ages obtained from other debris apron locations on Mars. Geomorphometrically derived area ratios of the depositional zone and source area show values that are comparable to estimates given in Barsch (1996) for terrestrial rock glaciers, indicating that the genetic configuration is comparable. Geologically recent degradational and thermokarstic processes are in good agreement with modeling work of obliquity variations of the planet's rotational axis and variations of the planet's eccentricity and precession (Murray et al. 1973, Pollack 1979, Toon et al. 1980, Jakosky et al. 1995). It was shown that prolonged periods of higher obliquity lead to mobilization of volatiles at the poles and to precipitation at lower latitudes (Levrard et al. 2004). This process (a) might have lead to saturation of remnant-related talus deposits with ice causing subsequently creep of debris, and (b) also contributed to a mid-latitudinal mantling deposit (Rossi et al. 2008).

Abstract

It has been recently reported that climatic change greatly influences Arctic rivers. The Yakutia region is a particularly interesting area for its spectacular floods, for its lowest temperature records, as well as for its maximum thickness of permafrost. The hydrology of the Lena and its tributaries is characterized by an extremely episodic flow regime. In spring during the break up period, the joined increase of the water discharge and stream temperature contributes to an active thermal erosion along the frozen river banks. Here we report recent climatic change in Central Siberia, and its impact on the thermal erosion. We first point out three major evolutions since the 1990s: a reduction of the river ice thickness in winter, a pronounced increase of the stream temperature in the spring, and a slight increase of the discharge during the break up period (May–June). A GIS analysis based on aerial pictures and satellite images highlights the impact of the water-warming on the frozen banks. The vegetated islands appear to be very sensitive to the water temperature increase, showing an acceleration of head retreat (+21%–29 %).

Keywords: climatic change; fluvial dynamics; fluvial islands; GIS analysis; Lena River; thermal erosion.

Introduction

The Lena River is one of the largest Arctic rivers located in a permafrost environment. With its huge basin (2.49 million km²) and its south-north orientation (exceeding 4000 km) the Lena crosses several latitudinal belts (Fig. 1). Central Siberia is one of the coldest and driest zones (with mean temperature of 9°C and mean precipitation of 190 mm yr^{-1}) and has very thick and continuous permafrost (1500 m). For these reasons, the hydrology of the Lena and its tributaries is characterized by an excessive fluvial regime and exhibits a spectacular flood mostly controlled by periglacial dynamics. This study examines current climatic change and its impacts on the middle Lena River dynamics, from the Tabaga gauging site (located upstream of Yakutsk) to the junction of the Aldan River (Fig. 1). From the beginning of November to May, a continuous ice cover can be observed as thick as 2 m in Central Siberia; the discharge of the Lena River is low, 900–1500 $m^3.s^{-1}$ (Tabaga gauging site). The break up starts around May 15 for the Lena, corresponding to an increase of the stream temperature up to 18°C from May to July and to a rise of the water level up to 8–10 m, which inundates flood plain and islands. Highest floods occur generally in June and can be 50,000 $m^3.s^{-1}$ at Tabaga. Then, in July, the discharge rapidly decreases. The fluvial landforms consist of a large number of shallow, wide channels that are between several hundred meters and three kilometers wide. These multiple channels are separated by sandy bars and large forested islands. Downstream of Yakutsk, the flood plain width can be up to 25 km and exhibits various thermokarstic landforms due to the local melting of the continuous permafrost.

During the annual fluvial outburst (May–June), the joined increase of river water temperature and discharge induces the propagation of a thawing line within the frozen riverbank. The interaction between thermal erosion and fluvial erosion during the flood creates specific forms on the banks (‘thermo erosive niches’) and locally causes important bank retreat (Are 1983, Jahn 1975, Walker & Hudson 2003). Our previous studies highlighted the spatial and temporal variability of the thermal and mechanical erosion on banks of the middle Lena River. We showed that the island heads are particularly subjected to this erosion process, with mean values of 15 m year and maximal values of 20 m, and an exceptional rate up to 40 m was measured locally (Gautier et al. 2003, Costard & Gautier 2007).

Arctic regions respond disproportionately to global warming. In Yakutia, a mean air temperature increase of 1.2°C was registered since the end of the 1980s; this impacts directly the permafrost temperature (Fedorov & Konstantinov 2003,

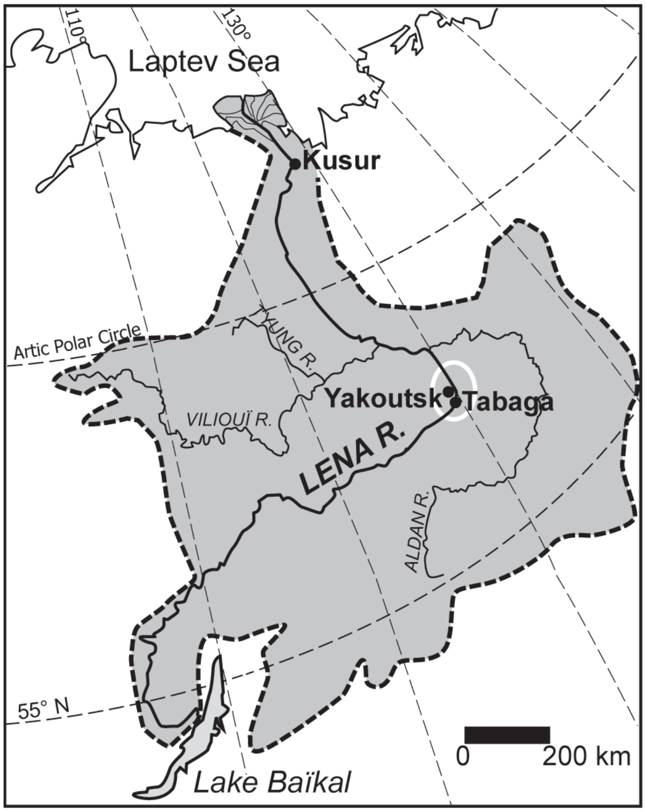

Figure 1. The Lena Basin and the study zone.

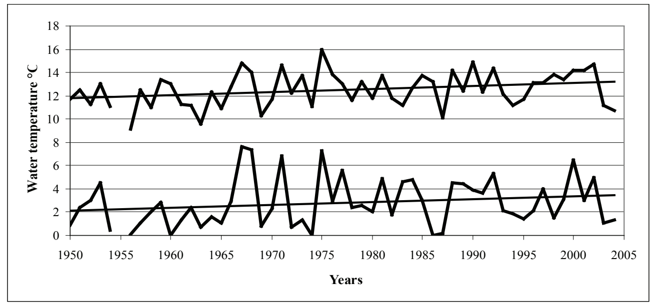

Figure 2. Water temperature of the Lena River since 1950 (May: below and June: above).

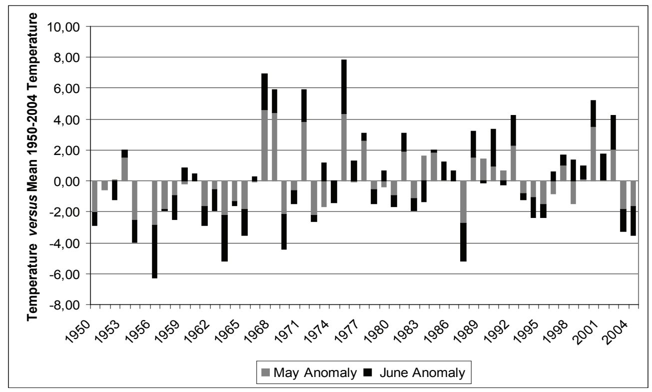

Figure 3. Anomaly of stream temperature in May and June (1950–2004, in °C).

Pavlov 1994). The thickening of the active layer reinforced by the increasing precipitation related to cyclone activity in the North Atlantic provokes a marked rise of the Arctic rivers discharge (Peterson et al. 2002, Serreze et al. 2000, Yang et al. 2002). Therefore, the objective of the present study is (1) to characterize precisely the hydro-climatic change in Central Siberia (water, air, permafrost temperatures, and river discharge) and (2) to quantify the impact of the change on erosion and sedimentation processes on the Lena River near Yakutsk.

Data and Methods

Firstly, the study is based on different sources of environmental data such as climatic data (air, permafrost, and river water temperatures) since the 1950s. We especially examined the water temperature because of its impact on thermal erosion (Costard et al. 2003). Parameters concerning the river were also detailed: discharge, water level, thickness of river ice during the winter, and date of the beginning of the outburst since 1936 at the Tabaga gauging site.

Secondly, we conducted a 35 years diachronic GIS analysis (1967–2002) of 300 km of the fluvial landforms on the Lena River upstream and downstream of Yakutsk in order to evaluate the effects of recent global warming on the mobility of the fluvial units. On aerial pictures (Corona declassified pictures, 1967 and 1980) and satellite images (Landsat 4–7: 1992, 1999, and 2002), landforms were precisely analyzed. The delineation (1) of the channel banks and (2) of the vegetated island banks allows us to quantify their erosion rates since 1967. The position of the islands in the channel, their area, and their form were also determined. Finally, we examined the correlation between the erosion rate variations and the various hydrometeorological variables (discharge, stream temperature, river ice thickness).

Hydro-Climatic Change and Morphodynamics Disruption

Influence of current climatic change on hydrology

All studies concerning Siberia clearly identify the signs of climatic change in the 1980s or at the beginning of the 1990s. On the right bank of the Lena River, 50 km southeast of Yakutsk, A. Fedorov & P. Konstantinov (2003) clearly underline a strong air temperature change, the mean temperature since 1992 being 1.2°C higher than for the whole period (1931–2002). Furthermore, the period 1992–2002 was marked by a pronounced raise of the summer temperature. Correlatively, since the beginning of the 1980s, the soil temperature at 3.2 m depth is also characterized by positive anomalies (Fedorov & Konstantinov 2003). This observation agrees with D. Yang et al. (2002), who show a strong warming in winter and spring over the Lena basin.

On the middle Lena River, the stream temperature has undergone an important change since 1950, that is characterized by positive trends during the flood season (May and June) up to 2°C (Fig. 2). More precisely, the river temperature increase has been particularly pronounced since

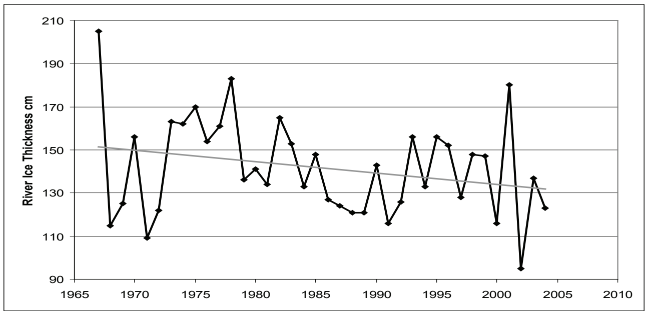

Figure 4. River ice thickness of the Lena River at the Tabaga gauging station since 1967.

1990: +0.73°C (May) and +0.97°C (June) (Costard et al. 2007).

On Figure 3 two periods can be seen: the first 25 years are characterized by an important variability, whereas water temperature since 1975 is more regular and generally marked by positive anomalies. The frequency of temperature anomaly is particularly significant; between 1950 and 1975, positive anomalies of water temperature occurred every 4 years in May and every 2.66 years in June; during the period 1976–2004, they were registered every 1.87 year in May and 1.71 in June (Fig. 3).

The ice cover of the river is the third factor showing a marked evolution. From the beginning of November, a continuous ice cover can be observed as thick as 2 m. Even if the ice cover varies greatly each winter, Figure 4 clearly shows its thinning since 1967. Before 1987, the river ice thickness was 1.48 m on average during winter and exceeded 1.5 m every two years. From 1987 to 2004, the mean thickness was 1.34 m and exceeded 1.5 m every 4.25 years.

The water discharge of the Lena River shows a strong interannual irregularity. Because of this irregularity, it is difficult to detect easily a possible hydrologic change. However, two signs seem to reveal a recent evolution. First, a very moderate increase of 3% of the discharge can be noticed at Tabaga since the 1980s. The winter undergoes greater water discharge since the 1980s, particularly at the end of the cold season (March–April: +22%-23%, Fig. 5). The break up period (May–June) is characterized by a slight but progressive increase: +4% for 1980–1992 and +7% since 1992.

Second, the frequency of abundant discharge has clearly increased during the last 25 years. In April, the frequency of the highest discharge doubled: discharge exceeding 1000 $m^3.s^{-1}$ (the mean discharge) was registered nine times between 1936 and 1980 (i.e. every 4.88 years), and it has occurred ten times since 1980 (every 2.4 years). In May, the frequency of discharge higher than 15,000 $m^3.s^{-1}$ also doubled (frequency of 7.33 years before 1980, frequency of 3.42 after). Furthermore, the evolution of the discharge in May is particularly marked for the period 1996–2004, that underwent repeated high water discharge exceeding by 22%–57% the mean value. The evolution is less clear for June and July. June discharge is characterized by the strongest interannual variability; the highest water levels were registered between 1956 and 1963,

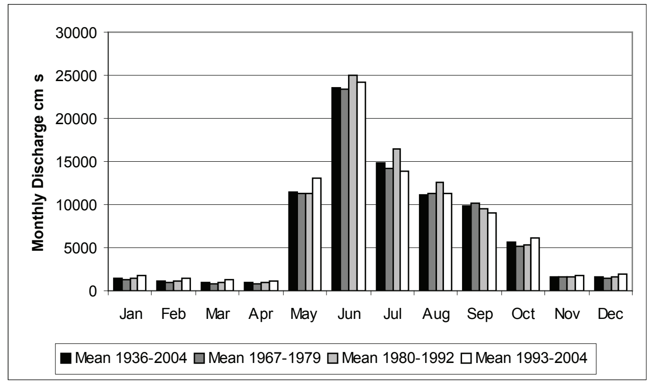

Figure 5. Evolution of water discharge of the Lena River since 1936 (Tabaga gauging station).

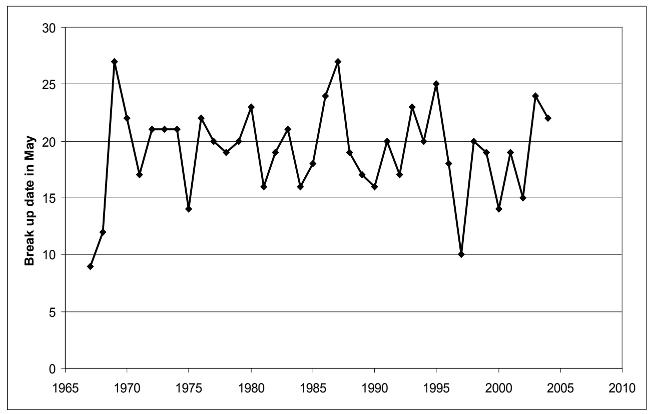

Figure 6. Break up date in May on the Lena River at Tabaga since 1967.

corresponding to a period of low water temperature (Fig. 2). However, an increase of high discharge was also observed since 1980; discharge exceeding 30,000 $m^3.s^{-1}$ was registered six times between 1936 and 1980 (i.e. frequency of 7.33 years), and this value was reached five times for the period 1981–2004 (every 4.8 years). May and June discharges are inversely correlated; it must be remembered that the local inundation is controlled by the flood wave coming from the south and the water provided by the thawing active layer and by the snowmelt. No important rainfall or groundwater supply sustains the river discharge in Central Siberia during summer.

Therefore, the relative abundance of water discharge in May and June must be examined with regards to the break up date. The date of the beginning of the break up is highly variable in May; at Tabaga, it occurs generally around May 15–20, rarely before May 10 or after May 25 (Fig. 6). No important change can be seen nowadays concerning the date of break up. An early break up generally induces an important discharge in May; on the contrary a late break up favors a higher discharge in June.

Impact of hydro-climatic change on fluvial landforms

The middle Lena River develops a multiple-channel pattern. Two types of channels can be distinguished: (1) wide active channels (some of them are dewatered at the end

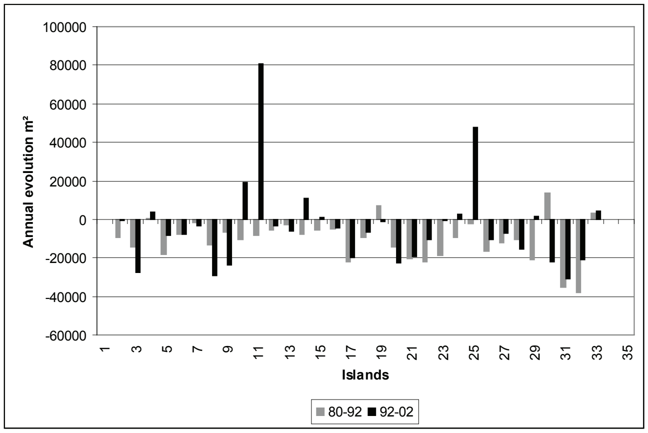

Figure 7. Area evolution of 35 islands since 1980.

of summer and during winter); (2) small sinuous and narrow branches crossing islands and flood plain (these channels are inundated only during the flood peak). A previous study based on satellite image analysis documented the erosion rates on main channels banks (Costard et al. 2007, Costard & Gautier 2007). Actually, for the 1967–2002 period, the mean retreat of the channel banks was low or moderate, with an average value of 2 m per year; maximal values of 14–18 m per year were registered locally. These values must be considered with regard to the active channel width; the bank retreat represents only 0.05%–0.1% of the main channel width. For this reason, active channels remained relatively stable during the study period; no migration or avulsion was observed on the middle Lena River.

The large, forested islands represent important mesoforms of the hydrosystem. Just upstream of Yakutsk, because of the widening of the flood plain, the Lena River forms huge islands. Several km long, these islands are densely vegetated. We could classify these islands in three types: (1) T1: islands located in the central part of the channel; (2) T2: islands located near the river bank and (3) T3: islands located downstream of an unvegetated bar (Costard et al. 2007). We noticed that island heads undergo a stronger erosion than channel banks, with mean value of 15 m per year. The erosion is located on the head of the island; therefore, the island migrates progressively downstream, keeping its general shape. Most interesting is the variability of the island head retreat depending on its type. T1 and T2 islands are subjected to a higher erosion rate, with mean bank retreat of 20 m per year and maximal retreats exceeding 40 m. Because of the position of these islands, the river water is in permanent contact with the frozen banks during the flood, and the thawed sediments are swept away by the current; thus thermal and mechanical erosion are jointly at work, explaining the rapid migration of the form. For the third type, the upstream bar protects the island head from rapid erosion (7 m per year).

The diachronic study of the fluvial landforms since 1967 (date of the first picture) reveals a disruption of the river morphodynamics, that is expressed by the island mobility. For the three types of islands, a marked acceleration of erosion was measured since 1992. Actually, the mean erosion rate of T1 islands increased by 29% (reaching 23 m per year) and by 22% for T2 islands (21 m per year). T3 Islands also undergo a rapider migration (+21%).

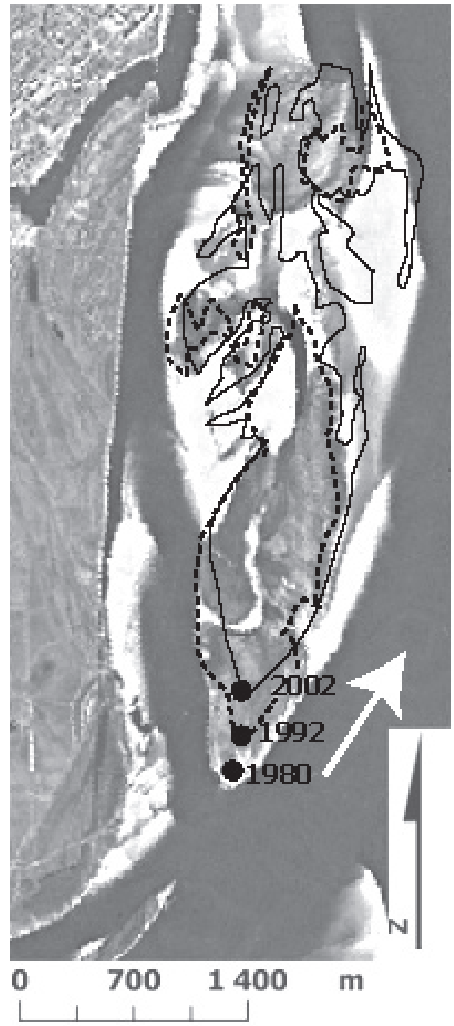

Figure 8. Evolution of an island located upstream of Yakutsk (1980–2002). Lines: limit of the perennial vegetation; points: island head; background image: Corona 1980 (adapted from Hammadi 2007).

The erosion of the island heads could have just implied a progressive reduction of the island areas. In fact, the evolution of islands is relatively complex.

The comparison of the total area of 35 islands located just upstream of Yakutsk between 1967 and 2002 reveals two main models of evolution (Fig. 7). The first model is a progressive decrease of the island area; this evolution is noticeable especially for small islands that are disappearing. On the contrary, eight islands undergo a greater sedimentation on their downstream part, that compensates for the head retreat. An important aggradation on bars located downstream of these islands is observed (Fig. 8). This evolution model is generally observed on very large islands. This accelerated deposition is accompanied by vegetation colonization on the middle part and tail of the island.

Discussion

The hydro-climatic change on the middle Lena River is complex. The discharge increase (+3%) at Tabaga is less pronounced than on the low Lena River at Kusur. B.J. Peterson et al. (2002) calculated for six large Eurasian Arctic rivers (including the low Lena River at Kusur) a mean annual rate of discharge increase of 7%. At Kusur, the spring discharge increases strongly (Yang et al. 2002). But, the dam regulation on the Viliou river (an important tributary of the Lena River, Fig. 1) has a strong influence on the water temperature and discharge on the low Lena River (Liu et al. 2005, Ye et al. 2003). On the contrary, we can consider that the hydrological change of the middle Lena River mainly depends on climatic change, because of the lack of large dams in the upper Lena basin. In this part of the valley, the most significant sign of a possible hydrologic change is the increasing frequency of high discharge, especially in May.

The accelerated erosion on island heads induces an increase of sediment supply in the channel. But, the progressive growth of several islands lets us suppose that the greatest part of the sediment load (mainly sand) provided by the thermal and mechanical erosion process does not migrate over long distances downstream and accumulates on wide bars and long islands. One of our projects is to evaluate precisely in the field this erosion and sedimentation rhythm.

Two hypotheses can be proposed to explain the accelerated erosion of island heads. The first is the increase of the discharge during May and June. The increasing frequency of high discharge in May and June is certainly an important factor of fluvial bed erosion. It has been demonstrated that the duration of efficient discharge determines the bank retreat. But the observed hydrological change alone seems too weak to explain such an aggravation of erosion rates. The second hypothesis is the impact of the water temperature during the flood season by up to 2°C. Actually, the ablation model developed by F. Costard et al. (2003) and R. Randriamazaoro et al. (2007) helped to determine the role of different factors (mainly discharge, permafrost, air and water temperatures, and Reynolds Number) on thermal erosion. Relative effects of water temperature and discharge have been studied separately. The model demonstrates that water temperature is four times more important than Reynolds Number. The measured increase up to 2°C of the stream temperature alone could increase the erosion rate respectively by 26% and 16% in May and June. The laboratory simulation experiment and the physical approach (Costard et al. 2003) demonstrated that exceptional erosion rates can be best explained together with a high water temperature, and mechanical erosion in association with some particular geometry of the channel. In the near future, a more precise numerical modeling will take into account the impact of global warming on the erosion rate for fluvial systems in a periglacial environment.

A last but very important factor must also be taken into account: the vegetation. The islands are densely vegetated with pioneer bushes on freshly dewatered areas and mature forests on stable and higher zones. This vegetation cover seems not to protect efficiently the island heads against the erosion: the thermal process during the flood destabilizes the thawed and non-cohesive deposits. But, the progressive colonization by pioneer sequences (mainly composed by *Salix*) on the middle and downstream section of the island exerts a great control on the sedimentation. The sediment trapping effect of the vegetation is well known (Gautier & Grivel 2006, Hickin 1984, Steiger & Gurnell 2003). For this reason, one of our future objectives is to examine precisely interactions between river and vegetation dynamics.

Conclusion

In the case of the Lena River, fluvial islands are indicative of ongoing dynamic change; the islands express the readjustment of the fluvial system to physical factors (increasing water temperature and secondly, increasing discharge). This study clearly highlights the first sign of destabilization of the fluvial bed directly related to global warming and it appears that climatic change has a strong impact on fluvial forms of this Arctic river. The increasing water temperature directly impacts the erosion rate of the islands, and a greater instability of these fluvial forms is clearly observed. Furthermore, we previously demonstrated that the middle Lena River is a low-energy fluvial system in spite of its great floods, because of its very gentle slope and the brevity of the morphogenic discharge (Gautier & Costard 2000). Thus, the rapidity of the fluvial form readjustment is indicative of the very deep impact created by the present climatic change. It can be supposed that continuation of the recent global warming will induce an increasing destabilization of the river banks and amplify the sediment supply in the riverbed. For society, the increasing mobility of the fluvial bed and the increasing flooding represent very important risks: the great majority of towns and industrial infrastructures are installed on the river banks. The Lena River represents also a major transportation axis in winter and summer. The precise quantification and location of erosion will participate to the prevention of the risk.

Acknowledgments

Hydrological data were provided by the Hydrometeorological Center of Yakutia, under the auspices of the Permafrost Institute at Yakutsk. This program is supported by “Programme Reliefs de la Terre” INSU, CNRS, France, and GDR «Mutations Polaires: Société et Environnement».

Inter-Alas Agricultural Landscapes and Active Layer Trends and Dynamics in Response to a Warming Climate in Central Yakutia

P.P. Gavriliev
Melnikov Permafrost Institute, SB RAS, Yakutsk, Russia

Abstract

This report presents the new long-term (1989–2006) data on monitoring of diverse reaction of active layer, permafrost table, and agricultural landscapes to the climate warming. We have investigated the genuine patterns in the dynamics of progressive development of anomalous cryogenic processes and phenomena, such as intensive degradation of the ice complex up 0.5–0.9 m during sporadic anomalously warm summer-autumn seasons, rich in precipitation; 2.9 times increase in the depth to the permafrost table; sudden activation of different stages of thermokarst, from barely visible *bylar* to young lake thermokarst within 15–18 years, in conditions of rapid climate warming (about 0.09°C/year) and diverse agricultural land use.

Keywords: agricultural landscape; climate warming; ice complex; permafrost process; thermokarst.

Introduction

The peculiarities of formation, stages, and activations of cryogenic processes and phenomena, which cause fundamental changes in thermal condition of permafrost, active layer, and cryogenic relief of geosystems, are permanently in the focus of interest of renowned scientific centres, and their significance needs to be periodically defined more precisely because new data permanently occur. Since the 1950s a great number of works exploring these issues was published and much progress achieved in understanding anthropogenic and natural cryogenic processes and phenomena in northern regions and countries of the world (Russia, Yakutia, western Siberia, Alaska, northern Canada, etc.) (Soloviev 1959, Kachurin 1961, Grechishchev et al.1980, Feldman 1984, Shur 1988, Pewe 1954, Washburn 1988, Osterkamp & Romanovsky 1998, Osterkamp et al. 2000, Gilichinsky & Kimble 1997, Racine et al. 1998, Gavriliev 2001).

Many works, summarizing the available data, state that in context of global climate changes and intensive natural resource development, different regions differ in pace and scale of changes in geocryologic conditions and development of cryogenic processes.

Huge agricultural land resources of Yakutia occupy 67,435.6 thousand ha or 22.2% of its total area. From 20 to 60% of large masses of taiga, valley, and shallow valley soils are underlain by shallow (1–2.5 m) permafrost with wedge ice (ice complex). Considerable areas of territory of the north and the subarctic are characterized by low resistivity to anthropogenic impact (Grechishchev et al. 1980, Gavriliev 2001). Melioration and agricultural development of the permafrost-covered area result in both, advantages, and, in some cases, irreversible negative cryogenic processes and their consequences for the northern nature and ecosystems (Gavriliev 2001). In permafrost area and, especially, in the areas of ice complex distribution, cryogenic (cryogeological) processes activation and the way they influence stability and transformation processes of agricultural and natural permafrost landscapes is very specific and still needs to be thoroughly investigated, taking into account the rapid climate warming (about 0.09°C/y) and existence of a variety of ways of agricultural land use.

This work aims at revealing patterns of permafrost processes dynamics, specifically patterns of activation of initial stages of thermokarst in agriculture-affected lands with ice complex sediments at present day.

This study is a continuation of our earlier work (Gavriliev & Efremov 2003).

Research Methods

In 1989–2006 Melnikov Permafrost Institute, SB RAS, carried out monitoring of active layer, frost phenomena, and permafrost and wedge ice tables (up to 10–15 m deep) in taiga, alas, and valley landscapes, both natural and agricultural, in different physical-geographical regions of Yakutia (Fig. 1). This monitoring network, being multipurpose, includes 6 test sites and 36 experimental plots.

In 1989–2006 we have implemented monitoring observations of dynamics of seasonal thawing-freezing depth, water-saturation and temperature of soil; identified their hydrophysical properties and plasticity; studied the peculiarities of grain-size classification and cryogenic structure of close-to-surface tables of permafrost and ice wedge (ice complex sediments), development of cryogenic and post-cryogenic processes and phenomena, as well as parameters of soil cover (snow, moss layer, forest floor, etc.). In investigating the regularities of permafrost processes and phenomena dynamics, we used detailed permafrost and landscape methods and topographic shoots(at scale range 1:100–1:5,000), and photointerpretation, used in geocryology. The methods for cryogenic processes investigation are specified in works (Grechishchev et al. 1979, 1980, Shur 1988, Pavlov 1997, Gavriliev & Efremov 2003).

Results and Discussion

Diverse reaction of ice complex soils, active layer, and agricultural landscapes to the climate warming and agricultural development

Central Yakutia is among the regions in the north of Russia with maximal effect of global climate warming, reaching 2–2.5°C (Pavlov 2000). According to the data from weather stations of the region, dramatic changes of climate elements were registered during the past 25 years, including: 14 warm winters and 6 anomalously warm winters with air temperatures exceeding the normal by 3–4°C, and during some months by 5–8°C. There was not one cold winter (Skachkov 2000 et al.).

The amount of precipitation ranged during warm period ±1.5–3 times of the regular one, this included anomalously warm and dry summer of 1998 and mean annual air temperature higher than the normal by 4.5°C, as well as increase of snow cover height in some years by 1.5–3 times of the background value, and in subsidence by 1.4–3 times higher than background standard, according to the data of snow survey.

It was determined that during past 15–20 years in central Yakutia at high rate of climate warming and ice complex landscape surface disturbance, a trend towards permafrost degradation is indicated. Thus, in inter-alas areas, depending on landscape-anthropogenic conditions, at forest stubbing, and agricultural development, mean annual temperatures of perennially frozen ground rose to 1.5–2.5°C.

At sporadic inter-alas areas of agricultural landscapes of sixth-seventh terraces of the River Lena, an unprecedented high thawing rate of ice-rich permafrost was indicated, reaching 0.5–0.9 m during some excessively rainy, relatively warm summer-autumn seasons (1994, 1997, 2004–2006), preceded by anomalously warm winters. In 1989–2006 the trend of ice complex soils thawing in inter-alas areas of agricultural landscapes averaged from 0.03 to 0.27 m/y, and in the natural (undisturbed) landscapes, it is considerably lower: from 0.007 to 0.01 m/y (Figs. 2, 3).

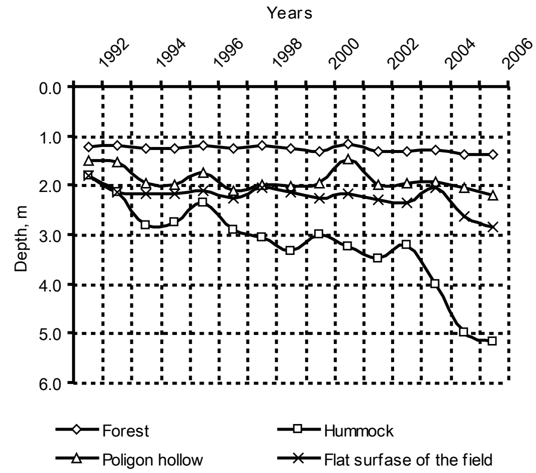

Figure 2. Dynamics of thaw depth at Dyrgebai site on the right bank of the River Lena, 1992–2006.

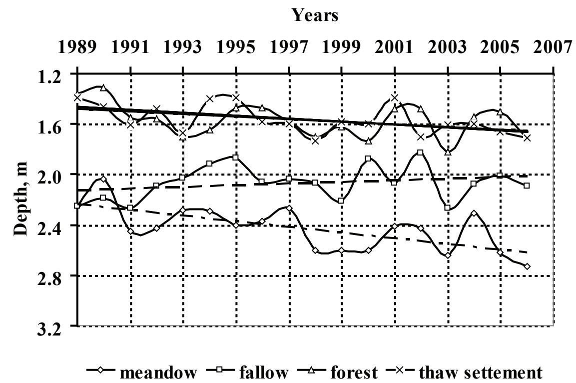

Figure 3. Dynamics of seasonal thaw depth at Kerdyugen site on the left bank of the Lena River, 1989–2006.

During the period of 1993 to 2006 anomalously intensive increase of perennially frozen ground occurrence depth was registered, making 2.9 times, at permafrost and wedge ice thawing starting from 1.8 to 5.17 m. At the same time the thickness of thawed zone in the upper layer of the ice complex ground (Δh_i) in Dyrgebai site at Abalakh (sixth) terrace of the Lena River made, correspondingly, from 0.3–0.5 m to 1.5–3.7 m, which resulted in intensive development of thermokarst subsidence, deformation, and surface degradation in various types of cryogenic relief: from hardly-visible thermal subsidence (undeveloped *bylar*) to undeveloped lake thermokarst (see further).

According to the degree of dangerousness and non-dangerousness of the results of reaction–development of undesirable geocryologic and soil processes caused by surface disturbance, different types of agricultural landscapes form the following consequences (in descending order): inter-alas fallows, used as pastures, in case of wedge ice immediately beneath the seasonally thawed layer (STL); inter-alas irrigated farming areas (fallows, sowed grasslands) at presence of wedge ice in the zone of potential seasonal thawing; inter-alas fallows where wedge ice occurs out of STL; irrigated valley lands; irrigated alas lands; shallow valley haylands; and natural alas lands (alas landscapes).

Along with an overall positive trend of permafrost degradation (thawing), we can note some short-term fluctuations (rhythms, reflecting cycles ranging between 3–4 and 9–11 years), activations and fadings of negative and positive nature (i.e., permafrost table descending and ascending). These fluctuations of seasonal thawing depth reduce, to considerable extent, the danger of fundamental disturbance of frozen-complex ground stability eventually resulting in occurrence of low-grade anthropogenic landscapes and lake thermokarst, but not inevitably.

Activation of natural-anthropogenic cryogenic processes and phenomena in inter-alas agricultural landscapes

New spatial-temporal patterns were revealed in cryogenic processes and phenomena dynamics in inter-alas lands of permafrost agricultural landscape complexes in nowadays conditions.

The analysis of results of long-term research work (1989–2006) on agricultural landscapes condition in Central Yakutia revealed, within the mentioned above landscapes, the activation of destructive cryogenic processes, related with the general 1.5–2.5°C increase of mean annual air temperature in the region and increasing anthropogenic stress.

Yu.L. Shur, a well-known permafrost scientist, has noticed: "There are few thermokarst observations and they refer to initial stages of the process. Such observations applied to areas with ice complex sediments include two or at the most three stages of thermokarst relief development: undeveloped bylar, mature bylar, iyo" (1988, 106).

Our field observations conducted in 1989–2006 in the agricultural areas, which are situated on the V–VII medium-height terraces of the middle Lena River on its left (Kerdyugen site) and right (Maia site) banks and are underlain by ice-rich permafrost, identified and assessed 8 and 12 manifestations of anomalous natural-anthropogenic cryogenic processes and phenomena, respectively. These include:

1) inter-alas surfaces unaffected by cryogenic processes (thaw subsidence, thermal erosion, frost fracture, etc.);
2) polygonally fractured areas;
3) undeveloped bylar, i.e., flat area, affected by separate micro-subsidential crater 0.3 m depth above ice wedges;
4) destabilized (weakened) areas in active layer and disruption of sensitivity of ice complex grounds with subsurface voids, loose sediments, i.e., with drastic changes in permafrost soil composition, construction and in all properties;
5) anomalously rapid surface deformations and active layer destruction by thermokarst subsidences of various forms and sizes (up to 1.8 m and more);
6) bylar, i.e,. deformated area with subsidences and polygonal shallow gullies network above ice wedges (at 0.3–0.5 m depth);
7) iyo, i.e., feeble shallow gully with water within bylar limits;
8) thermokarst mound, i.e., deformated area with bumpy-hollow microrelief;
9) hollow-like subsidence (subsidence hollow gullies, extended in one direction (e.g., in direction of dyodya);
10) subsidence thermoerosion formations (focuses of thermoerosion draft);
11) initial thermokarst depression (or primary areal thermokarst) without lake, but still watering in some particular rainy periods (2005–2007). These thermokarst phenomena often cause permafrost bogging.
12) undeveloped (young) thermokarst lake (dyodya).

These results improve and significantly enlarge already-known patterns of thermokarst formation development stages (Soloviev 1959, Shur 1988, Gavriliev & Efremov 2003, and others). Besides, they evidence an anomalously rapid progressive development of thermokarst stages, not sufficiently studied before.

Activation of primal thermokarst (or primal areal thermokarst)

Five thermokarst stages are observed *in situ* at Dyrgebai test site. For rather short period (1991–2006) clearly-defined primal thermokarst depression with polygonal bumpy-hollow microrelief without lake, but watering in particularly rainy periods (2005 and 2006) formed in one of the key areas of Dyrgebai. For the last 15 years, the longitudinal profile of the primal thermokarst depression (or primal areal thermokarst) increased from 6.2 m in 1994 up to 101.3 m in 2006 (or by 16.3 times), its width—from 40–50 m (by 12.5 times), and its depth increased from 0.35–2.1 m (by 6 times).

The most rapid surface subsidences (14–24 cm/y) above the thawing ice wedge occurred in central watered areas of developing thermokarst depression (primal areal thermokarst). Thus interpolygonal surface hollow gully deformation is 2.02 m, and in polygonal block, which replaces ice wedge, deformation is 0.95 m (*vide* Figs. 2, 3). No significant surface level depression of permafrost agricultural landscapes was noticed in the droughty basin-like subsidences in inter-alas arable lands, grassland, and long-fallow soils.

Other test sites Dyrgebai and Kerdyugen saw correspondingly 11 and 6 similar primal thermokarst depressions develop with the same polygonal microrelief. Three of them in inter-alas agricultural landscape Dyrgebai revealed a tendency of passing onto undeveloped thermokarst lake stage.

Activation of undeveloped thermokarst lake

Here and there in the agricultural lands, small thermokarst lakes form (dyodya, tympy) in taiga inter-alas areas at upper relatively flat and concave meso-relief areas of fifth-seventh terraces in the middle Lena river. For development of these natural-anthropogenic lakes at least 10 factors and criteria are needed:

1) ice complex within the potential (maximum) depth of the seasonal thawing;

2) climatic conditions: humid and warm years;

3) permafrost-hydrological conditions and criteria for thermokarst lake development, including:

- assemblage of effect of several water delivery sources (types): atmospheric (P_{os} = precipitation), hillside (deluvial) ($S_n > S_{om}$ = the recharge from surface-water exceeds their discharge), permafrost (W_m and $W_{лв}$ = water amount from structure-formative permafrost ices thawing and from ice wedge thawing to depths h_m accordingly), suprapermafrost water input ($S_{мв}$) of active layer to subsidence (or basin) from outer spillway, and water does not drain from closed subsidence and thermokarst basins $W_{лв}$ and $S_{ом}$;
- drastic increase of permafrost water source fraction $W_{лв}$, $W_{тв}$ and $S_{мв}$ during the undeveloped or young lake formation as a result of intensive permafrost and wedge ice thawing;

4) geological and geomorphological conditions: undrained area with slopes of less than 0.5°;

5) positive subsidence water balance formation;

6) ice content of ice complex grounds of more than 50-60% of their volume;

7) water cover appearing in subsidence or thermokarst depression having width exceeding the critical value: from 0.7–1.0 up to 1.5–1.8 m (Feldman 1984);

8) area of thermokarst depression should be rather large for spontaneous thermokarst;

9) activation of mechanisms of self-enhancement of permafrost processes and phenomena;

10) irrational land use.

Undeveloped (young) thermokarst lakes are developed and evolve mostly at fallows and along the arable lands edges, sometimes at very various territories. For example, four lakes formed at test site Dyrgebai, two lakes at Kerdyugen site, and at other inter-alas masses such as Khaya-Yurdya, Urasalakh, etc. All dyodyas have rounded shape, with the diameter from 25–80 m, basin depth from 1.5–6 m, and sides are abrupt. These dyodya formed about 35–60 or more years ago as a result of forest clearance, soil cover removal and thawing of large ice aggregation etc. Thermokarst lake (dyodya) #4 at Dyrgebai test site is the youngest one; it formed only 20 years ago after agricultural development of the area.

Conclusions

1. Rather realistic reaction (weak, moderate, strong) of the soils active layer, permafrost processes and ice complex table of inter-alas agricultural landscapes up to 10 m deep to discontinuous climate warming and various ways of agricultural land use.

2. Results and data obtained during 18 years of integrated monitoring observations (1989–2006) helped to reveal spatial-temporal patterns in progressive development of anomalous natural-anthropogenic permafrost processes and phenomena, which were not sufficiently studied before. That includes the research of 6 thermokarst stages from bylar to young lake thermokarst at rapid climate warming (about 0.09° C/y) and various ways of land use.

3. Rhythmical and trend patterns of dynamics of seasonal thawing depth, permafrost processes and table fluctuation of ice complex grounds of inter-alas agricultural areas, which were not sufficiently studied before are nowadays revealed.

4. If the present tendency of climatic warming in central Yakutia with air temperature trend around 0.09°C/y and agricultural land use ratio increase keep on, the possibility of activation (manifestation) of permafrost processes and especially that of thermokarst remains very high.

A Model for Calculating the Effective Diffusion Coefficient of Water Vapour in Snow

Rev Gavriliev
Melnikov Permafrost Institute SB RAS, Yakutsk, Russia

Abstract

A model is proposed for calculating the effective diffusion coefficient of water vapour for snow to account for its particulate structure. This is an improvement of the model presented in Gavriliev (2004), based on more adequate treatment of heat and mass transfer in snow. The model considers a cubic cell containing a spherical particle with point contacts on the apexes. The vapour concentration distribution on the particle surface is controlled by its temperature field. The temperature field is calculated based on generalized conduction theory for composite bodies, represented in the model by ice and vapour-air mixture. A quantitative relation between the diffusion coefficient of water vapour in snow and the snow density is established which provides a good explanation for the large scatter of experimental data. Because of the particulate structure of snow, the diffusion coefficient of vapour in snow is several times greater than the molecular diffusion coefficient of vapour in air (six times for compact snow).

Keywords: air; diffusion coefficient; snow; vapour flux.

Introduction

Experimental values for the vapour diffusion coefficient in snow, D_s, reported in the literature (Yosida 1950, Pavlov 1962, Kuvaeva 1966, Morozov 1967, Saveliev et al. 1967, Kolomyts 1971, Sommerfeld et al. 1986, Fedoseeva & Fedoseev 1988, Nikolenko 1988, Voitkovskii et al. 1988) scatter widely. There is also no agreement among authors whether this parameter depends on snow temperature, density or structure. The average D_s values measured in experiments vary from 0.17 to 1.20 cm²/s, although the authors used the same standard methods, a crystallizer pan or cans. Some writers (Woodside 1958, Dyunin 1961) adopted the air diffusion coefficient of 0.20 cm²/s at 0°C in their theoretical analyses of the heat and mass transfer in snow, assuming that the coefficients for vapour and air are approximately equal. The experimental results indicate, however, that the measured coefficients of diffusion of water vapour in snow are much larger than the molecular diffusion coefficient in air (4 to 6 times in Yosida [1950] and Pavlov [1962]). Yosida and Pavlov attribute this to the fact that in snow the water vapour is transferred not only by microscopic diffusion across the pores (free diffusion in air), but also by the passage through snow flakes, in which vapour is condensed on one side and evaporates from the other (macroscopic or hand-to-hand diffusion). In both cases, however, the mechanism of vapour transfer through the pore space is the same, namely, the molecular (free) diffusion of vapour-air mixture. Vapour is transferred in the pore space of snow due to the temperature gradient which establishes a vapour pressure gradient. The present author is of the opinion that the large differences in the diffusion coefficients of vapour in snow and in air are due to the particulate structure of snow, because actually vapour evaporates from the entire particle surface. Previous investigators estimated the vapour flux caused by the temperature gradient based on the plane area of a particle (the crystallizer model), which is evidently less than the area of its evaporating surface, i.e., as if the vapour flux is artificially increased. It should be borne in mind that instrumental measurements give the effective values of vapour diffusion coefficient in a unit area.

In order to prove this idea, a model for calculating the vapour diffusion coefficient was proposed by the author (Gavriliev 2004) which took into account the particulate structure of snow. The first attempt of model representation of snow structure to study vapour diffusion in snow was undertaken by Auracher (1978). Auracher's model consisted of plates of ice oriented either perpendicular or parallel to the flow, and the results were very dependent on the assumptions made. More recently, Colbeck (1993) proposed a particle-to-particle model. He considered a cubic packing of non-contacting, equally spaced spheres of ice in the air space. The vapour flux between particles was estimated using the electrostatic analogy. Colbeck found that the effective coefficient of vapour diffusion in snow D_s is related to the porosity of snow m according to

$$D_s = D_m \left[m^n + 10.0\,(1-m)^{0.51} \right] \tag{1}$$

where D_m is the coefficient of vapour diffusion in air and n is the exponent (n = 0, 1, 2, …). The D_s expression is highly insensitive to the exponent n and for practical purposes it can be taken equal to zero.

There are, however, several objections to the particle-to-particle model of Colbeck. First, the model virtually neglects the effect of vapour bypass around the particles through the free pore space, because by analogy with the electric force lines, the vapour flow lines close on the particles. So, Colbeck had to introduce the first term in Eq. (1) in order to obtain the coefficient of vapour diffusion in air D_m, when the particles disappear, i.e., at m = 1. Second, Colbeck's model assumes that the particles are isothermal, resulting in increased temperature gradients across the pores. The vapour flux is thus overestimated.

The model proposed in Gavriliev (2004) develops a very different approach to accounting for the vapour flow and temperature distribution, although it is outwardly similar to Colbeck's model in that it considers a cubic packing of spherical particles, but the particles have point contacts. Based on this model, a linear relation was found between the vapour diffusion coefficient in snow and snow porosity. Clearly some simplifying assumptions have to be made, as in any model investigation. The purpose of this paper is to improve my earlier model by treating heat transfer in snow in a more adequate way.

A Revised Model of Vapour Diffusion Flux in Snow

An outline of the proposed model is as follows. Since snow is cooled from above, the vapour concentration increases downwards. The vapour and heat flows move in the same direction, from the soil to the snow surface (upward). Snow has a complex multi-branch openwork structure with numerous contacts between particles. Modeling of this structure is a difficult task. However, some important advances have recently been made in three-dimensional modeling of snow structure, based on X-ray microtomopgraphic images of snow samples. Two lines of modeling research can be identified. The first one involves the development of simple physical models, based on Kelvin and Langmuir-Knudsen equations, to describe the isothermal and temperature gradient metamorphism of snow (Flin et al. 2003, 2005). Another approach is discrete element modeling (DEM) (Kaempfer et al. 2005, 2007). This snow model has an explicit geometric structure composed of large aggregate of discrete, individual snow grains with axisymmetric particle shapes, including spheres, tapered cylinders, and elongated or oblate spheroids and ellipsoids. The model was used by Kaempfer et al. to reproduce experimentally the radiative and heat transfer in snow. The above models provide realistic representation of the snow structure. However their application to the analysis of heat and mass transfer involves some difficulties. Usually in such a case, the model schemes are simplified; for example, the random structure is replaced by an ordered structure. The simplest models of mixture structure are based on the following rule (from chaos to order) (Dulnev & Zarichnyak 1974): the effective generalized conduction coefficients are equal for the ordered and chaotic systems, if their structures are similar and the properties and volumetric concentrations of the components are the same. This is the case for the model with changing particle shapes developed by the present author to calculate the thermal conductivity of snow (Gavriliev 1996, 1998). The model consists of three intersecting ellipsoids of revolution in a cubic cell and adequately reflects the main features of metamorphic changes in snow structure through the whole cycle from deposition to the glacial state. Depending on snow porosity, particles attain a large variety of shapes, such as stellar, needle, irregular, rounded, faceted and rounded cubical. It is a three-dimensional, ordered and rigid model with coordinate number 6. Contact spots exist where the model figure contacts with the planes of the cubic cell. The size of contact spots and the model porosity are determined by the semi-axes ratio of the ellipsoids of revolution. The model porosity ranges from 0 to 1. The model is purely geometrical and the system's porosity is changed by assigning ellipsoid parameters with no consideration of snow metamorphism.

For the vapour diffusion study, we have restricted ourselves to the special case of the model where the particles have a spherical shape (Gavriliev 2004), and are arranged cubically. In snow, the vapour evaporates from the upper surface of a lower-lying particle and, due to the temperature gradient, moves upward to the lower surface of a higher particle where it condenses in nearly the same amount according to the thermodynamic equilibrium condition. Therefore it is sufficient to consider one of the two processes, evaporation or condensation (the hemisphere scheme in the model). Evaporation has been chosen for the present research. The temperature field in the snow cover gives rise to concentration gradients, thus controlling the rate of vapour diffusion. There is no reverse transport of vapour in snow.

The earlier work (Gavriliev 2004) considered the scheme shown in Figure 1 for a hemisphere in a semicubical cell. At the tops, the particle has a plane of contact with other particles. The bottom $(y = 0)$ and the top $(y = R)$ of the sphere are maintained at constant temperatures t_1 and t_2 $(t_1 > t_2)$, which cause constant vapour concentrations c_1 and c_2 $(c_1 > c_2)$. Since vapour evaporation is a surface phenomenon, along the heat flow axis oy the vapour concentration distribution on the sphere's surface $c(y)$ or $c(x)$ is given over a range from c_1 to c_2.

Snow sublimation is a diffusive process and can be described by Fick's Law. According to the principles of Maxwell's diffusional theory of evaporation (Dyunin 1961), the general equation for the rate of evaporation of a body of arbitrary shape is

$$\frac{dM}{dt} = -\int_S D_o \, grad \, c \, \overline{dS} \tag{2}$$

where dM/dt is the diffusive flux of vapour from the surface; D_o is the general coefficient of diffusion of vapour which depends on molecular diffusion and the character of medium movement relative the body; S is the surface area; $\overline{dS}$ is the vector element of surface area; and c is the weight concentration of vapour in air.

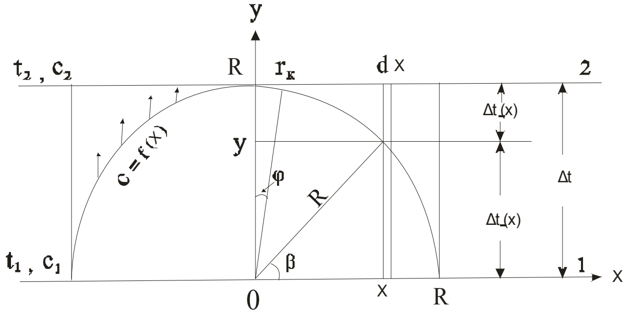

Figure 1. Schematic model of evaporation, vapour diffusion and snow temperature (Gavriliev 2004).

Since the exact theory of evaporation of solids is extremely complex, it is common to consider only the case of steady-state evaporation: $i = dM/dt$ = const. From Eq. (2) it follows that the amount of vapour in the space above the hemisphere depends on the surface area of evaporation and the vapour concentration gradient. The larger is the specific surface area, the more vapour is formed. The particulate structure of a body facilitates water evaporation. This can explain the great difference between the vapour diffusion coefficient in snow and that in air.

For the scheme shown in Figure 1, the concentration gradient in Eq. (2) is taken to be that outside the sphere, i.e., in the region R-y, and considered are the external surface of the sphere S and its differential dS. In the previous work (Gavriliev 2004), an error was made in selecting these parameters when y was taken instead of R-y and the differential dS was calculated from the bottom area of the sphere, i.e., the vapour flux within the sphere was computed.

The differential of the external surface of the sphere is $dS = 2\pi x dl$ (here $dl = (dy^2 + dx^2)^{1/2}$ is the arc length of the sphere's external surface intercepted by an inclined ring with radii x and $x+dx$). Taking into account that $y = (R^2 - x^2)^{1/2}$, we obtain

$$dS = \frac{2\pi R\, x\, dx}{\sqrt{R^2 - x^2}} \quad .$$

Considering the above remarks, the vapour flux i through the cylindrical region of the model is written:

$$i = -D_m \int_{S_c}^{S} \frac{c(y) - c_2}{R - y}\, dS =$$

$$= 2\pi R\, D_m \int_{r_c}^{R} \frac{[c(x) - c_2]\, x\, dx}{\left(R - \sqrt{R^2 - x^2}\right)\sqrt{R^2 - x^2}} \tag{3}$$

where r_c and S_c are the radius and the area of the contact spot at the top of the sphere. In this equation, the concentration gradient is reckoned from c_2.

The distribution of vapour concentration on the particle surface, *c(x),* is controlled by temperature. For an approximate estimate of this parameter, Kaganer's (1966) solution for the sphere with two contact areas was used in Gavriliev (2004) (see Fig. 1). The problem assumes that heat is transferred only through the contact surfaces of the particles, i.e., there is no heat transport across the pore space. This assumption is not entirely correct for snow and is only valid for very low temperatures (about -20°C or lower) when the diffusive transport of vapour is comparatively small and heat is predominantly transferred by conduction.

In the general case, calculation of the temperature distribution on the surface of a snow grain should account the additional heat convection by vapour diffusion due to a temperature gradient. This can be done by using the effective thermal conductivity of air λ_{ae}, which incorporates the thermal effect of vapour transfer in snow by thermal diffusion (Gavriliev 1998).

$$\lambda_{ae} = \lambda_{\mathrm{a}} + \frac{L\, D_{\mathrm{s}}\, e_o}{R_{\mathrm{v}}\, T^2}\left(\frac{L}{\mathrm{R_v}\, E} - 1\right)\exp\left[\frac{L\,(T - T_o)}{R_{\mathrm{v}}\, T_o\, T}\right] \tag{4}$$

where λ_a is the thermal conductivity of calm air; $e_o = 6.1 \cdot 10^2$ Pa is the saturation vapour pressure at 0°C (T_o = 273 K); $R_v = 4.6 \cdot 10^2$ J/(kg·K) is the gas constant of water vapour; T is the absolute temperature; L is the latent heat of ice sublimation; and D_s is the diffusion coefficient of water vapour in snow.

For calculating λ_{ae} within the model space, however, the molecular diffusion coefficient of vapour, D_m, should be used in Eq. (4). The equation for the temperature dependence of D_m at atmospheric pressure (1 atm) given by Kikoin (1976) is

$$D_m = D_0 \left(\frac{T}{273}\right)^{1.5} \tag{5}$$

where D_0 is the diffusion coefficient for vapour at 0°C (T_0 = 273 K).

The D_0 values for water vapour in air reported in the literature (see references in Gavriliev 2004) vary from 0.205 to 0.277 cm²/s, the more frequent values being within the range of 0.230 to 0.277 cm²/s. Jumikis (1962) gives D_0 = 0.426 cm²/s, the value which was obtained in a test with similar conditions to the crystallizer experiments but stands out of the common range. In this study, the value chosen for D_0 is 0.25 cm²/s.

The thermal conductivity of air in relation to temperature may be calculated by an equation given by Vargaftik (1963)

$$\lambda_{\mathrm{a}} = \lambda_0 \left(\frac{T}{273}\right)^{0.82} \tag{6}$$

where $\lambda_0 = 0.0244$ W/(m·K) is the thermal conductivity of air at 0°C (T_0 = 273 K).

The temperature dependence of the effective thermal conductivity of air, based on Eqs. (5) and (6), is shown in Figure 2.

An approximate estimation for the temperature distribution on the surface of a snow particle can be obtained based on the theory of generalized conductivity of composite bodies. The distortion of flow lines in the system components is usually neglected, which introduces some errors into the calculations. However, these errors are largely removed by fragmenting the elementary cell by adiabatic and isothermal planes and by using the arithmetic means of thermal conductivity (Dulnev & Zarichnyak 1974).

Let us consider the scheme in Figure 1, assuming that only point contacts exist between the spherical particles. Select a circular ring with width dx and inner radius x. The heat flux Q is the same across the particle (1) and the medium (2):

$$dQ = -\lambda_1 \frac{\Delta t_R}{y}\, dS = -\lambda_2 \frac{\Delta t_2}{R - y}\, dS \tag{7}$$

where λ_1 and $\lambda_2 = \lambda_{ae}$ are the thermal conductivities of the ice particle and the air with water vapour, respectively (the effective coefficient); dS is the cross-section area of the ring; $\Delta t_R(x) = t_R(x) - t_1$ and $\Delta t_2(x) = t_2 - t_R(x)$ are the temperature

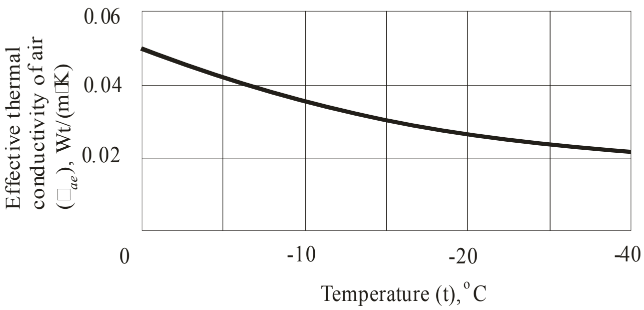

Figure 2. The effective thermal conductivity of air in snow versus temperature.

differences on the particle surface and in the air space of the circular ring, respectively; $\Delta t_R(x)$ is the temperature of the sphere's surface at points (x and y) of intersection with the cylindrical ring. Eq. (7) is valid for any radius x.

Considering expressions $y = (R^2 - x^2)^{1/2}$ and $\Delta t_R(x) + \Delta t_2(x) = \Delta t$ (the total temperature difference in the cell $t_2 - t_1$), the equation

$$\frac{\Delta t_R(x)}{\Delta t} = \frac{1}{1 + \dfrac{\lambda_1}{\lambda_2}\left(\dfrac{1}{\sqrt{1 - x^2/R^2}} - 1\right)} \qquad (8)$$

is obtained from Eq. (7) for the relative temperature difference over the particle surface.

Hence it follows that the temperature distribution on the particle surface depends on the ratio between the thermal conductivities of the particle and the pore medium (Fig. 3). Taking into account the effective thermal conductivity of air, curves 6–8 fit for snow over a temperature range 0 to -10°C.

Because the vapour in snow is saturated, its concentration is determined using the well-known equation

$$c = \frac{c_0\, T_0}{T} \exp\left(\frac{22.46\, t}{T}\right) \qquad (9)$$

where $c_0 = e_0 \mu_l / R_v T_0$ is the vapour concentration at T_0; μ_l is the molecular weight of the vapour.

When the temperature distribution at the particle surface is given by curves 6-8 (Fig. 3) (within the temperature range of 0 to -10°C), the calculations of vapour concentration with Eq. (9) result in a single curve (with few departures) relating the relative difference in vapour concentration over the sphere, $\Delta C_R(x)/\Delta C$, and the dimensionless coordinate x/R (Fig. 4). For convenience of integration in Eq. (3), this curve is expressed by the equation

$$\frac{\Delta C_R(x)}{\Delta C} = 2.4\frac{x}{R} - 1.4\frac{x^2}{R^2} \qquad (10)$$

where $\Delta C = C_1 - C_2$ is the maximum difference in vapour concentration between the equatorial and vertex planes of the spherical particle; $\Delta C_R(x) = C_R(x) - C_2$ is the vapour concentration difference over the particle surface relative the vertex plane.

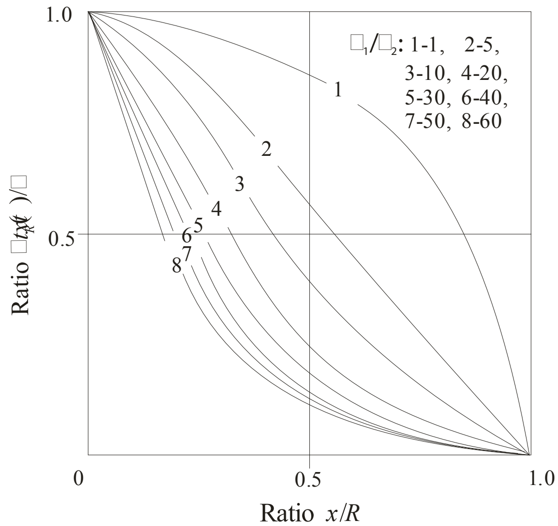

Figure 3. The distribution of the relative temperature difference over a spherical particle at various ratios between thermal conductivities of ice (1) and pore space (2).

Since the particles have only point contacts ($r_c = 0$), Eq. (43) is integrated over dx from 0 to R. Then the vapour flux in the cylindrical region of the model will be calculated using the equation:

$$i = -2\pi R\, D_m (C_1 - C_2) \int_0^R \frac{\left(2.4\dfrac{x}{R} - 1.4\dfrac{x^2}{R^2}\right) x\, dx}{\sqrt{R^2 - x^2}\left(R - \sqrt{R^2 - x^2}\right)} =$$

$$= -2\pi R\, D_m (C_1 - C_2)(1.2\pi + 0.3). \qquad (11)$$

Effective Diffusion Coefficient of Vapour in Snow

The effect of the particulate structure of snow on the vapour diffusion coefficient is estimated as above by comparing the vapour flux calculated by Eq. (11) and the flux through the bottom of the cylindrical region $i_{fl} = -\pi R D_s'(c_1 - c_2)$ where D_s' is the effective diffusion coefficient for vapour in the cylindrical region of the snow model. Then we obtain, as above, the equation

$$D_s' = K\, D_m \qquad (12)$$

where $K = 2(1.2\pi + 0.3)$ is a parameter for the particulate structure of snow which shows how many times the vapour diffusion coefficient in snow is greater than that in air due to the increased evaporation area of snow particles.

For the considered case of the vapour concentration distribution near the surface of the spherical snow particle, we have a different value of K which is equal to 8.2.

When the contribution of a through space to vapour diffusion is taken into account, the total diffusion coefficient is calculated by the equation in Gavriliev (2004)

$$D_s = D_m\, \left[1 + 1.5(K - 1)(1 - m)\right] \qquad (13)$$

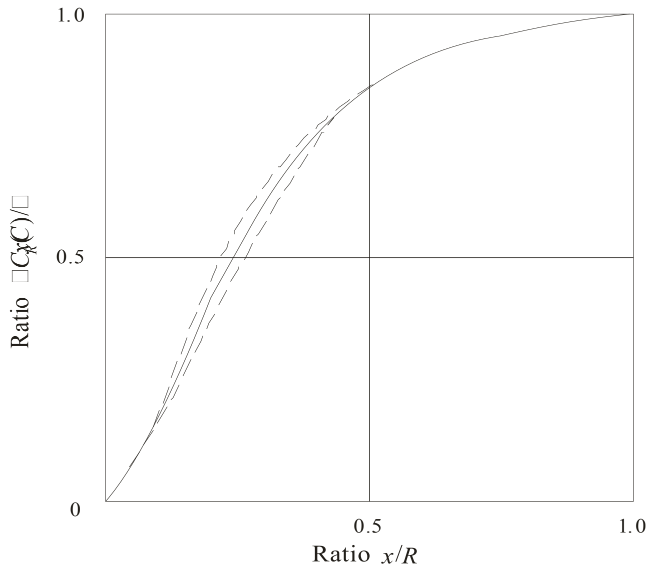

Figure 4. The distribution of the relative vapour concentration difference on the surface of a spherical snow particle.

where $0.33 \le m \le 1$. At $m = 1$, we have $D_s = D_m$, and at $m = 0.33$, $- D_m = K D_m$.

Thus the diffusion coefficient of water vapour in snow depends on porosity (density).

Discussion of Results

Computations have been made for snow densities varying from 0.1 to 0.4 g/cm^3 ($m = 0.56 \div 0.89$). The obtained values of the diffusion coefficient for snow, D_m (cm^2/s), range from 0.55 to 1.45 and are compatible with the experimental results of most workers. It is interesting to compare the relative effective coefficients of vapour diffusion in snow (D_s/D_m) calculated by Eq. (1) (Colbeck 1993) and Eq. (13) (Gavriliev 2004). Figure 5 shows that the D_s/D_m ratio values from Colbeck's equation are invariably higher than those obtained by Eq. (13). The possible explanation is that calculations with the particle-to-particle model use the overestimated vapour flux due to the increased temperature gradient across the pores and the adding of the first term in Eq. (1) which leads to the results higher by unity. Curve 2′ for the results obtained without adding the first term in Eq. (1) agree better with our results (curve 1). It should be noted that actual computations with the particle-to-particle model led Colbeck to Eq. (1) that did not include the first term which was added later so that the logical reasoning would be complied for $m = 1$. Colbeck (1993) admitted that, because of the above reasons, the D_s/D_m values obtained by Eq. (1) were higher (4 to 7) than the D_s/D_m range (3.5 to 5) found by Yosida (1950).

Figure 5 also shows the experimental results of the authors mentioned in this paper. It is evident that there is no clear relationship between D_s/D_m and snow density and that the data scatter from 0.6 to 5.1. This is probably due to the effect of snow temperature on the measured coefficient of vapour diffusion in snow observed in the experimental data of Morozov (1967), Kolomyts (1971) and Nikolenko (1988). Most of the experimental data are lower than the theoretical results. Further investigations will be made to find an explanation.

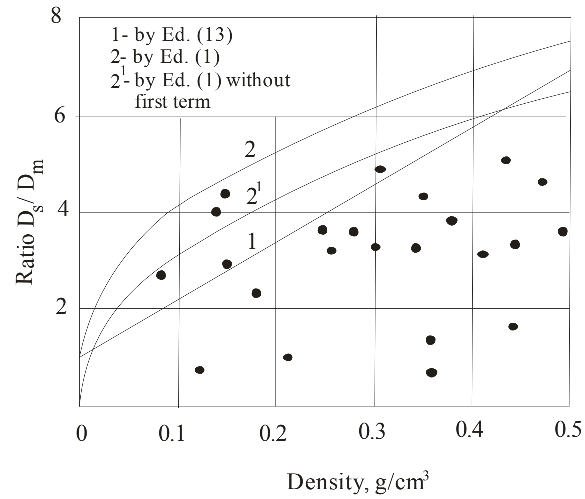

Figure 5. D_s/D_m ratio vs. snow density.

It is interesting to note that, according to the proposed model, the diffusion coefficient of vapour in snow can reach a maximum of 2.06 cm^2/s at a porosity of 0.33, or a porosity of about 0.62 g/cm^3. This can be considered to be a purely theoretical value for dry snow which is hardly possible in real situations.

Conclusions

A model was developed to describe the process of water vapour diffusion in snow which takes into account the particulate structure of snow. Based on this model, a linear relation was found between the vapour diffusion coefficient and snow density. It has been theoretically established that because of the particulate structure of snow, the effective diffusion coefficient of vapour in snow is many times that of water vapour in air (up to six times for compacted snow).

Abstract

During the last decades the permafrost regions in the Lena River basin, Eastern Siberia, have experienced substantial climate warming. The analysis of long climatic and hydrological series revealed an inhomogeneous distribution of climate warming over the territory. Climate warming is shown to be accompanied by pronounced runoff changes, particularly in the cold season, that also exhibit significant space-time inhomogeneity. According to the hydrological modeling results, the expected anthropogenic climate warming in the 21st century can cause more perceptible runoff changes in the Lena River basin, as compared with the recent climate change. The hydrology-related consequences of climate warming are evaluated from a macro-scale monthly water-balance model (Georgiadi & Milyukova 2002, 2006).

Keywords: eastern Siberia; monthly water-balance model; permafrost; river runoff changes; scenarios of global climate warming.

Introduction

The river flow forming in the cryolithic zone of Eurasia, especially within the largest river basins (Lena, Enisey, Ob'), has a strong effect on the regional climate and the surrounding seas, affecting the chemical composition of water, the sea ice formation, and the circulation in the Arctic Ocean and the North Atlantic. Changes of the river runoff can have a pronounced effect on the processes involved.

During the recent decades significant global climate warming has been observed. Climate warming has been the largest in Northern Eurasia, particularly in the permafrost regions of Eastern Siberia (IPCC 2001). These changes include the winter air temperature and overall soil temperature rise (Varlamov et al. 2002). Regional climate changes are accompanied by river runoff changes in Eastern Siberia (Georgievsky et al. 1999, Savelieva, et al. 2000, Yang et al. 2002, Simonov & Khristoforov 2005, Berezovskaya et al. 2005, Georgiadi et al. 2006).

According to model forecasts of the climate change caused by the increased atmospheric greenhouse gases, the most perceptible changes take place in the permafrost regions of Eastern Siberia (IPCC 2001). Regional climate warming will cause a considerable increase in soil temperature and consequent permafrost thawing (Anisimov et al. 1997, Demchenko et al. 2002, Malevsky-Malevich et al. 2000). Such changes can alter the river runoff, particularly its intra-annual distribution (Georgiadi & Milyukova 2006). Possible changes of freshwater and heat flows going into the Arctic Ocean have potentially important implications for the ocean circulation and climate outside the region.

Until now, the processes regulating the river runoff in the large basins of the cryolitho zone have not been well studied, particularly the geographical (spatial and temporal) structure of their response to recent and projected global climate warming.

The Lena River basin in Eastern Siberia was selected as the main subject of investigation. It is one of the world's largest basins and occupies the area of 2,488,000 km^2 and extends as far as 4400 km. The basin is almost completely covered with deep permafrost ground whose upper active layer thaws out during the short summer season. In addition, the Lena basin is characterized by a small anthropogenic influence owing to a low population density. Analysis of the Lena basin is also facilitated by large intensive research programs carried out by Russian, bilateral, and international teams in the last 15 years.

The main objectives of this investigation is to analyze spatial and temporal heterogeneities of the recent river runoff changes over the Lena River basin, as well as to compute river runoff changes caused by the projected global climate warming.

Recent River Runoff Changes

The investigation of a spatial-temporal structure of the long-term runoff changes in the Lena River basin is based on the analysis of long-term series of hydrometric observations which are conducted on the national network of gage stations. Long-term series of annual, seasonal, and monthly runoff values for large, medium, and small representative river basins and annual and monthly series of air temperatures and precipitation are analyzed for characteristic zonal-landscape conditions. At the initial stage, the following methods were used:

1) Method to compare the characteristics of mean annual, seasonal, and monthly values of hydrological and climatic changes for the two periods: from the start of records to 1980 and from 1981 to the end of the 1990s and the beginning of the 2000s. It is the latter period alone, when the regional climate warming is most intensive.

2) Method of cumulative sum of normalized values which was traditionally used in the USSR and Russia to study the cycles of long-term changes in hydrological and climatic elements.

$$C_{si} = \sum (K_i - 1) / C_v \, , \; K_i = E_i / E_m \, , \qquad (1)$$

where C_v is the coefficient of variation, E_i is the value of the element for the i-year, E_m is the mean value of the element, K_i is the modulus coefficient of the element, C_{si} is the cumulative sum of the normalized values of the hydrological and climatic element.

Climatic changes

It follows from the calculations performed that in the period of the intensive regional climate warming, the annual air temperature rises considerably, with the temperature rise being distributed inhomogeneously over the territory of the Lena River basin. The maximal rise is registered in the central, eastern, and southern parts of the basin.

The character of the basin-averaged air temperature changes (provided that we do not consider the features of their spatial distribution) agrees with the classical idea, i.e. the most noticeable changes occur in the cold season of the year and insignificant warming and even temperatures fall in the summer-autumn period are observed. At the same time considerable spatial variation of changes throughout the year is typical for the basin.

Considerable spatial variation is also characteristic of the changes in average monthly precipitation values, especially in the summer.

The analysis of the cumulative sum curves of annual air temperatures indicates that beginning in the 1980s, the climate warming, which was synchronous enough in different parts of the Lena River basin, was recorded. The change of precipitation in this period is less homogeneous over the basin's territory.

River runoff changes

According to the analysis of the cumulative sum curves of the annual river runoff in different parts of the Lena River basin, the phase of the increase in the annual river runoff is observed in most of the basin during the last 15-25 years.

Only in some of the rivers, in the southern left-bank basin and in the upper course of the Lena, is the trend for the runoff decrease revealed.

The comparison of cumulative sum curves of annual and winter (November-April) river runoffs for the long period of observations (1935-2005) yields three types of their combinations (the list and the position of gage stations are shown in Figure 1):

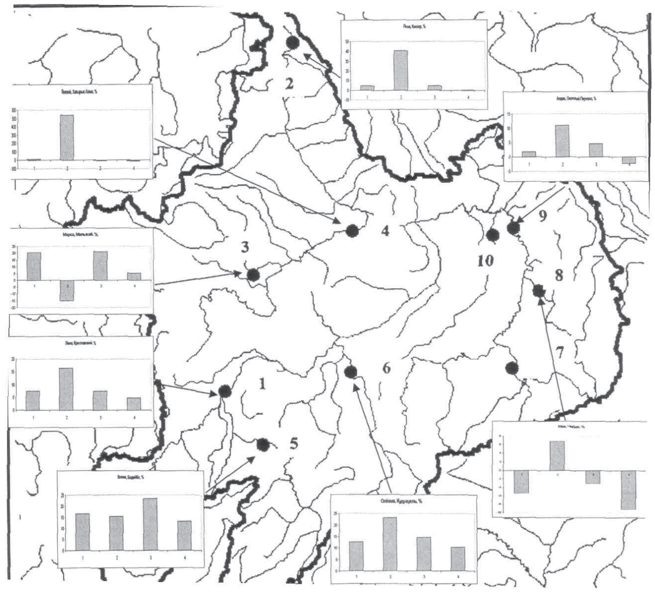

Figure 1. Deviations of mean annual and seasonal runoff for the period 1981-2005 and the period from the start of records to 1980 (in percent). Designations of diagram columns: 1 is the annual runoff; 2 is the winter (November-December) runoff; 3 is the flood (May-June); 4 is the low water (July-October). 1) Lena, Krestovsky; 2) Lena, Kyusyur; 3) Markha, Malyukai; 4) Vilyui, Khatyryk-Khomo; 5) Vitim, Bodaibo; 6) Olekma, Kudu Kuel; 7) Uchur, Chyul'byu; 9) Aldan, Okhotsky Perevoz; 10) Amga, Buyaga.

1) Phases of the annual and winter river runoff increase and decrease are almost synchronous, but for the winter runoff, these are usually better defined (Lena, Krestovsky; Vitim, Bodaibo; Olekma, Kudu Kuel; Aldan, Okhotsky Perevoz; Uchur, Chyul'byu; etc.).

2) Phases of the annual and winter runoff increase and decrease during the long period of observations can coincide or be asynchronous (Markha, Malyukai).

3) Relatively short and less intensive phases of the annual runoff increase and decrease are observed against the background of the long phases of increasing and decreasing winter runoffs (Lena, Kyusyur; Amga, Buyaga).

The comparison of intra-annual runoff changes in the Lena River basin for the periods considered shows the following (Fig. 1):

1) In the downstream of the Lena River, the most noticeable runoff increase occurs in the cold season of the year, while in the southern and southwestern mountain parts of the basin (with discontinuous and sporadic permafrost and more pronounced underground flow), the changes in runoff intra-annual distribution are more homogeneous and normally more intensive in all seasons of the year, as compared with the other parts of the basin.

2) The most noticeable increase in the Lena River runoff in the cold season is observed in the downstream of the Aldan and Vilyui rivers confluence.

3) The increase in the river runoff during the cold season in the downstream of the Aldan River can be related to the change of climatic conditions in its basin.

4) The considerable runoff increase in the lower portion of the Vilyui River in many respects can be connected with its artificial regulation as a result of the dam construction. This factor plays the main role in the winter runoff increase in the downstream of the Lena River.

Projected River Runoff Changes

Monthly water-balance model (MWBM)

The monthly water-balance model (MWBM), developed by the Institute of Geography of RAS to calculate hydrological consequences of the expected global climatic changes, was used to evaluate the large-scale hydrological changes (Georgiadi & Milyukova 2002, 2006). It can be referred to the category of macro-scale hydrological models with monthly resolution which are actively developed in the recent years (Willmott et al. 1985, Yates & Strzepek K. 1994, etc).

The model describes the main processes of the land hydrological cycle: infiltration and accumulation of water in the active layer; evaporation (based on the modified Tornthwite method (Willmott et al. 1985)); freezing and thawing of ground by using the Pavlov (1979) and the Belchikov & V.I.Koren methods (1979) which have been established as a simplified solution of the classical Stefan problem as applied to permafrost grounds; snow accumulation and snowmelt based on the Komarov method (Manual… 1989); formation of the surface flow and runoff from the active layer; and formation of the ground flow and river runoff.

The model allows for macro-scale inhomogeneity of hydrometeorological fields and other characteristics of the territory (permafrost, soil, hydrogeology). Such an approach provides the required accuracy in modeling climate changes that is achieved in the experiments with general atmosphere and ocean circulation models. The model calculations are performed in the regular grid cells. The existing version of the model employs a uniform spatial grid whose change makes it possible to take into account the main macro-scale inhomogeneity of the relief, the features of permafrost grounds including their active layer and hydrometeorological characteristics. The model is elaborated to estimate the changes of multi-year average characteristics of the water balance.

The principal approach to the account of inhomogeneity of the hydrogeological structure is to divide the underground zone into layers and calculate the runoff from each of them using our scheme of income and discharge of water for these layers.

The results of numerical experiments with ECHAM4/OPYC3 (Max Plank Meteorological Institute, Germany) and GFDL-R30 (Geophysical Laboratory of Hydrodynamics of the Princeton University, USA) were used based on the A2 family scenarios of global socio-economic changes in the 21st century from the last SRES scenario series accepted in the IPCC program. Calculations were made for the averaged conditions of the two periods (2010-2039, 2040-2069).

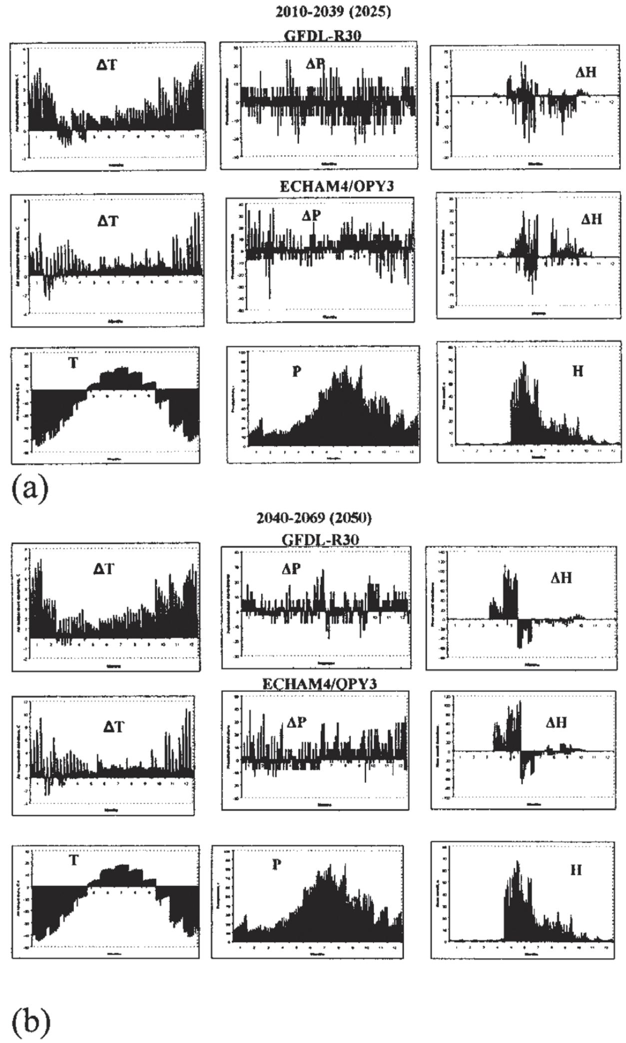

Figure 2. Deviations of mean monthly air temperatures (ΔT, °C), atmospheric precipitation (ΔP, mm) and river runoff (ΔH, mm) from their modern values generalized in the regular grid cells covering the plain part of the Lena basin, with regard for climate warming in 2010-2039 (a) and in 2040-2069 (b) by using scenarios of the Geophysical Laboratory of Hydrodynamics of the Princeton University (USA) and the Max Plank Meteorological Institute (Germany). The last line of figures shows mean monthly air temperatures (T, °C), atmospheric precipitation (P, mm), and stream flow (H, mm) under the modern climate conditions.

Discussion of modeling results for the plain part of the Lena River basin

Climatic conditions are shown in Figure 2. According to the considered scenarios for a plain in the central part of the Lena River basin, the climate is expected to warm essentially and more intensive in the middle of the 21st century.

Thus according to the scenario of the Max Plank Meteorological Institute, the climate warming can be more perceptible. Both scenarios predict a better pronounced air temperature increase in the cold period of the year, which is likely to lead to its duration reduction. The character of changes in atmospheric precipitation is more complicated. According to the both scenarios, the tendency towards the precipitation increase is to be evident as late as the mid-21st century.

It should be noted that the character of annual distribution of scenario changes of monthly average air temperatures and precipitation is very similar to the appropriate changes observed in this region during the last decades of the modern climate warming, though it differs from the current changes in scale.

Hydrological conditions are also shown in Figure 2. According to the climatic scenarios developed by the Geophysical Laboratory of Hydrodynamics, Princeton University and the Max Plank Meteorological Institute for the plain part of the Lena River basin, during the first thirty years of the current century it is not likely to expect any noticeable increase in both annual river runoff and river runoff for the spring-summer flood period (three months with the greatest monthly flow). For the two scenarios realized, a significant increase in annual and spring flood runoffs is expected to occur by the middle of the 21st century.

It should be noted that the distribution of the possible changes in the river runoff over this part of the basin is characterized by essential spatial inhomogeneity which is to be reduced appreciably by the middle of the century.

Both scenarios suggest significant changes in the intra-annual stream-flow distribution. Thus in the first third of the century, both scenarios give similar changes in the wave of the spring-summer flood, whereas the river runoff changes following the main wave of high water may be of absolutely opposite character. By the middle of the century, both scenarios give, in essence, the same pattern of changes in the intra-annual stream-flow distribution: the wave of spring-summer high water is to be shifted (with the form and volume of water nearly unchanged) one month backward, as compared with the current situation. By the way, the character of changes in the intra-annual stream-flow distribution in the Lena River basin is identical to the similar changes in the Volga River basin with the probable global climate warming in the current century.

The following conclusions can be made as to the probable impacts of the predicted climate warming in the central plain part of the Lena River basin.

1. According to the considered scenarios, the essential climate warming is likely to be expected, and in the middle of the 21st century this is to be even more intensive.

2. The character of the intra-annual distribution of the scenario changes in monthly mean air temperatures and precipitation is rather similar to the appropriate alterations observed in this region during the last decades of the modern climate warming, but differs from the recent climate warming in scale.

3. According to the climatic scenarios, a significant increase, both in annual runoff and in spring-summer flood runoff, is likely to be expected by the middle of the current century.

4. Quite a significant change in the character of the annual stream-flow distribution may take place. By the middle of the century, the both scenarios give, in essence, the same pattern of changes in the intra-annual stream-flow distribution: the wave of spring-summer high water is to be shifted one month backward, as compared with the current situation.

Permafrost Analogues of Martian Habitats

David A. Gilichinsky
Soil Cryology Laboratory, Institute of Physicochemical and Biological Problems in Soil Sciences, Russian Academy of Sciences, Pushchino, Russia

Abstract

Terrestrial permafrost, inhabited by viable microorganisms, represents a range of possible extraterrestrial cryogenic ecosystems on Earth-like planets without obvious surface ice, such as Mars. In a balanced permafrost environment, cells survive significantly longer than in other habitats. If life existed during the early stages of Martian development, then remnants of primitive forms may be found within frozen material that protects them against unfavorable conditions. This paper considers (a) the suggested age of Antarctic permafrost as an analogue somewhat closer to that of Mars than Arctic permafrost, (b) that free water can only exist on Mars in the form of cryopegs, as formed when Mars became dry and cold, (c) volcano-ice interactions in permafrost areas as one way to have liquid water on Mars, and (d) soil cover as a distant model of the Martian active layer.

Keywords: astrobiology; cryopegs; Mars; microorganisms; permafrost; volcanoes.

Introduction

Temperature is the fundamental aspect of the environment, where it acts as a regulator of physicochemical reactions and forms the basis of biological processes. Hard data indicate that biota survive over geological periods at temperatures <0°C within permafrost (for a recent overview, see Steven et al. 2006) down to -27°C (Gilichinsky et al. 2007a), and in ice sheets in Greenland (Miteva et al. 2004), the Tibetan Plateau (Christner et al. 2003), and in Antarctica down to -50°C (Abyzov 1993). In such environments, the dehydration leads to a considerable decrease of biochemical activities. This allows the survival of an ancient microbial lineage that can physiologically and biochemically adapt much longer than it would in any other known habitat.

The ability of microorganisms to survive on a geological scale forces us to redefine the spatiotemporal limits of the terrestrial and extraterrestrial biospheres and suggests that mechanisms of such adaptation might operate for millions of years. The long-term subzero temperature regime of the cryosphere is not limiting but rather a stabilizing factor. Organisms adapted to such balanced conditions represent a significant part of the biosphere—the cryobiosphere.

The cells, their metabolic by-products and bio-signatures (bio-minerals, bio-molecules, bio-gases), found in the Earth's cryosphere provide a range of analogues that could be used in the search for possible ecosystems and potential inhabitants on extraterrestrial cryogenic bodies. If life ever existed on other planets during the early stages of development, then its traces may consist of primitive cell forms. Similar to the Earth, they might have been preserved and could be found at depths within the ice or permafrost.

Microorganisms isolated from the ice cores of both hemispheres have been interpreted to be Earth's most representative analogues of icy inhabitants on Jupiter's ice-covered moon Europa, icy moon in Saturn's system Enceladus, and ice caps on Martian poles. Because ice thaws under geostatic pressure even at subzero temperatures, the existence of very old microorganisms is unlikely on the mentioned moons and caps.

The most inhabited and ancient part of the cryobiosphere's permafrost, being up to several hundred meters deep, harbors significant numbers of viable microorganisms, adhered on soil particles, and represents a wide range of possible cryogenic ecosystems for planets without obvious surface ice. Most intriguing are the traces of past or existing life on Mars, of interest due to upcoming missions. Because of unfavorable factors, life is unlikely to exist on the surface, and no terrestrial habitats duplicate Martian conditions. Anderson et al. (1972) and Cameron & Morelli (1974) first advanced the idea of using the terrestrial permafrost analogues, and the present paper considers these analogues as a bridge to Martian habitat and possible life forms. "Mars-Odyssey" observations of neutron fluxes that found water in the subsurface layer (Boyton et al. 2002) indicated Mars as a "water-rich planet." Hence, the requisite conditions for life have a place that makes the analogous models more or less realistic.

Soil Cover

Water ice within the top meters of the high-latitude regolith, as well as visual similarities on the Earth's and Martian surface—polygons formed by frost cracking—leads to consideration of the frost affected, seasonally thawed soil cover with mean annual temperature below 0°C underlain by permafrost as an extraterrestrial model. The leading factor in differentiation of these soils, named Cryosol, is temperature crossing through 0°C, resulting in freezing-thawing processes and ice-water phase exchange. The temperature oscillations crossing through the freezing point are also observed on the Martian surface. With respect to Mars, it is important to note that cryosol microbial communities, formed under the impact of multi-time freezing-thawing stress, did not change under such stress. Their maximal number and biodiversity correlate with the horizon A, decrease with

depth to the surface beneath the seasonal thaw layer, and have the accumulative sharp peak on the permafrost table. In spite of the tundra, the day surface is under the influence of solar radiation; the snow and vegetation covers decrease and minimize this impact, as well as temperature oscillations. Thus, Arctic cryosol has
distant similarities with the Martian surface.

The surface conditions in the Antarctic desert (the intensive level of solar radiation, the absence of snow and vegetation covers, and on account of the ultra-low subzero temperatures which can be as low as -60°C) and on Mars are closer. At elevations above 1500 m, there are no summer air temperatures above freezing. However, the surface temperatures of soil or rock can be 15°C warmer than the air due to solar heating; they may exceed 0°C for several hours (McKay et al. 1998), and for short periods even reach 10°C (Campbell & Claridge 1987). In addition to sharp temperature oscillations and high insolation, the main similarity between the Antarctic Dry Valleys and Mars is the vertical structure of their "active layers." In the Dry Valleys the upper 10–25-cm-thick sandy layer does not form a stable soil cover on the ice-cemented permafrost table. It is dry (W~2%) and lacks ice-cement due to sublimation. This dry-frozen permafrost—frosty, in the present author's terms—throughout the upper 100 cm (including the active layer) covers ~60% of the Dry Valleys area (Bockheim et al. 2007). The overcooled ground, with no water and thus no ice, is often mobilized by storm winds similar to the instability of Martian dunes. Such layering structure and distribution of water ice within the first surface meter on Mars is proposed according to HEND/Odyssey and MOLA/MGS data (Mitrofanov et al. 2007).

The upper ~2 cm layer of the Dry Valley surface often contains a low number of viable cells in comparison with the underlying horizons (Horowitz et al. 1972). In some cases, these microorganisms cannot be isolated on agar plates, correlating with a poor diversity of bacterial phylotypes, a low number of mycelia fungi strains, and a minimum of chlorophyll content. The occurrence and biodiversity of microorganisms is higher at depth than in the top of the active layer, and suggests that a search for life on Mars should not sample the surface but the bottom of the "active layer." In particular, because the upper horizons contain low cell counts, Antarctic frosty soils are useful for testing equipment for searching for life on Mars.

Cryolithosphere

It has been established that numerous (up to a dozen millions cells/g) and various ecological and morphological viable microbial groups have survived under permafrost conditions since the time the permafrost formed. They are the only known living organisms preserved over a geologically significant time. This approach is relevant to questions concerning the protective properties of permafrost, especially for astrobiology, because the Odyssey's discovery of water ice within the top meters of the high-latitude regolith points to the existence of near-surface permafrost on Mars. It also raises the question of liquid water presence as a necessary condition for life forms. Unfrozen water films play the leading role in the preservation of microorganisms. These films coat the soil particles and protect the viable cells adhered onto their surface from mechanical destruction by growing crystals of intrusive ice, and make possible the mass transfer of microbial metabolic by-products in permafrost, thus preventing the cells biochemical death (Gilichinsky et al. 1993). Therefore, the unfrozen water might be considered as a main ecological niche where the microorganisms might survive. In fine dispersed Arctic permanently frozen sediments at temperatures -3 to -12°C, the amount of unfrozen water can be estimated as 3–8% by weight. Because of temperatures below -20°C in the coarse Antarctic Valley's sands, the unfrozen water values are so small that the instrumental methods fail to record them. The unfrozen water must, therefore, only be firmly bound "liquid" water with binding molecules, and indicates a "biologically dry" environment. Based on experiments, Jakosky et al. (2003) calculate that liquid water can exist at ice grain-dust grain and ice grain-ice grain contacts above about -20°C. Below this temperature, water would not be present in soils in sufficient thickness and amount to physically allow the presence of microorganisms; i.e., this temperature is the lowest at which life can function. Both conclusions are not fully clear at this moment and not quite correct: First, R. Sletten has determined that, for Victoria Valley, the unfrozen water is ~2% at -20°C and ~1.5% at -30°C due to the salt content. The same amount of unfrozen water is expected in Beacon Valley, where the soil has a higher salt content (Gilichinsky et al. 2007). Second, considerable research has shown that microorganisms metabolize at extremely low temperatures in ice and permafrost—between -10 and -20°C (Rivkina et al. 2000, 2004; Carpenter et al. 2000; Bakermans et al. 2003; Junge et al. 2004), and down to -28 and -35°C (Gilichinsky et al. 2007a; Panikov & Sizova 2007). Mars polar and high-latitude temperatures rise above this level (up to 0°C for hours), and similar to cryptoendolithic microbial communities within Antarctic sandstone (Friedmann 1982) make the near-surface past and present permafrost layers potentially favorable sites to search for evidence of life. Probably, in such ecological niches, thin brine films might be formed within Martian permafrost as proposed by Dickinson & Rosen (2003) through their studies of minerals and accumulation of ground ice on Table Mountain, Sirius Group sediments.

From the astrobiological point, it is important that the permafrost, where 92–98% of water is in solid state, and subzero temperatures slack off the cumulative effects of background terrestrial gamma radiation on cells for thousands and millions of years. The lower the water content and the rate of metabolic processes, the less is the radio lesions of biological objects. This is why the irradiation sensitivity of soil microorganisms at temperatures above 0°C, differs from the sensitivity of microorganisms preserved in permafrost. Responses of the permafrost microbial complex to irradiation in nonfrozen and frozen states is different. At the irradiation

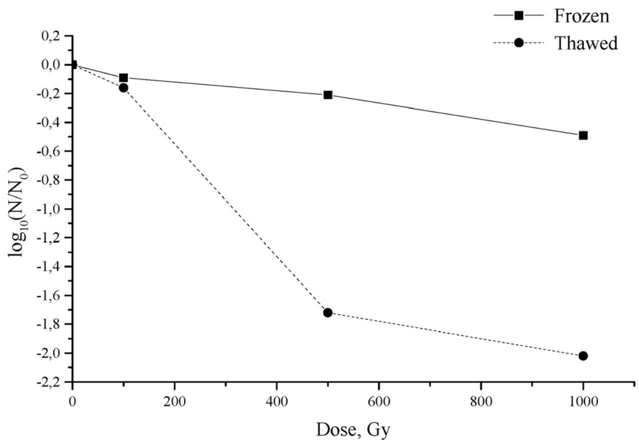

Figure 1. Differences in microbial complex survival rates after γ-irradiation in frozen or thawed state.

dose of 1 kGy, there is one magnitude difference in the number of viable cells between the nonfrozen and frozen samples (Gilichinsky et al. 2007b), and the cell survival rate was estimated to be, respectively, 1% and 10% from the initial number (Fig. 1). In the model γ-irradiation, the dose of 5 kGy was lethal for microorganisms in the nonfrozen samples.

The *in situ* measurements in the boreholes on the Eurasian northeast showed that the dose received by the immured bacteria in frozen sands and loams is about 2 mGy per year. Taking into account the oldest, ~3 Myr, late Pliocene age of permafrost and bacteria, the total dose received by cells would be 5–6 kGy. Under these conditions, most of the cells survived. This fact shows that freezing increased the cells' resistance to radiation and uniqueness of permafrost as an environment, where microorganisms display a high resistance to radiation. From these data the doze from radionuclides diffused through the permafrost is not fatal, but should be large enough to destroy the DNA of ancient viable cells. Their viability and growth implies the capacity for DNA repair, probably in the frozen environment; i.e., at the stable rate of damage accumulation, a comparable rate of repair also exists (Gilichinsky 2002). This is why the "biologically dry" (at temperatures deep below -20°C) Antarctic permafrost, with extremely low and inaccessible organic matter, is nevertheless inhabited by up to 10^4–10^5 viable cells/g, providing an analogue for the Martian ecosystem.

Antarctic Permafrost

Antarctic desert deposits beneath the frosty active layer are unexpectedly icy (Table 1); that is, of the same order as the more humid Arctic. This means that ground ice instability due to the processes of sublimation at ultra low humidity and air temperature is in a very thin surface layer only, and revises the earlier thesis of dry Antarctic permafrost. This is why we can also expect the existence of high icy subsurface layers on Mars.

Permafrost on Earth and Mars vary in age, from a few million years found on the Earth to a few billion years on Mars (Carr 2000, Baker 2004, Tokano 2005). Such a difference in time scale would have a significant impact on the possibility of preserving life on Mars because the number and biodiversity of microorganisms decrease with increasing permafrost age. This is why the longevity of life forms preserved within the Arctic permafrost can only work as an approximate analogue for Mars. The suggested age of Antarctic permafrost (~30 Myr) is somewhat closer to that of Mars. A number of studies indicates that the Antarctic cryosphere began to develop soon after the final breakup of Gondwana and the isolation of the Antarctic continent. It is believed to have been started on the Eocene-Oligocene boundary (Barrett 1996, Wilson et al. 1996, DeConto & Pollard 2003). The discussion of Neogene stability has focused mainly on the state of the ice sheet, which is the most variable part of the cryosphere. Permafrost is the more stable end-member of the cryosphere, and the conditions needed for ice degradation, even if they existed in the climatic optimum, are not enough to thaw the permafrost. Permafrost degradation is only possible when mean annual ground temperatures, -28°C now, rise above freezing; i.e., a significant warming, 25°C or more, is required to degrade the permafrost once formed. There is no evidence to date of such significant temperature variation, which indicates that the Antarctic climatic and geological history was favorable for the formation and persistence of pre-Pliocene permafrost. Antarctic permafrost may, therefore, be more than 30 Myr old (Gilichinsky et al. 2007a) and date from Antarctic ice sheets predicted in early Oligocene times (Zachos et al. 2001).

Table 1. Ice content (I, %) in Taylor Valley permafrost sands.

depth, m	1	3	6	8.8	10	12	15	18
I, %	50	30	26	30	27	30	34	52

Viable microorganisms were isolated from the cores taken in Beacon Valley from beneath an 8.1 Myr volcanic ash layer that has been interpreted as a direct air-fall deposit (Sudgen et al. 1995), and this age is supported by several studies (Schäfer et al. 2000). The age of isolated communities remains controversial because the recent investigation has questioned this age relation, and the calculations indicate that sublimation rates would be too high for the ice to persist for 8.1 Myr (Ng et al. 2005). However, the last paper of Bidle et al. (2007) isolated microorganisms from the ice beneath this ash; these authors again affirm the 8.1 Myr age. From an age perspective, the Glacigene Sirius Group sediments on Mount Feather may be even older. They were estimated to be at least 2 Myr in age (Webb & Harwood 1991) and possibly as old as 15 Myr (Marchant et al. 1996). The ages for the superficial deposits, where bacteria were sampled in the permafrost, are 5 Myr (Wilson et al. 2002). If this age is correct, these are, to date, the oldest confirmed viable microorganisms discovered in permafrost and the oldest viable communities reported on the Earth (Gilichinsky et al. 2007a).

Permafrost distribution in Antarctica is well described by Bockheim (1995). It would be advantageous to locate relics of the oldest Antarctic permafrost. These are possibly to be found at the high hypsometric levels of ice-free areas such as the Dry Valleys, along the Polar Plato and Trans-Antarctic mountains, on Northern Victoria Land. It is desirable to date the layers within them and test for the presence of viable cells. The limiting age, if one exists, within the most ancient Antarctic permafrost cores, where the viable organisms were no longer present, could be established as the age limit for life preservation within permafrost at subzero temperatures. Any positive results obtained from the Antarctic microbial data will extend the geological scale and increase the known temporal limits of Cryobiosphere; i.e., duration of life preservation. The author proposes this activity in accordance with the resolution of the International Workshop on Antarctic Permafrost and Soils (Madison 2004) and in the frame of the IPY ANTPAGE project, which has the following objectives:

- To integrate existing geological records and produce a thematic map of areas where climate and geological history of the last dozens of millions years were favorable for formation and persistence of early Oligocene permafrost and identify the most suitable drilling sites.
- To develop the hand-carried equipment for sterile drilling and sampling, and use these boreholes and cores for ground radiation and temperature measurements, cosmogony dating, ice and organic content, textural and chemical composition, microbial, pollen, diatom, and microfauna analysis.
- To develop the methods of direct dating of permafrost using the cosmogony radionuclides in ice-cement and segregated ice as a natural chronometer and biological clock, based on the racemization rates and differences of microbial communities immured in permafrost.
- To provide arguments that the Antarctic permafrost may have existed earlier than the Arctic permafrost by a factor of ten, and present the Earth's model with only one cold pole in the Southern Hemisphere during this period.
- To define the limit of dormancy of frozen life on Earth and in ancient permafrost on other planets and, potentially, provide a model for Martian ecosystems.

Volcanoes

Despite active volcanism, permafrost often exists on slopes of high-elevation or high-latitude volcanoes in places such as Hawaii, Iceland, Mexico, Peru, North America, and Antarctica. One way to have liquid water on Mars at shallow depths would be through subglacial volcanism. Such volcano-ice interactions could be going on beneath the polar caps of Mars today, or even within the adjacent permafrost around the margins of the ice caps. Basalt lava fields are common on Martian surfaces and some cinder cones have been found near the polar caps. The rover traces on the terrestrial ash fields and Martian surface, as well as the chemical composition of basalts on Earth and Mars, are similar (Squyres et al. 2006). This is why permafrost research on terrestrial volcanoes is expected to be a valuable step in understanding extraterrestrial volcanoes as one of the Earth's analogue. The main question is whether such ecological niches as volcanoes and associated environments contain microbial communities. The task is to find thermophylic microorganisms associated with volcanoes that have been deposited with products of eruption, and that have then survived in permafrost after the freezing of scoria and ash. Our study was carried out on the Kluchevskaya Volcano Group (Kamchatka Peninsula) which was formed starting from the late Pleistocene (Braitseva et al. 1995). The mean annual ground temperature decreases from -1°C on the lower boundary of permafrost (~900 m) to -7°C at 2500 m (Abramov et al. 2007). During the volcano eruptions in the last 2000–3000 yr, the thick (12–16 m) layers of volcanic ash, sand, and scoria accumulated on the elevations occupied by permafrost and at that time became frozen. The last eruption was in 1975–76, and ~500 km^2 were covered by scoria and ash (Fedotov & Markhinim 1983). The cores extracted from the borehole crossing these young volcano deposits contained biogenic CH_4 (up to 1900 μl/kg) and viable bacteria, including thermophilic anaerobes (10^3 cells/g), and among them, methanogens growing on CO_2+H_2. Because thermophiles have not previously been found before in permafrost, the only way for these bacteria to appear within frozen volcanic horizons is through the eruption of a volcano or its surrounding associated strata. The important conclusion is that thermophiles might survive in permafrost and even produce the biogenic gases. For future space missions, the permafrost volcano areas are promising test sites and provide opportunities to study analogues of possible Martian ecosystems. Their original microbial communities represent an analogue for Martian communities. The methanogenic bacteria found at such sites can likely adapt to temperatures <0°C as compared to other studied groups of anaerobes.

Cryopegs

Microorganisms have survived in natural conditions at subzero temperatures in ice and permafrost, but also have been reported to survive at above zero temperatures for dozens to hundreds of millions of years in amber (Cano & Borucki 1995) and saliniferous sediments (Vreeland et al. 2000), respectively. All these very different environments have common features: complete isolation, stability, aridity, and waterproof-ness, and represent the niches where microorganisms retain viability in the absence of free water. Based on the present study, it is possible that microorganisms might also survive in closed ancient aquatic ecosystems. Such habitats have overcooled water lenses formed during the Quaternary when the dynamics (transgression and regressions) of the Polar Ocean of the High Arctic favored the formation of overcooled brines (cryopegs) against a cold climatic background. Freezing in cryopegs is prevented by freezing-point depression due to the dissolved-solids content of the pore water. The cryopegs are embedded in permanently frozen coastal Pleistocene/Holocene marine strata. They are the only hydrological systems on the Earth with permanent subzero temperatures, high salinity, and isolation from external factors throughout their geologic history.

Cryopegs were exposed by boreholes along the Polar Ocean coastal zone with mean annual ground temperatures varying between -2 and -12°C on Cape Barrow (Alaska), the Barents Sea coast, the Yamal Peninsula (surrounded by the Kara Sea), and the Kolyma lowland (East Siberian Sea). At the last site the cryopegs are confined to a 20-m-thick marine horizon, sandwiched between non-saline terrigenous layers at depths of 40–50 m below the tundra surface (the mean annual ground temperature varying -9 to -11°C). Finely dispersed sand and sandy loams were deposited in shallow lagoons at temperatures slightly above 0°C. After regression of the Polar Ocean, the water-bottom sediments were exposed sub-aerially and froze. Because of the pressure caused by freezing, water was released as the freezing front penetrated downward. This was accompanied by a freezing out of salts in the water to form lenses of overcooled sodium chloride brines with salinities of 170–300 g/L. Later, the marine horizon was buried by a 15–20–m-thick unit of lacustrine-alluvial late Pleistocene icy complex that was built up under harsh climate conditions, was syngenetically frozen and has never thawed. Within the marine horizon, the lenses occur at different depths, their thickness varying 0.5–1.5 m and their width 3–5 m. Some of them represent non-artesian water, and some exist under low pressure with a hydrostatic head. Different salinities of the brines confirm their lenticular nature and isolated bedding.

Bacteria isolated from cryopegs not only were adapted to subzero temperatures, but also were tolerant to the high salt concentrations. What is more, detected microorganisms are both halophilic and psychrophilic organisms, and have never been isolated from natural habitats. In the cold saline conditions of cryopegs, special communities were formed. Active adaptation to low temperatures of already-studied bacteria gives hope that fully active and reproducing bacteria can be discovered in saline habitats at subzero temperature. Biotic survival in the aquatic environment on a geological time scale indicates unknown bacterial adaptations. The microbial activity detected in cryopegs at temperatures as low as -15°C documents the fact that subzero temperatures themselves do not exclude biochemical reactions and provides reason to conclude that in overcooled water the metabolic strategy of microbial survival operates, and that this strategy does not accept that cells can multiply *in situ* (Gilichinsky et al. 2005).

The salt tolerance may be associated with cold tolerance. Experimental data showed that in the presence of 25% NaCl halophiles survive better than non-halophiles under low (-20 to -80°C) temperatures (Mancinelli et al. 2002). Mars is a cryogenic planet where free water only has the opportunity to exist in the presence of high solute content, probably as brine lenses within permafrost. These brines, like their terrestrial analogues, may contain microorganisms adapted to low temperature and high salinity. This is why unique halo/psychrophilic communities preserved hundreds of thousands of years in mineral-enriched Arctic cryopegs provide the plausible prototype for Martian microbial life (Gilichinsky et al. 2003), either as an "oasis" for an extant, or the last refuge of an extinct biota (Mancinelli et al. 2002).

Conclusion

The future mission priorities for the search for life on Mars must be based on studies of the most probable environments in which the life might be found, and the maximum period of time over which such life could be preserved. This is why terrestrial subsurface frozen layers represent the analogues of extraterrestrial cryobiosphere, where the probability of finding life is the highest. Hemolithotrophic psychrotolerant anaerobes with their unique mechanisms to assimilate CO_2 are more like life- forms on Mars, which has no free oxygen; as well, cryopeg halo/psychrophilic communities provide the other prototype for Martian microbial life.

Abstract

Permafrost has attracted considerable interest from an astrobiological point of view (Wynn-Williams & Edwards 2000), due to the recently reported results from the Mars Exploration Rovers. The possible existence of past or present water in the subsurface of the red planet increases the probabilities of life existence on Mars. Considerable studies have been developed on extreme ecosystems and permafrost, in particular, to evaluate the possibility of life on Mars. The biodiversity of permafrost located on the Bering Bridge National Preserve has been studied. Different conventional (enrichment, isolation) and molecular ecology techniques (cloning, fluorescence in situ probe hybridization-FISH) have been used for isolation and bacterial identification.

Keywords: Alaska; astrobiology; biodiversity; Imuruk Lake; permafrost.

Introduction

Due to reported Mars surface environmental conditions (Klein 1978) (oxidative stress, high UV radiation levels, etc.) the possibility for life development in the surface of the red planet is very small. The identification of water-ice on the subsurface on Mars by the Thermal Emission Spectrometer onboard the Mars Odyssey (Kieffer & Titus 2001) and from the High Energy Neutron Detector (Litvak et al. 2006) has important astrobiological connotations, because in addition to being a potential source for water, these locations are shielding habitats against the harsh conditions existing on the planet, like UV radiation (Gomez, et al. 2004, Gomez et al. 2007).

Several authors have discussed similarities between Earth and Martian permafrost (Frolov 2003) and the structures that could play a protective role for subsurface ecosystems (Gilichinsky et al. 2007).

Chemolithotrophic microorganisms have the ability to use inorganic compounds, like reduced minerals, as energy sources for metabolism in isolated environments of the subsurface. Better understanding of permafrost ecosystems on Earth is needed to evaluate the possibilities that life could have developed in these types of structures on Mars. Permafrost on Earth is located at circumpolar latitudes. Of special interest is the permafrost on volcanic areas due to their similarities with Mars geology (Dyar & Schaefer 2004).

Future space missions will be focused on searching for life on the subsurface of Mars. New techniques and methodologies for studying these putative habitats need to be developed (Frolov 2003).

Material and Methods

Imuruk Lake campaign

We identified an interesting volcanic area associated with permafrost in the region of Imuruk Lake (Alaska). An exploration campaign was developed during July 2005 to study the geology and microbiology of the area. Imuruk Lake is located at 65.6ºN, 163ºW. This region is a volcanic area in the Bering Land Bridge National Preserve (Fig. 1).

The 2005 campaign was developed in the eastern part of the lake, near Nimrod Hill. Previous geologic studies (Hopkins 1963) of the area have been reported. The area is characterized by volcanic formations with basaltic composition. Some basalt lava flows are present. Over the lava structures there are two covers with different composition: the first is a wind blown silt layer, and the second is a peat cover at the top. Some intermediate terraces can be found around the hill with sedimentary material.

With the idea of future development of instrumentation for automated remote life detection systems on permafrost, three main objectives were considered during the expedition: (1) permafrost localization by geophysical techniques and drilling; (2) microbial diversity analysis, with special interest on deeper parts of the column, the oldest part of the permafrost (pattern preservation of biosignatures in cold environment is of extraordinary astrobiological interest); and (3) understanding cold ecosystems to facilitate permafrost niche detection and mapping.

An Arctic area has been selected for permafrost characterization. Field camping was developed on the Bering Land Bridge National Preserve (Fig. 1). Permafrost was localized using geophysical sounding techniques over several traverse lines on the Imuruk Lake area. A particular place for sampling was chosen, and a borehole 4 m deep

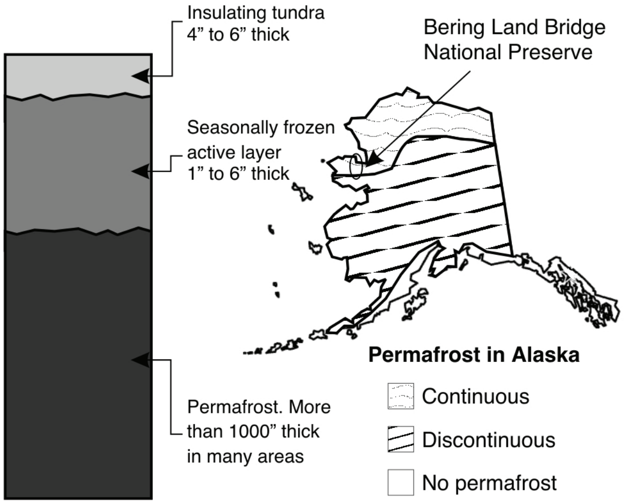

Figure 1. Bering Land Bridge National Preserve situation. Imuruk Lake is located on a volcanic area.

was drilled for sampling along the soil column. The active layer at the surface and subsequent permafrost were sampled at several depths. Samples were used for biodiversity determination using complementary techniques.

Geophysical studies

Permafrost depth was identified by geophysical techniques (electric tomography sounding, ERT). *Syscal KID Swich-24* equipment was used. Thirteen parallel lines were deployed from the lake to the top of the hill (see Prieto et al. in this issue for details). Each tomographic line was 48 mm long, separation between electrodes was 2 m, and the space between lines was 15 m.

Temperature recording during core sampling indicated a permafrost depth of around 30 cm, but tomographic data indicated that permafrost began at a mean depth of 0.50 m from the surface. After tomographic data interpretation a place for drilling was chosen.

Stratigraphic column

A portable drilling system was used for stratigraphic sampling at different depths. A Cardi E-400 fuel-powered system was adapted for core retrieval. The dimension of the pits was 0.5 long and 50 mm diameter. Pits could joint each other to obtain a maximum depth core of 4 m. Microbiological studies were performed over tomographic Line 11 core. Maximum depth on this drill was 3.6 m.

Microbial diversity studies

From ERT studies, a particular place was chosen for drilling and sampling at several depths. Proximity of permafrost to the surface was the criterion chosen for drilling. Several core depths were chosen for microbiological analysis (Table 1). Some ice pockets were detected in Line 11 (Fig. 2). From every core depth selected for sampling, two aliquots were used: the first for direct media inoculation, and the second for hybridization analysis. In the second case, the first step was to fix the sample with formaldehyde as soon as possible

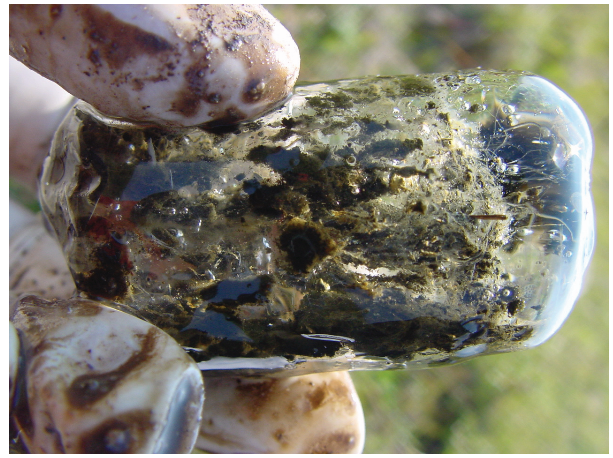

Figure 2. An 0.8 m deep sample from tomographic Line 11.

in order to maintain the structure of the microbial population without any alteration. These fixed samples were transported to the laboratory for further processing and hybridization with DNA probes of different specificity (species, genus, and phylum).

Two different methodologies for microbial population analysis were used:

(1) media inoculation for microbial enrichment: Three different media were chosen for microbial growth: chemolithotrophic media enriched with ferrous iron, heterotrophic organic media and several anaerobic specific media enriched with different energy sources (methanol, formate, proteolytic and volatile fatty acid). Growth was followed by optical density at 580 nm in a WPA Lightwave spectrophotometer. Qualitative values for growth were assigned depending on the slope of the growth curve. After growth, microbial populations were identified by 16S rRNA amplification of DNA, cloning, and sequencing.

(2) Fluorescence in situ hybridization techniques (FISH) with specific DNA probes, used for microorganism identification: The DNA probes used on this study were specific for *Bacteria* and *Archaea* domains, Alfa-, Beta-, and Gamma-proteobacteria subclasses, a CF (Cytophaga-Flavobacterium cluster) and a HGC (High G+C content bacterial cluster) specific group probes. Samples were directly fixed on the field with formaldehyde (4% v/v) and incubated at 4°C for 2 h. After incubation, samples were washed twice with PBS and filtered. Filters were stored under frozen conditions in PBS-ethanol (1:1). Samples from several depths were chosen for further analysis with different DNA-specific probes. Cell density was determined by cell counting with a microscope. Filters were dried and maintained at low temperature until further processing in the lab.

Results and Discussion

Thirteen transects along Nimrod Hill were chosen for electrical resistivity tomography studies, and thirteen tomography lines were obtained. The existence of different resistivity values along the lines at different depth determined the presence of several units. Typical resistivity values of pits and sedimentary units were recorded. The tomography diagrams obtained from the 13 lines were used for permafrost localization (Fig. 3) to determine the drilling points (vertical arrow in Fig. 3) and the sampling depths for microbiology analysis. Samples were taken at 30 cm, 1 m, 1.5 m, 2.1 m, 3.1 m, and 3.6 m. From every sample, two aliquots were taken.

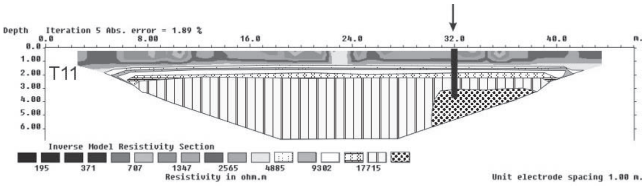

Figure 3. Electrical Resistivity Tomography for Line 11. This section was chosen for drilling a 4 m deep borehole for microbial sampling.

Microbial growth was observed in most of the media. Table 1 shows the results obtained on the inoculated media after 72 h of incubation at 12°C: - is no growth; +/- is less growth to +++, much growth; *Gas* indicates gas production during growth); Fe^{2+} indicates basal media enriched with ferrous iron on aerobic conditions; *Het.* indicates enriched media for heterotrophic bacteria cultures under aerobic conditions; *P* indicates media enriched with peptone and yeast extract for proteolytic bacteria and cultured under anaerobic conditions; *M* indicates methanol-enriched media under anaerobic conditions; *F* indicates formaldehyde-enriched media under anaerobic conditions; and *VFA* indicates volatile fatty acid (C2 plus C4) enriched media under anaerobic conditions.

The most efficient growth (Table 1) was obtained using

Table 1. Growth obtained on different inoculated media after 72 h of incubation at 12°C.

	Fe^{2+}	**Het.**	**P**	**M**	**F**	**VFA**
T11-1 (30 cm)	-	+++	+++ Gas	+++	++	++ Gas
T11-2 (1 m)	+/-	Gas	Gas	++	+	+

heterotrophic media under aerobic and anaerobic conditions inoculated with samples from all along the column. There was no obvious relationship between depth and bacterial growth, indicating that viable bacteria are present along the column at all depths. Chemolithotrophic media produced less efficient growth, indicating that chemolithotrophs were not present in high numbers on these ecosystems. The opposite was observed for heterotrophic microorganisms, which have both aerobic and anaerobic representatives. Different microorganisms are present in the Imuruk Lake permafrost, since different media gave positive growth. In the case of sample T11-1, growth was observed in heterotrophic media under aerobic conditions and in the basal media under anaerobic conditions enriched with peptone plus yeast extract, methanol, formaldehyde, and volatile fatty acids. There was also gas production in the media enriched with peptone and yeast extract and VFA. These cultures inoculated with sample T11-1 were used for total DNA extraction, amplification, cloning and sequencing of the 16S rRNA gene (Table 2). Gas production could be congruent with the presence of methanogenic bacteria (Kotsyurbenko 2005). Amplification, cloning, and sequencing of the 16S rRNA confirmed this observation.

The 16S rDNA amplification from DNA extracted from cultures allowed identification of the presence of members of the *Psychrobacter* genus (Table 2). Also, the presence of some members of *Propionibacterium* genus, characterized by anaerobic growth using fatty acids for energy uptakes with production of propionic acid, was confirmed. Some uncultured Antarctic sea water representatives were also identified by 16S rRNA sequencing.

Soil samples from several depths were hybridized with specie- or genera-specific DNA probes and compared with universal staining (DAPI) for cell counting and evaluation of cell density along the column. Figure 4 shows a universal stained microbial preparation of a sample from tomographic Line 11 obtained at a depth of 2 m. Bacterial counting by light microscopy was used for cell density quantification. Figure 4 shows the population gradient (cells/gr of soil) with depth.

The presence of active bacteria on frost soil was determined by FISH techniques (Fig. 5). Hybridization of the RNA probe is done over the 16S rRNA, thus only active bacteria, which are sometimes uncultivable, can be detected. This technique requires the sample to be fixed at the moment of sampling to ensure the viability of the 16S rRNA molecule population.

Population gradient along the core (Fig. 5) was determined by direct counting of stained samples from 30 cm, 1 m, 1.5 m, 2.1 m, 3.1 m, and 3.6 m depth. Hybridized samples with genera- and group-specific DNA probes were counted to evaluate the correspondent percentage of the cell population (Fig. 5).

Bacterial density decreased with depth (Fig. 5), which is congruent with a permafrost model. An active layer develops during the summer on the first 50 cm cross section of the crust, and soil became completely frost down to this depth all through the year. This active layer develops a dense active bacterial population that is reduced during winter due

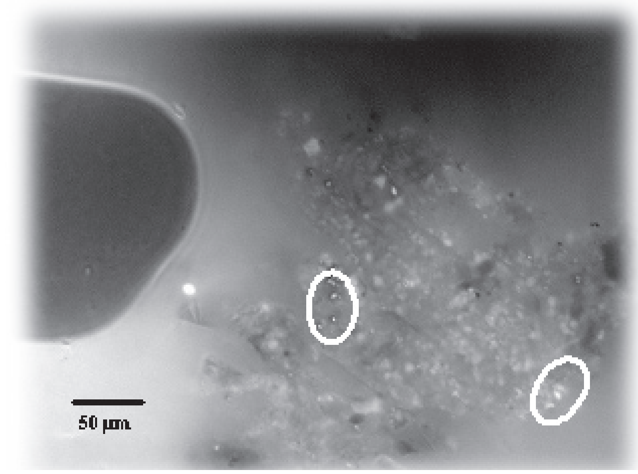

Figure 4. Soil sample from tomographic Line T11 stained with DAPI and used for cell quantification. Bacteria are the white spots inside the circle.

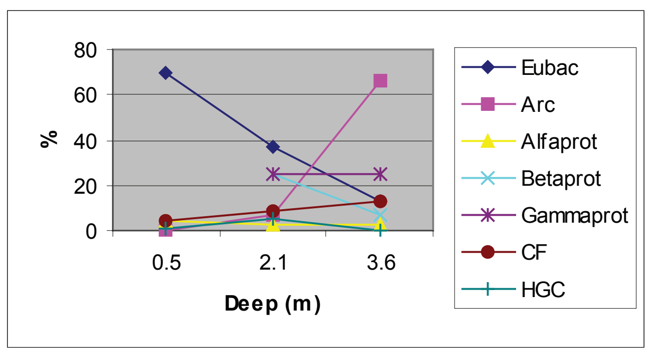

Figure 6. Percentage of different group pf microorganisms along the T11-1. Column identified by FISH techniques.

to lower temperatures. The permafrost model is congruent with lower bacterial density on soil frosted year-round. An interesting result was the location of active bacteria under 50 cm depth. 16S rRNA sequencing results confirmed the presence *Psychrobacter* gen. representatives, corroborating the results obtained in culture experiments and underlying the identification of active microorganisms on the frosted layer of the soil.

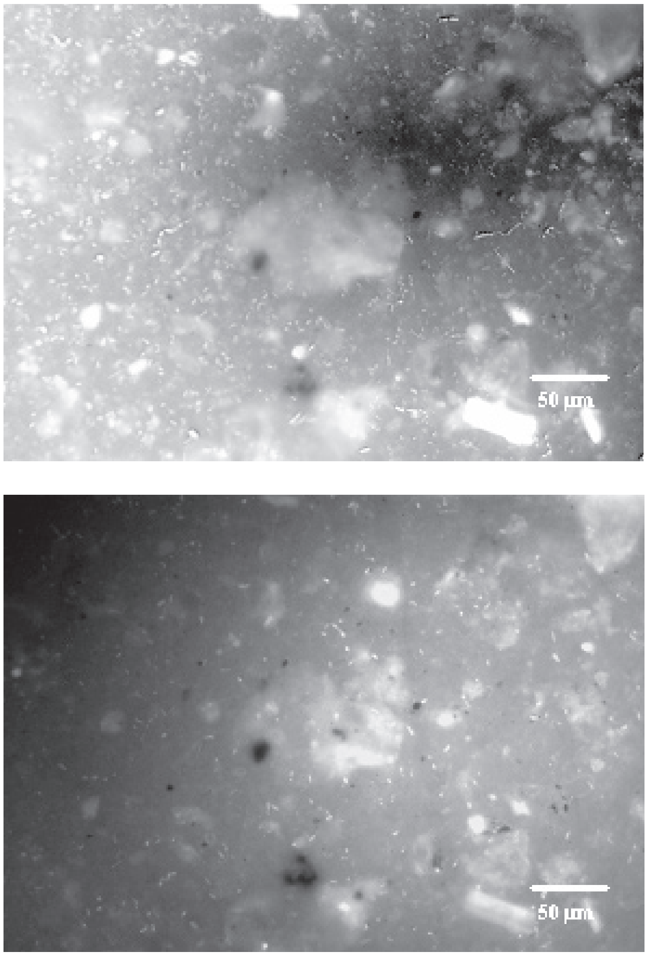

Figure 7. Universal staining DAPI preparation of a sample from the culture T-11-6 soil in heterotrophic media (top). Same culture preparation hybridized with *Alfaproteobacteria*-specific DNA probe labeled with CY3 fluorophore. Bacteria are small white spots.

The cell density decreased with depth; the lower the depth, the lower the bacterial population—a consequence of the harsh conditions of permafrost environments. Not only is reduction of the bacterial number the interesting data reported by these experiments, but also the fact that several microorganism groups were detected all along the column (Fig. 6). The percentage of every group varied with depth. On the first 50 cm of the soil column the main microbial population was composed by *Bacteria*. The presence of this type of microorganisms is constantly reduced with depth. While members of the domain *Archaea* have a low representation in the upper part of the column, its population increased with depth.

The Archaea identified on the grown media T11-1 P and T11-1 VFA (Table 2) are closely related to acetoclastic and hydrogenotrophic methanogens (Kotsyurbenko 2003).

The viability of microorganisms on the permafrost was tested by sample inoculation on growth media and following the growth of the cultures. Figure 7 shows bacteria preparation from the aerobic heterotrophic media inoculated with a 3.6 m deep sample from T11 borehole. The quantification of every metabolic group of bacteria was done by comparison of the total bacteria stained with the universal stain DAPI (Fig. 7, top) and the positive hybridization signals with group specific DNA probes (Fig. 7, bottom).

Conclusions

Abundant cells per mg of sample were detected in the first 60–70 cm of the column (the permafrost active layer). Accordingly to in situ hybridization and metabolic analysis, an active microbial layer was detected on the first 60–70 cm. Hybridization with specific 16S rRNA probes reported the presence of a high number of microorganisms from the *Bacteria* domain in the upper part of the column, which is congruent with the higher temperature reached at this depth during the summer. In contrast, deeper samples gave decreasing numbers for members of the bacterial domain, while the cell density for *Archaea* started to grow. From 2.1 m depth to the 3.6 m, the *Archaea* are the most abundant, and it correlates with the fact that, at this depth, the soil is permanently frozen. The production of gas and the identification of archaeal-related sequences on the T11-1 enrichment cultures are congruent with the presence of methanogenic *Archaea* and with the permafrost model.

These results are congruent with a putative ecosystem completely isolated from the surface and protected against possible harsh atmospheric conditions with the production of methane. The detection of this type of ecosystem in permafrost increases the possibility of existence of life in other planetary bodies like planet Mars, especially after the detection of methane in the Mars atmosphere by the Mars Express Planetary Fourier Spectrometer (Formisano et al. 2004).

Acknowledgments

Abstract

With little precipitation (<10 cm water equivalent annually as snow), soils of the McMurdo Dry Valleys (MDV) have limited water available to support hydrological or biogeochemical processes. Active layer depths across most of this landscape are <1 m. Saturated sediments are obvious in wetted margins on the shorelines of lakes, extending for up to ~10 m into a zone where typically arid MDV soils prevail. We propose that wetted margins of MDV lakes will differ from arid soils across the rest of the landscape in their active layer depth and temperature regimes because of the consistent presence of water within these wetted margins. We have monitored temperatures along a wetted margin of Lakes Fryxell, Bonney, and Joyce. During the austral summer, we found that drier soils promoted shallower thaw depths and that, at the same depths, wet soils generally had lower temperatures and smaller diurnal fluctuations than dry soils.

Keywords: active layer; Antarctica; McMurdo Dry Valleys; temperature time series.

Introduction

Soil temperature dictates physiological constraints on biological activity (Kirshbaum 1994) and is especially important in the McMurdo Dry Valleys (MDV) of Antarctica (Fig. 1) where temperature is a primary control over biogeochemical cycling and biotic communities (Doran et al. 2002b, Parsons et al. 2004, Aislabie et al. 2006). Similarly, soil moisture is a limiting factor in Antarctic soil ecosystems where low temperatures severely limit the availability of liquid water (Kennedy 1993). Most soil studies in the MDV have emphasized the top 10 cm of the soil profile, within the active layer that is generally 60 cm thick (Campbell et al. 1998).

There has been extensive research on active layer thermal dynamics in the Arctic, with emphasis on numerical modeling of these dynamics (Hinkel 1997), and their response to changing climate (Hinkel et al. 2001). Arctic active layer soils exhibit seasonal changes in surface energy balances comparable to those in the MDV, though the magnitudes and types of energy exchange differ greatly due to the presence of extensive vegetation in the Arctic, as well as substantial spring snowmelt infiltration and rain infiltration during the summer. There have been several studies of permafrost and active layer processes in the Victoria Land (Bockheim et al. 2007, Guglielmin 2006), but little attention has been paid to active layer thermal dynamics on floors of the MDV, particularly with respect to dependence upon soil moisture. Bockheim and Tarnocai (1998) note that most of the surficial permafrost in the MDV is dry permafrost, which has very low water content (<5%), and Pringle et al. (2003) have documented thermal properties of MDV permafrost and active layer from two fairly high elevation sites in the region.

The shores of MDV water bodies are continually proximal to liquid water during the austral summer, and wick water from the lake and stream edges to the dry mineral soil. These wetted margins are visually apparent, and represent a hydrologic gradient in soil moisture from saturated at the water body to dry conditions at distal locations. Around lakes, Gooseff et al. (2007) found that the dimensions of these wetted margins vary as a function of both shore slope and depth of the active layer. We propose that, because these wetted margins represent an obvious gradient of soil moisture, the active layer thermal dynamics across these wetted margins should vary, with general soil moisture condition, due to the differences in thermal conductivity and heat capacity of the soil matrix with changes in soil moisture status.

Site Description and Methods

Site description

The MDV are located on the western edge of the Ross Sea, at approximately 78°S 162°E. The climate is cold, with annual mean temperatures of -20°C, and dry, with <10 cm precipitation (all as snow) annually (Doran et al. 2002a). The water balance of closed-basin lakes on the valley floors are maintained by incoming glacial meltwater stream flow and losses due to annual ablation of perennial ice covers, and evaporation of open water "moats" that form along the lake shores during the austral summer. Thus, lake shore soils and sediments are immediately adjacent to liquid water for approximately 2.5 months annually. Due to the dry nature of the MDV and the presence of continuous permafrost, these shoreline sediments wick lake water several meters inland from the shoreline.

Methods

In January 2005, we deployed thermocouple strings with 10 cm vertical spacing along transects across wetted margins of the north shore of Lake Joyce, the south shore of the east lobe of Lake Bonney, and the north shore of Lake Fryxell (Fig. 1). Five thermocouple strings were deployed at each lake-side location (Fig. 2A): String I at the water edge, String II 20 cm from the shoreline, String III at a point bisecting the wetted margin, String IV just before the outside edge of the wetted margin, and String V outside of the wetted margin (Fig. 2B, Table 1). Thus we collected active layer temperature data across three hydrologic gradients, from saturated conditions at String I to dry conditions at

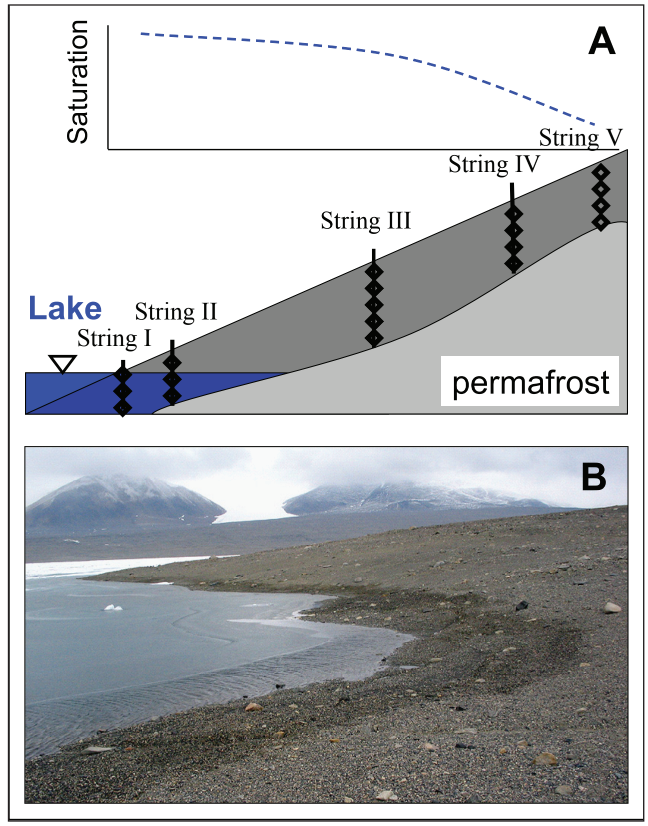

Figure 2. (A) General layout of thermocouples along transects, across wetted margins, (B) wetted margin around Lake Fryxell, extending ~10 m from shoreline.

String V. Thermocouple strings were built in a lab prior to deployment and then inserted into the ground using a thin steel rod attached to the end of the thermocouple string. The rod was subsequently removed after being inserted to the point of refusal.

At each transect, thermocouple data was collected by a Campbell Scientific CR-10XT datalogger via an AM-25T multiplexer. In addition, a thermistor was also deployed which collected air temperature data near the soil surface, in a shaded location. During the 2004-05 and 2005-06 field seasons, we were able to visit the dataloggers intermittently. Records are not continuous for the entire time of deployment due to datalogger failures. At Lake Joyce, data was collected on a 4 h interval from 18–22 Jan. 2005, from 12 Jul. to 15 Dec. 2005, and on a 15 min interval from 27 Dec. 2005 to 04 Jan. 2006. At Lake Fryxell, data was collected on a 15 min interval from 18–25 Jan. 2005, on a 4 h from 02 Jul. to 05 Dec. 2005, on a 1 h interval from 07 Jan. to 01 Feb. 2006, and on a 4 h interval from 01 Feb. to 30 Jan. 2007. At Lake Bonney, data was collected on a 15 min interval from 15–22 Jan. 2005, and on a 4 h interval from 03–30 Jan. 2006, and from 14 Dec. 2006 to 02 Feb. 2007.

We analyzed the collected subsurface temperature data by calculating 1) total degree-days of thaw (DDT) for each thermocouple record and 2) the daily amplitudes of temperature at every site, for days on which complete data collection was available (539 d at Lake Fryxell, 81 d at

Lake Bonney, and 166 d at Lake Joyce). We then computed frequency-duration curves (FDCs) using these data to illustrate comparisons among the thermocouple strings at each site, along the hydrologic gradients. Temperature FDCs that plot to the right on such graphs indicate a greater proportion of large diurnal cycles compared to those that plot toward the left. Our expectation is that thermocouple records in the drier shore sediments (i.e., Strings IV and V) will have greater diurnal variation than strings in more saturated conditions (Strings I-III). Because each thermocouple string is not deployed to a common depth, we cannot compare all FDCs on the same plot. Thus, for a more fair comparison, we have only plotted FDCs for thermocouple strings that have common or very similar depths (within 3 cm of each other). From Lakes Fryxell and Bonney, we plot only Strings III, IV and V. From Lake Joyce, we plot only Strings II, III, and IV.

Results and Discussion

Temperatures in the subsurface vary throughout the year from -50°C to just above 10°C. At Lake Fryxell, the time series data indicate a tight coupling of the temperature records near the shore (Strings I and II) and increasing vertical temperature gradients at more distal locations (Strings III, IV, and V) (Fig. 3). Similar patterns are evident from data collected at Lake Bonney (Fig. 4) and Lake Joyce (Fig. 5). It is worth noting that none of these locations appear to go through an extensive periods of zero-curtain condition during thawing (Figs. 3–5), as has been observed in arctic active layers (Hinkel et al. 2001). The only freeze-up data available is from Lake Fryxell, which does indicate a few days of zero-curtain condition close to the shorelines (Strings I and II) at Lake Fryxell (Fig. 3).

The vertical temperature gradients (Figs. 3–5) are not perfectly comparable as the thermocouples are deployed at different absolute depths along each thermocouple string. Despite these differences, these gradients are approximately comparable for Strings I-IV at Lake Fryxell, as the penetration depths are 50 cm, 50 cm, 45 cm, and 45 cm, respectively. At Lake Bonney, Strings III, IV, and V are all deployed to the same depths, and it is evident that String IV appears to have the greatest diurnal fluctuation in temperature, at the 10 cm depth (Fig. 4). At Lake Joyce, String IV is offset by 3 cm from Strings II and III (Fig. 5).

To compare integrated heating among locations along the soil moisture gradients, the DDT values are presented in Table 2. As expected, there is a pattern of diminishing degree-days above freezing with increasing depth. Similar to the analyses of temperature time series, these data are not ideally comparable among thermocouple strings within a site because of different absolute depths. The vertical pattern exceptions are String II and String V at Lake Fryxell, and String I at Lake Bonney. These unexpected results are likely due to one of three explanations: (1) surface evaporation which may drive cooling in the upper layers of the soil, (2) longitudinal movement of cool water from

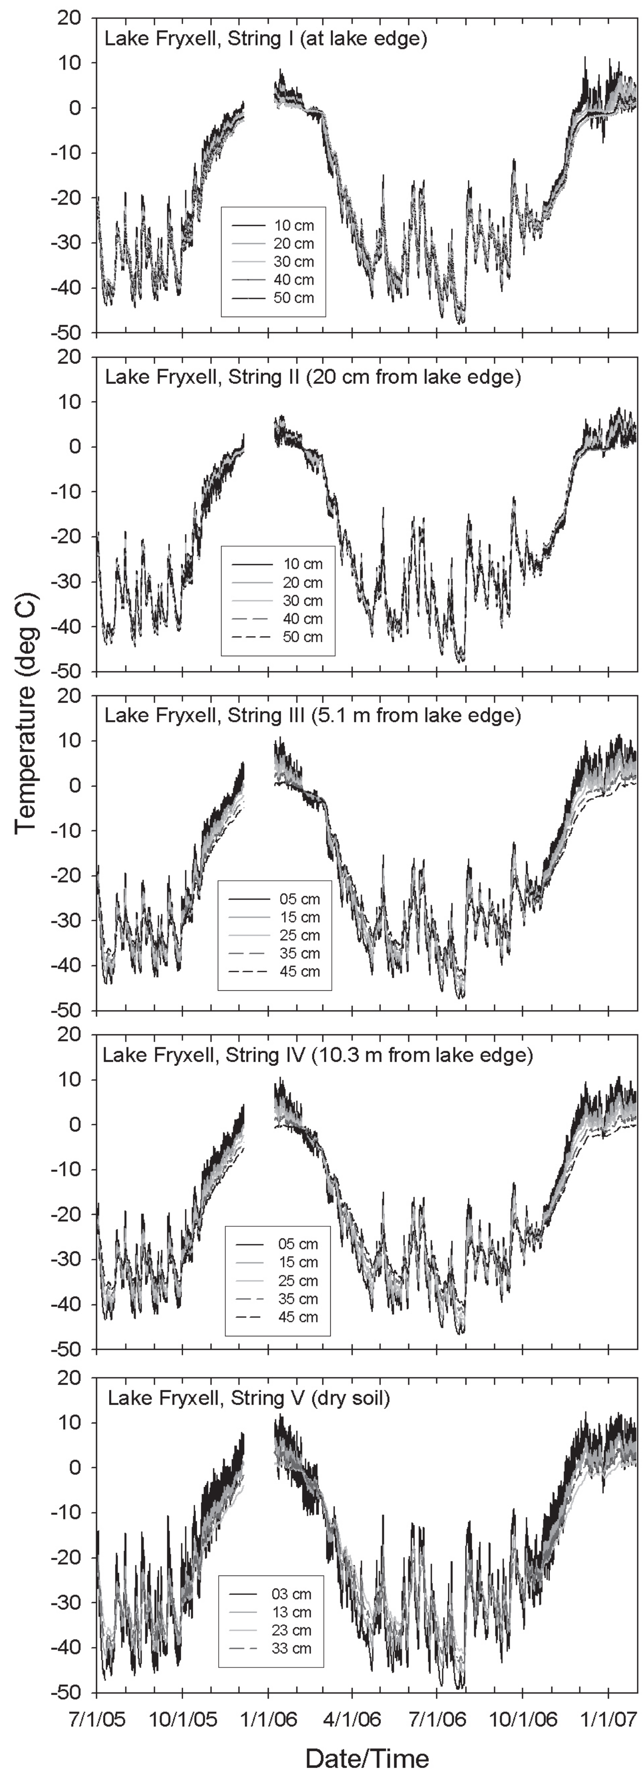

Figure 3. Lake shore soil temperatures from thermocouple strings I through V at Lake Fryxell.

Table 2. Degree-days of thaw (DDT, °C·d) for entire temperature records of thermocouples and thermistors. The table is organized by thermocouple string and position along the string with 1 = shallowest and 5 = deepest.

the shoreline outward toward the dry soils, or (3) change in surface conditions. String I at Lake Bonney was found to be inundated at the surface in Jan. 2006, due to rising lake levels. Thus the temperature signal at this location becomes more representative of benthic interaction with a water column than a soil exposed to atmosphere. The longitudinal movement of water is a possibility at String II at Lake Fryxell, given that the water at the lake shore (String I) is generally cooler within the same ~depths (positions 4 and 5).

The comparisons of temperature dynamics are also informed by the frequency analysis of diurnal temperature amplitudes (Fig. 6). At the Lake Fryxell transect, the diurnal amplitudes of temperatures increase for near-surface thermocouples from String III to IV to V, with similarities between III and IV, and much more variable overall at V (red curves, Fig. 6A). The same pattern exists at the thermocouples in the 2nd position (green curves, Fig. 6A), but changes at the 3rd thermocouple position, with Strings III and V similar in their FDC curves, and that of IV being generally less variable (blue curves, Fig. 6A). This is unexpected, and may be due to (1) the fact that these mid-transect locations are buffered at depth because of greater soil moisture or (2) lateral movement of water (i.e., along a direction that is parallel to the shoreline), which was not investigated here. At Lake Bonney, String IV is more variable at thermocouple positions 1 and 2, than Strings III and V (red and green curves, Fig. 6B). Similar to the patterns observed at Lake Fryxell, this sequence changes at position 3, and String IV becomes generally less variable than Strings III and V (blue curves, Fig. 6B). This

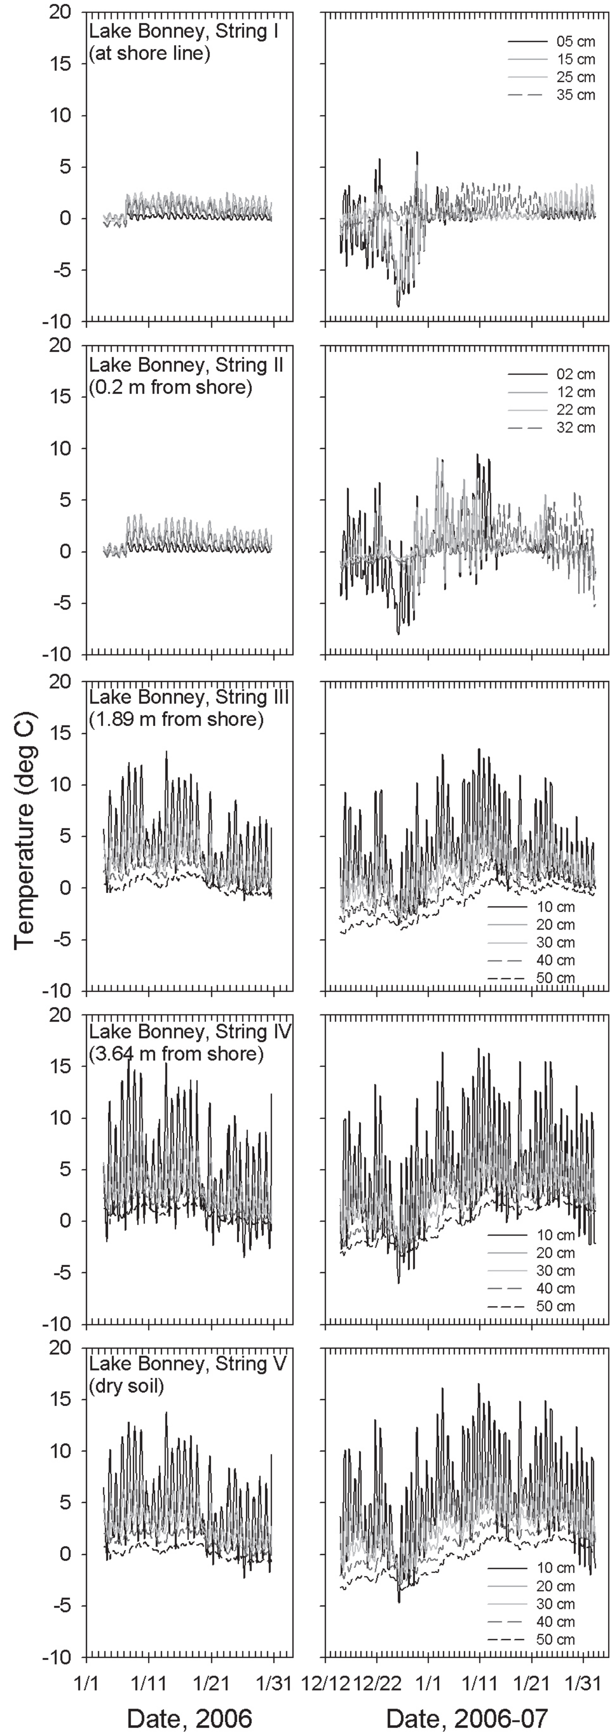

Figure 4. Lake shore soil temperatures from thermocouple strings I through V at Lake Bonney.

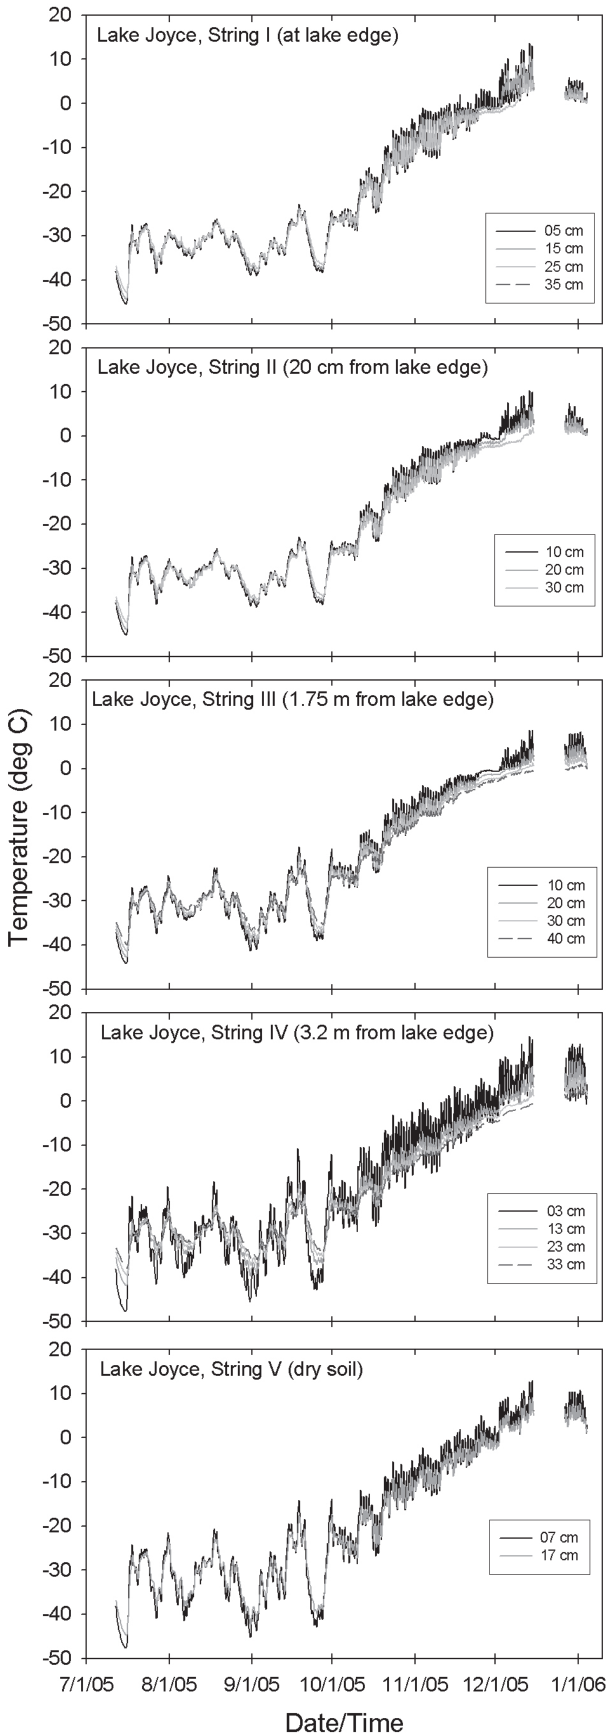

Figure 5. Lake shore subsurface temperatures from thermocouple strings I through V at Lake Joyce.

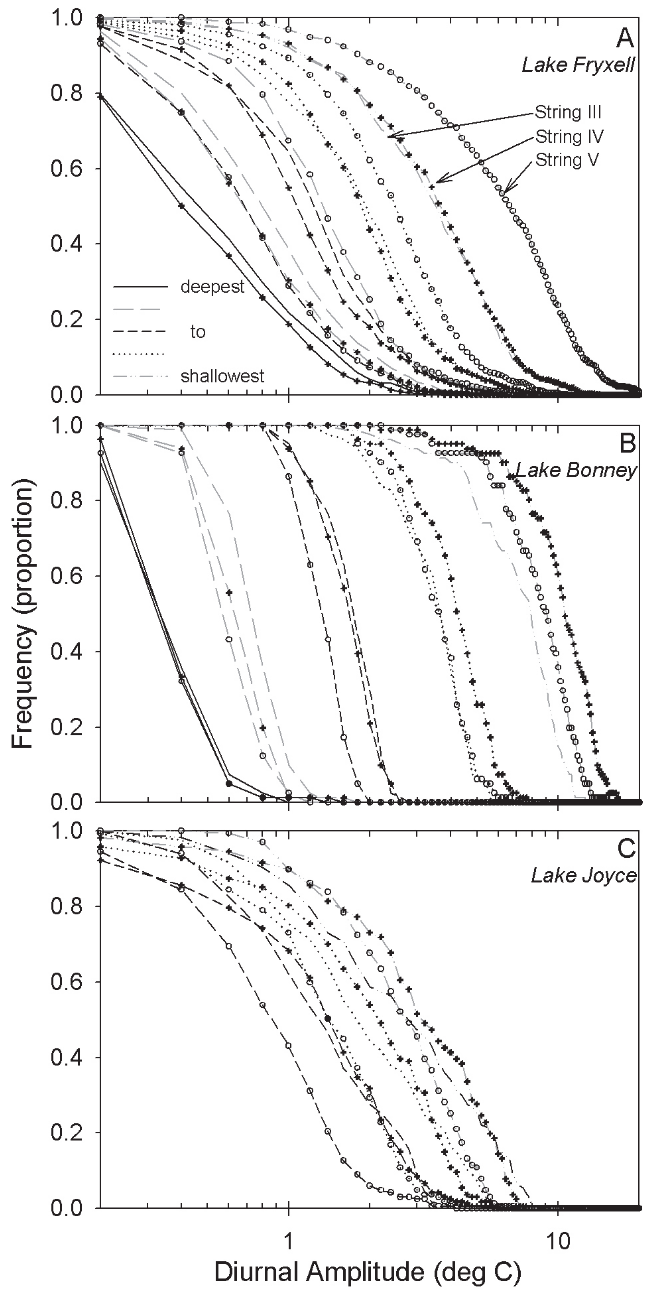

Figure 6. Frequency-duration curves (FDCs) for daily amplitudes in soil temperatures at A) Lake Fryxell, B) Lake Bonney, and C) Lake Joyce. Each curve represents the entire record for a single thermocouple. Strings with comparable depths of thermocouple deployments are presented for comparison. Strings are distinguished by symbols on the curves: nearest the lake has no symbol, the next one out has a cross symbol, and the furthest an open circle. Similar depths are indicated by pattern.

may indicate here too that String III is well buffered because of (1) enhanced soil moisture at depth at this position, (2) this mid-transect location is a transition point between the influence of convected heat from either longitudinal (i.e., away from the shoreline) flowing water from the shore to the dry soils, or (3) the influence of lateral flow of water not investigated here. At Lake Joyce, there is a consistent pattern of String IV having greater diurnal variability, in general, than String V at thermocouple positions 1, 2, and 3 (red, green, and blue lines, respectively, Fig. 6C). At the 4th thermocouple position (next to deepest), String V is much more variable in daily temperature fluctuation than String III at Lake Fryxell (black curves, Fig. 6A), and very similar for Strings III-V at Lake Bonney (gray curves, Fig. 6B). At the deepest thermocouple location (positions 5) temperature amplitudes are similarly buffered at Strings III and IV at both Lake Fryxell (Fig. 6A) and Lake Bonney (Fig. 6B).

These three sets of results generally support our expectation, that drier soils would be warmer and more variable than wetter soils. In particular, this notion is supported by the evident temperature time series magnitudes, which are greater at the distal thermocouple strings than at the near-shore strings, as well as by the general patterns of increased DDF at the distal locations compared to the nearshore locations. Finally, for the most part, locations that have less soil moisture are more variable in daily temperature amplitude than more saturated soils.

Conclusions

We found that, in general, soils with little soil moisture were warmer and more variable in temperature than wetter soils. This investigation focused on locations of soil moisture gradients near three lakes in the MDV, which may host variable microbial communities due to potential dependence upon habitat conditions, namely soil temperature and water content. These factors also influence biogeochemical processes across these hydrologic gradients.

The Mechanism of Ice Formation in Connection with Deformation of the Freezing Layer

J.B. Gorelik
Earth Cryosphere Institute SB RAS, Tyumen, Russia

Abstract

The freezing of a closed volume of water-saturated sands is considered in this report. The separate clay body may be situated inside sand. Only the freezing layer may be deformed under action of cryogenic pressure. It is shown that a layer of ice may be formed in the volume. For its formation, it is necessary that the effective radius of the water-supplying area be more than some critical value. In this condition, the frozen layer is similar to the frozen part of a pingo with a water lens in its base. In the opposite case, only the frozen soil with different ice content may be formed. If the vertical length of the clay body is less than some limit, it will be pulled out from its sandy environment or it will be broken along some of its horizontal cross section.

Keywords: cryogenic pressure; deformations; frozen layer; ice content.

Introduction

Thick ice bodies are spectacular features of the permafrost environment. The mechanisms of formation of some of them are still debatable and there are ten hypotheses concerning their formation. They are subdivided into two groups: a) ice body formed inside the ground; b) ice body formed on the surface of the ground and then buried by alluvium. Different viewpoints on this problem are reflected in several books and in numerous articles. Recently some articles were published where mechanisms from both of these groups are discussed and differences in ideas are not resolved.

The idea of ice body formation as a result of segregation or injection is mostly found among hypotheses of the first group. The burial of glacial ice is the most recognized hypothesis of the second group. Existing approaches cannot completely explain ice body formation under certain conditions, as well as structure ice and structure of the enclosing sediments.

The mechanism of ice body formation is proposed in this paper. It attempts to explain a number of important characteristics of the structure of ice body deposits.

Deformations of Freezing Layer

Let us consider the freezing of a closed volume of water-saturated soil which includes clay and sand. The bottom and sides of this volume are formed by dense clay with sand inside it. It is assumed that a separate clay body may be situated inside the sand (Fig. 1). Additional assumptions are: 1) the freezing layer is connected rigidly with clay sides of the volume and 2) the additional water supply of the considered volume may be realized from the sands which are outside of the clay sides. Thus, only the freezing layer may be deformed in such a system. These deformations are caused by cryogenic pressure which arises in a closed system, with increase in the volume of freezing water due to a difference in the density of water and ice.

During freezing of a closed volume, the cryogenic pressure increases, causing the plate of freezing ground to curve upwards. The upward-directed force acts on the central clay body while it is freezing; simultaneously the opposite direction force acts on the freezing layer and holds it back from deformations. The force causes tension stresses in the horizontal direction at the unfrozen part of the clay body. These stresses have a maximum at the contact of frozen and unfrozen parts, and they increase in time. When the cohesion value of the unfrozen material is reached, then the clay body is broken along this frozen/unfrozen contact. The crack between broken parts is filled with water which freezes, resulting in ice body formation. For analysis of the transformations in the system, it is necessary to consider the deformation process of the freezing layer first.

For general consideration, let us introduce the "closing" depth of the volume h_0. It determines the freezing depth at which surface water is not connected with freezing soil. The source of surface water in Figure 1 is nonessential anymore. It is assumed that the deformations of the freezing layer at all clay bodies and at the peripheral water-supplying zone are negligible. We use R_w and R_f for the effective radii of the water-supplying zone and of the rigid connection contour accordingly. The inequality takes place in general: $R_w \geq R_f$ (Fig. 1). Assuming that the thickness of the frozen layer, h, is much less than the value of R_f, its mechanical behavior may be described as deformations of the thin plate. Real configuration of all the elements of the considered system is very complicated. Theoretical analysis may be realized for the system with any symmetry. Later on, we shall use the mechanical analog of the Figure 1 scheme,where all vertical walls are cylindrical. This analog has the axis symmetry. In this analog, the vertical deformation of freezing layer ζ_r is the function of the radial coordinate r and time t.

It is considered that the deformations of the freezing layer are started after freezing of the surface sources of water. These deformations are limited if the acting stresses are smaller than the long-term strength of frozen sands, and they are increased with no limit in the opposite case. The attenuated deformations are described by the equation of

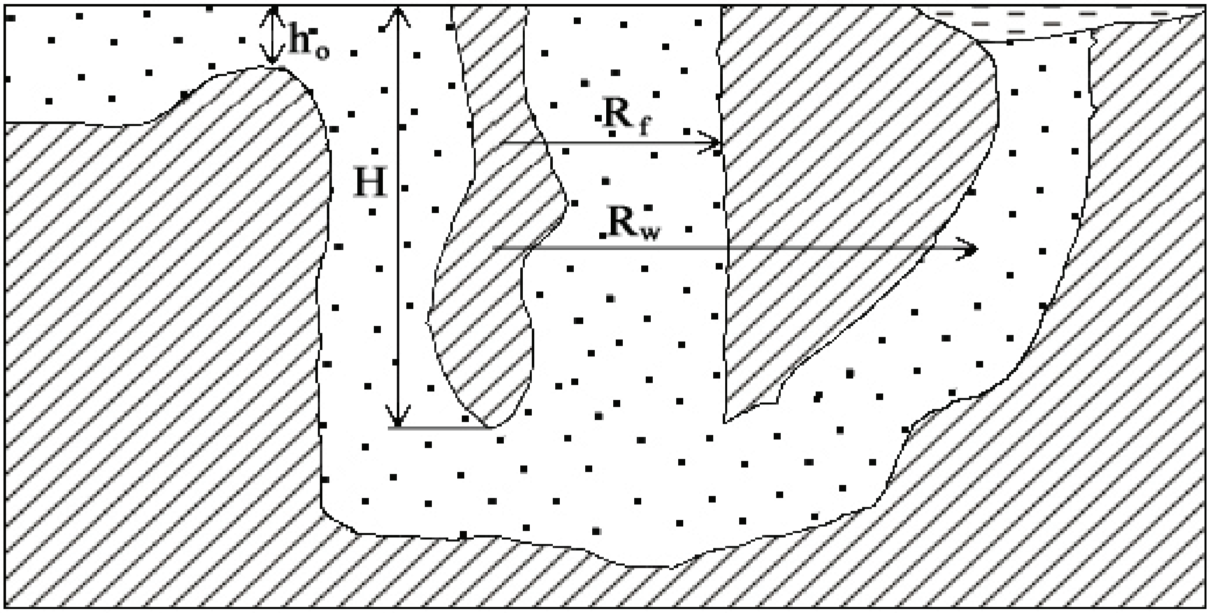

Figure 1. The scheme of closed volume before freezing. - clay, - sands, - surface basin. The notation of the values is in the text.

hereditary creep theory (the instantaneous deformations are negligible):

$$\varsigma_r(t) = t_r^{-1}\int_0^t \varsigma_r^u(\tau)\cdot \exp\left[-(t-\tau)/t_r\right]d\tau \quad (1)$$

where E, v, η are elastic modulus, the Poisson ratio and viscosity coefficient of frozen sand; $t_r = 2(1+v)\eta/E$ is relaxation time; $\zeta_r^u(t)$ is elastic solution of the task (its change in the time is due to the slow change of cryogenic pressure and of the thickness of the freezing layer at the same time). The characteristics of frozen soils should be defined from the tests with attenuated deformations. Methods and results of the frozen soils tests, both for the attenuated and for no-limited deformations are fully presented by Grechishev (1963). The constant E should be defined at the stabilized state in the tests of frozen sample and constant η should be defined by measuring the deformations rate through the same tests in the beginning of the test. Then equation (1) describes satisfactorily these experimental data of frozen sand attenuated deformations in time. For frozen sands, the relaxation time is not more than 15 days as a rule. For a closed system, the elastic bend, ζ_r^u, is defined by equation:

$$D\cdot\Delta^2\varsigma_r^u = -\rho_s gh + P_c - \rho_w g\varsigma_r^u \quad (2)$$

where P_c is the value of cryogenic pressure; ρ_s, ρ_w are the densities of frozen soil and of pore water; $D=Eh^3/12(1-v^2)$ – plate rigidity; Δ is the Laplasian operator; g is acceleration of gravity. The term $\rho_s gh$ is the pressure associated with weight of the freezing layer and the term $\rho_w g\zeta_r^u$ is pressure due to Archimedean force. The last arises owing to deformations inequality of the plate as it takes place for floating plates (Timoshenko 1967). It is important that the elastic reaction from the sandy bed to the freezing plate is absent because the effective stresses are equal to zero in a closed system (Gorelik 2007b). The last statement is true for the uniform loadings acting on the plate, considered here. The value $P=P_c -\rho_s gh$ defines the prevalence of cryogenic pressure over pressure of the freezing layer weight. It is always positive in a closed system, and it is upward-directed.

We shall consider the non-limit deformations only at the stage of stationary creep. These deformations may be described by the viscous-plastic soil flow model. The scheme of this flow is analogous to the flow of the viscous-plastic liquid in the cylindrical tube. At the stage of stationary creep, the freezing layer is shifted continuously relative to the clay walls of the volume. The elastic deformations are negligible, and the kern of the flow may be considered as rigid. Near the walls, there is a thin layer which is deformed as viscous uncompressible liquid. The beginning of the creep stage occurs when the intensity of the stress at the attenuated deformations stage reaches the value of long-term strength of frozen sands on the contour of the rigid connection. The definite values of abundance P_s and of freezing depth h_s correspond to execution of this criterion. The rigid kern velocity of the flow v_s for $h\geq h_s$, $P\geq P_s$ is defined by expression:

$$v_s = -\frac{\tau_s}{\eta}(R_f - r_s) + \frac{P}{4\eta h}(R_f^2 - r_s^2) \quad (3)$$

where r_s is rigid kern radius. For running values of h and P it is defined by $r_s=2\tau_s h/P$; τ_s is long-term strength of frozen sands defined under shear-tests of the samples. The viscosity coefficient, η, in equation (3) is different than its value in equation (1) in general, and it must be defined under the same shear-tests during stationary creep stage. The shear-test may be realized by the rotation of a frozen soil tube with acting axial force as presented by Grechishev (1963).

Both cryogenic pressure P_c in equation (2) and the abundance P in equation (3) are not determined up to now. For its determination it is necessary to use the equation of water mass conservation in a closed system:

$$\frac{1}{\pi R_f^2}\int_0^{R_f} \varsigma_r 2\pi r dr = \qquad (4)$$

$$= \left(\frac{\rho_w n_u - \rho_i n_f}{\rho_w \sqrt{n_u n_f}} + \frac{\Delta\rho_{wi}}{\rho_w}(\alpha^2 - 1)\right)(h - h_0)$$

Here: ρ_i is the density of ice; $\Delta\rho_{wi}=\rho_w-\rho_i$; n_u, n_f are the soil porosities at the unfrozen and frozen states (they are constants here); $\alpha=R_w/R_i\geq 1$; $h\geq h_0$. For the determination the value of P in equation (3) it is necessary to derive the relation (4) over t taking into account $v_s=\partial\zeta_r/\partial t$ for the creep stage. In the equation (4) the average deformation of freezing layer (left part) is proportional to its thickness after closing the system. It occurs because of change it porosity migration of water from peripheral parts of the system (right part). These deformations are purely connected with nonzero densities difference $\Delta\rho_{wi}$. It may be shown that $\zeta_r=0$ for all r if we shall take on formally $\Delta\rho_{wi}=0$ in equation (4). Later on, we take the simple form of the relation between frozen depth and time: $h=(\beta t)^{0.5}$, where β is a constant proportional annual mean surface temperature and to the value of n_f^{-1}.

The written equations and the formulated additional conditions are sufficient to determine cryogenic pressure and deformations of the freezing layer in time. The behavior of the value P as a function of the freezing depth is shown on Figure 2a at the following initial data: $E=10^8$ Pa, $\eta=10^{13}$ $Pa{\cdot}sec$, $\tau_s=1.8{\cdot}10^5$ Pa, $R_f=300$ m, $h_0=0$ m, $n_u=0.3$, $n_f=1.5n_u$, $\beta=1.3{\cdot}10^{-7}$ m^2/sec, $\alpha^2=7$. It can be seen that the value of P has a bend at the deformations transition to the stationary creep stage.

The criterion of breaking of the central clay body may be written as: $P=cR_c/R_f$. Here c is the cohesion of the unfrozen clay and R_c is the radius of the central clay body. The clay bodies may be broken at any deforming stage (if, of course, the freezing depth will reach the needed value). For example, the dotted line on Figure 2a demonstrates the breaking stress with the parameters: $c=0.5{\cdot}10^5$ Pa, $R_f=300$ m, $R_c=50$ m. Figure 2b shows the correlation between bend lines of the freezing layer before and after breaking of the central clay body. At the breaking at the attenuated deformations stage, the bend line from double convex is transforming to the convex one. The experimental modeling of this process shows that this transformation is accompanied by increasing of the temperature and abrupt falling of the cryogenic pressure. Electromagnetic emission and crack formation in the freezing layer were observed during the process. But the frozen layer was unbroken as whole (Gorelik 2007a).

The further fluent lifting of the broken (upper) clay body part is possible, together with the frozen layer itself, for breaking at the stationary creep stage.

The breaking criterion does not take into account the vertical length of the clay body, H. But such interval of values H exists ($0\leq H\leq H^*$) that for every H from this interval the clay body will be pulled out from its sandy couch before it will be broken. The limiting value H^* is defined by two conditions: 1) the vertical stress at the contact of frozen and unfrozen parts reaches the value of c and 2) the upward-directed force is equal to the sum of the unfrozen part weight and the friction force at its lateral contact with sands. The expression for H^* is:

$$H^* = h^* + \frac{cR_c}{\Delta\rho_{sw} g R_c + 2\tau_t}; \qquad (5)$$

where τ_t is the lateral stress of the friction; h^* is the freezing depth at which the unlimited in vertical direction clay body is broken. Similar conditions can be used to develop the equation for the freezing depth h^{**} at which the pulling out takes place at any H from the interval.

The ice body must be formed directly under the base of the clay body on its pulling out. The main tendencies in the deformation of the freezing layer under this process will be the same as at its breaking.

Water Flows and Ice Accumulation

All deformations of the freezing layer in a water-saturated closed system are connected with water inside this system. So, the deformations are negligible near the points of the rigid connection contour, and water is driven away from the freezing front here. The water flows to the freezing front in this area. It means that the porosity, n_f, is a function of radial coordinate r in general and it cannot take arbitrary values (as it is considered above approximately). The function $n_f(r)$ characterizes the local ice accumulation along the freezing layer by coordinate r. As it was noticed above, the constant β is proportional to n_f^{-1}; then the freezing layer thickness h_r at any radial point is connected with it at the points of the rigid connection contour h by dependence: $h_r=h(n_u/n_f(r))^{0.5}$. To find the function $n_f(r)$ it is necessary to use an additional correlation as the local equation of the skeleton's mass conservation (Gorelik 2007b):

$$(n_f - n_u)\partial z_f / \partial t = -(1 - n_f)v_f \qquad (6)$$

where $\partial z_f/\partial t$, v_f are the rates of the freezing front movement and lifting of the upper surface of freezing layer relatively to the unfrozen part of the volume ($v_f=\partial\zeta_r/\partial t$ at the attenuated deformations stage and $v_f=v_s$ at the stationary creep stage). Between values of $\partial z_f/\partial t$, v_f and $\partial h_r/\partial t$ the connection exists: v_f-$\partial z_f/\partial t=\partial h_r/\partial t$ (Fig, 2c).

The rate v_s does not depend on r at the stationary creep stage and the values of n_f, v_s and $\partial z_f/\partial t$ may be calculated as functions of parameter α (Fig. 2d). Such critical value α^* exists that for $\alpha<\alpha^*$ $n_f<1$ and $n_f=1$ in the opposite case (for $n_u\approx 0.25$ we have $\alpha^*\approx 4.5$). With the increasing of α from one to α^* the value of n_f increases to one monotonously. The rate $\partial z_f/\partial t$ is less than zero always in this case. For $\alpha\to\alpha^*$ we have $n_f\to 1$ and very icy soil is formed. For $\alpha\geq\alpha^*$ only

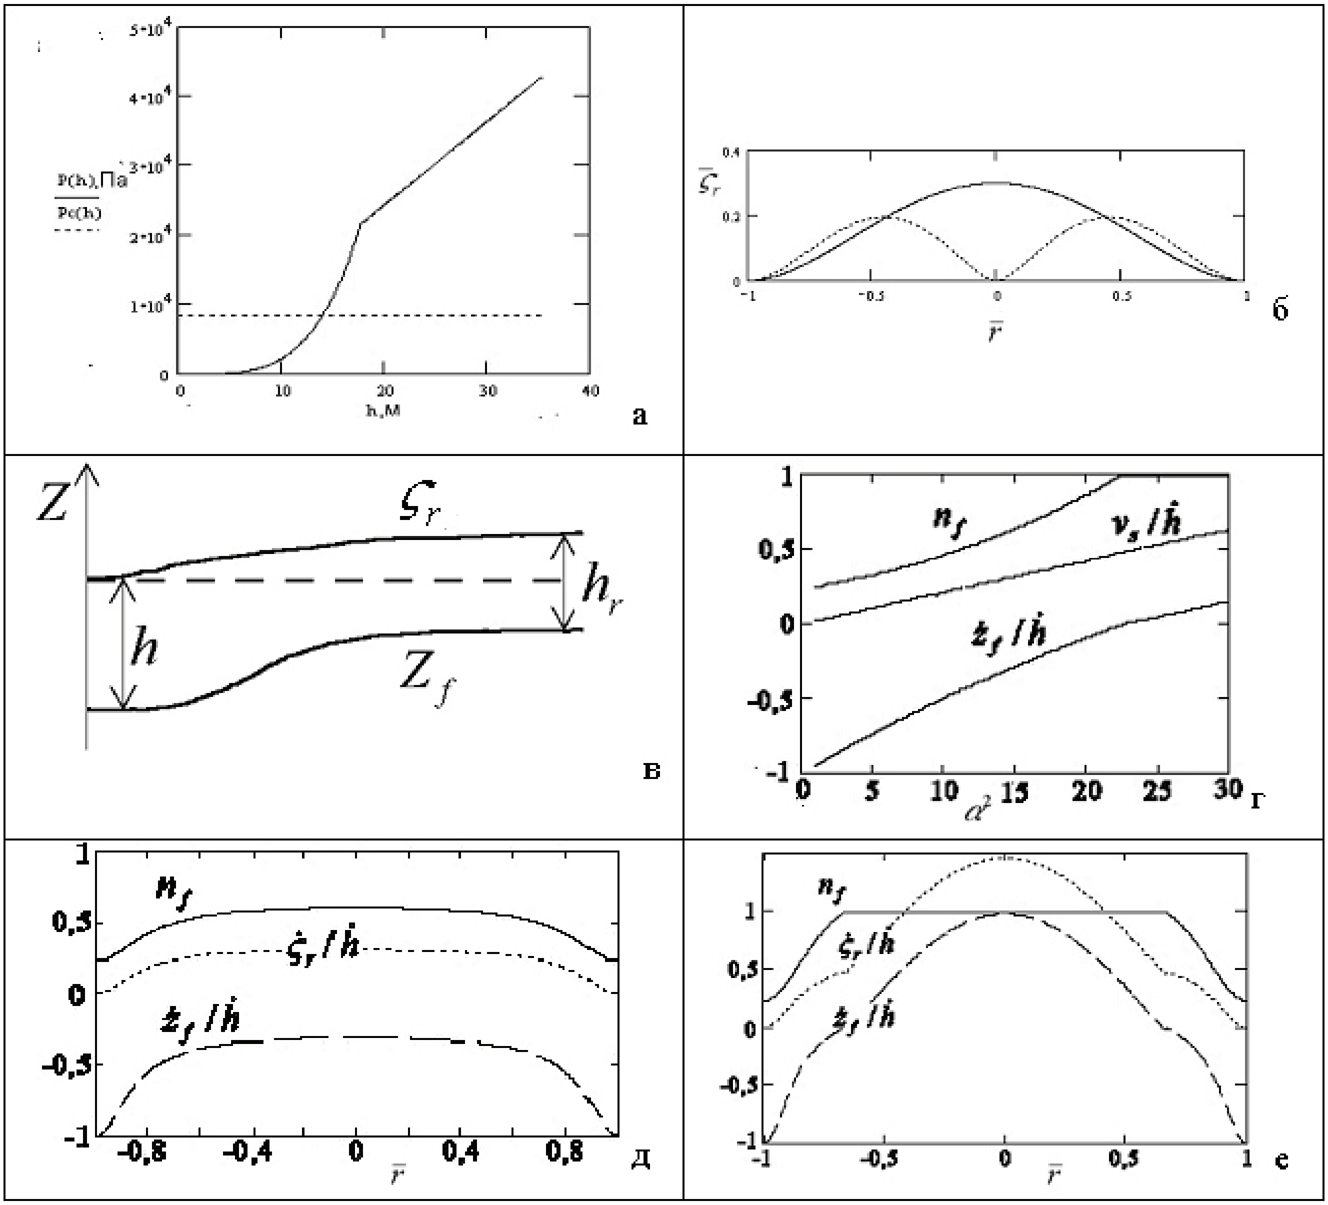

Figure 2. The characteristics of cryogenic pressure, deformations and ice accumulation at the freezing of closed volume: a) the dependence of cryogenic pressure abundance on freezing depth (continuous line), dotted line is the breaking stress in the central clay body; b) the bend lines before (dotted line) and after (continuous line) the break of the central clay body (in non-dimensional coordinates); c) the scheme of frozen layer near the points of rigid connection; dotted line is the initial position of the ground surface; d) the dependences of frozen soil porosity, relative velocities of deformations and of freezing on value of α at the stationary creep stage; e) the dependences of frozen soil porosity, relative velocities of deformations and of freezing on non-dimensional coordinate r at attenuated deformations stage (α=3.5<α^*); f) the dependences of frozen soil porosity, relative velocities of deformations and of freezing on non-dimensional coordinate r at attenuated deformations stage (α=4.8>α^*).

clear ice is formed and rate $\partial z_f/\partial t$ is more than zero. The last means that the freezing front is retired from the unfrozen soil, and a clear water lens is formed under the ice body. The vertical thickness of the lens should increase with time. All these transformations may be interpreted as changes in the character of ice accumulation at the variation of the radius R_w and at fixed radius R_f.

At the attenuated deformations stage, the value of n_f is a function of r. In this case the critical value α^* exists also: if $\alpha<\alpha^*$, we always have $n_f<1$ for all values of r from the deformations zone, and if $\alpha>\alpha^*$, the area with radius R_α exists inside the deformations zone ($R_\alpha<R_f$) where n_f=1 for all the values of r from this area (for $n_u\approx0.25$ we have $\alpha^*\approx4.2$). For $\alpha=\alpha^*$, we have R_α=0 and the value of R_α is increased with increasing of α.

The dependence of the functions n_f, v_s and $\partial z_f/\partial t$ on r for $\alpha<\alpha^*$ is shown on Figure 2e. In this case we have $n_f<1$, $\partial z_f/\partial t<0$ for all $r\leq R_f$. For $\alpha>\alpha^*$ the limited area with n_f=1 and $\partial z_f/\partial t>0$ is present inside the deformations zone (Fig. 2f). It means that the kern of the clear ice is formed in the freezing layer. This kern is surrounded by very icy soil, and the water lens underlies the kern. This structure of the frozen layer is

analogous to the structure of a pingo, which is presented by Mackay (1978). The likeness of the structures of some ice body deposits and a pingo is noted by Fotiev (2003).

Geological Aspects of the Considered Problem

The soil section in Figure 1 has a specific structure characterized by the certain combination of sand and clay. The important role in a ice body formation belongs to the lower clay layer which forms bottom and walls of the volume. Continuous bodies of massive ice widely occur on the Yamal Peninsula. It is interesting to compare their occurrence and relationship with the surrounding soil with a soil section in Figure 1? Although field descriptions and photographs of the sections with ice bodies are presented in many publications, information about soil beneath ice bodies is limited. However, the clay layer is found under sands, which underlain ice (Velikotsky 1987, Baulin et al. 1996, Solomatin & Konyahin 1997, Dubikov 2002, Streletskaya & Leibman 2002, Fotiev 2003, Shpolanskaya et al. 2006). The role of the lower clay layer in an ice body formation has not been previously discussed. All the sections described in these papers have had a three-layer structure before ice formation: clays, sand, and clay. It created the conditions for freezing of the sands in a closed system. For example, Figure 3A shows such a section presented by Solomatin and Konyahin (1997). It shows that the ice bodies are covered by clay, and they have sand in its bedding everywhere, but under these sands, the clay layer is present. Without ice (before freezing), the section has a three-layer structure. It is of interest to deduce the role of each of the layers in the ice body formation. Let us consider the question for the hypothetic section presented in Figures 3B, 3B-a, and 3B-b for different stages of freezing (the small and big tongues in upper clay layer are analogs of small and big clay bodies in the sands of Figure 1). Figure 3B shows this section before freezing. The dotted lines a-a and b-b are the positions of the freezing front at intermediate and final stages of freezing (in assumption that mass transfer processes are absent in the system). Figure 3B-a shows separate fragments of the ice body, water lens, and deformations of the separate layer boundaries and the surface of the massif at the intermediate stage. Figure 3B-b shows the final form of the ice body and final deformations of the layers and boundaries.

In this process, the lower clay layer is a confining layer at the bottom and walls of the closed volume. There is a solid connection between the freezing layer and these walls. Without this connection, the cryogenic pressure that occurs will not be enough to deform the upper layers. The lower clay layer is not deformed at ice body formation process as a rule.

The sandy layer is the main water-containing and water-conductive layer. The ice accumulation and deformations of the upper layer and the structure and composition of the ice body are essentially connected with an extension of this layer in horizontal and vertical directions. At the deforming of the upper layer, the fractures and cavities are formed between the upper and sandy layers. As far as cohesion of sand is equal to zero and under an impact of the water flow, sand partially fills these defects. Hence, the upper boundary of the sands has to take on a subhorizontal position under the water lens and ice bodies (Figs. 3A, 3B-a, 3B-b).

The upper clay layer is the main layer which is subjected to transformations during ice body formation. Configuration of the ice body depends on size and configuration of this clay layer. The only clay composition of this layer is not obligated, but if clay is present here, the freezing layer moves its unfrozen parts upwards. Deformations arise and expand at mostly weak parts of the layer (Figs. 3B, 3B-a). Its more solid parts (as the big tongue on Fig. 3B-a) hold the freezing layer from deformations. (On the real section of Fig. 3A it is the central clay body. It is possible that the upper left part of the clay layer on this section is broken during ice body formation.) At the final stage, the solid parts of the layer may be deformed, too. For example, the big tongue of Figure 3B-b has some rotation to the right. It may be cracks formation in the tongue's body at this rotation. The upper boundary of the ice takes over the configuration of the lower boundary of the upper clay layer (Fig. 3B-b).

Acknowledgments

The author is indebted to Professor S.E. Grechishchev and to Professor S.M. Fotiev for discussing the problem and for their useful criticisms.

Technocryogenesis Controls on the Permafrost Environment and Geotechnical Factors in Towns of the Permafrost Zone

V.I. Grebenets
Geographical Faculty, Lomonosov State University, Moscow, Russia

Abstract

Currently, due to the significant landscape modification that alters the thermal and mass exchange between permafrost and the atmosphere, special geocryological conditions are formed in urbanized areas of the permafrost zone. It is suggested that the specificity of changes in geocryological, landscape, geoecological and geotechnical environments should be delineated with the technocryogenesis concept, which has four basic features. Technocryogenesis is the specific exogenous process taking place in urbanized areas of the cryolithozone (1); it occurs at the contact of technogenic loads and the permafrost environment (2); it has an irreversible character (3); and appears as specific natural geocryological complexes (4). Regional studies of technocryogenesis revealed its varied influence on permafrost and ecological environments and geotechnical condition.

Keywords: cryogenic processes; deformation; permafrost degradation; technocryogenesis; temperature regime.

Introduction

Currently, due to significant landscape modifications that have altered the thermal and mass balance between the permafrost and the atmosphere, special geocryological conditions are developed in urbanized areas of permafrost. In addition, engineering and mechanical loads force permafrost soils to change physical, thermal, and mechanical properties. Consequently, the soil temperature beneath the affected surface rises and dangerous cryogenic processes are activated. This results in the overall reduction of geotechnically stable areas.

Methods

To study the relation between the permafrost conditions and geotechnical environments, we measured the temperature of permafrost in boreholes. This was done in built-up areas, and the results were compared to the thermal field that existed before construction. Geodetic survey data of the surface prior to embankment construction was also analyzed to determine the trends and rates of cryogenic processes taking place at the study sites. Visual and instrumental observations of the state of buildings and constructions were collected.

Results

There are several types of forces acting on permafrost soils in urban basements, as described below:

Mechanical disturbance

Exploitation of soils for basement construction, borrowing and excavation, and mining and tunneling, alter the strength capacity and continuity of the permafrost. Dirt piles, montons, and embankments favor either formation of permafrost bodies or permafrost degradation.

Technogenic inundation and salinization

The release of unrefined effluents on the daylight surface, accidental release from sewerage, and penetration of contaminants into the active layer notably alter the geochemistry of soils. This has been observed in Yakutsk, Vorkuta, Igarka, and many others towns in the permafrost zone. For instance, soil water of the active layer in Norilsk (where there exist the largest nonferrous-metal industries in the world) is rich in sulfates and chlorides, making the environment aggressive to the foundation concrete. The maximal salinity is found in areas being built up at the outset of the Northern exploration– up to 21 mg/l is the concentration of salts in sands under the Nickel Plant built in 1940 (Grebenets 1988). Chemical contamination of soils lowers the freezing temperature, increases active layer thickness, and favors thawing of ice-rich sediments with consequent thermokarst.

Alteration of surface thermal conditions

The vast majority of both domestic and rural areas of northern towns are free of vegetation and covered with asphalt. Asphalt allows soil heat flow to increase due to summer heating and winter cooling from snow clearing. Observations showed that the snow collecting areas have warmer (by 2–3°C) permafrost than that under the snow cleared roads. Ventilating cellars lower the soil temperature due to shading in summer and protection from snow accumulation in winter. Correct operation of a ventilating cellar could lower the permafrost temperature by 2–4°C. However, multiple failures in service were found and include the following: missing the solid waterproof cover and catch-water drains; malfunctioning of the sanitation system; insufficient number of weep holes in ventilating cellars or weep holes covered with snow; and low altitude of ventilating cellars turning them into encatchments. Serious service failures were found in 85% of the buildings in Dudinka. Failures favored degradation of permafrost, resulting in local taliks or warmer soil body formation as well as formation of non-anchored permafrost bodies. Bedding courses without lateral watertight faces have a generally negative influence on permafrost (Grebenets 2003). The bedding courses consist of roughly sorted coarse grained wastes including crushed rock, pebble, and sand that could be easily supplemented with construction debris or snow. Moss and vegetation is covered, consequently increasing heat flux into the soils. Moreover, due to high filtration coefficient of 10 to 50 m/day, the bedding course material is permeable for surface waters. For example, residential 9-storey buildings on Laureatov st., Norilsk were constructed in 1975–1980 having 2–3 m to 8–10 m of the bedding course in the basement damaged several years after due to a reduction in the soil bearing capacity. The soil temperature under the bedding courses changes in range from -2.5°C to +2°C (Grebenets 2001).

Thermal forcing

Enhanced flow of heat into the soil from industries, residential buildings and communications, water released in rural areas or accidentally, lack of storm canalization, will all lead to permafrost degradation. Large heat-emitting utility collectors contribute most to permafrost warming. The collectors in Talnakh, Vorkuta, Dudinka, and other populated towns represent a distributed net of technogenic systems dug 4 to 6 m into the soil. We recorded above zero temperatures in the annual thermal regime of the collectors, which is the reason the thaw bulb is expanding. There were icings found in winter, while snow melt water and effluents flow in summer. The thermal forcing could be prevented if the collectors were laid on the ground like those in the Yamburg and Novozapolyarnyi settlements.

We suggest that technogenic impacts are the reason for the change in the soil temperature profile. Measurements in a deep borehole in downtown Norilsk evidence the temperature increase at a depth of 20–60 m by 0.5°C to 1°C during the period 1955–1985. Geothermal studies in a 135 m borehole in the suburbs of Norilsk revealed a increase of temperature over the last 50 years from -3.5 or -4°C to -1.5 or -2°C at a depth of 20 to 90 m. It is thought that temperature changes below the 15–20 m layer is not controlled by seasonal changes in climate parameters, and thus are associated with continuous technogenic pressure. It is confirmed by air temperature data recorded at meteorological stations in Norilsk during the period 1933–2005 and at Dikson (1917–2003); the data do not evidence any regional air temperature warming. However, the permafrost temperature before the construction in the 1940s varied from -0.1 or -0.5°C to -6 or -7°C, and the soil temperature in domestic areas was -3°C (Sheveleva & Khomichevskaya 1967). By the year 2005, it had risen up to -2.5°C. Consequently, great warmed areas appeared and hugh technogenic taliks formed over about 30% of the territory. Thermokarst is indicated as the asphalt breaks up, and due to the increase in the active layer depth, the frost heaving of soils and foundations is widespread in built-up areas.

The temperature regime changes, with subsequent lowering of the bearing capacity of the soils and activation of dangerous cryogenic processes. This has led to a growing number of deformed buildings and constructions. More than 75% of buildings in the permafrost zone of Russia are built on frozen basements, with permafrost supporting the basement. Under the tendency for permafrost degradation in the largest towns of the permafrost zone (Grebenets & Sadovsky 1993, Grebenets 2003), the increase of the soil temperature, often supplemented by ground thaw, consequently lowers the bearing capacity of the frozen foundation. The deepening of seasonal thaw expands the zone of cryogenic weathering of concrete. Acting together, these processes lead to mass destruction of buildings and constructions. Currently, 60% of buildings are deformed in Igarka, Dikson, and Vilyuysk; literally 100% in tribal settlements of Taymyr Autonomous District; and around 40% in Vorkuta. The number of deformed constructions in Norilsk Region of northern Siberia during the last 10 years has markedly exceeded that of the last 50 years. Currently, there are nearly 300 large buildings in towns of the Norilsk Industrial Region that are significantly deformed due to unfavorable permafrost, and geological consequences arose. More than 100 objects were in the state of failure, with 50 of the 9-storey and 5-storey buildings constructed during 1960–1980 recently being deconstructed.

A growing number of building breakdown, constructions, water lines, oil lines, and industries causes increased technogenic pressures on permafrost in urbanized areas, leading to new changes in the permafrost and forming a new geocryological environmental reality. Due to the factors of physical and economical geography, industrial exploration of permafrost is spotty. Permafrost in urbanized areas can be characterized by the altered intensity of cryogenic processes that have taken place in the region, or even a new set of processes. Occurrence, activity, intensity, reversibility, the formation of a paragenic series of geocryological phenomena, together with other characteristics of the cryogenic processes on urbanized areas, significantly differ from that of natural areas or those having no analogues in the natural environment.

Specific naturally-technogenic geocryological complexes form in urbanized areas. Each identity has various permafrost dynamics that differ from that under natural conditions. There were thirteen (13) basic identities marked in the territory of Norilsk Industrial Region (Grebenets 2001), ranging from technogenic badlands (tailing dams, waste and ash disposal areas) where permafrost is disturbed and the natural landscape destroyed, to relatively weakly modified sites in tundra and forest tundra where the active layer deepens due to an increase in thermal conductivity of soils impacted by acid rains and technogenic salinization. Listed below are the natural-technogenic geocryological identities allocated for Yamburg gas-condensate field:

1) sites currently occupied with gas-preparation facilities; having water drains; systems for basement soil cooling; with the geotechnical state and engineering geocryological conditions being stable;

2) urban areas having water drains in operation; regular snow removal; on-ground utilities; maintained with ventilating cellars; with a tendency for aggradation of permafrost and controlled damping of cryogenic processes;

and lacking deformation of buildings or constructions;

3) sites with residential and service buildings built during the 1980–1990s, among which are many that are heat emitting; these are areas with degrading permafrost and multiple deformation of buildings and constructions;

4) sites of the infrastructural objects including rural areas where the objects are being used on disturbed permafrost; having extensive warming and thawing areas; intensive thermokarst and frost heaving; with a number of objects being destroyed or even being in the breakdown state;

5) areas occupied with coarse wastes and where rubbish accumulation takes place; where permafrost warming occurs due to chemical reactions;

6) linear zones along multiple pipelines where the conditions of heat exchange on the surface are significantly modified; with active frost heaving of pipeline supports; thermokarst and thermoerosion development;

7) relatively stable tundra areas of thermokarst, thermoerosion, and gully expansion along heavy vehicle pathways.

Nonstandard permafrost-ecological problems arise under housing compaction or reconstruction of objects in areas of continuous (years to decades) technogenic loading on permafrost basements. For example, in Talnakh in northern Siberia, to provide stable building constructions on the spot where old buildings were located for 25–30 years and then demolished, the pile footing depth needed to be increased by 50 to 75%. Rebuilding the areas of recently deconstructed buildings in Yakuts and Norilsk resulted in tackled the serious problem connected with anthropogenic cryopegs. The aggressive medium actively corroded ferroconcrete piles of the new buildings.

Conclusions

Permafrost dynamics in towns, involving the state, temperature, bearing capacity, seasonal thaw depth, and activity of cryogenic processes is controlled by the following factors: 1) geocryological (features and properties of permafrost before construction); 2) geotechnical (town-planning parameters, technogenic impact type, intensity and effective area); and 3) temporal (duration of influence and climate changes). Factors could often act multi-directionally, at various scales, and asynchronously; this results in spotty pattern of permafrost change in the urbanized areas.

It is suggested that the specificity of changes in geocryological, landscape, geoecological and geotechnical environments should be delineated with the technocryogenesis concept having four basic features. Technocryogenesis is the specific exogenous process taking place in urbanized areas of the cryolithozone (1); occurring at the contact of technogenic loads and the permafrost environment (2); having irreversible character (3); and appearing as specific natural geocryological complexes (4). Regional studies of technocryogenesis revealed its varied influence on permafrost and ecological environments and geotechnical condition.

The study of technocryogenesis accounting for the size of the town system, number of elements involved and duration of interaction with nature, and permafrost stability is thought to present interest. The important issue is to assess technocryogenesis interaction with climate change trends at the regional scale for permafrost areas.

A Study of High Arctic Retrogressive Thaw Slump Dynamics, Eureka Sound Lowlands, Ellesmere Island

J.D. Grom

W. H. Pollard
McGill University, Montreal, Canada

Abstract

To better understand retrogressive thaw slump dynamics and their potential response to a warming climate, this study investigates the form and process of a thaw slump located in the Eureka area of Ellesmere Island in the Canadian High Arctic and attempts to identify microclimatic variation induced by its morphology. Preliminary analysis indicates that microclimates develop at the ablating ice face and within the mudflow that potentially create a feedback process for headwall retreat. Furthermore, trends in development indicate spatial variation in energy input and morphological influence on the landform.

Keywords: massive ground ice; retrogressive thaw slump; thermokarst.

Introduction

Polar regions are expected to exhibit a strong response to projected warming trends, and a significant concern is the expansion of thermokarst—land surface affected by permafrost degradation—and the resulting terrain instability throughout the Arctic. Retrogressive thaw slumps, a type of erosional backwasting resulting from the exposure of ice-rich permafrost, are a prominent thermokarst feature in arctic landscapes and have a profound potential for landscape alteration (Fig. 1). They consist of three main structural components: 1) a nearly vertical "headwall" made up of permafrost soil; 2) a steeply inclined (20°–80°) "headscarp" of ice-rich sediment acting as a thermal erosion belt; and 3) the slump floor, consisting of a low-angle (1°–10°) mud pool expanding to form a lobate pattern at the base of the slump (Burn & Lewkowicz 1990, de Krom 1990, Lantuit & Pollard 2005). The headwall and headscarp are the most dynamic components of the thaw slump and contribute the thaw material, flow deposits, and water accumulation of the mud pool. The landform often has a characteristic "horse-shoe" or linear shape and typically ranges from tens to hundreds of meters in length and width (Barry 1992, Lantuit & Pollard 2005). Retrogressive thaw slumps are initiated by various activities and are sensitive to climate and morphology, providing for periods of activity and stabilization (Burn & Lewkowicz 1990).

Rates of retreat for active retrogressive thaw slumps are variable and dependent upon climate and morphology, including slope, rate and patterns of erosion, and ground ice distribution and quantity (McRoberts & Morgenstern 1974). Radiation and sensible heat transfer have been identified as the principal energy sources for ice face ablation (Burn & Lewkowicz 1990, Lewkowicz 1986a, b, Robinson 2000); therefore, warm and clear days are the most conducive to retrogressive thaw slump activity and headwall retreat.

In an attempt to further define controlling parameters on retrogressive thaw slump development, this study investigates the potential formation of a microclimate existent within the retrogressive thaw slump as compared to the surrounding area, with increased temperatures developing at the ice face during periods of high incoming shortwave radiation (↓K), creating a positive feedback for melt of the ice face and headwall retreat. This paper also describes the methodology used to quantitatively define associated process and morphology. Field activities, including the collection of microclimate and morphologic data, were performed at a retrogressive thaw slump near Eureka, Ellesmere Island, Nunavut, Canada, over a 17-day period. Data were then analyzed to describe retrogressive thaw slump activity and characterize the development of a microclimate unique to the landform.

Study Area

Field observations were conducted from July 3–22, 2007, in the Eureka Sound Lowlands, located at the Fosheim Peninsula of Ellesmere Island, in the Nunavut Territory of Northern Canada (Fig. 2). Specific data collection focused

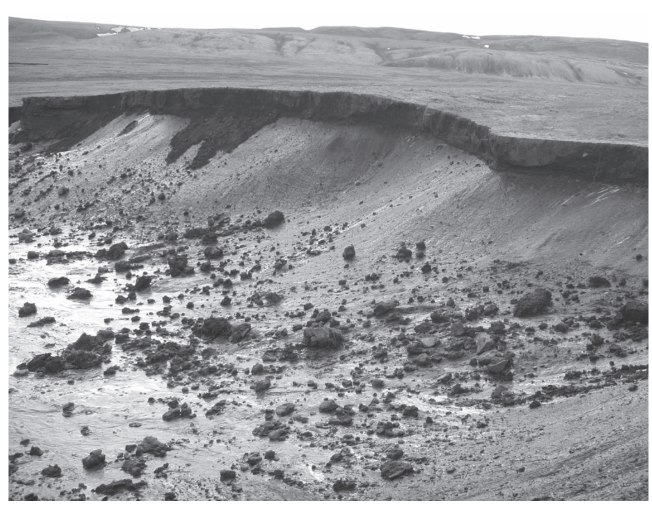

Figure 1. Photograph of retrogressive thaw slump, July 4, 2007.

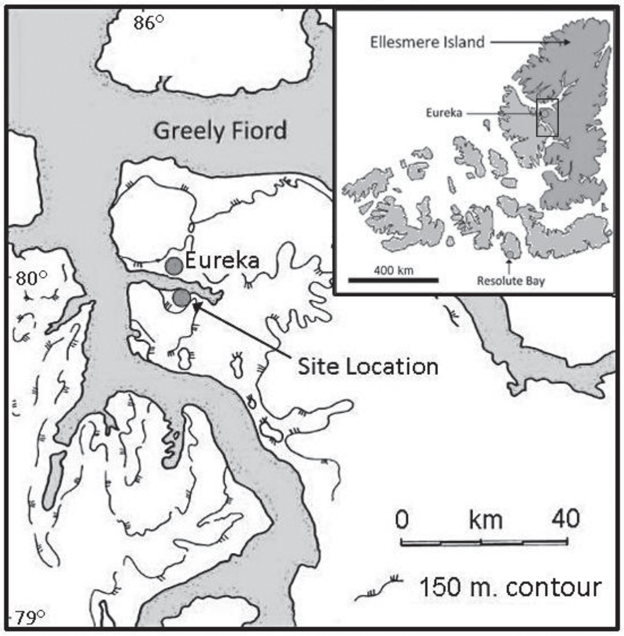

Figure 2. Map of site location and Canadian Archipelago. (150 m contour obtained from Pollard & Bell 1998).

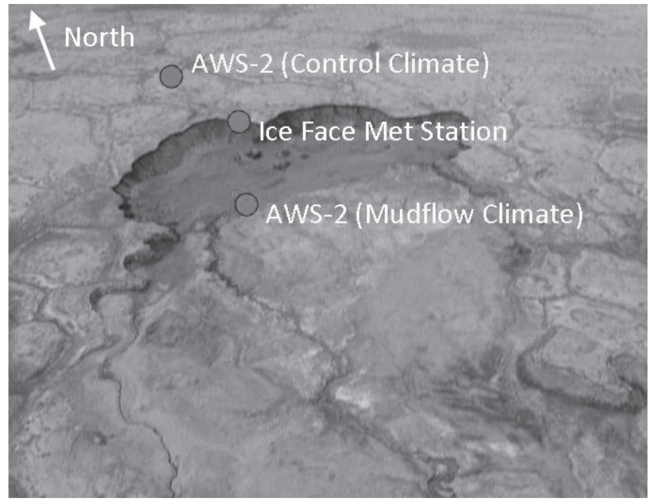

Figure 3. Oblique overhead photograph of retrogressive thaw slump investigated in study, including headwall, mudflow, micrometeorological equipment.

on a southerly-oriented, active, retrogressive thaw slump located at 79°53.782′N, 85°59.357′W, approximately 10 km southeast of Eureka. This region is a polar desert, experiencing an average mean annual air temperature (MAAT) of -19.7°C and an average of 64 mm of precipitation per year, 60% of which is snow (Pollard & Bell 1998, Pollard 2000). Permafrost thickness can exceed depths of 500 m, with active layer depths ranging from 0.15–0.9 m and an extrapolated mean ground surface temperature of -20.8°C (Robinson 1993, Robinson 2000). Regional topography consists of broad, undulating lowlands.

Massive ground ice up to 17 m thick is present throughout the Eureka Sound Lowlands, and as such, substantial thermokarst activity is found along slopes experiencing active erosion and/or former thermokarst events (Robinson 2000). Ice exposures, the majority of which are overlain by marine sediments of varying thickness, are often up to 8 m thick and result in retrogressive thaw slump activity and development. Field studies performed in 1991/1992 at the nearby Hot Weather Creek revealed at least 20 active thaw slumps within an 80 km^2 area (Robinson 2000). Average rates of retreat for the duration of the study ranged from 8–14 m/year for high-angle slumps and 5–9 m/year for low-angle slumps, indicating the importance of morphology in ablation of the ice face. Additionally, several active and inactive retrogressive thaw slumps were observed in the vicinity of the studied thaw slump during the recent site reconnaissance.

Field Methods

Morphology

The outline of the headwall was identified on July 12, 2007, using differential global positioning satellite (DGPS), and aerial photographs were obtained for the site. Headwall retreat was obtained manually by installing a series of 10 coupled stakes along the headwall and measuring the change in distance between the stakes and headwall using a 50-m tape measure. Measurements were recorded to the nearest millimeter; however, accuracy was possible to the nearest centimeter.

Additionally, headwall retreat was obtained for the portion of the headwall situated directly above the ice face meteorological station in order to integrate morphologic and climatic data impacting the landform. The headwall was measured 4 times over the 17-day period, including July 5, July 6, July 12, and July 22. Surface angles were obtained at the beginning of the site investigation using a handheld abney level for the inactive portion of the slump mudflow and the surrounding terrain in addition to 10 points along the ice face corresponding to the aforementioned locations of headwall retreat measurement.

A profile of the ice face was obtained in the vicinity of the ice face meteorological station in order to characterize ground ice and stratigraphy. Additional samples were obtained from the ice face for the laboratory determination of gravimetric moisture-content in order to determine the volumetric latent heat of the ice to be applied in future analysis in conjunction with the ice face meteorological weather station data to gain insight to the energy balance at the ablating ice face.

Microclimate

In order to investigate the potential formation of a microclimate induced by retrogressive thaw slump morphology, two automatic weather stations were strategically placed at the site; one weather station was placed within the slump mudflow (AWS-1), approximately 78 m from the ice face and headwall, and the second was placed atop the slump (AWS-2), approximately 67 m upslope of the headwall, in order to represent the control climate (Fig. 3). It should be noted that AWS-1 could not be placed closer to the headwall as originally intended due to the viscous nature of the mudflow, making it inaccessible to installation and repeated access. The placement of these stations was

Figure 4. Ice face meteorological station.

intended to capture the microclimates within the thaw slump in comparison to the surrounding area, or the control climate, using the data collected from AWS-1 and AWS-2, respectively. Both of the stations were equipped with an SP-LITE silicon pyranometer (measuring ↓K), an HMP45C shielded thermistor and relative humidity probe (measuring ambient temperature and atmospheric relative humidity), an RM Young wind monitor (measuring wind speed and direction), and a barometric pressure sensor. AWS-2 was also equipped with a temperature sensor, measuring subsurface temperatures at depths of 50 and 70 cm below surface grade. It should be noted that the temperature sensors and SP-LITE, which provide the basis of data for this analysis, are considered accurate within ±0.35°C and approximately ±2 W/m^2, respectively. Climate data were scanned at 60-second intervals and compiled to produce 1-hour averages. Data output was stored on automated data loggers (AWS-1 and -2: Campbell Scientific CR10X; ice face station: Campbell Scientific CR10).

Additional instrumentation was suspended approximately 0.5 to 1 m above the ice face in order to provide additional quantification to retrogressive thaw slump microclimate development, in addition to defining the microclimate and energy activity at the ablating ice face (Fig. 4). This station was equipped with an NR–LITE (measuring net radiation), an HMP45C shielded thermistor and relative humidity probe, and a model 014A wind speed sensor.

Results and Discussion

Morphology

The observed retrogressive thaw slump consisted of 2 well-developed units, consisting of a layer of massive ice with an average surface exposure of approximately 4 m, overlain by massive sandy/clayey silt with a depth of 0.8–1.0 m; refer to Figure 1. The massive ice unit consisted of an intersedimental ice unit with exposed ice wedges embedded throughout.

The headwall of the retrogressive thaw slump was horseshoe-shaped and approximately 240 m along its perimeter. Retreat was variable among the points of measurement along the headwall - spaced at 24-m intervals along the perimeter, ranging from 1.5–5.6 m over the 17-day period (Fig. 5). Greater retreat was observed along the central portion of the headwall as opposed to the sidewalls, further contributing to its horseshoe-shaped morphology. This trend reflects the characteristic pinching of the sidewall attributed to lower ice angles, as identified in previous investigations (Barry 1992). However, it should be noted that no significant trend was observed between ice angle and cumulative headwall retreat in this study. Therefore, the spatial variation in headwall potentially reflects differences in ablation of the underlying massive ice in response to differences in energy distribution and morphology, including both depths of the overburden and ice and terrain angles.

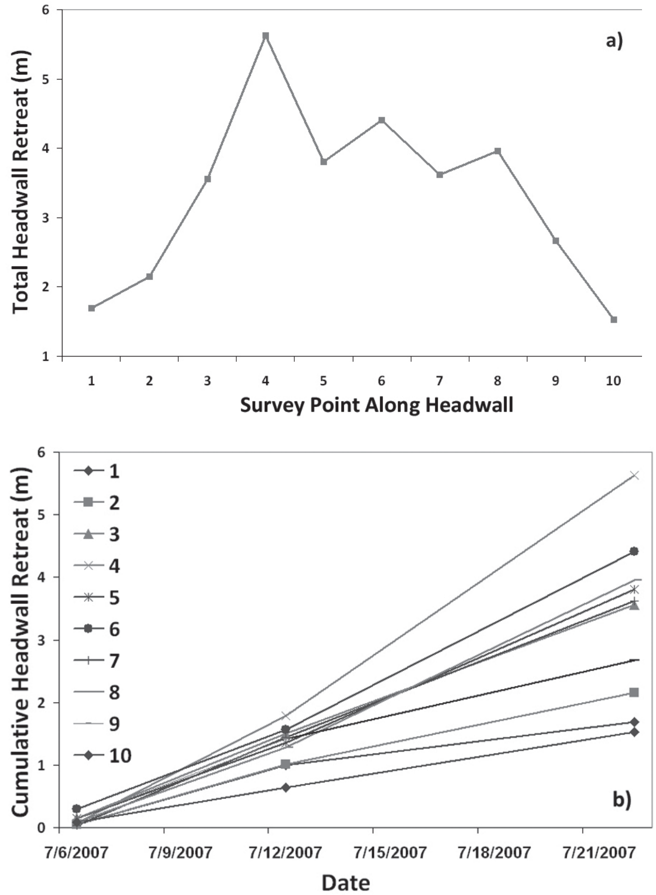

Figure 5. a) Total headwall retreat observed at studied retrogressive thaw slump, with each number representing a survey point spaced in 24-m intervals, moving west to east along the headwall. b) Retreat at all 10 survey points along the headwall over time.

Microclimate

Previous studies have identified solar radiation as providing a primary energy contribution to ablation, and therefore headwall retreat, of retrogressive thaw slumps (Lewkowicz 1985, Pufahl & Morgenstern 1980). It has been noted that net radiation alone can accurately capture approximately 60% of the variation in energy available for ablation (Lewkowicz 1986b) and that ice face orientation, which impacts periods of direct ↓K exposure, influences ablation rates (Lewkowicz

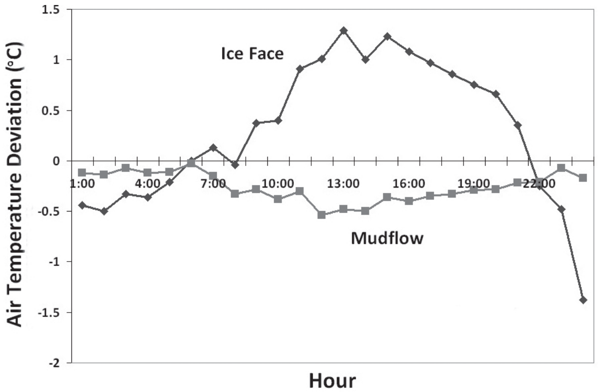

Figure 6. Air temperature deviation from control climate at ice face and within mudflow on a sunny day.

1988). An additional study also observed relatively high near-surface temperatures within the active portion of a retrogressive thaw slump (Mackay 1978). Data provided by the current study indicate that the influence of ↓K, which is inherently related to net radiation, is potentially further exaggerated by a feedback process that induces increased temperatures within the thaw slump, specifically at the ice face, during periods of high ↓K.

Initial analysis suggests the potential creation of unique microclimates existing near the ice face and in the mudflow in comparison with the surrounding climate. Temperatures appear to be heightened at the ice face in response to increased amounts of ↓K, whereas the temperatures are simultaneously slightly dampened at the automatic weather station located within the mudflow, potentially due to increased evaporation. In 119 of the hourly cases in which the ice face air temperature was greater than the control temperature by at least 0.35°C, 117 (98%) were under conditions of ↓K exceeding 250 W/m^2. In addition, of the 28 hourly cases in which mudflow air temperature was at least 0.35°C less than the control temperature, 27 (96%) were accompanied by a ↓K greater than 250 W/m^2.

Figure 6 displays a characteristic response of these spatial temperature differences on July 19, 2007, a relatively sunny day, characterized as having an average daily ↓K exceeding 250 W/m^2. As displayed, temperatures are increased up to 1.3°C at the ice face as compared to the control temperature and are decreased by 0.5°C within the mudflow, with an average increase of 0.29°C at the ice face and an average decrease of 0.26°C within the mudflow for the day. ↓K on July 19, 2007, averaged 315.6 W/m^2 (min 141.2 W/m^2, max 500.6 W/m^2), and the studied portion of the ice face received direct solar radiation from approximately 10:00–20:00, which strongly correlates to the period of observed increase in ice face air temperature. Winds were northerly/northeasterly with an average speed of 3.4 m/s, and air temperatures averaged 12.5°C ± 6.4°C (Fig. 7).

In contrast, the above air temperature deviations are not displayed during periods of low ↓K. Under these conditions, temperature deviations at the ice face and within the mudflow are minor, supporting the hypothesis that ↓K is a controlling factor in microclimate development. These

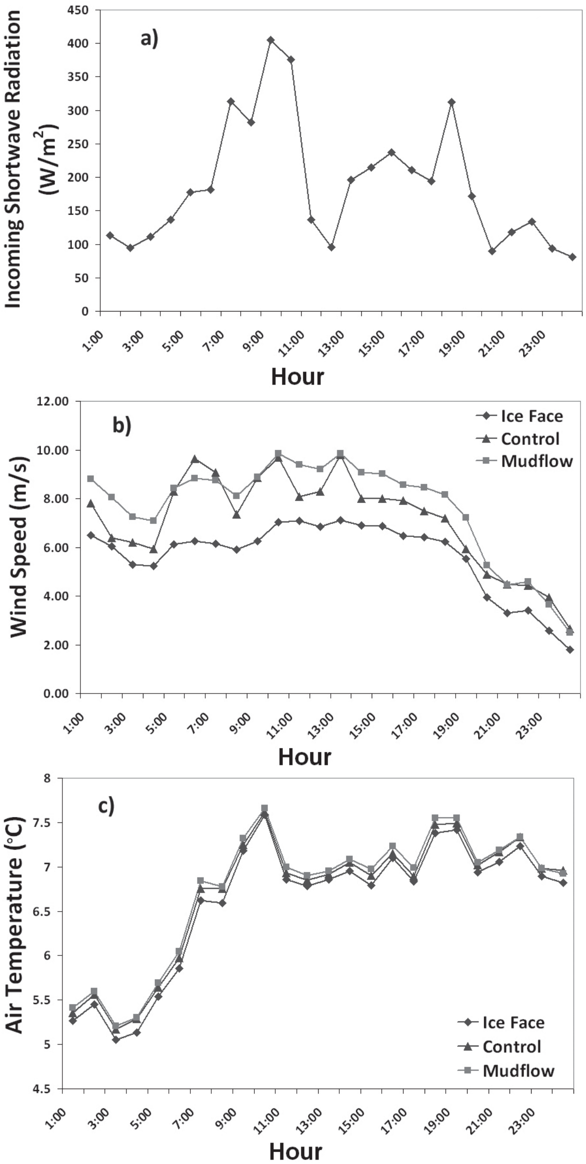

Figure 9. a) ↓K (measured at AWS-2), b) wind speed, and c) air temperature trends for July 7, 2007.

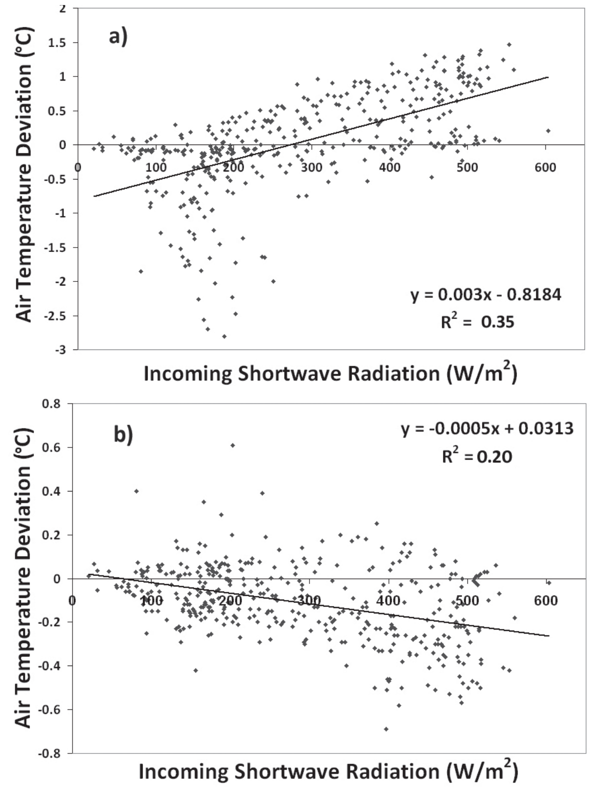

Figure 10. a) Ice face air temperature deviation versus ↓K, and b) mudflow air temperature versus ↓K; July 6–22, 2007.

trends are displayed in Figure 8, which displays temperature deviation trends on July 7, 2007, a relatively cloudy day, characterized by an average ↓K of 186.6 W/m^2. Additionally, southerly winds with an average speed of 7.1 m/s and an average daily air temperature of 6.7°C were observed on this day (Fig. 9). Under these circumstances, average daily air temperature deviations are -0.1°C and 0.0°C for the ice face and mudflow, respectively. It should be noted that trends within this range are considered relatively insignificant due to the aforementioned accuracy of the temperature sensor.

In order to further support the formation of spatial microclimates within the retrogressive thaw slump, a regression analysis was performed on the full dataset of temperature deviations and ↓K (Fig. 10). This analysis reveals significant trends between air temperature deviations from the control temperature under increasing ↓K conditions, identifying an overall positive trend in air temperature difference at the ice face ($p < 0.001$) and a significant but slight decrease in mudflow air temperature ($p < 0.001$). It should be noted that the r^2 values are relatively low for the ice face air temperature ($r^2 = 0.35$) and mudflow ($r^2 = 0.20$); however, this indicates the influence of additional factors in the formation of the observed microclimates and supports the need for additional investigation.

It is suspected that these deviations are the result of retrogressive thaw slump morphology (i.e., ice angle, sediment content, slump shape) and the associated differences in parameters such as albedo and wind speed. This could also be related to spatial differences in ablation rate previously identified, in which microvariations in energy input were identified as the most likely factor contributing to these conditions (Lewkowicz 1985). Additional investigation of available microclimate data is required in order to further define the conditions observed in field data.

It should be noted that climate data were also obtained from the nearby Eureka Weather Station and compared to the data obtained at the site. Previous studies have displayed that temperatures are typically significantly warmer in the Fosheim Peninsula as compared to the nearby Eureka Weather Station (Atkinson 2000). The site control station recorded temperatures in average exceedance of 4°C as compared to measurements reported from Eureka, and measured and reported temperatures rarely coincided with one another (Fig. 11). These differences, in addition to the microscale variations measured at the site, display the need for location-specific on-site weather measurements when investigating process-based dynamics of a landform.

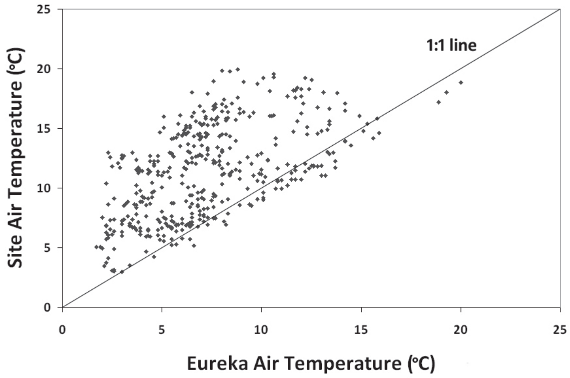

Figure 11. Recorded site air temperature vs. air temperature recorded at the Eureka Weather Station, July 4–22, 2007.

Summary and Conclusions

This study describes the methodology developed to capture and explore the dynamic interaction of climate and morphology in retrogressive thaw slump activity. The 17-day study period represents the most annually active period of ablation and headwall retreat, which was variable along various points of the headwall. These variations have previously been linked to changes in angle of the underlying ice face. However, this study does not support the sole influence of ice angle and indicates that additional investigation addressing the interplay of morphology and surficial energy activity is required.

Additionally, significant temperature variations in microclimates were identified at the site, specifically in the vicinity of the ice face. Preliminary analysis indicates that ↓K influences these conditions and further supports the importance of solar radiation on ablation and retrogressive thaw slump activity, as identified in previous studies. Further definition of these temperature variations is required to understand their formation and impact on retrogressive thaw slump morphology.

Microclimate data derived at the ablating ice face during this study are also being analyzed to further quantify the energy balance. These investigations will provide important information into retrogressive thaw slump process and provide the foundation for understanding the potential responses under altering climate conditions.

Abstract

Thermokarst lake formation in ice-rich yedoma deposits in north Siberia has a major impact on regional landscape morphology, hydrology, and biogeochemistry. Detailed assessment of lake distribution characteristics is critical for understanding spatial and temporal lake dynamics and quantifying their impacts. The distribution of thermokarst ponds and lakes at three different sites with ice-rich permafrost (Bykovsky Peninsula, SW Lena Delta, and Cherskii) in northeast Siberia was analysed using high-resolution remote sensing and geographical information system (GIS) tools. Despite similarities in geocryological characteristics, the distribution of thermokarst lakes differs strongly among the study regions and is heavily influenced by the overall hydrological and geomorphologic situation as a result of past lake-landscape dynamics. By comparing our high-resolution water body dataset with existing lake inventories, we find major discrepancies in lake distribution and total coverage. The use of low-resolution lake inventories for upscaling of thermokarst lake-related environmental processes like methane emissions would result in a strong underestimation of the environmental impacts of thermokarst lakes and ponds in Arctic lowlands.

Keywords: lake distribution; remote sensing; Siberia; thermokarst lakes; yedoma.

Introduction

Global lake inventories currently used in Earth system modeling contain only lakes larger than 10 ha (Lehner & Döll 2004, Downing et al. 2006). Most of these lakes are found in the Northern Hemisphere; that is, in permafrost-influenced or formerly glaciated regions. In permafrost regions with unconsolidated sediments most of the lakes are thermokarst lakes or ponds which formed due to the melting of massive or segregated ground ice and subsequent surface settlement. Thermokarst lakes are a major component of vast arctic and subarctic landscapes in Siberia, Alaska, and Canada. Thermokarst lakes and ponds can laterally expand by thermo-erosion and thaw slumping along shores. Usually a positive relation is established between thaw subsidence, horizontal basin extension, and water body growth, resulting in continued thawing of underlying permafrost and thermo-erosion on its margins. This runaway effect is mostly dependent on ground ice content in the underlying permafrost, and it continues going until thawed-out sediments form an insulating layer preventing further thawing and subsidence. Consequently, ice-rich unconsolidated permafrost deposits like those of the widespread Late Pleistocene Yedoma Suite in northeast Siberia (Schirrmeister et al. 2008) are especially vulnerable to thermokarst development initiated by natural or anthropogenic environmental change.

Regional medium-resolution studies aimed at the classification and spatial analysis of thermokarst lakes in Arctic regions were mostly based on Landsat satellite imagery, which has proven valuable for water body detection (e.g., Frazier & Page 2000). Such studies were conducted for the North Alaska Coastal Plain (Sellmann et al. 1975, Frohn et al. 2005, Hinkel et al. 2005), the Siberian Lena Delta (Morgenstern et al. 2008), the Lena-Anabar Lowland (Grosse et al. 2006), and the Tuktoyaktuk Peninsula (Côté & Burn 2002). These and other works reveal a very large number of lakes and ponds between 1–10 ha for most permafrost lowland areas. Based on field experience and spatially limited aerial surveys, it is known that there is very likely an even larger number of thermokarst ponds smaller than 1 ha.

The lacking representation of small lakes and thus bias towards large lakes in existing global lake inventories might result in a strong underestimation of the environmental impact of thermokarst lakes, which would seriously hamper the understanding of their role in the Arctic hydrological cycle and global biogeochemical cycles. First qualitative and quantitative studies on the environmental impact of thermokarst lakes over both geological and historical time frames suggest a potentially large role of such lakes in the

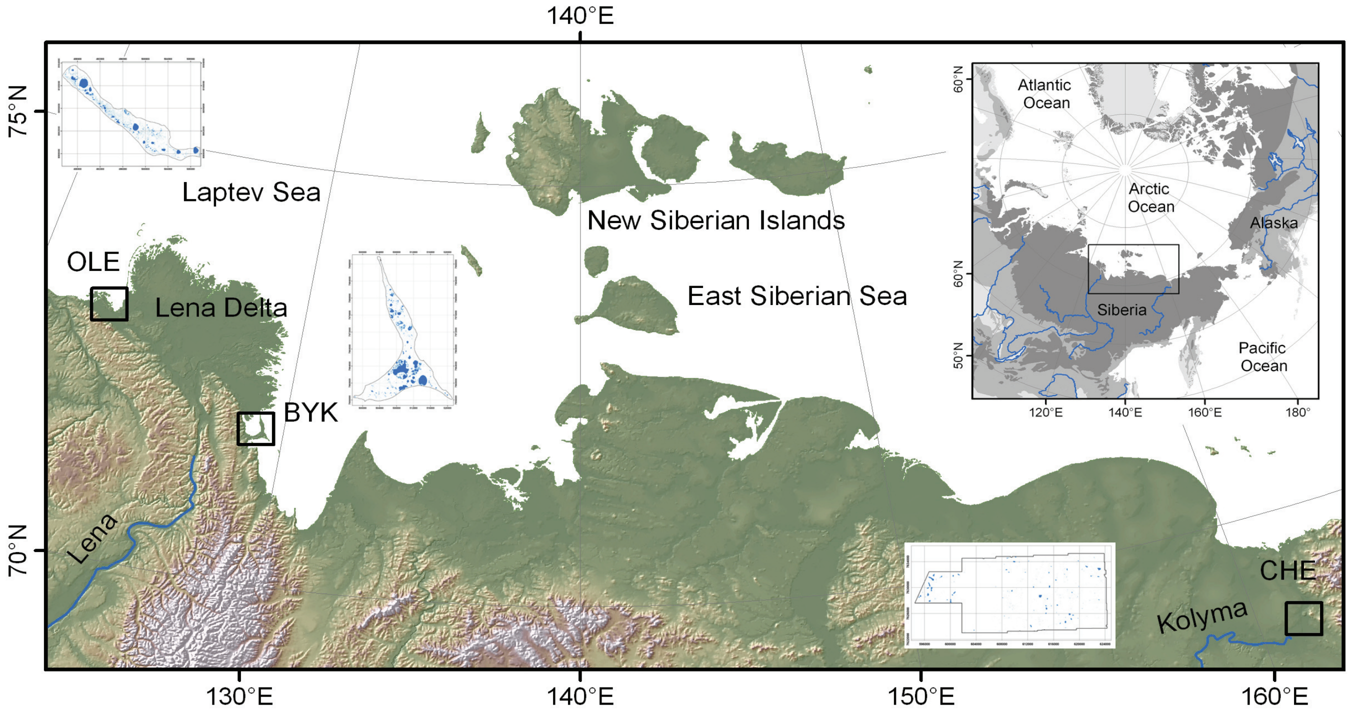

Figure 1. Relief map showing the location of the three study sites: Olenek Channel (OLE), Bykovsky Peninsula (BYK), and Cherskii (CHE) in NE Siberia including maps showing the lake distribution. Small inset in upper right indicates the location of the large map (black rectangle) in Siberia and the distribution of continuous (dark grey) and discontinuous permafrost (medium grey) after Brown et al. (1998).

arctic carbon cycle by unlocking vast amounts of permafrost-stored organic carbon and thus also for global climate dynamics (Zimov et al. 1997, Walter et al. 2006, Walter et al. 2007). Other studies indicate e.g., the impact of arctic wetland and lake distribution on atmospheric circulation patterns (Gutowski et al. 2007). Many studies also show that small water bodies in permafrost lowlands, e.g., polygonal ponds, are an important component for methane emissions from tundra wetlands (e.g., Wagner et al. 2003, Schneider et al. in review). To quantify the environmental impact of such arctic lakes and ponds it is necessary to have detailed information on their distribution and extent.

Several studies suggest a direct connection between thermokarst lake distribution and underlying permafrost characteristics, as well as between lake dynamics and permafrost dynamics. Widespread lake drainage in the discontinuous permafrost zone is related to a beginning disappearance of permafrost due to current climate warming (Yoshikawa & Hinzman 2003, Smith et al. 2005, Riordan et al. 2006). On the contrary, in the continuous permafrost zone an increase in lake area was observed in Western (Smith et al. 2005) and Eastern Siberia (Walter et al. 2006), but not on the Alaskan North Slope (Riordan et al. 2006, Hinkel et al. 2007). Most of these studies are based on the medium-resolution (30–80 m) Landsat satellite data record spanning about 35 years and some additionally involve historical aerial photography. However, although Landsat data may be sufficient to detect complete drainage and drying of some large lakes or the formation of new large lakes, it has serious limitations in detecting changes in lake extent due to thaw slumping and thermo-erosion. A high-resolution dataset of recent lake and pond distribution in combination with historical imagery would form an excellent base for studying change in lake extent and link these changes to permafrost or climate dynamics.

In this study a dataset of recent thermokarst lake and pond distribution on ice-rich yedoma deposits is developed based on high-resolution (1–2.5 m) satellite remote sensing data for three sites in Northeast Siberia and then compared with data from the Global Lake and Wetland Database (GLWD: Lehner & Döll 2004).

Study Region

All three study sites are situated in the continuous permafrost region of northeast Siberia (Fig. 1). The size of the study areas, a set of basic environmental characteristics, and information about the geocryology are provided in Table 1. The Bykovsky Peninsula (BYK) is situated southeast of the Lena River Delta. The peninsula is surrounded on three sides by large bays and the Laptev Sea. It is an erosional remnant of a Late Pleistocene accumulation plain consisting predominantly of silty to sandy ice-rich permafrost deposits of the yedoma (Grosse et al. 2007). Lakes, predominantly of early Holocene thermokarstic origin, are abundant at BYK (Grosse et al. 2005). They are located either on the yedoma uplands or as lake remnants and polygonal ponds in drained lake basins. These basins were formed by large thermokarst lakes during the early Holocene climate warming. They subsequently shrunk or drained after the middle Holocene due to climate deterioration and coastal erosion, leaving behind lake remnants and drained lake basins, which upon freezing

could support formation of polygonal ponds (Grosse et al. 2007). The land surface at BYK ranges from 0–45 m a.s.l. The study area around Cherskii (CHE) is part of the Kolyma fluvial lowland and located in the surroundings of the Rodinka hill (351 m a.s.l.). The wide, undulating slopes of this hill are mantled by ice-rich deposits of the yedoma stretching down to the banks and flood plain of the Kolyma River.

The study area in the southwest Lena River Delta along the Olenek channel (OLE) is part of an erosional remnant of Late Pleistocene sediments incorporated into the Holocene river delta architecture. It has the form of a peninsula and is bordered by the Laptev Sea and the wide channels of the delta. The permafrost deposits consist of ice-poor fluvial sands (ca. 0–17 m a.s.l.) overlain by yedoma (Schirrmeister et al. 2003) (Table 1). The topography is dominated by a flat plain with some thermo-erosional valleys and thermokarst basins. Water bodies are abundant in sizes ranging from polygonal ponds to large thermokarst lakes.

Remote Sensing Data

Spatially high-resolution recent satellite imagery was acquired from all three study sites to study thermokarst lake distribution and extent (Table 2). All images are from the snow-free early summer period.

For the BYK and the OLE sites two Spot-5 images were georeferenced to topographic maps of scale 1:100,000, for CHE several Ikonos-2 images were ortho-rectified (Table 2). All imagery used in this study is panchromatic and showed excellent contrasts for land-water separation.

Table 2. Satellite imagery used for mapping lake distribution.

Site	Platform	Date	Ground Resolution
BYK	Spot-5	2006-07-09	2.5m
OLE	Spot-5	2006-07-08	2.5m
CHE	Ikonos-2	2002-07-09	1.0m

Total water body area A (ha)	1327.6	1541.6	83.8

Methods

A simple density slice classification was applied to the most recent images at each site to distinguish water and land in the panchromatic imagery. A threshold that best separated image pixel values (Digital Numbers, DN) of water from land was chosen. Usually, there is a strong difference in reflectance between water bodies (dark or black, low DN) and bare or vegetated land surfaces (bright, high DN). A visual comparison was conducted to verify the classification. The DN of some lakes was found to be influenced by either very shallow water levels (probably less than 1 m), resulting in higher DN due to reflectance of the lake bottom, or turbid water with high sediment suspension, resulting in higher DN from the sediment load. On some lakes remaining lake ice (highly reflective, very high DN) resulted in misclassification. Additional misclassifications occurred for pixels associated with deep thermo-erosional valleys and steep north-facing cliffs or slopes. In both cases shadows were misclassified as water. These misclassifications were corrected by applying manually generated masks in ArcGIS™ to either exclude pixel (shadows, stream water bodies, man made structures) or to include pixel (lake ice, turbid and shallow water) from the lake dataset. Based on our visual examination and manual correction the resulting datasets can be considered a conservative minimum of standing water bodies in the study areas.

Based on the ground resolution of the available imagery, a minimum of 5 pixels was considered acceptable for successful water body detection. For better comparison between all study areas we therefore only included and analyzed standing water bodies larger than 0.003 ha. Since our classification approach was conservative and aiming at open water surfaces, we assume to have missed especially small ponds overgrown by vegetation in our inventory. At BYK, three thermokarst lagoons were included in the dataset, since they morphologically belong to the peninsula. Eventually, ArcGIS™ was used to analyze the spatial distribution of water bodies in the resulting datasets. The resulting dataset was then compared with the GLWD dataset (Lehner & Doell 2004) for all study areas.

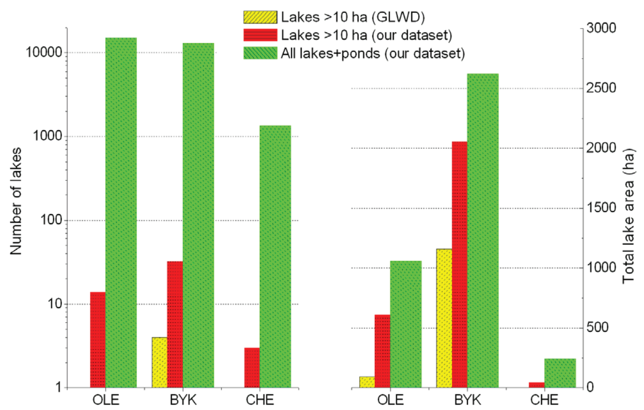

Figure 2. Comparison between GLWD (Lehner & Döll 2004) and high-resolution lake inventory for all study sites.

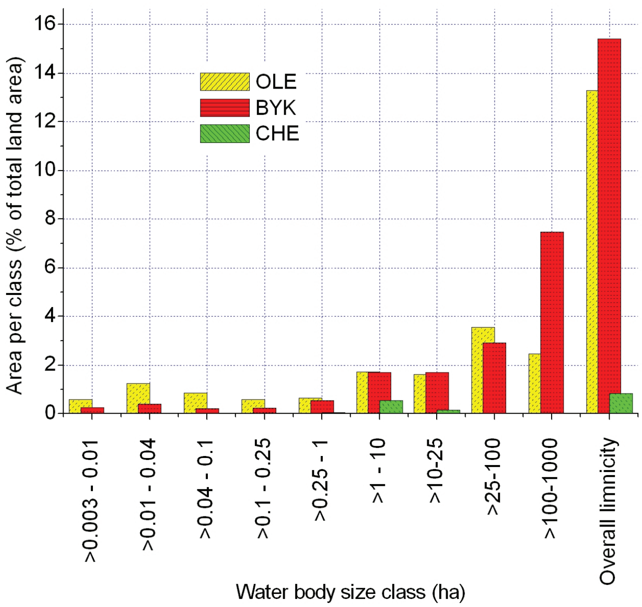

Figure 3. Histogram of total water body surface area for various sizes classes. Last bar shows the overall limnicity in the study areas.

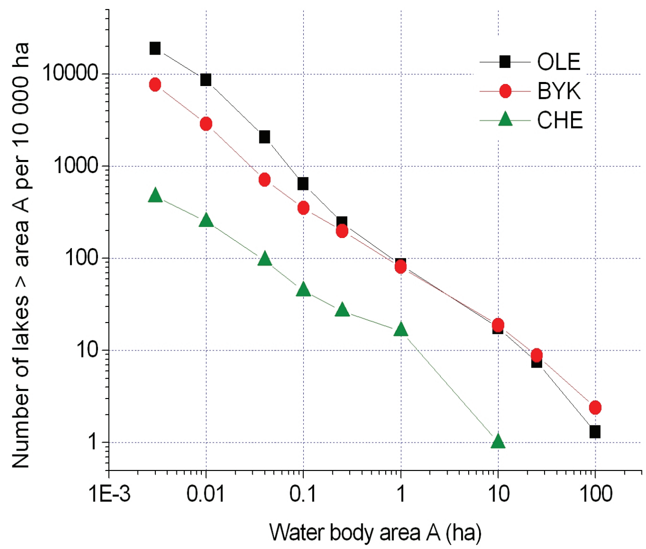

Figure 4. Area-normalized distribution of water bodies per 10,000 ha in the study areas as total number N of water bodies > area A.

Results

Despite similar basic geocryological conditions at all three sites (ice-rich yedoma deposits), the distribution of thermokarst lakes strongly differs among them. A total number of 29,361 lakes >0.003 ha were classified in the study areas (Table 3). The highest lake cover by land area (limnicity) was found at BYK (15.4%), closely followed by OLE (13.3%). Though CHE is the largest study area, its lake portion is lower than at both other sites by more than one order of magnitude (0.8 %).

Of the lakes >10 ha (49 lakes), 14 belong to OLE (609 ha), 32 to BYK (2053 ha), and 3 to CHE (44 ha) (Fig. 2). When comparing the water body distribution in various size classes, strong differences between the three study sites become even more obvious (Fig. 3). The OLE region has more than double the number of small ponds (0.003–0.01 ha) when compared to the BYK region, and almost 50-fold that of the CHE region. This disparity is also expressed in the low mean lake size for OLE. The dominance of lake numbers in the OLE area is true for all size classes except the three largest (>5 ha), where BYK dominates.

Comparing the area-normalized (per 10,000 ha) number N of water bodies larger than area A versus the area A in a logarithmic scaled diagram reveals an almost linear trend for the lake size distribution in all three study sites (Fig. 2). The possibility of describing a lake distribution with such a power law function of type $y=ax^b$ is well known from investigations of other large lake inventories (Lehner & Döll 2004, Downing et al. 2006). It seems to be also applicable to the NE Siberian dataset of comparably small-sized thermokarst lakes investigated in this study. However, obviously for the CHE water bodies the trendline is situated about one order of magnitude below BYK and OLE.

Comparison of lake density between the sites shows a generally highly dense water body population at OLE due to a large amount of small ponds, the clustering of water bodies and thus lake density at BYK, and the overall sparse lake cover at CHE. At CHE, the presence of Rodinka hill in the study area and the lack of lakes on the bedrock hill itself creates an additional cause for the scarcity of lakes. However, it appears not to be the main reason, since flat areas with unconsolidated yedoma farther away from the hill also have much lower lake densities then OLE or BYK. Image analysis and ground truthing reveal that the large lakes in the BYK area usually occur in deep thermokarst basins (subsided up to 40 m below surrounding surface) and often are only the lake remnants of previously partially drained lakes. Many polygonal ponds are situated in these drained basins. Small ponds and medium lakes are found on the yedoma uplands with poor drainage. Yedoma uplands with many thermo-erosional valleys do not contain many lakes. At OLE, most of the numerous, small ponds are found on the yedoma upland. There are only a few large, drained thermokarst basins. Remarkably, the OLE area is relatively homogeneously covered with numerous small ponds, while these small water bodies occur in irregular patterns at BYK and CHE. There are comparably few small thermokarst lakes at CHE. Many of

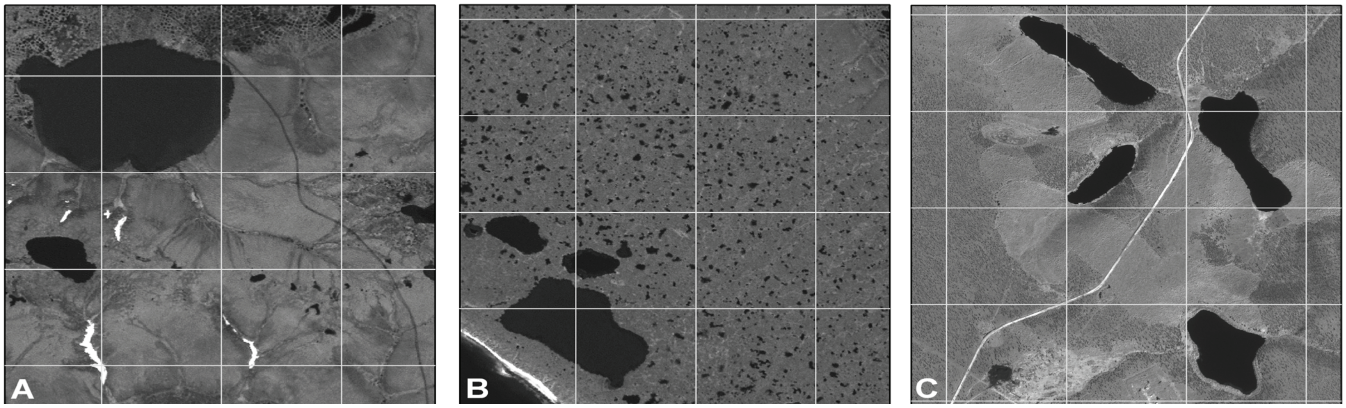

Figure 5. Subsets of study areas displaying characteristic landscape and lake patterns for all three sites. A – BYK; B – OLE; C – CHE. Image grid spacing is 600 m.

these were formed due to human activity in the area around the settlement of Cherskii, adding an artificial component to the natural lake distribution. Similar, at BYK human impact resulted in the drainage of several small lakes along vehicle tracks in the tundra. In contrary to CHE, the overall lake population is very high at BYK and therefore the human influence on the lake distribution characteristics is probably negligible here.

A comparison of our detailed water body dataset with the lakes in the GLWD (Lehner & Döll 2004) reveals large discrepancies in number and area of thermokarst lakes larger than 10 ha (minimum size GLWD) (Fig. 2). As a result, GLWD limnicity at OLE (1.1%), BYK (6.8%), and CHE (0.0%) is significantly lower than in our dataset for the same lake size category (7.6%, 12.1%, and 0.2% respectively). A large percentage of the total water body area (<10 ha) that is important for hydrological and biogeochemical cycles is currently not inventoried and used in environmental modeling (not inventoried water body area per 10 000 ha land area at OLE: 42.7%, BYK: 21.6%, and CHE: 82.2%).

Discussion

Thermokarst lake distribution in our study areas seems to be strongly connected to hydrological and geomorpho-logical factors rather than to geocryology alone. At BYK, a strong thermokarst relief developed during the Late Pleistocene-Holocene transition and many first-generation thermokarst basins and thermo-erosional valleys were formed (Fig. 5A). A large number of second-generation lakes appeared during the Holocene in drained basins. OLE is dominated by a flat yedoma surface with only some thermokarst basins and valleys. Also, yedoma thickness is considerably less than at both other sites with possibly impacts on lake expansion dynamics. The poorly drained upland plain is densely and relatively homogeneously packed with a large number of first generation lakes (Fig. 5B). At CHE (Fig. 5C) the yedoma is mantling the rolling slopes around Rodinka Hill. Comparably few small water bodies occur, but proportionally many medium-sized first-generation lakes. Compared to both other study sites, lakes are less abundant, most likely due to better overall drainage. However, there are plain regions east of Rodinka Hill with the same deposits but still very low lake density.

Vegetation either growing or floating in the lake can pose a challenge for any water-land classification method, be it manual or fully automated. Careful image interpretation, field experience, and in some cases ground truthing are required. We estimate the effect of unclassified water due to vegetation on the order of <2% of the overall water body area for some lakes. Seasonal hydroclimatology can also have an effect on lake surface area especially for lakes with shallow basin topography. While many of the ponds certainly fall into this category, many of the typical thermokarst lakes in ice-rich permafrost do not. These usually have steep banks and a more pronounced basin morphology resulting predominantly in vertical lake level changes rather than lateral lake area changes during seasonal water level variations. Many of the larger lake basins have subsided tens of meters below the surrounding land surface and are surrounded by steep banks. Lake extent changes for such thermokarst lakes are more related to thermoerosion, thaw slumping, or drainage than just seasonal water level changes.

A lake change study for the study areas is still in progress. The time series of lake extent for the BYK site will range for the period from 1951–2008, providing an observational high-resolution dataset for 57 years. For OLE and CHE the time series span a period of 42 and 37 years, respectively.

Conclusions

High-resolution satellite imagery provides the opportunity to characterize the distribution of thermokarst lakes on yedoma deposits in high detail. Spatial analysis of thermokarst features plays an important role in understanding thermokarst dynamics in northern regions and impacts on the global hydrological and biogeochemical cycles. It was shown that thermokarst lake distributions at three yedoma sites differ greatly. Lake distribution is distinguishable for areas with first and second generation lakes. Our comparison with the GLWD lake dataset demonstrates the necessity to quantify northern lakes; that is, thermokarst lakes, in a much higher detail than currently available. Any quantification and upscaling of thermokarst lake-related parameters like methane emission might be biased due to the exclusion of a large number of small lakes and ponds not represented in current global databases. This highlights the need for more intense research on thermokarst distribution and lake dynamics.

The Cooling Effect of Coarse Blocks Revisited: A Modeling Study of a Purely Conductive Mechanism

Stephan Gruber, Martin Hoelzle

Glaciology, Geomorphodynamics and Geochronology, Geography Department, University of Zurich, Switzerland

Abstract

Coarse blocks are a widespread ground cover in cold mountain areas. They have been recognized to exert a cooling influence on subsurface temperatures in comparison with other types of surface material and are employed in man-made structures for ground cooling and permafrost protection. The contrast in heat transfer between the atmosphere and the ground caused by thermally driven convection in winter and stable stratification of interstitial air during summer is usually invoked to explain this "thermal diode" effect. Based on measurements and model calculations, we propose an additional cooling mechanism, which is independent of convection, and solely functions based on the interplay of a winter snow cover and a layer of coarse blocks with low thermal conductivity. The thermal conductivity of a block layer with a porosity of 0.4 is reduced by about an order of magnitude compared to solid rock. We use a simple and purely conductive model experiment to demonstrate that low-conductivity layers reduce the temperature below the winter snow cover as well as mean annual ground temperatures by comparison with other ground materials. Coarse block layers reduce the warming effect of the snow cover and can result in cooling of blocky surfaces in comparison with surrounding areas in the order of one or several degrees. The characteristics of this mechanism correspond to existing measurements.

Keywords: coarse blocks; heat transfer; mountain permafrost; rock glacier; snow cover; thermal offset.

Introduction

Coarse blocks are a common surface cover in many cold and temperate mountain ranges. They have a cooling influence on ground temperatures compared with fine-grained soil or bedrock in otherwise similar settings (cf. Haeberli 1973, Harris 1996, Gorbunov et al. 2004, Juliussen & Humlum 2008). This cooling effect makes blocky substrates interesting for construction in cold regions (e.g., Goering & Kumar 1996, Guodong et al. 2007) and it is a significant factor influencing the distribution and characteristics of permafrost (Haeberli 1975). Therefore, the understanding and quantification of this cooling effect is important for spatial modeling of permafrost, estimation of its characteristics, and assessment of its temporal evolution.

Measurements in coarse blocky substrate as well as their interpretation are faced with a number of difficulties. To begin with, it is difficult to define the surface of a blocky substrate. Point measurements are bound to either the interstitial air or large clasts and integral macroscopic properties of the blocky material, such as temperature or albedo, are difficult to determine. Similarly, on a macroscopic scale, snow is partly deposited in a volume rather than on a discrete surface because the geometric surface roughness and the depth of voids can have the same order of magnitude as snow thickness itself. Despite these difficulties, a number of processes that may be responsible for the cooling effect of coarse blocks have been proposed and analyzed (e.g., Hanson & Hoelzle 2004, Juliussen & Humlum 2008, see Herz 2006 for a comprehensive review).

These processes are: (a) free convection; (b) forced convection; (c) chimney effect; (d) evaporation/sublimation/ice melt; (e) snow deposition deep into the active layer; and (f) protruding blocks reducing the insulating effect of the snow cover. While all of these processes are plausible, little is known about their relative importance and about the dependence of this importance on environmental conditions. However, understanding the importance of each process is vital to further progress.

One way to achieve this is the joint analysis of model results and measured data. The deviation between model and measurements is bound to contain (among other errors) the error produced by not including an important process in the model. Using such experiments, we were surprised to find that the thermal conductivity of the near-surface material decisively controls ground temperatures below the snow cover. For example, the depression of winter temperatures measured on coarse block fields (cf. BTS on coarse blocks, Haeberli 1973, 1975) in the Murtèl/Corvatsch area (Fig. 1) could be reproduced with two models (TEBAL, Gruber 2005; SNOWPACK, Bartelt & Lehning 2002) that do not include the process of air movement in blocks (cf. Frey 2007). This suggests that at this site, either convection is of secondary importance after an effect related to thermal conductivity, or, that errors in both models resulted in temperature depressions similar to those measured.

In this paper we explore and describe this combined effect of near-surface thermal conductivity and snow pack using a simplified model. While subject to strong generalization with respect to the measured situation, the simple model used here allows to isolate and properly demonstrate the relevant process in a framework that is easily traceable. The cooling mechanism, which we propose, does not contradict existing and well-established research on convective heat transport in coarse blocks (e.g., Goering & Kumar 1996, Guodong et al. 2007). Instead, it offers an explanation of measured cooling where snow cover is thick and signs of significant convection are absent.

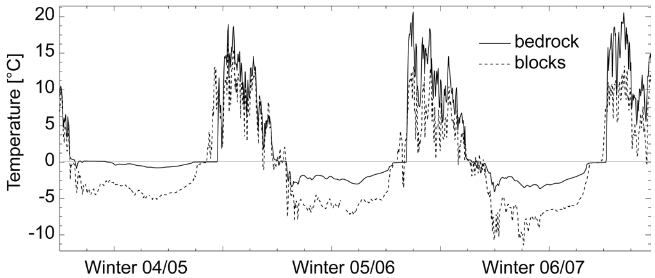

Figure 1. Near-surface temperatures at the rock glacier Murtèl. The solid line shows average daily temperatures 10 cm deep in bedrock adjacent to the rock glacier front. The dashed line shows daily temperature measurements about 50 cm deep within the blocky surface of the rock glacier. These measurements were taken around midnight and therefore have a cold bias during the snow-free time when significant diurnal amplitudes exist.

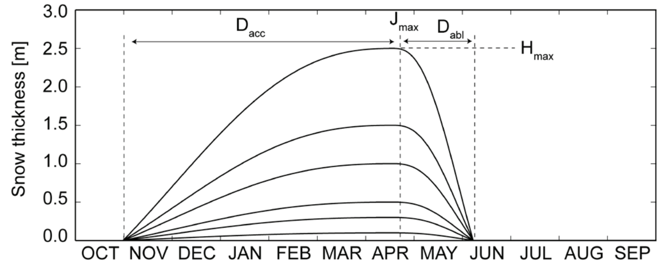

Figure 2. Synthetic snow cover evolution using H_{max} of 2.5, 1.5, 1.0, 0.5, 0.3, and 0.1 m.

Model Experiment with Synthetic Data

Based on a model experiment, we intend to illustrate that a lower thermal conductivity of near-surface material causes lower temperatures below the winter snow cover and that this also affects mean temperatures at greater depth. The model is reduced to only conductive components and effects of, e.g., water percolation or phase change are neglected. That way, this mechanism can be studied in isolation from other effects.

Model description

The model contains a finite-difference Crank-Nicolson solution of the heat conduction equation with no treatment of phase change or advective heat transport. The snow pack and the uppermost 5 m of the ground are discretized with a spacing of 0.1 m. Below, the interval gradually increases down to 15 m. The snow cover is added and depleted in steps of 0.1 m. Available model parameters are: maximum snow cover thickness (H_{max}), duration of the accumulation (D_{acc}) and ablation (D_{abl}) periods, date of maximum snow cover thickness (J_{max}), phase lag of temperature cycle (L), mean surface temperature (M), surface temperature amplitude (A), and the thickness of the block layer (B).

Equation (1) describes the temporal evolution of the snow cover thickness H (Fig. 2). The parameter Δt ranges from 0 to 1 and describes the relative distance to J_{max}, where $\Delta t=0$ at the date of J_{max} and $\Delta t=1$ at the dates of D_{acc}.and D_{abl}.

$$H = H_{\max} \cdot \left(1 - \left(\frac{e^{-\Delta t^{2.5}} - 1}{e - 1}\right)\right) \quad (1)$$

The influence of the snow cover on ground temperatures in nature has three main causes: (a) thermal insulation; (b) reduction in albedo; and (c) advection of latent heat because melt energy is required to remove the snow. In this model, only (a) is considered because the effect of thermal insulation is of interest here.

Ground properties

The snow cover has a uniform density of 280 kg m^{-3}, a thermal conductivity of $k_S = 0.13$ W m^{-1} K^{-1}, and a volumetric heat capacity of $c_S = 5.4\times10^5$. The thermal conductivity of the ground is $k_G = 2.5$ W m^{-1} K^{-1} and the volumetric heat capacities of the ground and block layers are $c_G = 1.6\times10^6$ J m^{-3} K^{-1} and $c_B = 0.8\times10^6$ J m^{-3} K^{-1}. This is based on typical rock thermo-physical properties (Cermák & Rybach 1982) and a porosity of the block layer, which is assumed to be 0.4–0.5. For the block layer, different thermal conductivities k_B are considered between that of pure rock (2.5 W m^{-1} K^{-1}) and a rather low estimate (0.2 W m^{-1} K^{-1}). The low values of thermal conductivity for the block layer are in accordance with values in the range of 0.3 W m^{-1} K^{-1} published for dry sand and for theoretical values when calculating a mixture of rock and air using the geometric mean that usually approximates random aggregates rather well.

Boundary conditions

A harmonic temperature boundary condition (Dirichlet) representing seasonal variation drives the heat conduction scheme at its upper boundary for the duration of several hundred years. This condition ($T_{surface}$) is prescibed at the snow surface during winter and at the ground surface during summer. It is described by Equation (2), where φ is the duration of one seasonal cycle (one year). Similar to conditions at Murtèl/Corvatsch, we assume M = -2.5°C, A = 10°C, L = 45, J_{max} = 105, D_{abl} = 50, D_{acc} = 170, where $D_{abl/acc}$, J and L are given in days and days of the year, respectively.

$$T_{surface} = \sin\left(-(t+L)\frac{2\pi}{\varphi}\right) \cdot A \cdot M \quad (2)$$

Results

The insulating influence of the winter snow cover increases with thicker snow cover (Fig. 3). The temperature T_0 refers to the temperature at the ground surface. Changing the thermal conductivity of the block layer modifies the warming influence of the snow cover (Fig. 4A) and, in accordance with observations (Fig. 1), lower temperatures are modeled under the snow when using lower thermal conductivities of the near-surface, which are characteristic of the block layer. During winter, the heat conduction through the snow pack is very small and, as a consequence, the heat conduction from deeper ground layers

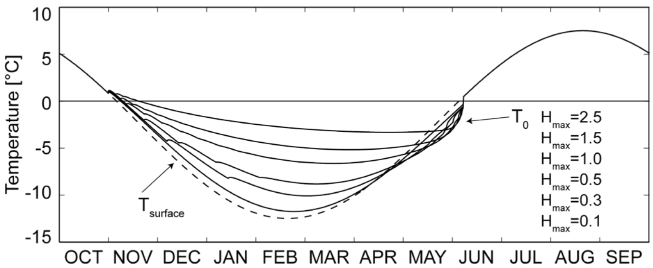

Figure 3. Temperature evolution at the ground surface during one year and for diverse snow cover conditions defined by H_{max}. All cases have a thickness of the block layer B = 3 m and a thermal conductivity of the block layer k_B = 0.2 W m^{-1} K^{-1}. The dashed line represents the prescribed surface temperature $T_{surface}$. In the cooling phase, slight kinks are visible in the temperature curve. These are unimportant artifacts from the simple modeling scheme in which discrete elements of 0.1 m are added or removed as the snow pack evolves.

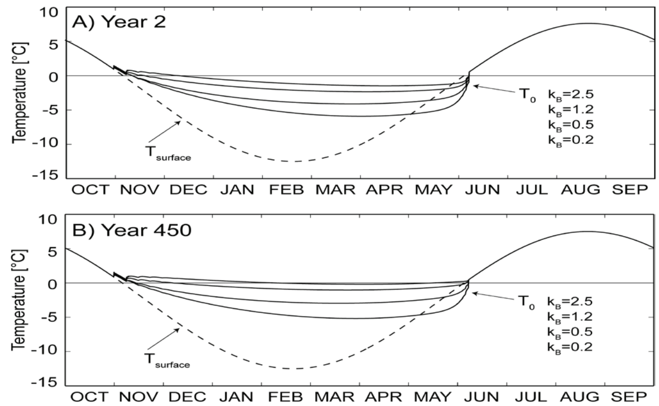

Figure 4. Temperature evolution at the ground surface during two different model years for a maximum snow thickness H_{max} = 1.5 m and a thickness of the blocky layer of B = 3 m. Different curves refer to different thermal conductivities of the block layer k_B.

dominates the temperatures at the snow/ground interface. The BTS method (Haeberli 1973) exploits this effect. If the thermal conductivity of the near-surface ground layer is significantly lower, then the relative importance of heat transfer through the snow increases and temperature at the snow/ground interface will respond more to atmospheric forcing. This is also visible in Fig. 1, where both time series contain similar temperature fluctuations in winter and where these fluctuations are more pronounced in the blocks.

It is now important to know whether this effect only results in lower temperatures under the snow cover, or, whether it also influences mean ground temperatures. In Fig. 4B we can see that over the course of about 450 modeled years, all temperatures have warmed with respect to Figure 4A, indicating exactly this effect over the longer term. This is also visible in the transient response of temperatures at 10 m depth (Fig. 5). After initialization with a temperature of M = −2.5°C and constant boundary conditions having the same mean, temperatures equilibrate at much higher levels due to the insulating effect of the winter snow. This insulating effect is modulated by the thermal conductivity of the blocky layer. These results can be explained as follows: The mean annual ground temperature (at some shallow depth) in first approximation contains a weighted average of surface temperatures. The weight and relative importance of winter temperatures in this average is reduced by the insulating effect of the snow cover (cf. Zhang et al. 2001) that impedes the heat transfer between the (snow) surface and the ground. Where the thermal conductivity of the near surface is low, the heat transfer in snow-free conditions is already slow. As a consequence, the contrast between summer and winter conditions is smaller than for situations with high thermal conductivity of the subsurface. The relative cooling effect of blocky material (compared to many other surfaces) is essentially an effect of reduced warming. This effect is a thermal filter with an effectiveness that is dependent on the thermal contrast between summer and winter conditions. A block layer reduces the overall thermal conductivity of the ground-atmosphere interface and thus reduces the contrast between summer and winter.

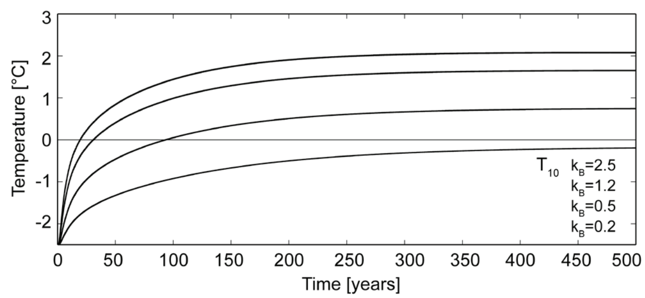

Figure 5. Temperature evolution at a depth of 10 m below the ground surface (T_{10}) during 500 model years for a maximum snow thickness H_{max} = 1.5 m and a thickness of the blocky layer of B = 3 m. Different curves refer to different thermal conductivities of the block layer k_B.

Discussion

This experiment illustrates that the temperature below the winter snow cover as well as mean annual ground temperatures at greater depth can be significantly reduced solely based on the low thermal conductivity of blocky material. The use of a one-dimensional scheme together with macroscopic properties of block layers is a challenging concept because the size of individual clasts can exceed the vertical discretization interval by far. Nevertheless, as long as the majority of clasts do not exceed the thickness of the block layer, this approximation should produce acceptable results, because the overall conductive heat transfer is impeded by the small surface of the contacts between individual pieces of rock. The comparison of modeling results with measurements, however, has to employ either spatial averaging or deeper measurements in order to average lateral variability (cf. Frey 2007, Hoelzle & Gruber 2008). Using the geometric average as an approximate mixing model (Clauser & Huenges 1995), the thermal conductivities of coarse blocks (cf. Binxiang et al. 2004) and sand should be the same because both materials have similar constituents and a similar porosity. This is only true for completely dry material because sand or other soil material usually holds significant amounts of water due to capillary forces in the more abundant small pores. This likely

Table 1. Example of the net effect of diverse near-surface layers.

Block layer thermal conductivity	Heat flux at lower boundary condition 0.0 W m^{-2}	0.06 W m^{-2}
k_B=2.5 W m^{-1} K^{-1}	4.6 °C	4.7 °C
k_B=1.2 W m^{-1} K^{-1}	4.1 (0.5) °C	4.3 (0.4) °C
k_B=0.5 W m^{-1} K^{-1}	3.2 (1.4) °C	3.5 (1.2) °C
k_B=0.2 W m^{-1} K^{-1}	2.3 (2.3) °C	3.2 (1.5) °C

Subsurface warming for a 3 m thick near-surface layer with diverse thermal conductivities and two different lower boundary conditions. The second column (zero heat flux) represents the conditions shown in Fig. 5. Warming values refer to final subsurface warming at a depth of 3 m with respect to the mean (prescribed) surface temperature (M). Numbers in brackets express this warming as relative cooling with respect to pure rock (2.5 W m^{-1} K^{-1}).

results in a distinctively higher overall thermal conductivity in fine-grained soil than in coarse material.

In many publications, the effect of ground cooling in block slopes is referred to as thermal offset, in analogy to common terminology in the Arctic. The thermal offset described in the Arctic is caused by seasonal differences in the properties of the active layer, which are due to the contrast in thermal conductivity between water and ice. This usually results in a curved temperature profile and a marked temperature difference between the top and bottom of the active layer. Convection of air would be similar to a temporary increase in the thermal conductivity and resembles this pattern. The mechanism we propose here, produces no temperature difference between the top and bottom of the active layer, and this behavior corresponds with several existing measurements (Juliussen & Humlum 2008, Hoelzle & Gruber 2008).

A block layer of very low thermal conductivity results in a strong thermal gradient with depth in the presence of a geothermal heat flux. This effect can reduce the relative ground cooling (Table 1) and varies with the thickness of the block layer and with the heat flux across it. In mountain areas, the deeper heat flux is usually reduced (Kohl 1999) and spatially highly variable (Gruber at al. 2004). Additionally, the advection of subsurface ice (moving rock glacier) and transient effects can reduce or even invert the heat flux in the uppermost tens of meters.

The effect of reduced warming by the snow cover as proposed here does not preclude the presence of additional processes that lead to relative ground cooling. Depending on environmental conditions, other processes may even be more important. The most prominent other process that is described in the literature is the circulation of air caused by temperature-driven free convection. This effect and the effect proposed in this paper are complementary in some way: conditions of little snow cover favor the effect of advection and reduce the purely conductive mechanism described here, whereas a thick snow cover inhibits convection and gives rise to the full effect of low thermal conductivity. Conditions may vary on a continental scale (low/high precipitation areas), locally (wind-swept ridge or snow-filled depression) or with time (dry winter, climate change). Because the proposed effect is "relative cooling by reduced warming," it cannot result in ground temperatures significantly below the MAAT as has been observed for block surfaces with strong air movement (e.g., Gorbunov et al. 2004, Delaloye et al. 2003).

Conclusion and Outlook

We have presented a simple and purely conductive mechanism that can cause lower temperatures at the snow/ground interface as well as lower mean ground temperatures in coarse blocky surfaces as compared to bedrock or fine-grained material. This mechanism is not an alternative but rather an extension of existing theory, and it can at least partly clarify previously unexplained measurement results.

The quantitative understanding of the influence of each proposed mechanism and its sensitivity to material properties and environmental conditions is an important topic for future research. This will determine, for instance, which processes have to be included in a specific model and which are of secondary importance, only. The creative combination of both modeling and measurements is expected to be a viable means to achieve this. Additionally, methods for the delineation of block fields (cf. Heiner et al. 2003, Gruber & Hoelzle 2001) are important because this can strongly improve the quality of simulations, even with simple methods.

Acknowledgments

We are grateful to S. Bircher and E. Frey who contributed to the ideas presented here with their MSc theses as well as many discussions and experiments. Three anonymous reviewers have provided valuable feedback—the question of the lower boundary condition being our favorite by far.

Interrelation of Cryogenic and Hydrologic Processes on Small Streams and Catchments of Central Yamal

A.A. Gubarkov
Tyumen Oil and Gas University, Tyumen, Russia
M.O. Leibman
Earth Cryosphere Institute SB RAS, Tyumen, Russia

Abstract

Small streams of the Yamal Peninsula provide the best opportunity to study the interrelation of cryogenic and hydrologic processes. A case study on the test river Panzananayakha was undertaken to assess catchment morphogenesis, water flow, and sediment transport in relation to cryogenic processes. Which dominating cryogenic processes most affect the river channel depends on channel morphology. In V-shaped valleys the low valley slopes end directly in the channel, and the influence of cryogenic landsliding on hydrologic processes dominates. Ice wedges close to the surface produce bead-shaped channels that slow the stream velocity. Cryogenic processes directly affect sediment transport as well. The complex cryogenic and hydrologic processes which are characteristic for upper, middle, and lower stream courses in the small catchments are specified. Channel processes include bottom and lateral thermoerosion. Trans-catchment processes include transitional landslides, earth flows, and ravine thermoerosion.

Keywords: bead-shaped channel; cryogenic processes; hydrologic processes; landslides; thermoerosion.

Introduction

More than 90% of the rivers in tundra regions can be considered as small rivers less than 10 km in length. These small rivers comprise more than 80% of the total length of all rivers. Small rivers in the cryolithozone are characterized by the interaction and interrelation of cryogenic and hydrologic processes. These processes result in specific valley slopes and bottom shape, stream mode and transport of sediments. The same scale of cryogenic and hydrologic processes in these small catchments is the main reason for such a relation. On middle-length and long rivers, the impact of cryogenic processes on a channel is not observed as the mass waste processes are not capable of changing the stream direction, or creating a full or even partial damming of the water flow.

The main cryogenic process affecting water and sediment runoff of these small rivers is thermoerosion, cryogenic landslides (active-layer detachments and earth flows), and thermokarst.

Thermoerosion studies have been carried out since the middle of 19th century. The Yamal Peninsula is discussed in numerous publications including: Kosov & Konstantinova (1973), Malinovskiy (1980), Dan'ko (1982), Sidorchuk (1999), Voskresensky (2001). Typically thermoerosion occurs only at the end of summer or in the fall when the active layer reaches its maximum depth. Dan'ko (1982) suggests that thermoerosion is possible during different periods of warm time of the year. Malinovskiy (1980) measured the ability of water flow to carry sediment load and bottom sediments under thermoerosion and found typical values of 700 g/l.

Sidorchuk (1999) conducted observations on the Bovanenkovo gas field at Central Yamal in 1987–1995 and found the hydrologic and morphometry factors of ravine erosion and thermoerosion in both natural and anthropogenic environments. Voskresenskiy (2001) emphasized the need to consider the complex interactions between thermoerosion and thermokarst. These studies showed an obvious relationship between the density of ravines and thermokarst distribution on the Yamal Peninsula.

The interrelation of thermoerosion and thermokarst is also discussed by Romanovsky (1961) who concluded that lake thermokarst and thermoerosion in alases result in a united system of erosion-thermokarst depressions, through which runoff of water and sediment takes place. Romanenko (1997) studied tundra lakes in the Siberian Arctic. He has showed that the proportion of erosion-thermokarst lakes at the Bovanenkovo gas field is maximal in all of northern Siberia and accounts for 15% of the total lake distribution of this region.

Study of the cryogenic landsliding (Leibman & Kizyakov 2007) shows that the greatest influence on water and sediment runoff, and the evolution of channels and valleys of small rivers is induced by landslides (both active-layer detachments and earth flows). Important features of landslides are the speed of descent, volume of the landslide body, and position on the valley slope. This last feature determines whether the landslide body has the potential to block the valley and small stream channel, and therefore, creates a temporary lake in the stream channel or valley. The duration of cryogenic landslides varies from several hours to minutes, while the lifetime of a resulting dammed lake depends on the time needed for the stream to cut through the dam formed by the landslide body. One directly observed dammed lake drained 11 years after a landslide event.

The level of activity of the erosion, transport and accumulation during the warm period in relation to a complex of natural factors can vary considerably from year to year. As determined from theoretical assumptions, laboratory tests and field observations, thermoerosion is most active in the

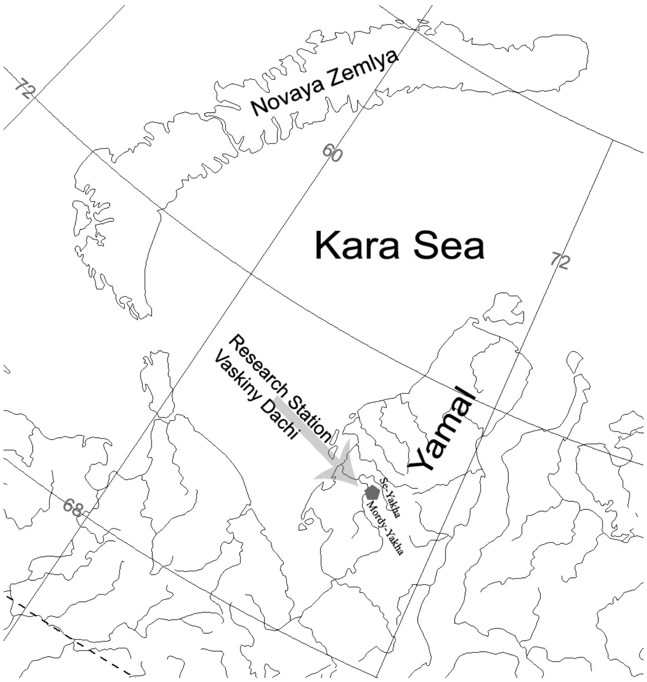

Figure 1. The study area on Central Yamal in the vicinity of Research station Vaskiny Dachi.

summer-fall, when air temperature and , water temperature are the highest. The heat energy of the flow is enough to melt permafrost under such conditions. This is especially true in cases where there is sufficient energy of flow to erode the thawed active layer soils first. However on Central Yamal in summer-fall, the slopes are protected by vegetative cover and thus are hard to erode. The active layer deposits consolidate and aggregate with time while the thaw depth increases, reducing the ability of the erosion of the active layer as well as underlying permafrost. Erosion of sands is easier compared to clayey and organic soils but the active-layer depth in sands is much higher. Consequently to promote thermoerosion in permafrost, intensive rains are required to provide the power of flow sufficient to erode the active-layer deposits. According to Russian Hydrometeorological Service records very intense rainstorms in these tundra regions occur once in 30 years, and intense showers occur only once in 10-20 years. More typical are drizzling rain, which do not increase streamflow sufficiently to allow intensive thermoerosion. Thermoerosion in summer-fall period most likely occurs in interrelation with cryogenic landslides and thermal denudation or other slope displacements forming cracks or bare surface.

Methods and Study Area

Both remote-sensing and land-based data were used to obtain information on cryogenic and hydrologic features in the study area. Both 1:25000 topographic maps and 1:10000 aerial photos were digitized and interpreted. Interpretation included counting and measuring both hydrological and cryogenic features. These features were then evaluated by field measurements.

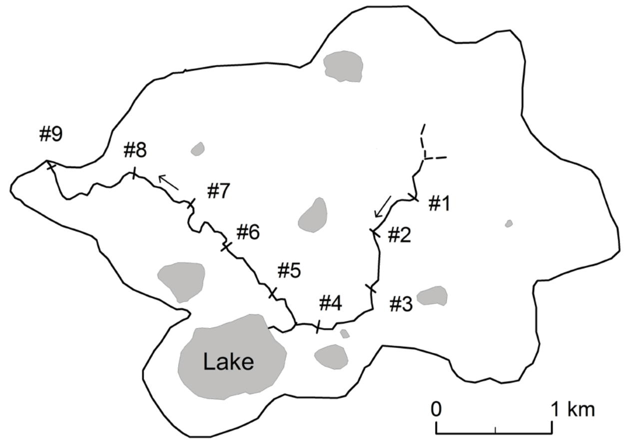

Figure 2. Panzananayakha river catchment. Numbers refer to section lines where water discharge was measured.

The test river Panzananayakha, which is 7 km in length and has a catchment area of 8 km^2, is representative of small rivers of the Central Yamal as shown from analysis of maps of various scale and field studies in the basin of Se-Yakha and Mordy-Yakha rivers and their tributaries. Average river length in this region is 5.99 km.

Land-based studies were used to determine features of beam-shaped river-channel forms, including width, length and depth, as well as stream velocity. Turbidity was measured in both middle and small sized rivers. This was done by water sampling, filtering, drying, and weighing the dried solids.

Field studies at the research station “Vaskiny Dachi” (Fig. 1) were undertaken in 2005–2007, considered the regime and morphology of temporary non-channel and channel streams, small rivers with catchment area under 10 km^2, and a middle-length river (catchment area about 3000 km^2).

The temporary non-channel and channel streams were located on 25 shear surfaces of landslides, in 3 thermocirques, and 3 ravines. Channel features, as well as water and sediment runoff were observed in 4 small and 1 middle-length rivers. On the Panzananayakha test river, all morphometry features of its channel, including landslides, thermokarst forms, erosion, and hydrology were measured (Fig. 2). In addition, alternation of erosive and accumulation zones, and channel shape along the crosscuts were studied in the test river valley.

Results and Discussion

In some years, the slope erosion in the spring may account for up to 75% of annual erosion (Dan’ko 1982). This suggests that most of the erosion is confined to frozen deposits (thermoerosion), including both active-layer deposits and permafrost that are in a frozen state. In the late summer–fall period, as mentioned above, thermoerosion and erosion are limited by active-layer properties and vegetative cover. However, according to our observations, the processes of cryogenic landsliding promoting thermoerosion and erosion events are most active during this period.

Table 1. Depth of shear surface against surrounding slope, and depth of thermoerosion landforms against the landslide shear surface at the upper, middle and lower portions of the landslide slope.

After landslide shear surfaces are exposed, they are susceptible to heavy erosion and thermoerosion, and as a result a significant quantity of sediments are often delivered into the stream network (Leibman & Streletskaya 1997). Under the influence of temporary stream erosion/thermoerosion, troughs develop in a specific sequence. We subdivide these into three zones of down slope thermoerosion: sediment mobilization (upper), sediment transition (middle), and sediment accumulation (lower). All three zones are developed only when the landslide body entirely moves away from the shear surface.

Cross-sections were set and slope morphology measured in the upper, middle, and lower portions of slope. Results are presented in Table 1.

Analysis of Table 1 shows that there is a relation between the depth of thermoerosion against the landslide shear surface and the depth of shear surface against the surrounding slope or hilltop edges. This relation is directly proportional in the sediment mobilization zone, and inversely proportional in the accumulation zone as shown on cross-sections of the landslide shear surfaces and erosion troughs (Fig. 3). In the upper portion of the landslide shear surface, the increase of the erosion trough depth is observed when landslide shear surface is deeper than the slope surface. This is due to the higher relief potential energy when the shear surface is deeper. At the same time, runoff from the catchment does not contain a high sediment load due to the vegetation coverage. That is why the erosional ability of the water flow in the sediment mobilization zone of a landslide shear surface is the highest.

In the lower portions of the landslide slope, the depth of the erosion troughs is less when the shear surface is deeper. This is a result of increased input of sediment from the higher shear surface rim. For this reason, maximum runoff observed in the lower portion of the shear surface performs minimal erosion because the sediment load

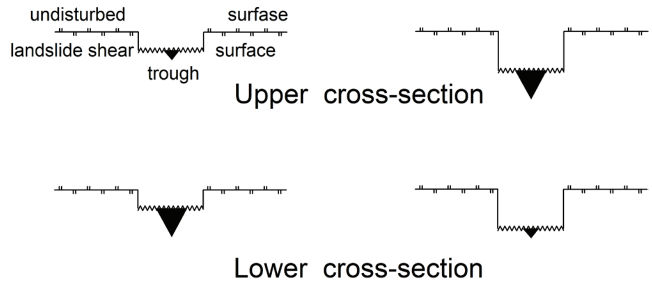

Figure 3. Erosion/thermoerosion trough in relation to the depth of cryogenic landslide shear surface cut into a slope surface in the zones of sediment mobilization (upper cross-section) and sediment accumulation (lower cross-section).

exceeds the potential eroding ability of the water flow.

In the middle portion of the slope, the depth of the shear surface cutting does not affect the erosion trough depths because up slope and down slope patterns compensate for each other.

Water runoff is higher here than at the upper cross section but erosion potential is used to transport larger sediment load (Fig. 3).

The most pronounced combined effect of cryogenic and hydrologic processes is the formation of thermoerosion pits and "tunnel thermoerosion" (term introduced by Poznanin 1995) in headwater gullies. Our observations are generalized in Figure 4. At the initial stage of snowmelt at the gully headwater, water flow and thermoerosion occur (Fig. 4, I). During melt, a thermal pit forms at the uppermost point of the headwater. These pits gradually increase in depth. Our measurements show that the depth of thermal pits changes from 2 to 6 m. Since the active-layer at the gully slopes is typically oversaturated with meltwater, they often start to creep, resulting in the formation of an earthflow. The snow surface may be dammed by the landslide mass, and thermoerosion may continue beneath the snowpatch undersurface as tunnel erosion (Fig. 4, II). It often takes 5–10 days for the landslide mass to cover the snow patch surface, and therefore exclude surface runoff. Finally the water-cut pit may be filled by collapsed pit walls and landslide masses so that runoff is forced back to the surface (Fig. 4, III). The entire cycle of thermal pit-tunnel thermoerosion process starting with spring snowmelt takes approximately one month.

In the upper cross-section (Fig. 4, I–III-A) both the depth and width of the gully can change from stage I through to stage III. However, in the lower cross-section (Fig. 4, I–III-B) only the width of the gully increases with time and the proportion of snow and silt deposits on top the snow change, with the ratio of snow decreasing.

River sediment transport is affected by processes in the inflowing ravines. In the ravine networks, the influence of erosion and thermoerosion on the river sediment transport is determined by the river length. The shorter the river, the greater the impact. Turbidity of the river may change twice depending on the remoteness of the inflowing ravine. This effect is much less significant in the middle-length rivers. For instance, our measurements in Se-Yakha river, a middle-

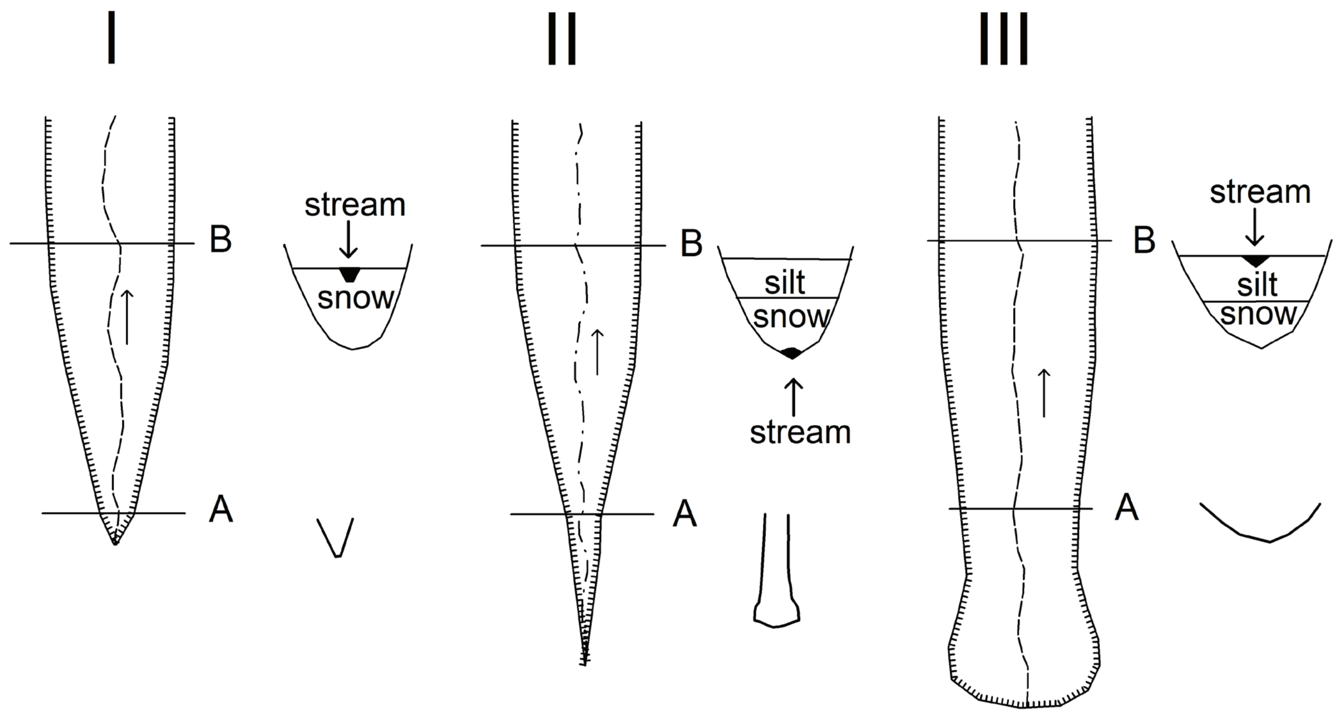

Figure 4. Stages of gully development and formation of thermoerosion water-cut pit: I, initial period of snowmelt on top of the surface of snow patch in the gully; II, the period thermoerosion water-cut pit formation and of meltwater flow below the snow patch; III, collapse of thermoerosion water-cut pit walls; A, plan (left) and cross-section (right) in the upper course of the gully; B, the same in the lower course.

length river in Central Yamal, showed that at the end of August 2007 turbidity was as high as 90 g/m^3, which is several orders of value higher than sediment runoff measured at the same time in the majority of small rivers-tributaries of Se-Yakha.

The cryogenic factors not only increase the sediment runoff, but also reduce it. Reduction of the sediment runoff in small rivers occurs when bead-shaped and dammed river channel features are formed. These can result first from polygonal structures and second from landsliding. In the upper stream of Panzananayakha river in August 2007, sediment runoff was as high as 5120 g/m^3 resulting from activation of erosion and thermoerosion. But in the middle course, sediment runoff reduced to 3 g/m^3 because of precipitation of sediments in the bead-shaped features. Analysis of aerial photography allows us to conclude that for the majority of small rivers with active cryogenic processes at the river banks sediment fans are formed at the ravine mouths, and landslide bodies often descend to the valley bottom and into the channel. Erosion and thermoerosion fans are comparable in size with the width of the valley bottom and river channel, and the lifetime of these fans is longer when compared to dammed lakes resulting from landslide activity.

Dams formed out of landslide bodies loaded in the valley bottom and small river channel may be 2–3 m high. They prevent any sediment transport downriver. After the dams' breakout on former flooded valley bottom, sheet runoff prevails over linear runoff that does not promote erosion, and also slows the sediment transport. The upper course of the test river Panzananayakha and river Halmeryakha at the study area show such features.

Mouth areas of small rivers inflowing into bigger rivers are separated from the river channel of a higher grade by the flood plain with numerous lakes. So, on the way to this channel small river sediment load precipitates within the flood plain lakes.

In small river catchments interrelation of channel and cryogenic processes is common. Depending on slope gradient, lengths and shape, as well as cryogenic features, different cryogenic slope and thermokarst processes are controlling the river runoff.

Small rivers with intensive linear and side erosion trigger landsliding to produce dammed lakes. The lifetime of these lakes is several years, thus prolonging the water cycle time by two to four orders of magnitude (Tab. 1). Thus on small streams even a single landslide event may affect river runoff for several years.

Polygonal ice-wedge features occurring close to the surface and subject to thermokarst, produce bead-shaped channels which last much longer compared to the dammed lakes. Being larger in volume, these channel features have a major impact on the water cycle. They reduce water runoff in the channel by three to four orders of magnitude as follows from measurements presented in Table 2.

Cryogenic processes determine the particularities of the sediment transport through the channel depending on their location at the upper, middle or lower course. Cryogenic landsliding at the upper course expose surface deposits which are eroded into the channel. Prior to the removal of dammed lakes, as mentioned above, the sediment load settles in these lakes, but after the dammed

lakes drain the sediment is transported downstream to fill in the bead-shaped forms of the middle course. In the lower course though there are no bare surfaces produced by landsliding, the water discharge is much higher than in the upper course, sediment load is reduced by middle-course bead shaped forms, so that the water flow can produce both thermokarst and erosive work in the lower course. Bead-shaped forms appear due to heat transfer, and sediment runoff increases due to erosive work in the sides and bottom of the valley. As a result, bead-shaped forms are filled in with the sediment and their depth reduces downstream as measured in the lower course of the test river (Fig. 5).

Conclusions

Interrelation of hydrologic and cryogenic processes in the small river catchments differs spatially. Valley slopes can be subdivided by temporary streams and small river banks and channels in the upper, middle and lower portions of the river valley. Activity of the erosion and thermoerosion in temporary stream network on slopes of the river valleys is determined by domination of landslide processes. Concave bare or sparsely vegetated landslide shear surfaces concentrate water runoff into temporary channels that are easier to erode. Hydrological processes depend on the position against the landslide headwall and on the depth of shear surface cutting into the surrounding slopes. Temporary streams on landslide affected slopes are important sources of sediment runoff in the small rivers.

In a small river catchment, interrelation of the hydrologic and cryogenic processes occurs in many locations. Depending on the catchment morphometry, the dominating cryogenic process affecting the river channel differs. In the V-shaped valley slopes, the influence of cryogenic landsliding on hydrologic processes dominates: dammed lakes are formed, which may exist from many years and increase the storage time of the water cycle.

In the U-shaped valleys, ice wedges are found close to the surface, and bead-shaped channels are formed. These bead-shaped channels may slow down the water cycle in the streams, exceeding the effect of dammed lakes as bead-shaped channels occur more regularly. All together they store a greater volume of water, and may exist much longer.

Cryogenic landsliding results in the active sediment washout from the exposed landslide shear surfaces into a channel, and the "bead" forms, occurring on adjacent portions of the channel are filled with these sediments. However when landslide bodies still dam the channels, they interfere with sediment transport and thus promote longer existence of bead-shaped channels downstream.

The complexes of cryogenic and hydrologic processes, characteristic for upper, middle and lower stream courses in the small catchments are: (1) a landslide complex in the upper course with subsidiary bottom thermoerosion and the prevalence of accumulation instead of sediment erosion; (2) thermokarst complex of the middle course with an equilibrium of accumulation and sediment erosion; and (3) thermoerosion complex of the lower course with subsidiary thermokarst, and a prevalence of sediment erosion over sediment accumulation.

Cryogenic and hydrologic processes are important drivers in the formation of the Arctic landscapes. Therefore, understanding the interrelation of these processes is a prerequisite for successful maintenance of infrastructure in the Arctic.

Abstract

Signy Island was one of the first Antarctic locations to be the subject of a detailed periglacial landform study which was completed in the 1960s. Several periglacial features such as patterned ground, block stripes, and gelifluction lobes have been analysed and monitored. More recently, the relationships between different vegetation coverage, soil type, and the underlying permafrost have also been studied. In this paper we present a geomorphological map of Signy Island that has been mapped with particular reference to the occurrence of periglacial landforms. Geomorphological features were mapped at 1:10,000 scale during the austral summer of 2004/05. A highly simplified permafrost model (PERMDEM) based on the digital elevation model and the air lapse temperature have been here presented and tested by comparing the distribution of some periglacial features together with thermal profiles and trenches excavated in the main geomorphological areas of interest.

Keywords: gelifluction; Maritime Antarctica; modeling; patterned ground; periglacial features; permafrost.

Introduction

Studies of permafrost distribution in Antarctica have recently been developed through the IPY–ANTPAS initiative and other linked research programs (Bockheim et al. 2008). Nevertheless in the South Orkneys, as in other parts of the maritime Antarctic, permafrost is still poorly understood. As far as we are aware, no permafrost maps of Maritime Antarctica have been produced, although some papers have presented information related to permafrost distribution such as; models of net radiation balance (Vieira & Ramos 2003), permafrost thermal profiles (e.g., Chen 1993), and active layer thermal regimes (Ramos & Vieira 2003, Cannone et al. 2006, Guglielmin et al. in press). Periglacial landforms have received more attention resulting in the production of maps for the South Shetlands (e.g., Serrano & Lopez Martinez 2000, Serrano et al. 1996, Zhu et al. 1996) and other islands (i.e., Mori et al. 2007, Strelin & Sone 1998). Investigations by Chambers (1966a, b, 1967, 1970) into periglacial processes such as frost heave, frost creep, and solifluction would have benefited from both permafrost and periglacial geomorphology maps. Signy Island, South Orkney Islands, provides a unique opportunity in Antarctica to compare new data on the active layer thermal regime with previous Signy Island data collected in 1963 by Chambers (1966b).

The main aims of this paper are to provide a preliminary permafrost and periglacial map of Signy Island and to analyze possible relationships between the mapped periglacial features, permafrost distribution, and some climatic factors such as air temperature, global radiation, and snow cover.

Study Area

Climatic and geological constraints

Signy Island (60°43′S, 45°38′W) in the South Orkney Islands is located in the maritime Antarctic and is characterized by a cold oceanic climate with a mean annual air temperature of around -3.5°C; mean monthly air temperature above 0°C for at least one, but up to three months each summer; and annual precipitation of around 400 mm, primarily in the form of summer rain and cloud cover of 6–7 okta year-round. The climatic records indicate a progressive warming of air temperatures of 2°C ± 1 over the past 50 years (Turner et al. 2005).

The substrate is mainly quartz-mica-schist, although in some parts of the island there are small marble outcrops (Matthews & Maling 1967). Half of the island is covered by an ice cap that is currently rapidly shrinking.

Glacial evolution

According to Sudgen & Clapperton (1977), during the Last Glacial Maximum (17,000–18,000 years BP) Signy Island was completely covered by the South Orkneys ice cap with the former coastline extended to the actual 130-150 contour b.s.l. The reduction of the ice cap has not been investigated in detail although some authors indicate a major period of shrinkage between 9000 and 6000 years BP (e.g., Nakada & Lambeck 1988), while others suggest that the disappearance of the ice cap occurred some time before 7000 yr BP (Herron and Anderson 1990).

Deglaciation has been confirmed by lake formation dated

Figure 1. Location of the study area. The black dot indicates the CALM grid. The black thick line indicates the extent of the glacier in 2004.

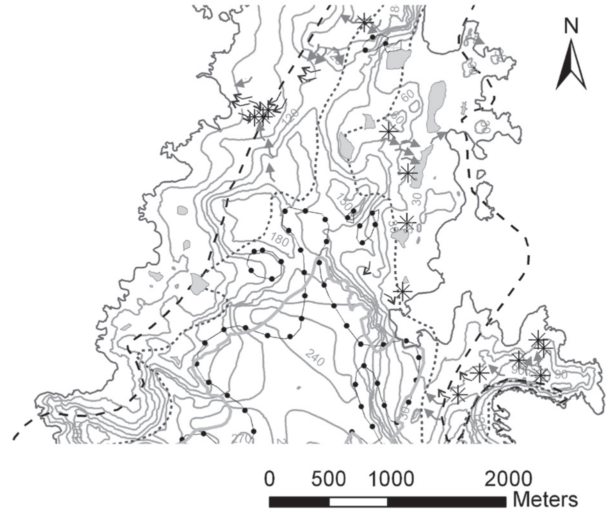

Figure 2. Geomorphological sketch of the center part of the Signy Island. Legend: 1) rock glacier; 2) gelifluction lobes; 3) soil stripes; 4) patterned ground; 5) glacier boundary 5000–3000 BC; 6) glacier boundary 400–600; 850–1000; 1150–1300 AD; 7) glacier boundary 600–850; 1000–1150; 1300–1450 AD; 8) extent of the glacier in 2004. The glacier limits at point 5–7 are suggested by Smith (1990).

between 5890 ± 60 14C yr BP at Heywood Lake and c. 5700 yr BP at Sombre Lake (Jones et al. 2000) and later by the oldest moss banks developed at c. 5500 yr BP (Smith 1990). During the middle and upper Holocene, different phases of cooling and warming occurred as established by proxy data. Radiocarbon data from the moss banks indicate several glacial advances between 1250 and 1600 AD and two advances between 1700 and 1850 AD (Smith 1990). Paleolimnological studies carried out particularly on Sombre and Heywood lakes suggest a different Holocene evolution characterized by cool conditions and slow sedimentation and colonization rates between c. 5900-3800 yr BP, followed by evidence for a late "Holocene climate optimum" (c. 3300–1200 yr BP) and finally a cooling period (Jones et al. 2000). More recently there is evidence of a strong reduction in size of the glaciers with an increase in new deglaciated areas of 35% between 1949 and 1989, (Jones et al. 2000) and an even faster shrinkage in the last 20 years.

Permafrost distribution and periglacial landforms

Permafrost on Signy Island was considered discontinuous by Chambers (1966b) with variable active layer thicknesses ranging from 40 cm in moss sites to more than 2 m in well-drained coarse deposits.

Most of the island is covered by cryptogamic vegetation which has a distinct influence on the ground surface temperature (GST) and also in some cases on the active layer thickness (Cannone et al. 2006, Guglielmin et al. in press).

During the austral summer of 2004/2005 a permanent CALM grid (40 x 50 m with the nodes every 10 m) was installed under the auspices of the framework of the project "Permafrost and Global Change in Antarctica II (PGCAII)" established by the Insubria University and the British Antarctic Survey (BAS) with logistical support by PNRA and BAS. An automatic station monitored the temperature of the active layer at 4 different points within a CALM grid located on a flat summit behind the Signy research station (Fig. 1). The system also recorded the main climatic elements at the site.

Despite the clear and innovative studies on the periglacial processes involved in the production of sorted and unsorted circles, sorted stripes and "stone streams" carried out here in the 1960s by Chambers (Chambers 1966a, b, 1967, 1970) few geomorphological studies have been conducted since. However there have been a few studies investigating weathering processes (e.g., Hall 1986, 1987, 1988, 1990).

Chambers emphasized in his works that only the upper part of the active layer (40-60 cm) was involved in sorting, gelifluction, and ice segregation.

Methods

During the austral summer of 2004/2005, two of the authors made a geomorphological survey of the island at the scale of 1:10,000 with particular attention to the periglacial and permafrost features. Transversal trenches were dug at the site of some selected periglacial features to explore their internal structure and to sample soils and underlying deposits.

Additionally, some trenches and pits were excavated to measure the active thermal profile and describe the main soil characteristics in different geomorphological areas and in different quaternary deposits.

Each trench and pit was included in a GIS system with the geomorphological map. Boreholes were drilled down to 2.5

m at Spin Drift Col and on the upper part of the Backslope close to the Signy research station (Fig. 1) to sample frozen ground. The digital elevation model (DEM) developed by BAS has a pixel of 7.5 m.

The permafrost model (PERMDEM) has been developed to obtain a mean annual GST (MAGST) using the available DEM of the island as an input to produce a map of the mean annual air temperature (MAAT) and a map of the global annual radiation (direct plus diffuse short wave).

The first map was achieved by applying the adiabatic lapse rate calculated between the only two available automatic weather stations (AWS) (Fig. 1). The lapse rate for 2006 was 0.011°C/m.

The solar radiation analysis tools calculate insolation across a landscape or for specific locations, based on methods from the hemispherical viewshed algorithm (Rich 1990), as further developed by Fu & Rich (2002). The total amount of radiation calculated for a particular location or area is given as global radiation.

Considering that snow/ice-free ground surfaces suffer GST almost always warmer than the air temperature we used the annual global radiation map (calculated for 2006) to compute a correction factor *Ir* to add to the obtained MAAT value according to the equation:

$$MAGST = MAAT + Ir \qquad (1)$$

where *Ir* is calculated as the regression between the difference ΔT (MAGST-MAAT) of two monitored points of the CALM grid (bare grounds) and the global annual radiation compiled in the same points.

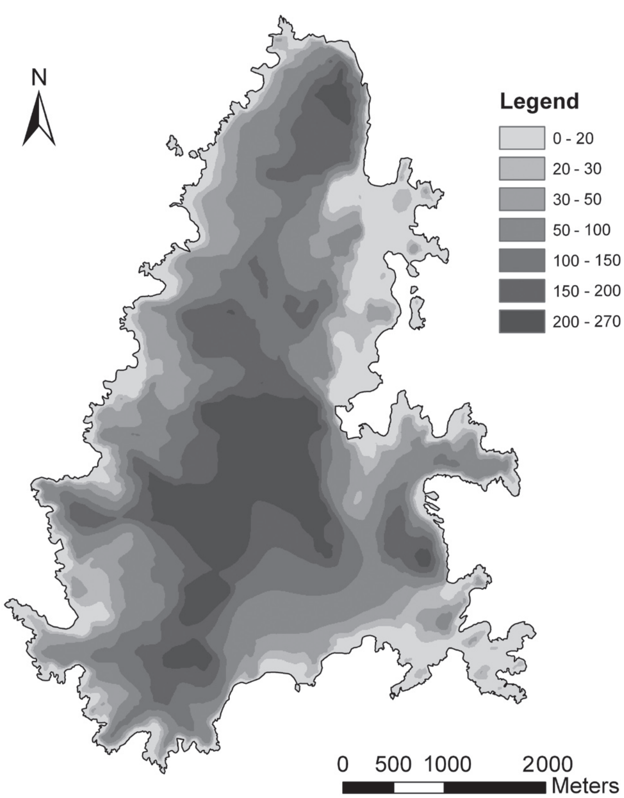
Finally, the permafrost map was tested comparing the obtained modeled results with the temperatures measured in the excavated trenches and in the monitored boreholes.

Results

Geomorphological mapping

An example of a very simplified geomorphological map is shown in Figure 2. The symbols that represent periglacial features (patterned ground; soil stripes; gelifluction lobes) indicate the areas in which more than 10 single features occur. Neither patterned ground nor soil stripes are differentiated between sorted and unsorted in this simplified sketch. In the field, low-centered sorted circles, sorted stripes and stone-banked lobes are the most widespread. Low-centered sorted circles are the most widespread form of patterned ground and show a high level of size variability with diameter ranging between 2 and 5 m.

Low-centered sorted circles occur preferentially in flat and depressed areas at altitudes lower than 80 m. High-centered sorted circles are less frequent than smaller ones (ranging between 10 and 150 cm) and generally occur on flat summits at higher altitudes. Unsorted circles occur quite often and generally have a size similar to the high-centered sorted circles, but do not show a clear distribution pattern. In some depressed and peaty areas, frost boils also occur with a diameter of between 0.2 and 0.7 m. No ice wedge



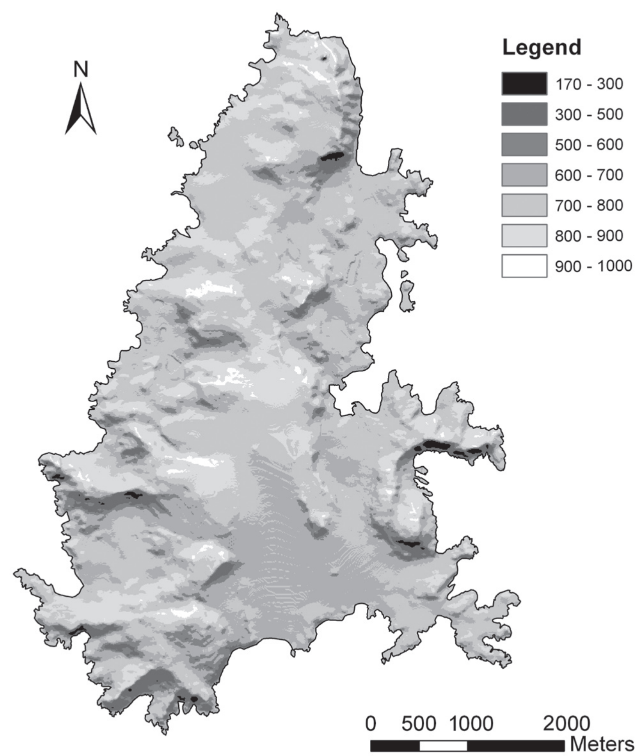


Figure 3. a) DEM classified according the elevation (m a.s.l.); b) global radiation (W/m^2) for the austral summer 2005/2006 (December 2005–February 2006).

polygons or sand wedge polygons were found. Only some poorly defined frost fissure polygons occur on the flat and highest ice-free areas of the island. Soil stripes are mainly sorted with a width ranging from 10 to 210 cm at the same site. Soil stripes are developed on glacial till and on colluvial deposits with slopes greater than 4°-6°. Transitional features from low-centered circles to sorted stripes are also present. Usually the coarse bands are raised with respect to the fine ones although sometimes can occur the opposite as unsorted stripes can occur very close to the sorted ones. Also soil stripes frequently end with low lobes (less than 1 m).

Gelifluction lobes are the most common periglacial feature which often occur on the same slope with a high variability of shape and dimension from stone-banked terracettes to lobes and stone streams (in Chambers *sensu*) and sometimes combine to form sheets. The gelifluction features are almost all stone-banked and develop on a wide range of slopes, but always greater than 4°-5° and show frontal ramps between 0.5 to 3 m in height. On the western side of the island moss-banked lobes which can be over 3 m high at the frontal ramp are quite widespread.

Only one active rock glacier has been detected on the island just northward of Sombre Lake. The rock glacier shows a convex profile along the flow direction and a very steep frontal scarp indicating the presence ice within it.

Permafrost distribution and modeling

PERMDEM is a very simplified model (derived by PERMACLIM, Guglielmin et al. 2003) which uses available climatic data (air temperature) and data automatically

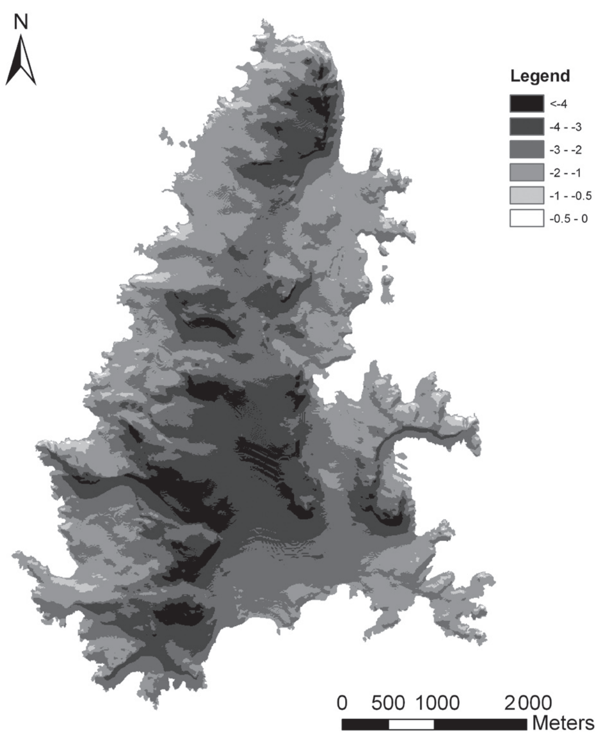

Figure 4. PERMDEM map of the Signy Island. The results MAGST are always negative, and only in less than 0.2% of the total area MAGST is between 0 and -0.%°C.

achievable by DEM that can influence the GST and consequently the permafrost distribution.

Figure 3 shows the DEM (classified according to the altitude 3a) and an example of the global radiation for the austral summer of 2005/2006 (3b).

From these layers and applying equation (1), a MAGST map has been obtained (Fig. 4). This model shows that permafrost conditions in 2006 (MAGST < 0°C) occur over the entire island from the sea shoreline upward. The model also shows that aspect and slope are important factors when considering global radiation and therefore the radiative balance and the energy balance of the surface. The major part of the ice-free areas of the island have a MAGST between -1°C and -2°C (41%) and between -2° and -3°C (34%), while only 4% have a temperature greater than -1°C.

The known effects of vegetation cover (Cannone et al. 2006, Guglielmin et al. in press) are not considered here, but the extensive cover of some mosses like *Sanionia* can significantly cool the surfaces. In contrast, the widespread black lichens (*Usnea*) and the patchy grasses can warm the surfaces compared to levels predicted by the model. Moreover, due to a lack of data on snow cover, thickness, and permanence on the island, its effect is also disregarded. The estimation of the snow cover from the preliminary observations of the available aerial and satellite images is difficult due to the high degree of cloud cover present for the majority of the time. From historical records and field data the depressions on the west side and on the south side of the island have the maximum snow accumulation and are more protected from the catabatic winds coming from Coronation Island. In 2006 the CALM grid remained completely snow free for all of the year suggesting that, at least for the year under study, the surface energy balance was not influenced on the exposed summit of the island and reasonably on the northward slopes.

The trenches carried out between December 2004 and the beginning of January 2005 had a target depth of 1 m. In several cases it was not possible to achieve this depth because (a) the water flow above the frost table filled the trench or (b) the presence of large boulders which prevented the holes from being dug. In the case of (a) above and where trenches could be dug to 1m depth, the frost table was found to be between 20 and 60 cm in depth. In all other cases, the 0° isotherm depth was estimated from the thermal profile according to Guglielmin (2006) and was estimated to range between 50 and 250 cm. Where the trenches were deeper than frost table, ice-cemented permafrost and subordinately ground ice (segregated ice) was found.

Discussion and Conclusions

The field excavations and the permafrost model indicate that permafrost does occur everywhere, although the periglacial features occurring on Signy Island do not provide conclusive evidence of permafrost because there is a lack of permafrost indicators such as ice wedge or sand wedge polygons and frost mounds. The gelifluction features do

Table 1. Distribution of the investigated periglacial features respect the MAGST classes calculated by PERMDEM for 2006. Legend: 1) -1<MAGST<1.5; 2) -1.5<MAGST<-2; 3) -2<MAGST<-2.5; 4) -2.5<MAGST<-3; 5) -3<MAGST<-3.5; 6) -3.5<MAGST<-4.

	N	1	2	3	4	5	6
Patterned Ground	14	28.5	43	28.5	0	0	0
Un/sorted Stripes	11	0	36	46	18	0	0
Gelifluction Lobes	23	30.5	30.5	17	4	9	9

not show any clear pattern with aspect and seem to prefer the areas where MAGST is higher (Table 1) confirming the conclusion of Vieira and Ramos (2003) for Livingston Island. The distribution of the different types of patterned ground seems to reflect their different genetic processes.

PERMDEM appears to be appropriate for use in Maritime Antarctica to model permafrost distribution because it requires only a minimum of air temperature data and a reasonably good DEM. The results obtained could certainly be improved by the inclusion of the effects of vegetation and snow cover. On the other hand PERMDEM indicates clearly that permafrost conditions are actually present everywhere on the Island even in the beach deposits.

The major limit of the model is that the *Ir* factor is actually calculated using only two points (the only two points located on bare ground and monitored all year round). It may be that the quite strong difference between the measured MAGST for the two areas of bare ground studied are related not only to the incoming radiation but also to difference of latent heat. The two sites were located less than 60 m apart and at the same altitude, but one had a southwestern aspect and the other a northeastern aspect.

The success of the model (more than 90% of accuracy) for the particular year studied may partly be due to the low snow cover for that year. As there was actually little snow cover, the lack of data on snow conditions had little effect on the predictions of the model.

It seems reasonable to conclude that, in any case, there are no altitudinal boundaries for permafrost occurrence at Signy Island as suggested by Serrano & Lopez Martinez (2000) for the South Shetlands and that permafrost is continuous and not discontinuous as suggested by Chambers (1966a). Further developments are required to improve the model and its calibration, especially to model active layer and permafrost thickness. Also more detailed geomorphological analyses of the periglacial features occurring on this unique island are required in order to understand their genesis and evolution in this period of climatic change.

Acknowledgments

We thank BAS and PNRA for their logistic and financial support of this research in the frame of the joint project “Permafrost and Global Change in Antarctica II (PGCAII).” We thank also BAS for permission to use and elaborate on the DEM data of Signy Island. Special thanks to James Bockheim, whose comments and suggestions allowed us to improve this paper significantly.

Abstract

Daily permafrost active layer heave and subsidence was simulated for a 1 km^2 study area in the Mackenzie Delta, NWT for a period of one year. This study involved the development and application of a simplified methodology for assessing the dynamic nature of the active layer. It is based on the adaptation and integration of previously developed empirical and theoretical relationships related to the formation of segregated ice within frozen soil. The model requires a limited dataset including: general soil characteristics, a representation of the terrain in form of a digital elevation model, and regional weather records. The model was able to simulate the active layer thermal regime, yielding thaw depth values well within the range of measured observations. Likewise, daily changes in ground surface elevation across the study area due to formation or melt of segregated ice lenses agreed with direct measurements.

Keywords: heave; permafrost; segregation ice; subsidence; thermal modeling.

Introduction

Freezing and thawing of the active layer and the resultant heaving and subsidence of the ground surface are of particular significance in the Arctic regions, as the vertical movement of the ground surface throughout the year presents a hazard for the infrastructure. With an expected increase in the production of oil and natural gas in the Canadian Arctic, and associated infrastructure development, frost heaving may become a significant engineering issue, as well as a safety hazard (Bergquist et al. 2003, Palmer & Williams 2003). Various efforts have been made to predict and prevent active layer heave and subsidence from an engineering point of view, especially for prevention of gas pipeline buckling and road pavement heave (Konrad 1994, Palmer & Williams 2003). The dynamic nature of the active layer also presents challenges in assessing the subsidence caused by the oil and natural gas extraction in the permafrost-rich Arctic regions. Precise monitoring of terrain deformation through methods such as differential interferometric synthetic aperture radar (DInSAR) requires an accurate assessment of the state of the active layer at the date of acquisition. To address this issue, an active layer heave and subsidence model was developed that provides daily estimates of the thermal state of active layer, cumulative active layer heave or subsidence and the resulting ground surface elevation change.

To enable easy application of the model in a variety of permafrost terrain, the model complexity is reduced to require minimal input parameters. These parameters include a single sampling of terrain (elevation) and soils data, as well as regional weather data or that from nearby weather stations. All other required parameters are derived from such inputs based on empirical and theoretical relationships.

Study area

The model was tested at a site approximately two kilometers upland from Reindeer Station, NWT on the East Channel of the Mackenzie River (68.68°N, 134.06°W), and forty kilometers north of Inuvik, NWT, as shown in Figure 1. The site is one square kilometer of rolling tundra in the Caribou Hills, with a local relief of 20 meters, on an elevated bench overlooking the Mackenzie Delta. This hummocky upland terrain features a variety of soil types, ranging from peat to clayey silt colluvium derived from carbonate tills. The vegetation in the area is typified by dwarf shrubs, sedges, and herbs characteristic of a tundra environment, with willow and ground birch occupying the transitional zone between the tree-line and the tundra. The climate of the area can be characterized as very cold and dry, with a mean yearly temperature of -8.8°C and mean annual precipitation of 248.4 mm at Inuvik, for the years 1971-2000. Snowfall can occur in any month of the year, contributing an average of 167.9 mm SWE annually, and remaining on the ground for up to 8 months of the year (Environment Canada 2005).

Data

Minimizing the amount of input data required to simulate the active layer heave and subsidence is pertinent to providing a very simple, yet accurate model that can be applied in a variety of scales and environments. Weather data can be obtained from a climatological record at a nearby station, or from an in-situ weather station set up in the study area. For this study, climatological records for Environment Canada station *Inuvik A*, at Inuvik, NWT were used. Daily air temperature, precipitation, wind, and snow records for the years 1995 to 2006 were used (Environment Canada 2005). Terrain is represented in form of a digital

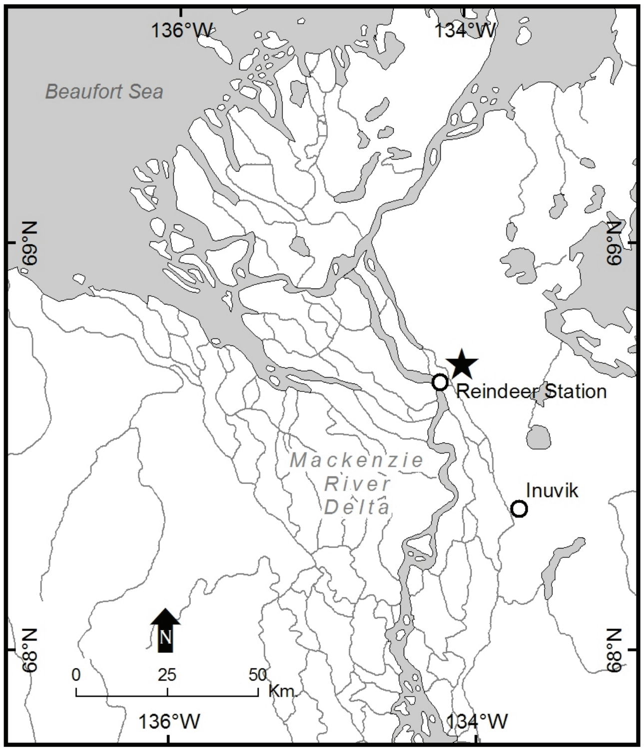

Figure 1. The star indicates the location of the study site in the Mackenzie Delta.

elevation model (DEM), which was created from a leveling survey conducted in the summer of 2004. A DEM with a 50-m resolution was generated from a dataset of 3962 points uniformly distributed across the study area. In addition, soil properties, water content, the presence and depth of the organics/peat layer, and active layer depth were obtained from a dataset of 36 sampling points also collected in the summer of 2004. Particle size analysis and moisture measurements were performed on the soil data, to obtain the necessary input parameters for the model. A 30-sample set of snow depth measurements was obtained at the study site in March of 2006, to be used to verify the predictions of the snow model.

Methodology

The simulation of the motion of the active layer was comprised of three sub-models. A snow distribution model was developed to predict the snow depth at the study site, in order to estimate the upper boundary (surface) thermal condition to be used in the thermal regime model, a thermal regime model estimated the temperature of the soil at different depths and so provided the location and character of the frost and thaw fronts, and an active layer heave/subsidence model calculated the amount of segregation ice formed or melted, and therefore the daily change in surface elevation

Snow distribution model

Spatial distribution of snow is fundamental for predicting the extent of permafrost in Arctic environments. Since snow acts as an insulator to the ground below, areas with long periods of thick snow cover usually remain permafrost free, while lack of snow cover promotes cooling of the soil and thus the growth of permafrost. Historically, the modeling of snow movement has been done through a variety of approaches, including empirical relationships between snow and wind, wind-tunnel testing, as well as one-dimensional and two-dimensional numerical models that predict the patterns of snow erosion and accumulation in a specified area (Liston & Sturm 1998, Pomeroy et al. 1993, 1997, Pomeroy & Li 2000).

Using a DEM of the study area in a geographic information system (GIS) environment, as well as the daily snowfall records and prevailing wind direction data from the weather station, the accumulation and redistribution of snow on the site was calculated. Implementation into a raster-based GIS environment was done through an iterative process using a 3 x 3 cell kernel which calculated the erosion or accumulation of snow in a given raster cell based on the above empirical relationships, as well as terrain characteristics. The results of this snow distribution model were then input into the thermal regime model.

Thermal regime model

Numerical models are generally the most popular approach to simulating and forecasting the thermal regime of active layer and permafrost (Miller 1979, Kane et al. 1991, Pustovoit 2000, Woo et al. 2004).

Determination of the thermal regime in this model was done using a simplified finite difference function (Rankinen et al. 2004) for calculating the ground temperature at a given depth. This calculation is based on a minimal set of environmental parameters, which include air temperature, snow depth, deep layer soil temperature at a known depth, and soil characteristics from field measurements. The thermal regime at each sampling point was calculated daily for each sample point for a period from July 1, 2002 to December 31, 2005. Allowing the model to stabilize for approximately 550 days before the needed values (years 2004-2005), the initial conditions were set sufficiently.

In order to provide an accurate estimate of the position of the freezing front within the soil, soil temperature was calculated at 1.0 cm increments to a maximum depth of 1.0 meter. Assuming a continuous flux between the soil surface and the air, through the snowpack and peat layers, surface temperature for every point was determined on a daily basis. Thermal properties of snow and peat were assumed to be constant over the study period.

Although snow becomes denser after snowfall, there was no practical solution to account for this change in density and thermal properties. However, on the tundra where considerable wind speeds are found at the ground surface, fresh snow quickly becomes reworked and reaches a steady state dense snow pack. Snow density value of 250 kg m^{-3} was used to represent tundra snowpack that was a few days to a week old. The thermal properties of snow used in this study reflect this density value (Williams & Smith 1989).

The model assumes that the soil properties below the surface (or peat layer where present) are homogeneous and do not vary with depth. This simplification of natural processes is necessary as the thermal properties of soil data at varying depths were not available for this study. Future versions of the model could include such variability.

The presence of water and ice close to the freezing temperature has significant effect on the thermal properties of frozen soils (Williams & Smith 1989). Therefore, thermal properties of soils must be modified accordingly for the proper interpretation and analysis of thermal conditions in the ground and for carrying out thermal calculations. Since the thermal conductivity and heat capacity of the soil were not measured for the soil samples, representative value for silty clay was obtained from Williams & Smith (1989) and used for all sampling locations. Silty clay, as defined in Williams & Smith (1989), was chosen as it was fairly representative of the soil samples obtained in the study area. The model accounts for the variability in thermal conductivity of soil with change in temperature, as well as adjusting for the variability of heat capacity due to influences from the ratio of unfrozen water and ice content in the soil, as well as those from the soil temperature.

It is argued that the water in soils freezes over a range of temperatures, depending on the chemical and geological properties of the host soil (Williams & Smith 1989). The frost front, defined as the location within the soil where the segregation ice will begin to form, often occurs close to the 0ºC isotherm, and the exact temperature varies with the aforementioned soil properties. Konrad & Morgenstern (1981) argue that the frost front for fine sands or coarse silts occurs very close to the 0°C isotherm. The present study therefore assumes that the frost front coincides with the 0°C isotherm based on the amount of fines present in the soil samples.

To identify the location of the frost front within the calculated thermal regime, the model identifies the location of the 0°C isotherm within the soil for each day, and returns the depth at which the frost front resides. The algorithm automatically recognizes the upper and lower temperatures on either side of the freezing front, and calculates the temperature gradient at the location. Since the thickness of the frozen fringe is fairly small (1.0 cm) it is assumed that the temperature gradient is linear. The model is robust enough to account for dual frost fronts that may occur as the freezing descends from the surface, and ascends from the underlying permafrost. In such situations, both depths and associated temperature gradients are used for the calculation of heave. The same function is used to identify the depth of thaw, as the soil is thawing during the warmer months. The location of the thaw front is identified, as well as the temperature gradient across it, and is used for subsidence calculations.

Heave and subsidence model

In its simplest form, the theory of frost heave is based on the freezing of water that is arriving at the freezing front in a saturated soil, as well as freezing of in-situ pore water. Formation of segregated ice lenses in the soil due to these

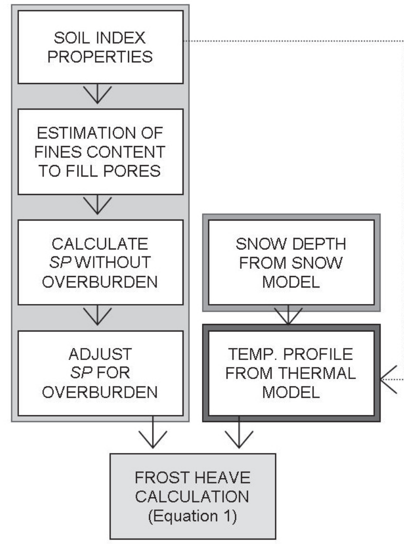

Figure 2. Model flowchart for calculating frost heave.

two phenomena cause significant structural disturbances in the soil. Segregated ice occurs as pure ice layers or lenses, millimeters to meters thick, within the soil. When ice lenses form, the overlying soil is pushed up (heaved) to accommodate for the volume of the ice itself, thus causing heaving at the ground surface. During the melt season, the disappearance of the ice lenses through melting causes weakening of the soil structure, which is often followed by collapsing of the ground surface (Konrad 1999).

The segregation potential model developed by Konrad & Morgenstern (1980) offers a very simple, but highly sensitive approach to simulating frost heave using a minimal set of input variables and is based on the concept of a segregation potential parameter (*SP*). Konrad (1999) defined a relationship between the *SP* parameter and four key soil properties (fines content, clay mineralogy, soil fabric, overburden pressure) and created a simple, soil index-based derivation of the *SP* parameter and the resulting frost heave. The amount of frost heave Δh (mm) that occurs during a given time interval Δt (s), is therefore defined as:

$$\frac{\Delta h}{\Delta t} = 1.09(SPgradT) \tag{1}$$

where *SP* is the calculated segregation potential value, and *gradT* defines the temperature gradient across the frozen fringe, as derived in the thermal regime model. Figure 2 summarizes this approach.

Required soil index properties were calculated for each sampling point from the samples obtained at the study site. Daily segregated ice content was calculated for each of 110 points across the study site and the depth at which it formed was identified. In situations where dual frost fronts occurred, both depths were identified and the amount of segregated ice was summed for a daily total. The calculations were performed for all days where freezing occurred, until the two freezing fronts converged and the soil was completely frozen.

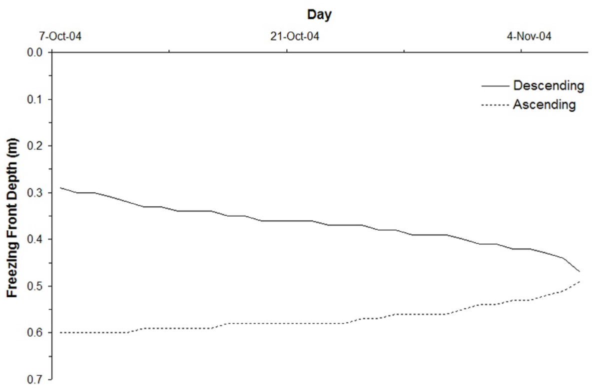

Figure 3. The progression of freezing front with time, for the end of the freeze-up period in year 2004.

During the thaw season, the amount of subsidence was calculated as the thaw front descended through the segregated ice formed during the previous year's freezing period. If the thaw depth coincided with the location of an ice lens, it was assumed that the entire ice lens that formed at that given depth will be melted and the ground surface will subside by the thickness of the lens. Changes in thermal properties of the soil due to presence of ice lenses were not accounted for. Elevation of each sampling point was modified daily, based on the amount of heave or subsidence that occurred. Heave and subsidence amounts were output into a database to be used in further spatial analyses.

Results and Discussion

Snow distribution model

The simplified approach to snow modeling provided a sufficient snow surface to be used in this model. Statistical comparison of the predicted snow surface and the set of 30 observed snow points show that the minimum and maximum snow depths are within one centimeter of each other, and the model overestimates the mean by 0.11 cm. The standard deviations of the two datasets are within 0.69 cm, indicating a similar variance of snow depths throughout the study area. The estimated snow distribution displayed the expected pattern, with thicker snow found in sheltered areas and thin snowpack on exposed slopes.

While having a more complex snow model (e.g., Liston & Sturm 1998, Pomeroy et al. 1993) would possibly be beneficial to accurately assess the daily snow cover over the study area, the method presented here is suitable for predicting the snow cover based on a minimal number of input parameters.

Thermal regime model

The thermal regime for all 110 locations was calculated for the test period (January 1, 2002, to December 31, 2005). In order to assess the change in elevation at each point due to heave and subsidence, the test period was considered to be from the first day of freeze-up in 2004 to the last day of thaw in 2005, thereby providing one full cycle of heave and thaw. Through the thermal model, these days were found to be October 7, 2004, and September 24, 2005, respectively.

As expected, the temperatures at depth respond well to the oscillations in air temperature, but with diminishing amplitude and an increasing phase lag with increasing depth. Figure 3 illustrates the depth of the frost fronts predicted for a selected station over time. The model successfully simulates the convergence of the descending and ascending freeze fronts in the soil, to completely freeze up the active layer.

Averaged across all locations, the depth of thaw for 2004 was found to be 56 cm. This is within the range of values measured in the Mackenzie Delta area. Kokelj & Burn (2005) estimate the thaw depth on the uplands near Inuvik to be between 30 and 100 cm. The thaw results also were validated by frost probing conducted through the summer.

To achieve a complete freeze-up the soil took an average of 40 days, starting on October 7, 2004. The soil was found to remain completely frozen for most locations until between May 15, 2005, and June 5, 2005. The average depth of thaw in 2005 was found to be 52 cm, with most locations achieving their maximum thaw depth by mid-September, approximately a week prior to the first day of freeze-up.

Heave and subsidence model

The amount of segregated ice, and therefore the amount of surface upheaval, was found to be an average of 10.33 cm per station during the freeze-up period in 2004. Approximately 78% of segregation ice formed at the descending frost front, at depths less than 30 cm below ground. This facilitated a fairly fast melt of the bulk of the segregated ice, as on average, the thaw front achieved a depth of 30 cm in approximately 35 to 40 days. Ignoring possible resultant alterations to the soil fabric and any factors that may inhibit the soil from returning to its original state, the subsidence due to melt of segregated ice has been modeled to be an average 9.10 cm. This therefore suggests that the soil does not return to its baseline elevation, and that an average of 1.24 cm of segregated ice remains into the next freeze-up season. This is a function of colder temperatures experienced in the second model year.

Figure 4a depicts the predicted progression of segregated ice formation through time at one sampling point. As the ground begins to freeze, the steep thermal gradient across the freezing front initially causes a significant amount of segregated ice to form. With a decrease in the gradient, less ice is formed, reaching a minimum at zero as either all water in the soil is frozen, or the two freezing fronts converge. Due to the lag time in the response to surface temperature changes at depth, the thermal gradient across the descending freezing front is always much steeper than that moving upwards from the permafrost below. Thus, the amount of segregated ice formed at the descending freezing front contributes much more to the total ice content, while leaving the majority of ice lenses within the first few tens of centimeters below the surface. This is also supported by the results presented in Figure 4b, showing the progression of the thaw front though the soil, as well as the associated subsidence due to melt of

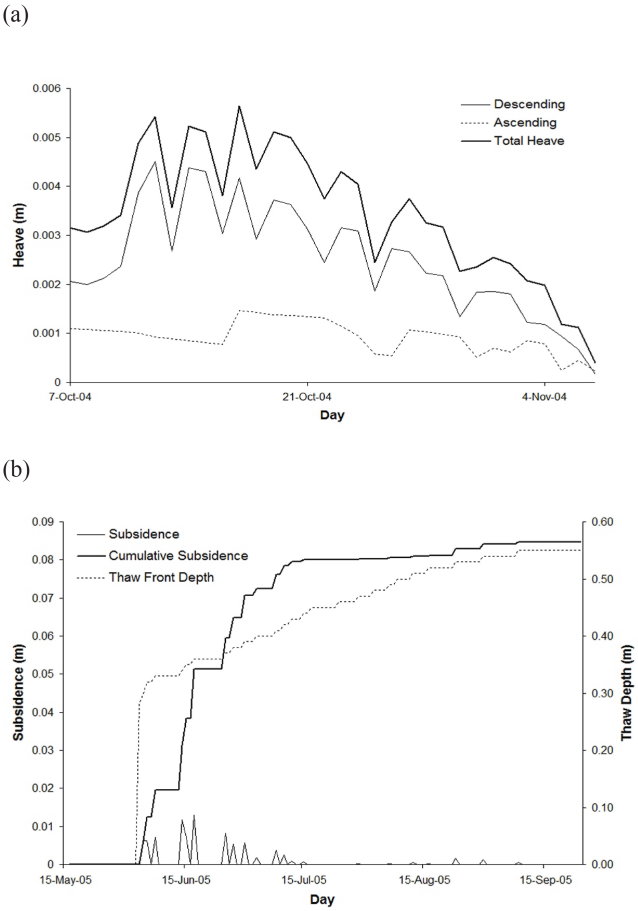

Figure 4. (a) Generation of segregated ice lenses (and therefore heave) at the descending and ascending freezing fronts at point #54, during the freeze-up season in 2004 (b) Progression of the thaw front during the melt season in 2005 and the consequent subsidence due to melt of ice lenses, for point #54.

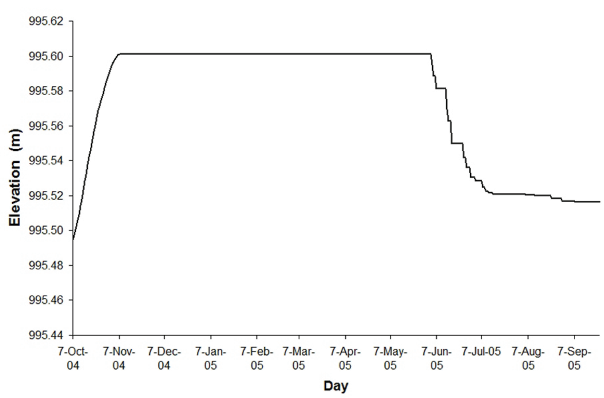

Figure 5. Predicted elevation changes during the study period (2004-2005) due to formation and melting of segregated ice at point #54.

ice lenses. Figure 5 illustrates the annual cycle of ground surface heave and subsidence due to formation and melt of segregated ice for a single sampling point, during the testing period. The overall change in elevation at the end of the melt period in 2005 is shown in Figure 6. As the thaw depths in 2005 did not reach all of the segregated ice that was formed in 2004, a lift in the ground surface is observed across the whole study area. Biggest elevation changes are seen in the northeastern quadrant of the study area, where the ground has been raised by up to 2.4 cm.

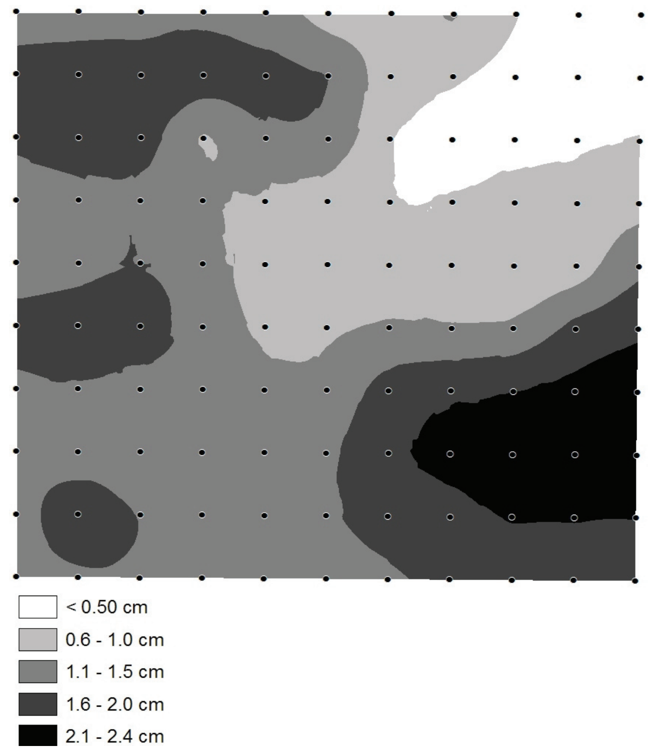

Figure 6. Total predicted change in elevation for the study area, after the melt season of 2005.

Conclusions

This work provides a simplified methodology for predicting active layer heave and subsidence on a daily basis based on a limited number of parameters. The approach integrated and modified a number of previously developed methodologies for snow distribution modeling, calculation of freezing soil thermal regimes and the formation of segregated ice within frozen soil.

The snow distribution and thermal models produced estimates that closely matched measured values at the test site. Based on the predicted frost and thaw front depths, the heave/subsidence model was able to simulate the daily changes in the surface elevation due to formation and melt of segregated ice lenses, also yielding values within the expected ranges for the area.

The model is also able to take into account inter-annual weather variability and the resultant changes in the depth of thaw and longer term surface elevation change resulting from changes to the active layer.

Future refinements of the active layer motion model presented in this study will focus on capturing the characteristics of layered soils. As well, implementation of lateral exchanges of heat and water would allow for full three-dimensional predictions of the thermal regime and have characteristics, thereby accounting for natural variations in microclimatic and terrain conditions that may play a role in the formation of segregated ice.

Shear Strength of Ice-Filled Rock Joints

Friederike K Günzel
University of Brighton, Brighton, UK

Abstract

Ice-filled rock joints are a common feature of high mountain permafrost areas. Warming of these joints in rock can lead to instabilities and rockfall events. In the following study, a series of direct shear tests was performed with artificial samples simulating ice-filled rock joints. The direct shear tests were carried out in two testing modes: constant strain and constant stress. In constant stress tests, the ice-filled joints show a parabolic relationship between normal stress and shear stress unlike the linear relationship usually found in mineral filled rock joints (Barton 1974). Constant stress tests were also conducted in which the samples were allowed to warm up until failure occurred while a constant normal stress and a constant shear stress were applied. Different failure modes could be identified, either driven by breaking the connection of ice and concrete or ductile deformation of the ice or a combination of both.

Keywords: direct shear; ice strength; rock joints; rock slopes; shear strength.

Introduction

In recent years, increased numbers of landslide and rockfall events have been reported in high mountain areas (Gruber et al. 2004). A connection between the landslide events and the warming of permafrost due to increasing mean annual air temperatures was observed in landslide events, such as the Val Pola Landslide in 1987 (Dramis et al. 1995).

Earlier laboratory experiments, carried out on a geotechnical centrifuge (Davies et al. 2003 and Günzel & Davies 2006) showed that ice-filled joints in rock are stable as long as the temperature of the ice is low (below about 2°C); however, both the strength and stiffness of ice in the joint reduce if the temperature rises closer to melting point. This leads to a reduction in strength of the rock joint which, if it is critical to maintaining slope stability, can result in slope failure or rockfall. However, the stability increases again when the ice from the joint melts and the rock surfaces come into contact with each other. That means that slope failure can occur at a joint during warming of the permafrost ice, even if a slope is stable both when the rock joints contain "cold" ice and when no ice is present. Slope failure might be avoided if these critical joints can be identified and stabilised temporarily during the period when the ice is warming and when the shear capacity of the joint is below that required for stability.

The current study systematically uses direct shear testing to investigate the shear strength of an ice-filled rock joint during warming of permafrost.

Laboratory Methods

Preparation of samples

In the study, artificial samples made of high-strength concrete (Densit Ducorit D4) were used. To simulate the roughness of the rock joint surfaces, a regular saw-tooth surface was used with the dimensions as shown in Figure 1. Regular, saw-toothed surfaces are a commonly used idealisation of rough rock surfaces in the literature (de Toledo & de Freitas 1993). The dimensions of the samples were 59mm x 59mm to fit inside a 60mm square shear box.

A thermocouple was cast into the concrete samples with the sensitive tip in a small cavity at the centre of the sample surface (Fig. 2). This allowed the temperature of the ice to be measured during the shear tests.

Initial tests were carried out without ice to establish the friction of the concrete surface. Then two different types of ice-filled samples were prepared: concrete-ice samples (Fig. 3) and sandwich samples (Fig. 4).

The concrete-ice samples consist of a concrete block with saw-toothed surface overlaid by an equally thick ice block (Fig. 3). This sample type simulates an ice-filled joint, with

the ice thickness being much larger than the amplitude of the surface roughness. The concrete-ice samples are prepared by placing concrete blocks into moulds filled with water and allowing them to freeze.

The sandwich samples consist of two saw-toothed concrete blocks with a 1mm thick layer of ice in-between (Fig. 4). This sample type simulates an ice thickness equal to the amplitude of the surface roughness. These samples are prepared as illustrated in Figure 5. The two concrete blocks are immersed in water in a mould. A bolt is glued to the top block. The top block is then lifted by turning the nut against the lid of the mould while the movement is measured with an LVDT (Linear Variable Displacement Transducer). After that, the surplus water on top of the sample is drained, and the sample is frozen.

Direct shear tests

Two different modes of direct shear tests were carried out in this study: constant strain tests and constant stress tests. Schematic overviews of both testing modes are shown in Figures 6 and 7. Normal stress is provided by hanging weights. Horizontal and vertical displacements are measured with LVDTs.

In the constant strain tests, shear stress is applied by an electric motor pushing the upper part of the sample while the lower part remains stationary. The shear stress is measured with a load cell. These tests were carried out at -2°C and -4°C, with normal stresses ranging between 135 kPa and 620 kPa. This is equivalent to a depth of 5–25 m below ground. This depth is above the range of the annual freeze-thaw depth of 5±2 m in the Alpine periglacial belt reported by Matsuoka et al. (1998). However, with increasing air temperatures, the freeze-thaw depth can be

expected to increase.

A constant horizontal displacement rate of 0.47 mm/hour was used for all tests. However, earlier studies (Barnes et al. 1971) found that not only the temperature, but also the strain rate, has a significant effect on the shear strength of an ice-granite interface. Also, failure of a rock slope is not controlled by constant strain, but rather by constant stress.

Therefore the shear box was modified to be able to apply a constant shear stress rather than a constant strain onto the concrete ice samples and the sandwich samples. Here, the motor was replaced by a pulley system and weights to apply a constant shear stress to the samples. The sample temperature was then increased slowly until the sample failed.

Cold room

The experiments were carried out in a cold room. To ensure a constant temperature of the sample during the defrosting cycles of the cooling element, the shear box was encased inside a Styrofoam box with 100 mm wall thickness. However, the electric motor of the shear box apparatus caused the temperature inside the Styrofoam box to increase during the constant strain tests. Therefore it was very difficult to control the temperature of the sample and subsequently the temperatures at failure varied by about 0.5 C.

Experimental Results

Samples without ice

To establish the frictional resistance of the concrete samples without ice, direct shear tests were carried out with normal stresses between 135 kPa and 620 kPa. The typical response of a sample is shown in Figure 8. Here the shape of the saw tooth surface is clearly visible from the vertical displacement. The development of the shear stress follows the same pattern with the maximum shear stress during the uplift of the top sample.

Figure 9 shows the maximum measured shear stresses of all concrete samples plotted against the normal stress applied to the sample. As expected, there is a clear linear relationship between the normal stress and the shear stress. The scatter of data above a normal stress of 400 kPa is due to abrasion of the concrete samples during the test.

Constant strain tests with concrete-ice samples

A total number of 26 constant strain tests were carried out at two different temperatures: -2°C and -4°C. Depending on the normal stress, the vertical displacement during the test showed different behaviour (Figs 10,11): at low normal stresses, the vertical displacement clearly reproduces the shape of the saw-toothed surface, albeit with a slightly reduced amplitude (Fig. 10). This behaviour can be

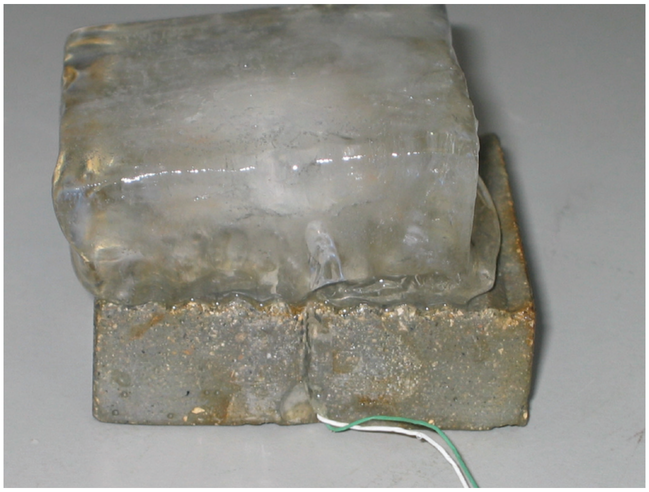

Figure 12. Shear deformation of a concrete-ice sample after a constant strain test with normal stress = 490 kPa.

interpreted as the ice becoming detached from the concrete surface, and the behaviour of the sample is mainly defined by the friction between surfaces of the ice and the concrete (Fig. 3). However, at high normal stresses, no dilation of the sample was observed (Fig. 11). Here the deformation of the sample is mostly due to a shear deformation of the ice itself rather than the sliding of ice over concrete. At the end of these tests, the ice was still firmly attached to the concrete surface (Fig. 12). No granularisation of the ice comparable

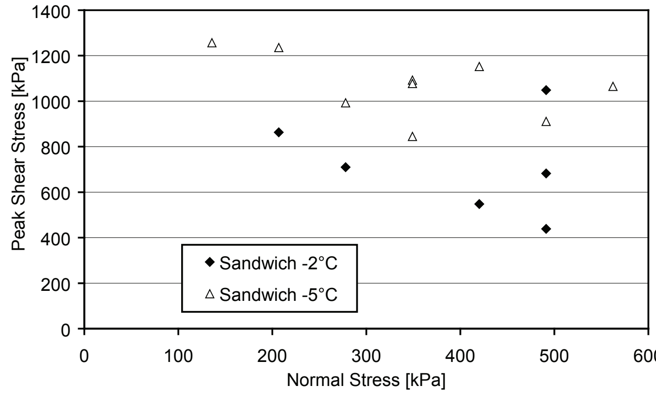

Figure 15. Overview of peak shear test results of sandwich samples in constant strain tests.

to the "rubblisation" reported by Yasufuku et al. (2003) was observed. It should be noted, that the initial stiffness of the samples is approximately the same, irrespective of the type of deformation.

The two different mechanisms of deformation also become apparent in the relationship of maximum shear stresses and normal stresses at failure (Fig. 13): at low normal stresses, the relationship between maximum shear stress and maximum normal stress appears to be linear (dashed lines in Fig. 13), which is in agreement with the behaviour of mineral-filled rock joints (Barton 1974). However, at normal stresses, above 220 kPa and 300 kPa for -2°C and -4°C, respectively, this relationship becomes parabolic. This result agrees with the parabolic strength envelopes of ice found by Fish & Zaretsky (1997).

Constant strain tests with sandwich samples

The constant strain tests with sandwich samples were carried out at -2°C and -5°C. Unlike the concrete-ice samples, the sandwich samples dilated even at high normal stresses (Fig. 14). It is also noticeable that the shear stress maximum forms a very sharp peak with a sudden drop when the ice becomes detached from the concrete surface. Again, the initial stiffness of the sample is very similar to the stiffness of the concrete-ice samples. Due to the sharp peak, a considerable scatter of the maximum strength at failure is to be expected (Fig. 15). It is unlikely that the scatter is enhanced to a large extent by the sampling rate: the shear stress increased with a rate of approximately 10 kPa per minute, so that with a one-minute sampling rate, the error would be not more than 10 kPa. Despite the large scatter, a decrease of the maximum shear stress with increasing normal stress can be observed.

Constant stress test

The tests were started at an ice temperature of approximately -5°C, and then the temperature was increased at a rate of about 0.3°C per hour until failure occurred. These shear tests were carried out at normal stresses between 136 kPa and 630 kPa. The typical result of a constant stress shear test with a concrete-ice sample is shown in Figure

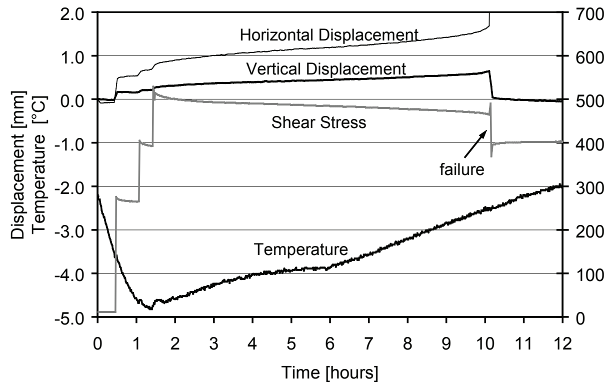

Figure 16. Results of a constant stress experiment (concrete-ice sample, normal stress = 207 kPa) plotted against time.

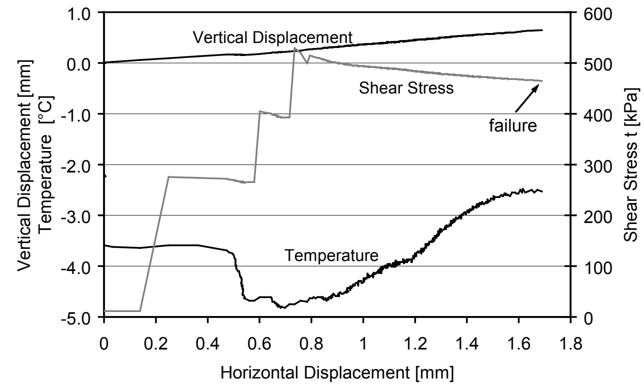

Figure 17. Results of a constant stress experiment (concrete-ice sample, normal stress = 207 kPa) plotted against horizontal displacement.

16 (plotted against time) and Figure 17 (plotted against horizontal displacement). The results for concrete-ice samples and sandwich samples are very similar. The steps of the shear stress at the beginning of the test correspond to adding weights to the pulley system. The decrease of stress during the test is due to friction in the pulley system: the tension in the nylon rope connecting the sample with the weight slackens slightly as the sample deforms, due to creep in the ice prior to failure. The apparent change of the rate of temperature increase is due to the increasing rate of horizontal deformation immediately before failure of the sample.

The horizontal displacement during the constant stress tests was considerably slower than during the constant strain tests; it varied between 0.002 mm/hour and 0.06 mm/hour. The deformation rate increased with increasing shear stress, but no significant change could be observed for increasing normal stress or temperature. The horizontal displacement at failure was between 1.5 mm and 2.5 mm, similar to the displacement at failure of the constant strain tests. The vertical displacement decreased with increasing normal stress.

Figure 18 shows the variation of failure temperature depending on normal stress and shear stress for concrete-ice samples and sandwich samples. The data points represent the shear stress at failure versus the normal stress acting on the sample. The temperature distribution for both sample types is very similar, with the only difference being that the failure temperatures of the sandwich samples were about 0.5°C lower than the concrete-ice samples. The data show decreasing failure temperatures with increasing shear stresses. However, the failure temperatures increase with increasing normal stresses throughout the test series up to normal stresses of 630 kPa. This behaviour differs from the constant strain experiment where, at normal stresses above 300 kPa, a decrease of failing temperature with increasing normal stress was observed (Fig. 13).

Figure 18 also shows the failure envelope of the concrete samples. It can be seen that, at low temperatures and low normal stresses, the ice-filled joints have a higher shear strength than joints without ice-filling.

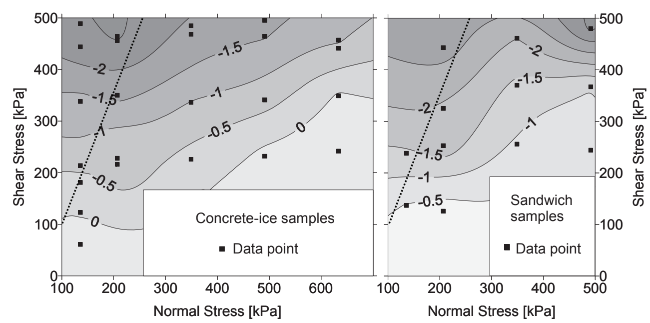

Figure 18. Temperatures at failure (measured by the sensor in the middle of the sample) during constant stress tests with concrete-ice samples (left) and sandwich samples (right). The dotted lines represent the linear relationship between shear stress and normal stress obtained for the concrete samples.

Discussion

Depending on sample type (concrete-ice or sandwich) and test type (constant stress or constant strain), three different types of deformation could be identified:

1. Deformation driven by breaking of the connection between the ice and the concrete surface;
2. Deformation driven by shear deformation of the ice itself; and
3. Combination of the deformation types 1 and 2.

In the constant strain tests with concrete-ice samples at low normal stresses, the first type of deformation is predominant. Indicators for this type of failure are the extent of the dilation of the samples during the test (Fig.10) and the visual examination of the sample after the test (Fig. 3) that clearly shows the ice being detached from the concrete surface. However, the same sample type shows ductile deformation of the ice at high normal stresses. Here the samples show no net dilation during the test (Fig. 11); any local dilation that may be present in the sample is counteracted by the ductile deformation of the ice, which is clearly visible in the sample after the test (Fig. 12).

In the constant-strain tests of the sandwich samples, a combination of the first two failure modes is observed. Visual examination of the samples showed the ice detached from one of the concrete surfaces. However, these samples show a reduced dilation of 0.4mm–0.6mm (Fig. 14) indicating that sliding of the ice over the concrete surface is not the only type of deformation in these samples. The other type of deformation may be shear deformation of the ice itself. The maximum shear strength reduces with increasing normal stress (Fig. 15), again indicating shear deformation of the ice.

Constant-stress experiments with both sample types show that here the predominant type of deformation is breaking the connection between the ice and the concrete. This observation is consistent with the data shown in Figure 18, where the shear stress at failure increases rather than decreases with normal stress for a constant temperature.

Conclusions and Outlook

In this study, three different failure modes of ice-filled joints could be distinguished. This adds to the understanding of the failure mechanisms of rock slopes in warming permafrost conditions.

Several issues that have not been considered to date will be addressed in the near future:

- The strength of ice depends on the strain rate; constant strain tests need to be carried out with the same strain rate as observed in the constant stress tests.
- Creep measurements of ice at constant temperatures, rather than increasing temperatures, need to be conducted.
- The strain rate measured in the laboratory needs to be compared with strain rates measured in full scale rock slopes rather than small-scale centrifuge model tests.

Acknowledgments

All experiments were carried out at the geotechnical laboratories of the University of Dundee, UK.

An Analysis of Land Suitability for Urban Construction in Permafrost Regions

Igor E.Guryanov
Melnikov Permafrost Institute, SB RAS, Yakutsk, 677010, Russia

Abstract

Natural conditions of sites varying in favorability for urban construction are discussed, based on the example of Yakutsk, northeastern Russia. Their role in overall land suitability is shown. Relationships between the initial land suitability level and the resulting ecological situation at the townsite are analyzed, with particular reference to the permafrost region.

Keywords: conditions; ecological situation; factors; land suitability; permafrost; urban construction.

Problem Statement

The common feature of community infrastructures in permafrost regions is the lower structural and maintenance safety of buildings and facilities compared to more temperate regions, and the frequent performance problems resulting from permafrost thawing due to anthropogenic changes. It is, therefore, important to determine to what extent these deficiencies are related to the design and construction solutions, the choice of which is dictated indispensably by considerations of economics.

Construction Area Quality Factors

Depending on the favorability of environmental conditions, areas vary in suitability for urban development. Development of the areas of limited suitability results in an additional burden on the urban environment. Development of unsuitable areas aggravates the situation, producing complex engineering and ecological problems.

The suitability of any area for urban land use is predetermined by five basic factors characterizing the general conditions for construction:

1) The geology of the area and the geological processes and features anticipated to occur beneath buildings and structures.

2) The topography of the area which affects the convenience of service lines.

3) The hydrogeology and the surface and subsurface drainage conditions.

4) The hydrology of rivers and lakes.

5) The thermal regime and the air and water quality.

These factors are analyzed during the planning process in order to create the most favorable conditions and control the quality of construction sites. Inadequate consideration or neglect of any of these environmental factors reduces the overall suitability of the construction area. Since the factor combinations are always specific, suitability evaluations are only made for specific areas.

Factor Assessment Criteria

First factor (geological conditions)

- Favorable conditions: Homogenous soils or rocks that are good foundation material for conventional foundation types; the stability and adequate performance of engineering structures are guaranteed;
- Provisionally favorable conditions: Ground properties that call for some restrictions of the effects from buildings and other structures to ensure their stability and good performance; special foundation types, soil improvement, and other measures can be applied;
- Unfavorable conditions: Weak soils that require special foundation designs, soil improvement, structural measures. and stringent controls on construction and maintenance.

Second factor (topography)

- Favorable conditions: Lowlands with slopes of 0.5 to 10%, local relief of up to 10 m, and low horizontal dissection (erosional incisions spaced at least 2 to 5 km apart).
- Provisionally favorable conditions: Slopes less than 0.5% and 10 to 20% in the lowlands and up to 30% in the mountains; 10 to 25 m local relief; moderate horizontal dissection with incisions spaced at 0.5 to 2 km.
- Unfavorable conditions: Slopes greater than 20% in the lowlands and greater than 30% in the mountains; local relief greater than 25 m; and high horizontal dissection with less than 0.5 km spacing between incisions (Solodukhin 1985).

Third factor (hydrogeology and drainage)

- Favorable conditions: Groundwater occurs lower than the foundation bottom; no protective measures against the influence of groundwater are required.
- Provisionally favorable conditions: Special precautions are required to ensure adequate construction and maintenance of buildings and structures (water proofing, drawdowning, drainage, corrosion control, etc.).
- Unfavorable conditions: A complex system of special measures must be taken to prevent the adverse effect of groundwater on the construction and maintenance of engineering structures and their performance.

Fourth factor (flooding hazard):

- Favorable conditions: Areas unflooded by 1% probability flood events (one in one hundred years).
- Provisionally favorable conditions: Areas that are not

flooded in a 4% probability flood event (one in 25 years).

- Unfavorable conditions: Areas liable to flooding during >4% probability flood events (more than one in 25 years) (Lomtadze 1978).

Fifth factor (temperatures and water and air quality)

Only two categories—favorable conditions and unfavorable conditions—are identified, based on the atmospheric circulation patterns and the environmental quality standards.

In accordance with favorability, provisional favorability, and unfavorability of each factor, study areas are categorized as suitable, limited suitable, and unsuitable.

Analysis of Land Suitability for Construction

The actual approaches to urban development in permafrost regions will be illustrated below, using the example of Yakutsk which faces the typical problems.

Considering the first factor of land suitability for urban construction which characterizes the geological structure and related geological processes, it should be noted that the special design and construction methods for engineering work in permafrost areas have less than one century of history (USSR Building Code 2.02.04-88, 1990). Based on technical experience, special-purpose permafrost zonation of Russia has been made, and special requirements for design and construction of foundations and buildings have been elaborated. However, the need for special foundation types and structural improvements, as well as the special considerations for construction and operation stages, imply the overall unfavorability of engineering-geological conditions. It means that any permafrost area is essentially unsuited for urban construction, and strict solutions to the problems posed by the first factor require that in each specific case, proper weight should be given to the other factors in order to prevent them from adding to adverse effects on the engineering geological conditions.

By the second factor (topography), the townsite of Yakutsk located on the first and second terraces of the Lena River has a general slope of much less than 0.5% per 10 km or more, and the distance between frequent oxbow depressions is about 1 km. These conditions are provisionally favorable, making the townsite limited suitable by the second factor which affects the quality of utility lines and roads.

Moreover, because of the flatness of the townsite, surface and subsurface (active layer) drainage is in fact lacking. In other words, the area is unsuited for urban development in terms of the third factor, since the problems of inundation and salinization remain unsolved due to the technical complexity. The 370 years of continuous anthropogenic saturation and salinization of the soils, as well as leaking service pipes, have resulted in cryopegs in the low-lying areas with salinities of up to 10 g/l. These cryopegs contain Na and Mg chlorides aggressive to foundation concrete.

Within the city limits, the first river terrace is from 93–95 m to 97 m in elevation. Surface runoff and drainage occur very slowly, from Lermontov Street to Khabarov and Chernyshevsky Streets. The lack of drainage results in frost jacking of the structures and frost cracking beneath the buildings. With the construction of a new residential district, Mirkorayon 202, on the Lena floodplain filled to a 97-m elevation, the first-terrace area between Lermontov and Khabarov Streets has become a depression, and drainage in the active layer has been disrupted.

The fourth factor (hydrological conditions) is of prime importance for Yakutsk, as it lies in the Lena Valley. Floods to levels between 1% and 4% probability make the area that of limited suitability for urban development, while the zones with levels of less than 4% probability are classified as unsuited. Flood levels of the Lena River in the Yakutsk area are 96.36 for 1% probability events and 95.46 for 4% floods. Since the level at Khabarov Street near the town dam is 95.5 m, the first terrace is entirely an area of limited suitability for construction.

Filling of the floodplain area for new construction is estimated by the project designer, Giprokomminstroy, to add 40 cm to flood levels, and a 4% probability flood thus would reach 95.86 m. As a result, the first terrace has become a flood-risk area, making the developed parts of the city unsuited in terms of the building standard. This change in the situation has already resulted, in that every spring flood-control action has to be taken along the first-terrace slope.

By the fifth factor, atmospheric quality, the urban land-use suitability is not evaluated. However, its ecological implications should be given consideration, because, being located in the river valley, Yakutsk is influenced by temperature inversion during the winter. The inversion is several hundreds of meters in vertical extent and up to 10º in temperature difference; the number of days with fog is up to 56 during the winter months. Weak air movement results in heavy air pollution with the maximum permissible concentrations exceeded by 10 to 20 times. The average maximum exceeding of the standards is 3–8 for SO_2, 9 for CO, 5 for NO_2, and 10–17 for H_2S. These levels are above high and harmful air pollution thresholds (Central Research and Design Institute on Urban Development 1986). The development of the floodplain has increased trapping of pollution emissions within the city area.

According to the recommended environmental criteria for urban areas (Central Research and Design Institute on Urban Development 1986), Yakutsk is now an extremely unfavorable (critical) zone in terms of air and water quality, as well as soil and vegetation conditions.

Osipov (2004), in his analysis of environmental problems in Russia, presents environmental degradation zonation of the country. The map shows that in the permafrost zone, local areas of degradation are those affected by mining activities. No degradation is indicated for the Yakutsk area. However, the above discussion makes us conclude that Yakutsk appears to be the only community in the permafrost zone where the arduous situation has resulted solely from the absence of an orderly pattern of development. The oldest city erected on permafrost has been an experimental plot with both building successes and failures.

Construction and Maintenance Problems at Yakutsk

The critical engineering and ecological situation has resulted in significant negative consequences, which are listed below in a decreasing order of the number of affected buildings and structures.

1. Anthropogenic salinization of the foundation materials and related reduction in the frozen soil strength and bearing capacity.

2. Warming and thawing of the underlying frozen ground due to insufficient heights of air space between the buildings and the ground surface, primarily due to overall saturation of the townsite soils resulting from the lack of surface runoff and hydraulic discharge of the active layer.

3. Repeated or contingent leaks from the internal, external, district and main water and heat lines into the ground near or below the buildings. Leakage results in large thaw bulbs, foundation settlement, and structural damage.

4. Concrete deterioration in the foundation sections within the layer of seasonal thaw due to frost and chemical action. Capillary suction of groundwater from the active layer to the masonry walls of the mid-20th century or older buildings (a demolished building on Ordzhonikidze Square, a number of buildings on Lenin, Khabarov, and Bestuzhev-Marlinsky Streets) and gradual damage to the bearing walls leading to complete failure.

5. Frost cracking in the foundation soil during the winter months resulting in damage to the basement walls.

Of about 500 residential and public buildings examined at Yakutsk, 182 buildings, or 36.4% of major infrastructure, show various levels of deformation. It is not surprising, since Yakutsk, which initially had no sanitary or storm sewer systems, is the oldest community on permafrost.

The current situation on the Yakutsk townsite calls for the following immediate measures:

1. Prohibit new construction in the floodplain areas. Develop measures aimed at minimizing the adverse effects of the built-up floodplain sections on the remainder of the townsite.

2. Establish, by the city of Yakutsk Department of Housing and Municipal Services, a special supervisory service for performance control, repair, and reconstruction of the district utility systems and the sewage main.

3. Prepare alternative reconstruction plans for the areas of sporadic construction, providing for green recreational zones to reduce the total burden on the city.

4. Enforce the re-opening of the Yakutsk permafrost station which would, at the initial stage, be subordinate to the Federal Emergency Management Department's Monitoring and Prediction Centre. Based on the existing experience (USSR Committee for Construction's Institute of Foundations and Underground Structures 1982), this station should be charged with developing a single network of thermal and level monitoring network of the city area and building sites. In the first years, the station should prepare regular reports on the permafrost conditions at the city and the performance of the existing infrastructure.

The recommended measures are certainly of regulative character and cannot be expected to solve the general problem. Land quality remediation is a task for many decades to come. City expansion should be diverted away from the inversion-affected valley (an ecological objective) and the low terraces of the Lena River (a planning objective). It is evidently the only way to improve the urban land use quality.

General Evaluation of Permafrost-Affected Infrastructure

Despite the diversity of construction conditions in northern communities, it is of interest to compare the infrastructure conditions survey data, since these figures provide some indication of the general situation. At Norilsk, for example, about 300 of the 1000 buildings examined required foundation stabilization; about 40 buildings are reconstructed and repaired annually by a specialized engineering company. At Chita, 132 of 526 buildings investigated (25.1%) are damaged or distressed. In the communities located on the Arctic coasts, 30% of the buildings show signs of deformation. Mosgiptotrans, the railroad design company of Moscow, reports that 27.4% of the northern railroad embankments show deformation. With Yakutsk, these findings indicate that, on average, 30% of the infrastructure in the permafrost areas is in distress, irrespective of its type.

An analysis of the survey results for 114 damaged buildings in Magadan Province showed that 25% of the cases were due to improper site investigation and design, 17% due to inadequate site preparation and poor foundation construction, and 58% due to maintenance deficiencies. It follows that at least 83% of the problems are caused by errors in evaluation of construction conditions, and this corresponds to the lower level of the probable number of problem buildings. Thus, neglect of the urban construction quality of an area as a whole and individual construction sites produces a practically exact range: 25–30% damaged buildings. This range means that the precision of achieving a design purpose, expressed as the confidence probability of a target result, corresponds to the square root of variance. Hence urban development can be viewed as a stochastic process characterized by a normal distribution; i.e., the system control of the urban design and construction process is entirely absent. This is the reality of the urban development process in the permafrost regions.

Conclusions

The neglect of technical requirements in the construction practice in the North has no objective reasons. The northern communities that came into existence in recent decades are characterized by the same failure rate as Yakutsk with its 375-year history. The only way to solve the problem is enact into law and enforce the current urban construction regulations for permafrost areas discussed above.

Abstract

Data obtained from spaceborne platforms offer a significant advantage for studies conducted in arctic and subarctic areas where measurement stations are geographically scattered. The Land Surface (skin) Temperature (LST) products of the Moderate Resolution Imaging Spectroradiometer (MODIS), aboard NASA's Terra and Aqua satellite platforms, were retrieved over continuous and discontinuous permafrost zones. A temporal interpolating model was applied to fill gaps due to extensive periods of cloudiness (more than 50% of cloudy days per year were observed from 2000 to 2005). Mean annual and monthly near-surface temperatures, as well as freezing (Fi) and thawing indices (Ti) and the ratio (Ti/Fi), were calculated pixel by pixel over the six complete annual temperature cycles for large geographical areas. This approach provides a new and original view of surface temperature patterns over Quebec-Labrador. It is suggested that conditions favourable for permafrost have recently moved northward.

Keywords: freezing index; land surface temperature; MODIS; permafrost boundaries; thawing index.

Introduction

Many authors have mapped the spatial distribution of permafrost in the past using various climatological and terrain parameters. For this purpose, different methods for interpolating climate data between dispersed stations were used. The first maps used mean annual air temperature isotherms (Brown 1960, 1970, Heginbottom 1984, Johnston 1981), some added mean July air temperatures (Allard & Séguin 1987), and included typical permafrost landform reconnaissance (Allard & Séguin 1987, Brown 1979, Harris 1982, Jorgenson & Kreig 1988, Rochefort & Payette 2001). Others have used thawing and freezing indices to delineate permafrost zones (Hinkel et al. 2001, Nelson 1986, Nelson & Outcalt 1987, Riseborough & Smith 1998). Recently, active layer thaw depth has also been mapped from these indices (Hinkel & Nicholas 1995, Riseborough 2003, Shiklomanov & Nelson 1999, 2002), and improved by n-factors (Klene et al. 2001, Riseborough 2004, Shur & Slavin-Borovskiy 1993).

The arctic and the subarctic regions are remote areas where to install and maintain measurement stations is technically difficult and excessively expensive. Even so, it remains necessary to assess surface temperatures over the landscape to monitor the climate. The large swath scanned by satellite sensors allows for broad-scale mapping in a single satellite overpass. As satellite sensors measure radiative temperatures at the atmosphere/surface boundary. The satellite temperatures are called "skin" surface temperatures or near-surface temperatures. Mapping at a regional scale a subsurface phenomenon such as permafrost using satellites is hence a challenge. But since permafrost owes its existence basically to the surface temperature regime, mapping this controlling variable seems to be the most logical approach. Hence, this type of measurement is physically different from those collected with temperature sensors (thermistors) either in the air or in the ground, usually at depths of 2 to 10 cm.

The MODIS sensor aboard the Terra and Aqua satellites was chosen for three main reasons. First, the Land Surface Temperature (LST) product is distributed online where it is easily and rapidly accessible. Second, this product is retrieved by two satellites that overpass the same region twice daily: in the morning and in the evening. Third, the spatial resolution chosen (pixel size of 1 km²), on one hand, is coarse enough to compute and store regional mapping, and on the other hand, is small enough to keep an acceptable accuracy for delimiting boundaries over vast landscapes. The LSTs are tile-shape distributed. Each tile is a piece about 1113 km by 1113 km in 1200 rows by 1200 columns, in a sinusoidal map projection. Three tiles (h14v02, h14v03 and h13v03) are needed to cover the entire Quebec-Labrador area. The LSTs used herein start on February 24, 2000, for Terra, and from July 4, 2002, for Aqua, and end on May 31, 2005, for both satellites.

Skin temperature validations were made previously for different landscapes, Lake Titicaca (Wan et al. 2002), rice fields (Coll et al. 2005) and homogeneous landscapes on the Tibetan Plateau (Wang et al. 2007), using field radiance measurements. Stations used for each of these studies were comprised within 1 km². The amount of radiation reaching the satellite radiometer is modified by both atmospheric water vapour effects and surface emissivity effects (spectral

Table 1. Comparison between TM, Ti and Fi from Reference calculation with the ones calculated from the fitted sinusoidal equations Tair_sin et LST_sin.

	Mean annual TM		Degree-days of thawing (Ti)		Degree-days of freezing (Fi)	
	REF/ Tair_sin	REF/ LST_sin	REF/ Tair_sin	REF/ LST_sin	REF/ Tair_sin	REF/ LST_sin
R^2	0.90447021	0.4955715	0.47103442	0.20069824	0.85643988	0.83075603
rmse	0.656	1.6044	189.6851	370.4642	232.7709	251.3852
P-value	0.0001	0.0001	0.0001	0.0101	0.0001	0.0001

and angular) over the land. The very complex (e.g.,, heterogeneity of mixed land covers) effect produced suggest that for them accuracy can only be done in a few special cases, when surface and atmospheric properties are very well known (Prata 2000). For the present study, instead of radiance measurements, the available stations, which were far apart from each other, collected ground temperatures and meteorological data. As these stations represent several tundra landscapes (low and sparse vegetation), comparisons between LST pixel values and ground station temperatures cannot be used to validate LST for a particular square kilometer. Nevertheless, the evaluation of the level of agreement between MODIS LST (LST data) and near-surface air temperature measurements (Tair data) at 2–3 m above ground, at ground-based stations located in the continuous permafrost zones of northern Quebec and Alaska, yielded a very good correlation ($R^2 > 0.81$; $4.41 < RMSE < 6.89$; $-3.58 <$ mean bias < 5.92). From this first assessment, it was deemed feasible to try to use MODIS LST products to map the surface temperatures dictating the presence of permafrost and its thermal regime (Hachem 2007).

Temporal Interpolation

The Arctic is known for its high cloudiness weather regime. This persistent cloudiness is evident through the analysis of measurements from 15 stations in Alaska and northern Quebec. The year had been divided in two parts to simplify calculations. As summer begins on June 1 and ends on September 30, it is composed of the four warmest months of the year. The additional months are defined as winter, i.e., from October 1 to May 31. All stations taken together showed a number of cloudless days of 23 (19%) during summer and of 88 (36%) during winter, summing to slightly more than a hundred days per year. As LSTs are measured at cloud-sensitive Earth-emitted thermal infrared wavelengths, for each cloudy day, LSTs are missing. Over a year, there are many weeks during which the presence of a cloud cover prohibited the determination of surface temperatures by space-based thermal infrared sensors. This setback was partly overcome through developing a statistical model of the temporal LSTs distribution.

Mathematically, the annual distribution of temperatures can be expressed by the following sinusoidal function:

$$T_t = T_m - A_0 . \cos\left(\frac{2\pi t}{P} - \phi\right) \qquad (1)$$

where T_t is the measured temperature at time t, T_m is the mean annual temperature, A_0 is the amplitude, P is the period (a constant equal to 365 days), and ϕ is the phase (Williams & Smith 1989).

From this equation mean annual temperature (T_m) is directly given, freezing (F_i) and thawing indices (T_i) are obtained by calculating the integrals under the sinusoidal curve, corresponding to the sum of negative temperatures (freezing degree-days) and positive temperatures (thawing degree-days), respectively (i.e., consecutive winter and summer). The sinusoidal curve was calculated to fit to LSTs and Tair data. Results from this calculus were named LST_sin, and Tair_sin, the sin abbreviation refer to the fitted sinusoidal equation.

As Tair were measured at field stations, we also calculated the Tm, Fi, and Ti as it is usually done, and named the results from these calculations REF.

We compared Tm, Fi, and Ti calculated with the year-by-year fitted equations from LSTs (LST_sin) and Tair (Tair_sin) data with Tm, Fi, and Ti calculated the usual way from Tair (REF). The LSTs used for comparison were taken from pixels which coordinates include a meteorological station in the field.

Table 1 shows statistical analyses of the different calculated Tm, Ti, and Fi. There are very good correlations between Tm and Fi, calculated from the LST dataset and recorded air temperatures, and a good correlation between the two sets for Ti (Hachem 2008). The statistical model gives excellent results for the two Tair datasets (REF and Tair_sin), which validates the use of this model. It still provides good results when REF is compared with LST_sin. Nevertheless, Ti correlations are very low (Table1). This is not necessarily related to the model used or to the absence of cloudy day values. Actually, Ti is known to be a highly variable parameter, as well as between two consecutive years than between stations only a few meters apart (Klene 2000).

The statistical algorithm was devised to derive the equation of the sinusoidal curve that best fits MODIS LST for each year of data and for each image pixel. Through applying that relationship to LST data over the pixels, Fi and Ti maps were drawn.

A New View of Quebec-Labrador Permafrost Distribution

Tm, Fi, and Ti maps description

The Tm, Fi, and Ti maps (not presented here) are an average over six years, from 2000 to 2005, and correspond to

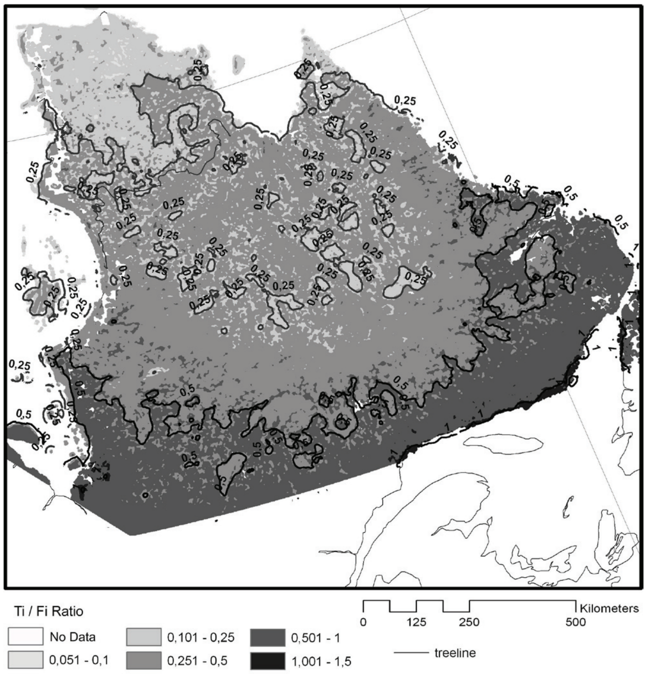

Figure 1. Ti/Fi ratio map.

Figure 2. After Payette & Rochefort (2001). A: continuous permafrost zone. B: discontinuous permafrost zone; B¹: more than 50% of permafrost; B²: less than 50% of permafrost; B³: maximal concentration of cryogene hillock and plateaus formed in Tyrrell Sea loamy silt. C: sporadic permafrost (less than 2%). D: annual frozen soils. Otish (1) mounts and Groulx mounts (2) are two high summit permafrost enclaves in sporadic permafrost zone. Chic-Choc mounts (3) and Lac des Cygnes mount (4) are high summit permafrost enclaves in annual frozen soil zone. (R. is used to indicate "reservoir," i.e., La Grande Reservoir.)

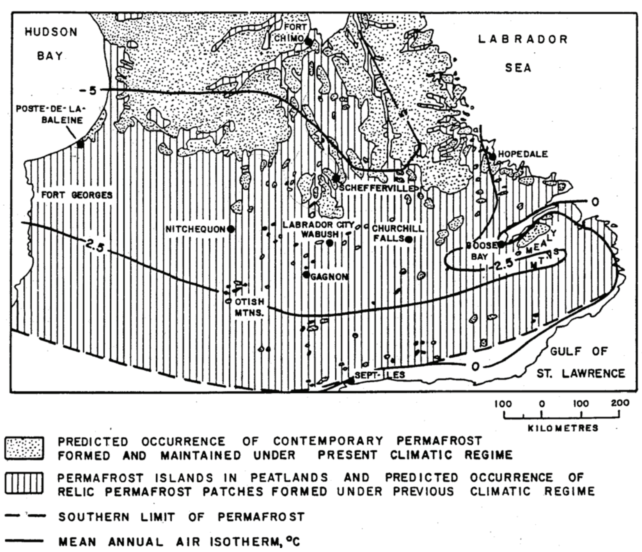

Figure 3. Discontinuous permafrost (Brown 1979).

a mixture of temperatures from different cover types included within a single pixel (1 km²). They all show a similar climate pattern (latitudinal, altitudinal, continental distribution, and large lakes). Colder areas are northernmost. The central section of northern Quebec is colder than coastal areas–a poorly documented observation until now as no stations are located on the high central plateaus of the peninsula. Also, due to Hudson Bay influence and barrier effects by the Torngat Mountains, the east coast of the Quebec-Labrador peninsula is colder than the west coast. Moreover, the maps show that large water bodies produce colder microclimates that influence the surrounding land areas (within 2 pixels of water bodies). However, in the continuous permafrost zone, large river basins show warmer temperatures than the surrounding plateaus (Hachem 2008). The high elevated topography is easily identifiable because of the cold tops which are colder than the plains.

The Ti/Fi ratio map

Anisimov & Nelson (1997) used Fi and Ti ratios to estimate the presence or absence of permafrost. If F_i is greater than T_i, it means that the mean annual temperature is below 0°C, suggesting that permafrost is likely to be present. Whereas if F_i is less than T_i, then the heat gain in summer is large enough to counterbalance the heat loss in winter, hindering permafrost to form, or in areas where it is present, leading to its disappearance over time. In addition, if T_i increases over time and remains greater than F_i, it can be deduced that the active layer is thickening, leading to the progressive disappearance of permafrost from the top downward. Here, we used the T_i/F_i ratio (Fig. 1) to provide a first estimate of the presence or absence of permafrost.

However, this estimate could be improved either by calculating the frost number (Nelson & Outcalt 1987) or by including the "buffer" information (Riseborough 2004). The frost number is defined by Nelson & Outcalt (1987) as a dimensionless ratio using freezing and thawing degree-day sums and gives a device for portraying the distribution of contemporary permafrost at continental scales. The "buffer layer" effect, often integrated in the n-factor, corresponds to the impact of factors affecting heat exchanges between the atmosphere and the ground surface (i.e., vegetation, organic layer, snow cover).

The Ti/Fi ratio map (Fig. 1) is divided into three main parts, by two isolines. The 0.25 isoline (i.e., when Fi is four times as large as Ti) corresponds and follows nearly the southern limit of the continuous permafrost drawn by Payette & Rochefort (2001), based on general knowledge of landforms and vegetation zones (Fig. 2), which corresponds also to the +10°C isotherm of the mean air temperature of the warmest month of the year (Allard & Séguin 1987). Herein, July was used as the warmest.

The 0.5 isoline (i.e., when F_i is twice as large as T_i)

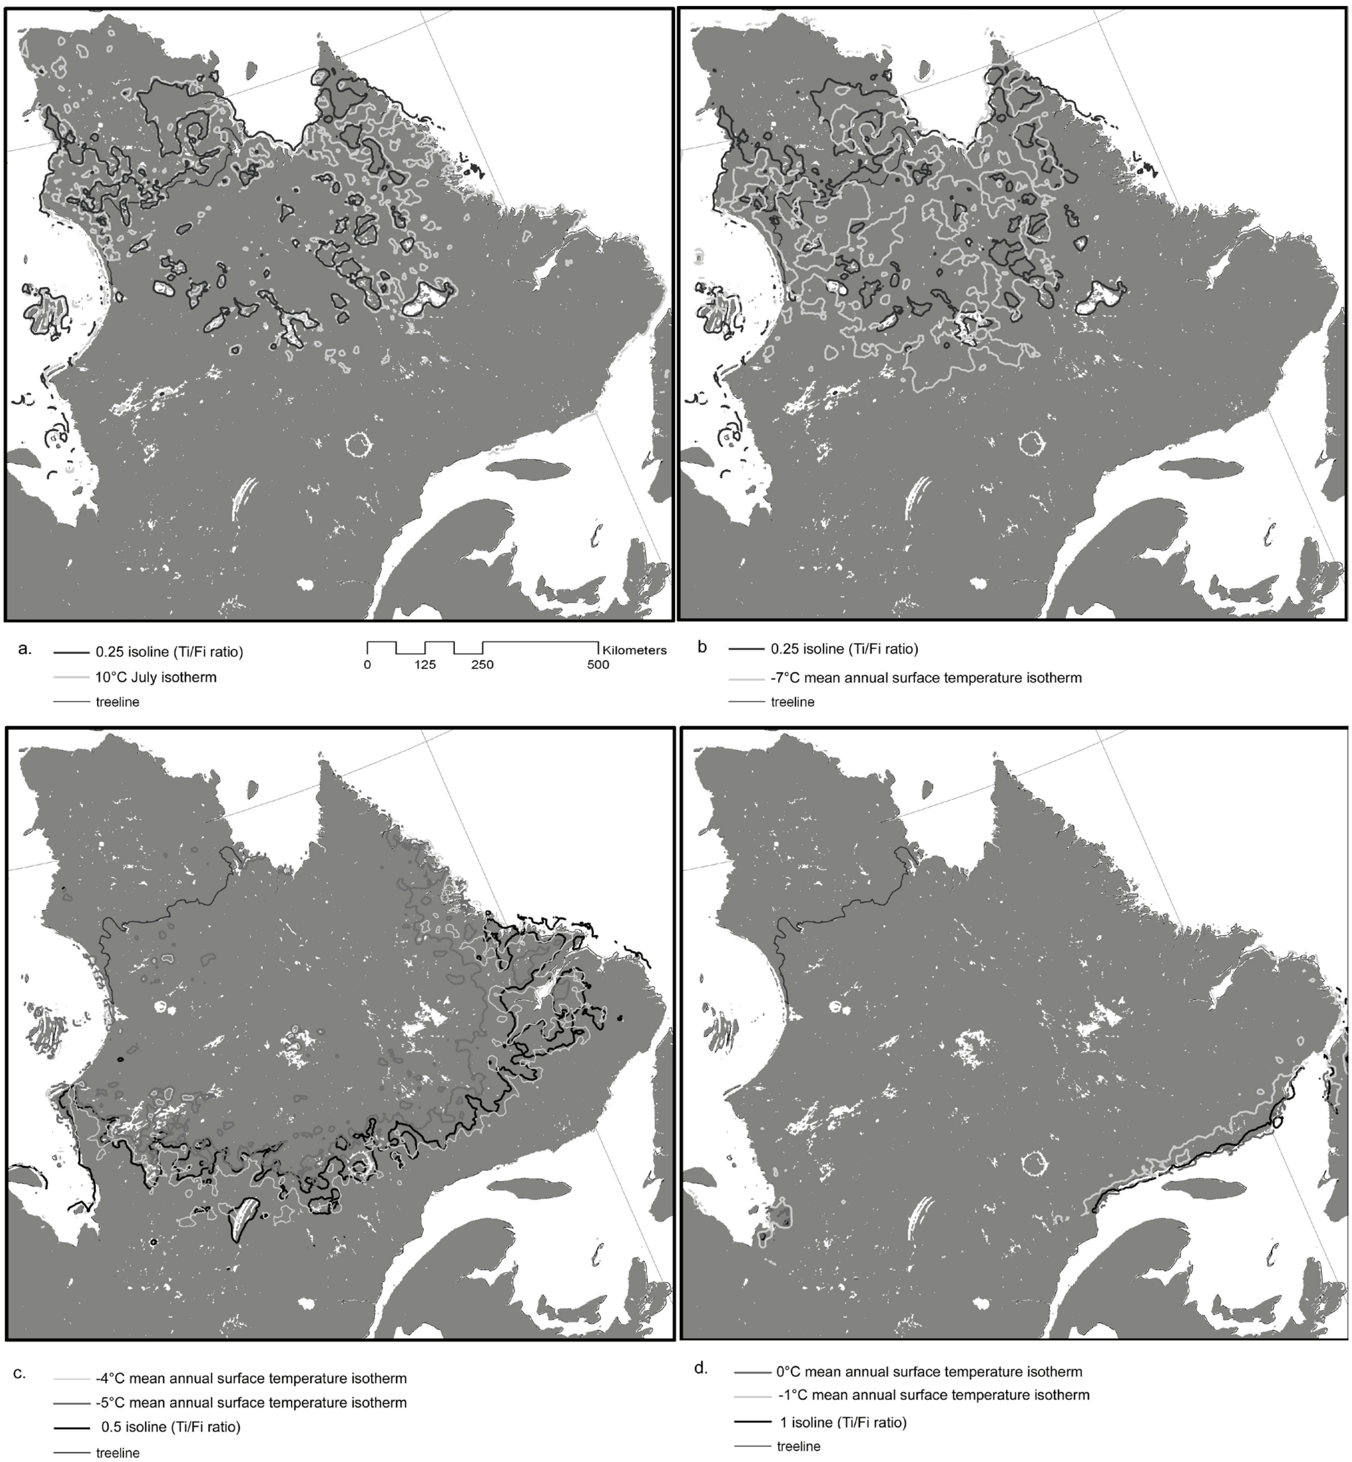

Figure 4. Comparisons of different potential limits of permafrost.

corresponds rather well to the known southern limit of the Brown's (1979) sporadic permafrost zone drawn by Figure 3.

Therefore, this first map is a promising starting point to pursue the next mapping steps.

Northern Quebec-Labrador permafrost limits

A consensus exists in the literature that permafrost extent can be mapped in three categories: continuous, discontinuous, and sporadic or isolated patches. The categories are not perfectly established and depend on what characteristics are mapped (e.g., percentage of frozen soil actually related to ground ice conditions, or air isotherms) and on mapping scale (Heginbottom 2002). While mapping the northern Quebec-Labrador peninsula one limiting criteria chosen by Allard & Séguin (1987) was the +10°C isotherm for the warmest month of the year (corresponding to the tree line) as the boundary between discontinuous and continuous permafrost. The limit between discontinuous and sporadic permafrost was roughly the -−1°C isotherm of mean annual air temperature. Inclusion of other information such as topography, physiography, surface geology, soil moisture, content vegetation, and snow cover would help to better define boundaries and map distribution of permafrost patches in greater detail.

A relatively good correspondence appears between key Ti/Fi ratio contour lines and key isotherms that are generally used for interpreting the boundaries of permafrost zones. For instance, Figure 4a shows the excellent correspondence between the 0.25 Ti/Fi ratio contour line and the +10°C July isotherm, both measured with the MODIS sensor, therefore supporting the idea that this contour fits roughly with the boundary between continuous and discontinuous permafrost. It is to be noted, however, that this line was further north than the tree line during the period 2000–2005, which agrees with observed recent climate warming. This suggests that climate conditions propitious for continuous permafrost are currently moving northward. The -7°C mean annual surface temperature (MAAT) isotherm derived by MODIS on Figure 4b is likely a better approximation of the diffuse boundary between widespread (>50%) and scattered discontinuous permafrost (<50%) than what was previously estimated. The overlapping 0.5 Ti/Fi ratio contour line and -5°C MAAT isotherm in Figure 4c can be associated with the southern limit of discontinuous permafrost. Finally, sporadic occurrences of permafrost can occur as far south as the 0°C MAAT isotherm, in good correspondence with Brown's permafrost map (Fig. 4d).

Conclusion

We developed a statistical model that uses MODIS LST to map mean monthly and annual surface temperatures as well as freezing and thawing indices, as an alternative to conventional ground-based measurements which are spatially limited. Thermal permafrost limits were added through the calculation and mapping of the Ti/Fi ratio contour lines. These maps compare rather well with maps drawn by previous authors based on ground-collected data. They can be used only as a first approximation since other (local) factors such as snow cover, vegetation, and organic layers—variable with moisture content—create a "buffer" effect between the atmosphere and the surface which is not included in the Ti/Fi ratio.

These maps bring in new knowledge regarding the spatial distribution of temperatures across northern Quebec-Labrador. In an upcoming study, maps similar to the ones presented in this paper will be produced to encompass the entire pan-arcticArctic domain. They could be improved if n-factors are available. Also it would be possible to input the Ti in different models calculating active layer thickness (TTOP [Riseborough 2003], the frost number [Nelson & Outcalt 1987], or the GIPL model [Sazonova & Romanovsky 2003]). This approach with MODIS data is also a new tool available for monitoring surface temperature changes at a high spatial resolution.

Research Challenges for Permafrost in Steep and Cold Terrain: An Alpine Perspective

Wilfried Haeberli
Glaciology, Geomorphodynamics & Geochronology, Geography Department, University of Zurich, Switzerland
Stephan Gruber
Glaciology, Geomorphodynamics & Geochronology, Geography Department, University of Zurich, Switzerland

Abstract

The past few decades have seen a rapid development and progress in research on permafrost in mountain areas with complex and rugged topography such as the European Alps. At the same time, it becomes increasingly clear that climate change impacts have the potential to severely affect future living conditions in areas with steep and cold terrain by influencing the chain of surface processes that link debris production via rock fall to talus/moraine formation, creep deformation of frozen deposits, and material evacuation by debris flows and fluvial transport. Key scientific challenges relate to special aspects induced by complex topography. Corresponding aspects are briefly outlined concerning the relation between the atmosphere and the permafrost in areas with highly variable snow cover and potentially strong lateral energy fluxes, permafrost thermal conditions in mountains with pronounced microclimatic asymmetries, the destabilization of steep to near-vertical rock walls and degrading permafrost, the flow and stability of ice-rich frozen debris with increasing subsurface temperature and melt water availability, interactions between glaciers and permafrost under conditions of rapid if not accelerating change, 4D-evolution of permafrost in rugged mountain topography, and hazards from permafrost slopes in densely populated high-mountain chains.

Keywords: climate change; cold regions; mountains; natural hazards; permafrost; slope stability.

Introduction

The first contributions in the Proceedings of the International Permafrost Conferences about permafrost in mid-latitude, high-altitude mountain regions started to appear in the late 1970s (e.g., Barsch 1978, Fuji & Higuchi 1978, Gorbunov 1978, Haeberli 1978, Harris & Brown 1978). This indicates the essential beginning of systematic research on permafrost in high-mountain areas and led to a first visibility peak at the International Workshop on Mountain Permafrost in Interlaken 1991 with a first set of overview papers (cf. situation reports by Barsch 1992, Guodong & Dramis 1992, Haeberli 1992, Harris & Corte 1992, King et al. 1992, Lautridou et al. 1992). During its rather young history, research on permafrost in steep and cold terrain developed and expanded rapidly. Perhaps the most important impulse was the EU-funded PACE project (Permafrost and Climate in Europe, Harris et al. 2001). The subsequent progress and increase in visibility is impressing: high-mountain permafrost is now described for many regions (for instance, Isaksen et al. 2007, Jin et al. 2000, Marchenko 2007, Trombotto 2000) and is regularly included in international assessments on cryospheric conditions, especially as related to climate change (IPCC 2007, UNEP 2007, cf. also Harris 2008).

Climate change indeed constitutes a major challenge for the science of mountain permafrost as it concerns a phenomenon that depends on atmospheric conditions in a complex way, is not directly accessible through visual observation, often involves logistic problems with difficult access and strikingly lacks observational series over extended time periods. As a consequence, even key questions are still open for detailed investigations. The present contribution focuses on special aspects related to rugged topography and steep terrain. It is primarily built on experience from the European Alps as summarized in recent reviews (Harris et al. 2008, Gruber & Haeberli 2008, Haeberli & Gruber 2008) and briefly outlines a set of high-priority research topics covering process understanding, numerical modeling and the anticipation/assessment of potential climate change impacts. The basic structure of the considered geo-system (Fig. 1) as is characteristic for mountain ranges with transitional to continental climate—where glacier equilibrium lines are far above the 0°C-annual isotherm—is the process chain leading from debris production via rock fall to debris cone or moraine formation, creep deformation of frozen deposits and sediment evacuation to larger valleys by fluvial transportation and debris flows.

In the following discussion, the most important conclusions based on existing knowledge are briefly outlined and major challenges concerning research on mountain permafrost are discussed. We thereby distinguish seven major topics: (1) atmosphere-permafrost coupling in complex topography; (2) permafrost thermal conditions inside mountains; (3) destabilization of permafrost rock walls; (4) flow and stability of ice-rich frozen debris; (5) glacier/permafrost interactions; (6) 4D-evolution of permafrost in mountain topography; and (7) hazards related to rock falls and debris flows from permafrost slopes.

Topics (1) to (5) are related to necessary improvements of our process understanding. The spatio-temporal consideration, on the other hand, is more and more urgently needed for realistically assessing consequences and impacts from continued atmospheric warming. The discussion

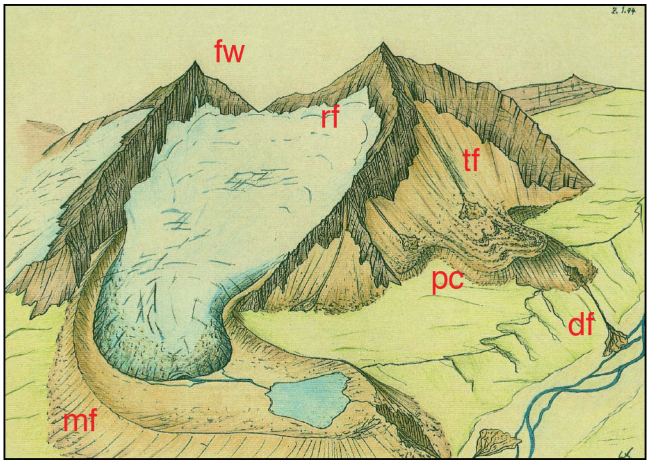

Figure 1. Scheme of the characteristic process chain in cold mountain areas: frost weathering (fw) and debris production, rock fall (rf), talus (tf) or moraine formation (mf), permafrost creep (pc), evacuation by fluvial transport and debris flows (df). Adapted from Haeberli (1996).

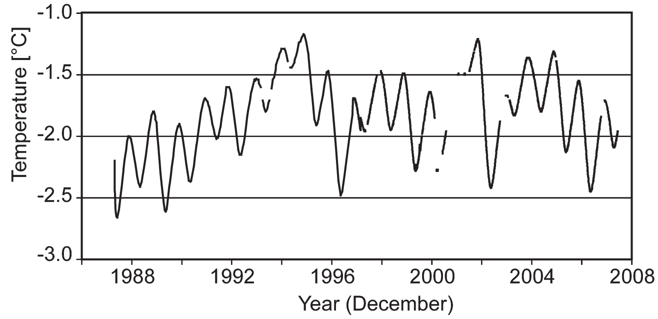

Figure 2. Borehole temperatures in the active Murtèl rock glacier. The winters of 1996, 2002 and 2006 had thin snow cover causing strong ground cooling despite relatively warm air temperatures.

therefore also includes two central aspects—topics (6) and (7)—related to the assessment of local, regional and global impacts of climate change and the anticipation of corresponding hazard potentials.

Atmosphere-Permafrost Coupling in Complex Topography

The now 20 years old series of borehole temperatures in the Murtèl rock glacier (Fig. 2) clearly shows the important influence of the winter snow cover on near-surface ground temperatures. This effect of snow on relations between the atmosphere and the permafrost has been investigated using measurements (Keller & Gubler 1993) and snow/permafrost models (e.g., Lütschg et al. 2003). A number of studies also address the cooling influence that coarse blocks exert on ground temperatures when compared with lower porosity or finer-grained surface materials (Hanson & Hoelzle 2004, Hoelzle & Gruber 2008).

The effect of topography on temperatures in steep rock has been investigated with measurements (Gruber et al. 2003) and model experiments (Gruber et al, 2004 a, b, Noetzli et al. 2007, Salzmann et al. 2007). Despite significant progress in understanding these processes of atmosphere-permafrost coupling, the high spatial variability of surface micro-climatology and subsurface properties in mountain terrain makes the generalization of findings to larger areas difficult. One example is the thermal effect of thin and intermittent snow cover in rock faces that has not been quantified to date.

The role of heat advection by moving water or air in sediments or in cleft systems is a further set of processes that is little understood but that bears high relevance for the anticipation of climate change impacts (fast thaw along frozen joint systems and corresponding rock fall) and for the understanding of permafrost dynamics (Gruber & Haeberli 2007). Especially lateral transfer of sensible as well as latent heat through ventilation effects in steep, coarse-grained debris or by melt water in heavily fissured, near-vertical rock walls appear to be essential.

Permafrost Thermal Conditions Inside Steep Mountains

Measured borehole temperatures (Harris et al. 2003, Gruber et al. 2004c, Isaksen et al. 2007) and combined time-dependent energy balance and heat diffusion modeling for complex topography (Noetzli et al. 2007) now document the main thermal characteristics of cold mountains. Summits can be frozen to depths of nearly 1000 m, and often have strongly asymmetrical thermal fields with steeply inclined isotherm configurations and predominant lateral heat flow from warmer to colder outer rock walls. The uppermost parts of such ridges and summits are essentially decoupled from geothermal heat and, due to their geometry, enable thermal disturbances to penetrate from two or more sides. Atmospheric warming during the 20th century has caused pronounced thermal anomalies to depths of about 50–70 m below surface. In perennially frozen debris (talus, moraines, rock glaciers) with high ice contents near the lower boundary of local permafrost occurrence, temperatures below the depth of zero annual amplitude have, in places, reached phase equilibrium condition (pressure melting) throughout (zero or near-zero heat flow).

The formation and existence of unfrozen zones within permafrost (taliks) as documented, for instance, in the borehole through Murtèl rock glacier in the Swiss Alps (Vonder Mühll et al. 2003), constitutes a disturbance and heterogeneity for subsurface heat and energy flow. Positive feedback between energy input and hydraulic permeability most likely causes such effects to be widespread in warm permafrost, to increase in importance with continued warming and often to dominate over heat conduction through extended subsurface layers.

The occurrence and intensity of corresponding processes, however, are hardly known and most difficult to predict. Individual observations at high-mountain railway and cable car stations (Fig. 3) point to the importance of the

Figure 3. A roof protects tourists from melt water that only recently began to percolate through the rock mass above the tunnel inside the Jungfraujoch rock crest, 3500 m asl, Swiss Alps.

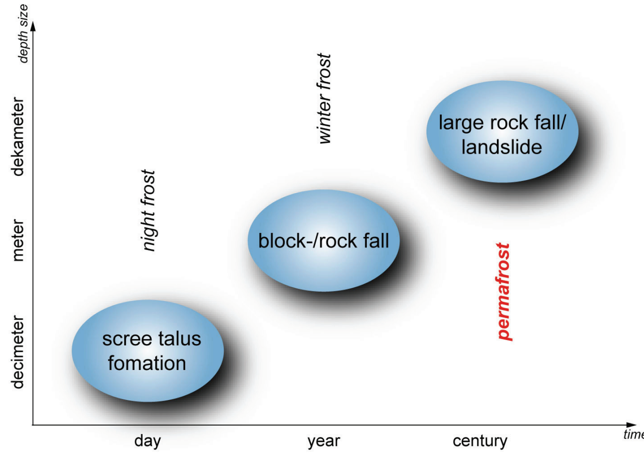

Figure 4. Scales of frost weathering and gravity driven mass wasting in rock walls.

phenomenon (Gruber & Haeberli 2007) and approaches to scientifically investigate these phenomena are now being developed (Hasler et al. 2008). Geophysical tomography (seismic refraction, electrical resistivity, Hauck & Vonder Mühll 2003, Krautblatter et al. 2007, Sass 2003), drilling/borehole temperature monitoring in fissured rock with warm permafrost (cf. Vonder Mühll et al. 2008) and the combination of heat diffusion modeling with other sources of information (Noetzli et al. 2008) for defining the conductive part of changes in the subsurface thermal field appear to be the most viable research avenue.

Destabilization of Permafrost Rock Walls

It is now quite well understood that frost-induced processes of rock destruction act on scales of time and depth that are often—but not always—connected via heat diffusion (Fig. 4). Seasonal to perennial frost, strong spatial temperature gradients in ridges and the availability of snowmelt water in active layers are likely to promote ice segregation involving depth scales of decimeters to tens of meters. Laboratory investigations (Davies et al. 2001) indicate that critical temperatures for the destabilization of frozen rocks with ice-filled cracks on steep slopes can also be reached at temperatures of -1 or -2°C. With continued warming, permafrost in cold mountains reaches such critical temperatures over more and more extended areas and over increasing depths. As a consequence, the probability of large rock falls from warming permafrost in steep to near-vertical rock walls is increasing. The process of rock destabilization by permafrost thaw is supported by observational evidence and theoretical consideration (Gruber & Haeberli 2007). However, we know little about the dominant processes responsible. Frequent rock fall during the extremely hot and dry summer 2003 in the Alps occurred in July, long before the active layer reached its maximum depth and long before it exceeded maximum thaw depths of previous years based on pure heat conduction modeling (Gruber et al. 2004c). Failure is therefore likely to have taken place under the influence of factors other than pure thaw to excessive depths. This finding points to the role of fast linear thaw along joint systems by heat advection during water transport. The influence of melt water penetrating into partially frozen rock may also be a reason for the strikingly high proportion of detachment zones from partially or at last strongly asymmetrically frozen summits and crests with marginal or even absent permafrost on the warm side. Reanalysis of recent rock falls (cf. Fischer et al. 2006, Noetzli et al. 2003) using energy balance modeling for defining pre-failure thermal conditions in the detachment zones is presently being undertaken in the Swiss Alps. International collaboration and exchange of information is important in order to expand the sample size and to enable reliable statistical analysis.

Flow and Stability of Ice-Rich Frozen Debris

The number of observations concerning flow phenomena in mountain permafrost using high-precision photogrammetry, geodesy and borehole measurements as combined with relative and absolute age dating and numerical modeling is rapidly increasing. The corresponding evidence now provides a quite coherent image of the processes, which govern cumulative long-term deformation of perennially frozen debris (talus, moraines etc.) containing ice in excess of the pore volume available between the rock particles under unfrozen conditions (Haeberli et al. 2006). Corresponding steady-state creep of ice-supersaturated debris over millennia—most probably since the end of the last Ice Age—led to the formation of the widespread and spectacular landforms called (active) rock glaciers. A major part of the straining obviously takes part within discrete shear horizons. The deforming fine-grained material from the upper part of talus cones thereby carries large blocks at its surface, which were deposited at the foot of the same talus cones, ride along the flow trajectory with maximum (surface) speed and, therefore, fall over the rock glacier front (where the creeping fine-grained material is exposed again), are overridden and

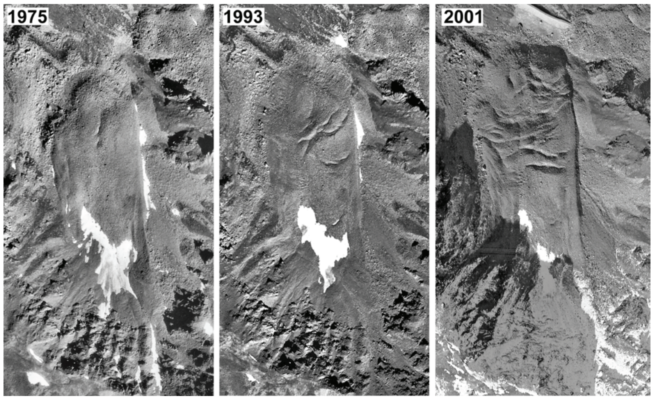

Figure 5. Grueo 1 rock glacier in the Turtmann Valley (Swiss Alps) showing signs of accelerating flow and intense crevasse formation (from Roer 2007).

form a saturated "structured" permafrost layer at depth with damped creep behavior. Seasonal and inter-annual variations of surface velocity can be observed where the permafrost base is not in bedrock but in non-frozen sediments.

The most surprising recent observation concerns the spectacular inter-annual variations of flow velocity as documented over wide areas in the European Alps in connection with the extremely hot/dry summer of 2003 (Delaloye et al. 2008, Kääb et al. 2006). Many rock glaciers with fronts near the local boundary of permafrost occurrence accelerated their flow speed almost simultaneously in the same year 2003 by a factor of two to five or even more and then more steadily decelerated to average long-term flow rates over the following about three years with less extreme conditions. The processes explaining this striking regional-scale phenomenon still remain to be explained (Roer et al. 2008). Rheological softening of ice/rock-mixtures by permafrost warming at temperatures close to phase equilibrium and at depths close to the expected shear horizons may have been part of the answer (Kääb et al. 2007). Increased melt water infiltration into already "temperate" or at least very warm permafrost may have been another contribution (Ikeda et al. 2007). Higher water pressure causing softening of subpermafrost sediments may also have come into play and enhanced mobility within the shear horizon itself cannot be excluded either. Continued high-resolution flow observations will help clearing the difficult question about corresponding interactions between the processes mentioned. Already now, however, the stability problem connected with warm permafrost in rock glaciers on steep mountain slopes received a new dimension. With the formation of striking crevasse patterns as a result of accelerated flow (Fig. 5, Roer et al. 2005), strong heterogeneities with respect to cohesion, hydraulic permeability and stress distribution developed within the creeping permafrost: possibilities for the triggering of debris flows and even landslides in such cases is no more restricted to the over-steepened frontal parts of rock glaciers alone (cf. Arenson et al. 2002).

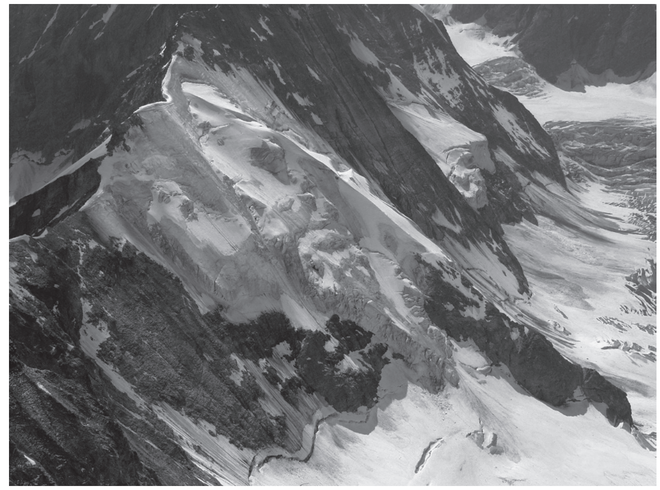

Figure 6. Hanging glaciers and ice faces on the northern side of the ridge extending between the Matterhorn and the Dent d'Herens along the border between Switzerland and Italy. Interactions between polythermal surface ice and subsurface permafrost are complex, especially with conditions of rapid atmospheric warming. Photo by S. Gruber.

Glacier-Permafrost Interactions

Interactions between glaciers and permafrost are widespread in regions with moderately to strongly continental climate, because the equilibrium line on glaciers is situated inside zones and altitudinal belts with discontinuous and continuous permafrost occurrence. Information concerning this important aspect is sparse at present (Haeberli 2005), especially because the scientific communities involved in permafrost and glacier research still communicate far too little. Results from geophysical soundings, miniature temperature data-logging, shallow borehole observations and photogrammetric movement determinations show that subsurface ice in glacier forefields successively exposed since the end of the Little Ice Age is often polygenetic (Kneisel 2003). It is most likely derived from recent ground freezing in cold microclimates of formerly temperate bed parts after glacier retreat, preservation of former subglacial permafrost underneath cold marginal parts of polythermal glaciers, burial of "dead ice" from the glacier itself or a combination of these processes. Ice-containing parts of morainic deposits commonly show signs of lateral flow and vertical displacements (heave, subsidence, cf. Kääb & Kneisel 2006).

Most important questions concern the evolution of permafrost in recently deglaciated moraines under the influence of changing surface conditions and continued atmospheric warming at lower altitudes and the thermal structure and stability of high-altitude hanging glaciers in steep, perennially frozen rock walls at higher elevations (cf. Gruber & Haeberli 2007). The stability of often polythermal hanging glaciers with temperate and permeable firn behind and above cold and rather impermeable cliffs (Fig. 6) and their thermal and hydraulic interaction with the permafrost inside the underlying rock walls (Lüthi & Funk 1997) may indeed constitute a key factor concerning large ice/rock avalanches with extremely far runout (Haeberli et al. 2004, Huggel et al. 2005). At a different level of process understanding, another common phenomenon deserves much more attention: basal regelation layers of glaciers are nothing else than epigenetic permafrost in fine grained sediments—often with large amounts of excess ice and ice lenses—attached to the base and deforming under peak stresses and at maximum strain rates of the corresponding glaciers. Improved knowledge about the rheology of the involved creep phenomena would provide essential insights with respect to non-isotropic flow characteristics of ice sheets, glaciers and rock glaciers.

Spatial Patterns and 4D-Evolution of Permafrost in Mountain Topography

Spatial distribution patterns of permafrost in complex high-mountain topography can be estimated by distributed modeling of the surface energy balance and sub-surface heat transfer. However, this implies knowledge of surface and sub-surface characteristics, proper initialization techniques, as well as methods for snow redistribution by wind and avalanches (Gruber 2007). Full energy balance models (e.g., Lehning et al. 2002) can make use of high (hourly or more frequent) time resolution, and thus resolve effects like the diurnal variability of convective cloud formation that often can have an essential influence on spatial ground temperature distribution.

A variety of models from empirical-statistical to more process-oriented approaches have so far been used with considerable success (Etzelmüller et al. 2001, Gruber & Hoelzle 2001). The Swiss Federal authorities have now produced a 1:50,000 map of permafrost distribution for the entire Swiss Alps. The model used for producing this map is more empirical-statistical but includes a discrimination between steep rock faces with little snow and less inclined slopes with thick winter snow (Gruber et al. 2006). First experiments with coupling regional climate models and GIS-based impact models indicate that warming trends are stronger in north-facing (shadow) than on sunny south-exposed slopes, because the relative influence of sensible heat effects in comparison to solar radiation is stronger (Salzmann et al. 2007). First successful attempts have also been made to couple surface energy balance with heat diffusion at depth for high mountains (Noetzli et al. 2007).

The main steps to follow this successful development consist in expanding such spatial modeling to all cold mountains on earth based, for instance, on SRTM or ASTER digital elevation and global climate data or model scenarios. Another important progress would be to further improve and validate modeling also on less inclined slopes covered by thicker and more irregular snow cover including cases with high ice contents using transient modeling. A possible result could be the coupling of thermal and geomorphic spatial models such as the modeling of creep phenomena as demonstrated in first encouraging attempts by Frauenfelder (2005). There is, undoubtedly, a long way to go for even

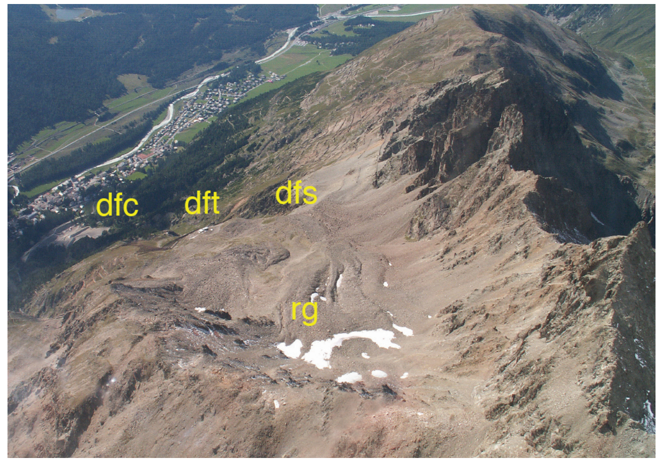

Figure 7. Creeping permafrost (rock glaciers rg) and debris flow starting zone (dfs), trajectory (dft) and cone (dfc) above Potresina (Swiss Alps). Note recently constructed avalanche and debris flow retention dam on cone. Photo by C. Rothenbühler.

partially reaching such research goals. However, already relatively rough approaches and early accomplishments could help with making it clear to scientists as well as policymakers and the public that permafrost belongs to the primary characteristics of cold mountain areas, that it relates to many other phenomena like snow, glaciers, erosion or slope stability, and that atmospheric warming causes growing disequilibria already now but even much more so in the foreseeable future.

Hazards Related to Rock Falls and Debris Flows from Permafrost Slopes

Debris flows from rock glaciers and moraines in permafrost areas (Fig. 7) can be among the largest debris flow events in mountain areas and cause devastating damage to settlements and infrastructure in valley bottoms.

Large-scale rock falls from steep to near-vertical rock faces seem to take place at increasing frequency and can propagate to areas far below timberline. They can dangerously erode or mobilize thick snow packs, glaciers, or water bodies, thereby undergo process changes, transform into high-speed flows or trigger flood waves which can reach extremely far runout distances and cause severe damage to human lives and economy. In the Swiss Alps, for instance, the 500,000 m^3 debris flow at Guttannen in 2005—probably the largest during decades back in time—started from a large moraine accumulation where (rather marginal) permafrost may have helped to transfer the water runoff from extreme precipitation to cross the flat cirque floor and to reach the steep outer moraine slopes. In the valley bottom, the large deposited debris volume dammed the Aare river which itself had peak flood discharge and soon started to overflow the debris dam and to cut a new bed on the other side of the principal road. As a logical consequence, the large river reached and damaged the village before heavy machines could cut an opening through the road and force the river back into its abandoned bed.

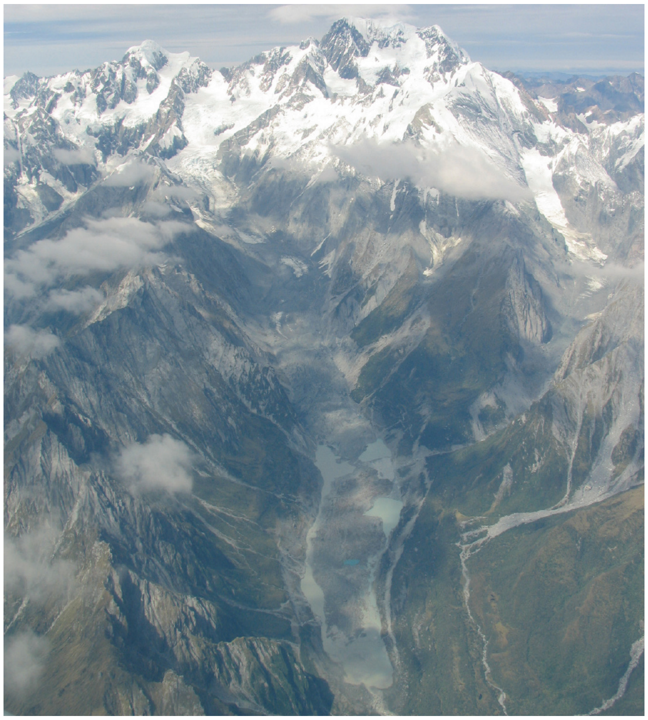

Figure 8. Disintegrating glacier tongue and formation of a large lake in the New Zealand Alps. Such lakes constitute an increasing hazard potential with respect to flood-waves triggered by rock falls from deglaciated slopes and/or slopes with warming and degrading permafrost. Photo by M. Hoelzle.

In the Caucasus, a combined ice/rock avalanche from the perennially frozen north wall of Dzimarai Khkok near Kazbek volcano eroded a medium size debris-covered glacier almost entirely. The mobilized mass squeezed out large amounts of probably subglacial water, turned into a high-speed two-phase mass flow and traveled over a runout distance of about 33 kilometers. Rivers from tributary valleys were dammed by the deposits to form lakes drowning parts of a local village and constituting a flood wave threat to people even in settlements situated far downstream (Haeberli et al. 2004, Huggel et al. 2005). Despite large uncertainties involved with the present understanding about the exact triggering and flow mechanisms of such events, hazard potentials from similar future phenomena must be anticipated and assessed at the best possible level of experience and knowledge.

GIS-based models to estimate flow paths and runout distances of ice/rock avalanches and debris flows in rugged high-mountain topography exist and can be applied already now (Huggel et al. 2003, Noetzli et al. 2006). Perhaps the most urgent need concerns the possibility of large ice/rock falls into existing lakes or lakes that newly form as a consequence of glacier retreat and downwasting (Haeberli & Hohmann 2008, Fig. 8). Debuttressing of formerly glacierized valley walls in combination with permafrost warming could thereby be an especially critical condition. In fact, primary factors influencing the stability of steep permafrost slopes are:

- slope inclination and topographically unsupported parts;
- geological structure (layer dipping, crack density and orientation);
- permafrost conditions (temperature, ice content, hydraulic permeability); and
- topographic evolution (erosion, glacier vanishing, earlier events).

Among these factors, permafrost and glacier conditions are changing most rapidly. Together with slope inclination, they can be spatially modeled in order to find most critical factor combinations. In a second step, possible flow trajectories of avalanches from such sites and their potential interactions and process chains involving snow, glaciers and/or water bodies could be modeled in order to detect places of highest risk. Such preliminary analyses over large areas would help to direct more detailed geological investigations and to establish focused monitoring or adequate protection measures. Integrative hazard assessment is far more than an academic idea: the potential for very large catastrophes is neither negligible nor undetectable. It rises at an accelerating rate with continued deep warming of high mountain permafrost, rapid glacier vanishing and drastic changing of alpine landscapes and habitats.

Further Issues and Perspectives

Besides the concrete challenges mentioned with respect to the described specific topics, three important challenges can be envisaged for future research on mountain permafrost: (a) holistic understanding; (b) increasingly quantitative methods; and (c) applied research. Holistic understanding is the broad understanding of all permafrost and its role in mountain landscapes. Our understanding at present is largely focused on special cases such as rock glaciers or steep bedrock but in fact, most permafrost has characteristics that lie in between these two cases and that are poorly constrained. Also, the transient interaction between permafrost and glaciers or the long-term influence of permafrost on the evolution of mountain topography remains largely unknown. Quantitative methods are necessary in order to understand and disentangle processes of increasing complexity. This requires not only infrastructure (such as data and models), but also novel concepts for the validation of models and for the analysis of uncertainty and scale issues that are among the most prominent characteristics of quantitative research in mountain areas. Applied research, for example in collaboration with public authorities or operators of high-elevation infrastructure, helps to transfer knowledge and evidence between researchers and people who work in permafrost environments on a daily basis, and, it is important in order to remain focused on research areas of direct importance to society.

Acknowledgments

Our special thanks go to all friends and colleagues who share with us the fascination and learning process related to mountain permafrost research. Their scientific progress, open discussions and feedbacks formed the basis of this review. An anonymous reviewer provided constructive comments.

Climate, Glaciers, and Permafrost in the Swiss Alps 2050: Scenarios, Consequences, and Recommendations

Wilfried Haeberli

Abstract

Climate scenarios for the time horizon of 2050 in the Swiss Alps, as simulated by using high-resolution ensemble modeling, indicate most likely changes in temperature/precipitation by + 2°C / + 10% in winter and + 3°C / - 20% in summer. Such a development would lead to the vanishing of about 75% of the existing glacier surface and deep warming of permafrost in mountain peaks. Corresponding impacts would mainly concern rather dramatic changes in landscape appearance, slope stability, and the water cycle. The formation of lakes in the forefields of retreating or even collapsing glaciers, together with the decreasing stability of rock walls, leads to an increasing probability of major rockfalls impacting onto water bodies and triggering dangerous flood waves. A special recommendation was therefore provided to systematically assess the safety of natural, artificial, and newly forming lakes in the Alps.

Keywords: climate change; cold mountains; glaciers; permafrost; slope stability.

Introduction

Climate change in cold mountain areas is faster than on the global average and strongly affects one of their most characteristic aspects – surface and subsurface ice (UNEP 2007). Increasing concentrations of greenhouse gases are likely to cause accelerating rates of change, which would lead within decades to environmental conditions far beyond historical and Holocene precedence and to commitments for the future probably lasting for centuries if not millennia. A primary challenge to cope with such a rather clearly foreseeable development is the anticipation of impacts from the reaction of complex, highly interconnected, and more and more disequilibrated natural systems (Watson & Haeberli 2004).

In March 2007, the Advisory Body on Climate Change created in 1996 by the Swiss Academy of Sciences on behalf of the Swiss Federal Government published a report on climate change and Switzerland for the year 2050 (OcCC 2007). Based on corresponding assessments for various sectors of the environment, the economy and the society, recommendations were prepared for the Swiss Federal Government. The present contribution deals with glaciers and permafrost in the Swiss Alps as an example of corresponding analyses and assessments relating to cold high-mountain regions at lower latitudes. It briefly summarizes the now-available knowledge based on climate projection and glacier and permafrost changes, and possibly resulting impacts. An example (Stein Glacier) is provided to emphasize the importance of combined glacier/permafrost considerations within the framework of recommendations to governmental policy makers.

Projections

Climate

Excellent data document the climate and its recent change in Switzerland. Atmospheric temperature rise during the 20th century was > 1°C and, hence, about twice the global average of 0.6°C. During the same time period, annual precipitation increased by some 8%. Due to the fact that evaporation also increased, river runoff remained more or less constant. The topography of the Alpine Mountain Chain only introduces relatively minor spatial variability of these changes with time.

Regional and seasonal climate change scenarios for Switzerland and the years 2030, 2050, and 2070 (Fig. 1) were calculated by Frei (2004) on the basis of the results from the EU-funded PRUDENCE project (Christensen et al. 2002). Uncertainties were estimated based on the distribution of the results from 16 model chains representing different combinations of 2 emission scenarios, 4 global, and 8 regional climate models. The estimates are based on the assumption that mitigation policies will only have a major influence in the second part of the 21st century and that the time horizon of 2050 could mark a transition to much more severe conditions at later stages. According to the applied scenario, temperatures will increase until 2050 with respect to 1990 by 1.8°C in winter (95% interval 0.9°C to 3.4°C) and 2.8°C (1.4°C to 4.9°C) in summer, both, north and south of the Alps. As a result the 0°C-isotherm will rise during winter by about 360 m (180 m to 680 m). Precipitation will increase by about 10% (-1% to +26%) in winter and decrease by about 20% (-36% to -6%) in summer. A trend towards more frequent and intense heat waves, probably also droughts, is expected in summertime. Cold waves in wintertime will probably decrease in number and intensity.

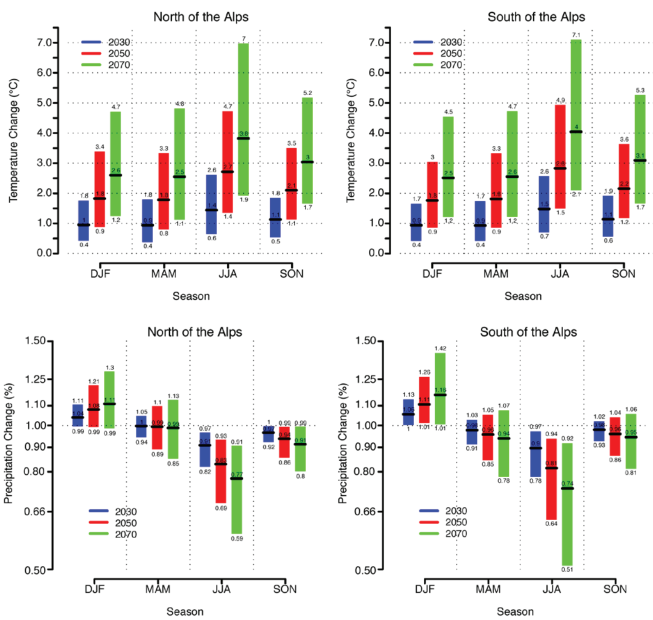

Figure 1. Seasonal climate scenarios (top: temperature, bottom: precipitation) for Switzerland and the years 2030, 2050, and 2070 for the parts north and south of the Alps (from OcCC 2007).

Glaciers

In the European Alps, a comprehensive database on glaciers and their long-term fluctuations has been built up over more than a century. This now enables the integration of *in situ* measurements (length change, mass balance), remote sensing (glacier inventories), digital terrain information, and numerical modeling for the entire mountain chain (Haeberli et al. 2007). The average loss in overall glacier volume was about 0.5% per year between 1850—the end of the Little Ice Age—and 1975, then increased to about 1% per year of the remaining volume between 1975 and 2000; and since the turn of the millennium, has accelerated to about 2–3% per year. The extremely hot and dry summer of 2003 alone eliminated some 8% of the remaining ice volume. Many glaciers started to waste down or even collapse and disintegrate rather than to actively retreat (Paul et al. 2007).

Alpine-wide estimates of future glacier evolution had first been made by Haeberli and Hoelzle (1995; cf. also Maisch et al. 2000, Maisch 2001) and proved to be rather robust. The latest and most differentiated model uses statistically calibrated relations between equilibrium line altitude as measured in long-term mass balance observations, summer temperature, and annual precipitation together with glacier inventory data and the SRTM3 digital elevation model (Zemp et al. 2006). Combination with the climate scenario applied for 2050 shows that the glacier surface area in the European Alps could be reduced with respect to conditions in 1971–1990 by a further 75% (50% to 95%) as soon as by 2050 (Fig. 2). Slightly smaller losses can be assumed for the Swiss Alps, where the largest glaciers exist. A remarkable part—roughly one-third—of this anticipated development has already taken place by now (in 2007).

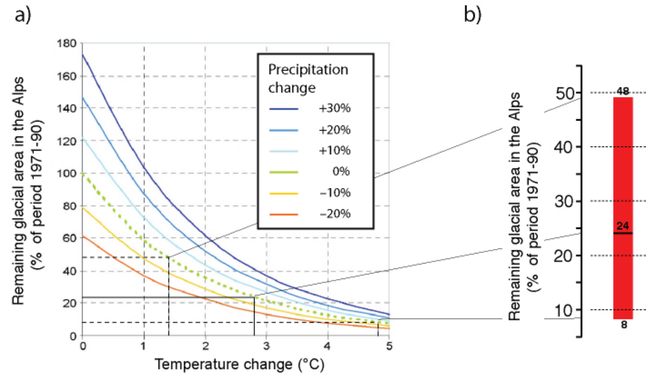

Figure 2. Glacier area in the Alps as a function of temperature and precipitation change: (a) as combined with the assumed climate scenario for 2050; (b) after Zemp et al. 2006, from OcCC 2007.

Permafrost

Systematic research on permafrost in the Alps only started well after World War II. First attempts to establish a long-term monitoring program began with the observation of borehole temperatures in the ice-rich debris of Murtèl rock glacier (Vonder Mühll & Haeberli 1991) and photogrammetric rock glacier monitoring (Haeberli et al. 1993). A decisive step forward was the installation of 100-m-deep bedrock boreholes in the permafrost of European mountains within the Permafrost and Climate in Europe (PACE) project (Harris et al. 2003). Numerical models for estimating spatial permafrost distribution patterns in the Swiss Alps were first applied by Keller et al. (1998). Most recently, a model simulation was done at a 1:50,000 scale for the entire Swiss Alps on behalf of the Federal Office for the Environment (FOEN). Permafrost in the Swiss Alps is now known to occupy a surface area, which is roughly twice as large as the glacierized area. Its development is observed within the framework of PERMOS (Permafrost Monitoring Switzerland; Vonder Mühll et al., 2008), one of the first networks of this kind.

Thermal conditions in commonly ice-rich permafrost in talus and moraines strongly depend on snow cover conditions and are thus difficult to predict. Because of latent heat effects, complete thawing of such frozen debris in any case takes many decades to centuries, even with warming to 0°C. Permafrost evolution in bedrock of steep mountain peaks with highly complex topography is less snow-dependent. The PACE boreholes indicate surface warming during the 20th century by about 0.5 to 1°C, and corresponding thermal anomalies (heat flow reduction) down to 50 70 m below surface. Future scenarios can be simulated using 3-dimensional transient heat diffusion models.

Corresponding calculations for idealized topographies (Noetzli et al. 2007) illustrate that the uppermost peaks are largely decoupled from the geothermal heat flow because of predominant lateral fluxes in strongly asymmetrical thermal fields and that warming trends can penetrate from two or more sides (Fig. 3). Due to the slow process of heat diffusion at depth, permafrost inside the mountains still persists after centuries, but with warmer if not near 0°C temperatures over wide altitudinal ranges and at great depths.

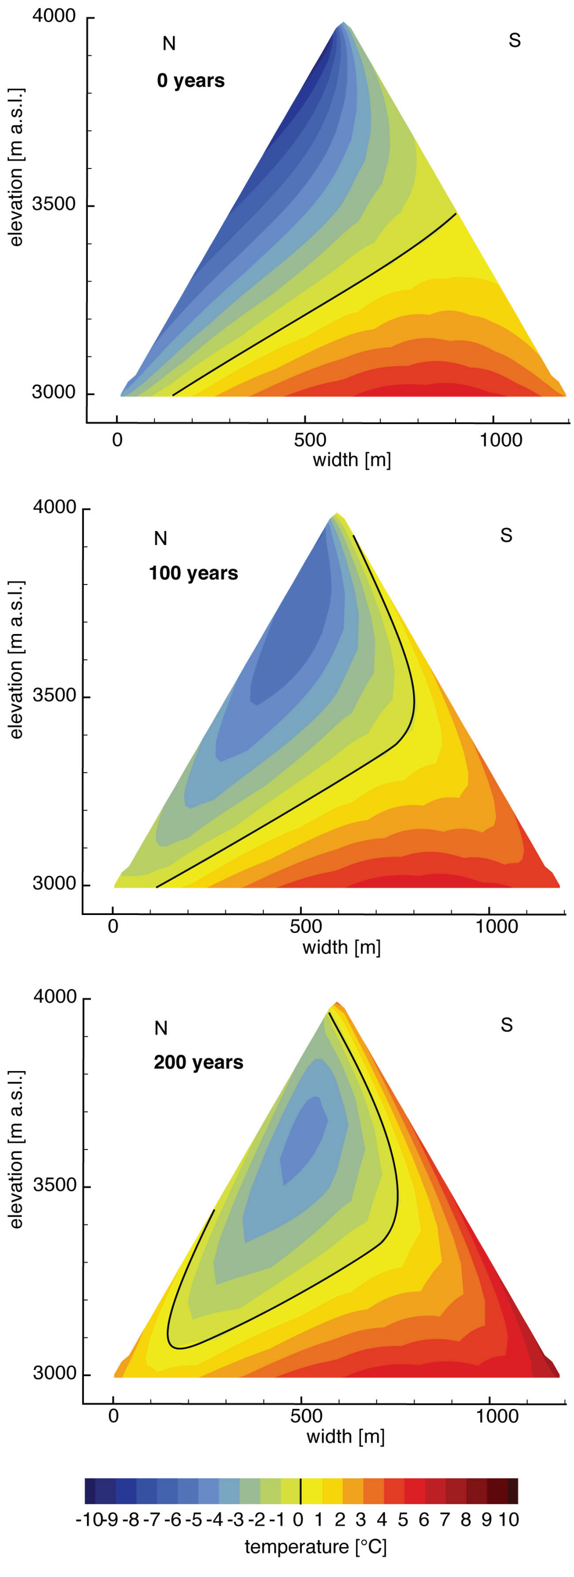

Figure 3. Model simulation (heat diffusion only) of the thermal field within a high Alpine mountain peak with realistic permafrost occurrence (from energy balance modeling), assumed centennial warming and idealized topography (after Noetzli et al. 2007; cf. OcCC 2007).

Impacts

Landscape and surface processes

Rapid glacier shrinkage is among the most obvious and visible phenomena related to ongoing warming trends. Already today, the perception of high-mountain landscapes is changing: the vanishing beauty of firn and ice as a symbol of an intact environment is more and more seen as a clear and easily understood indication of human-induced disturbance. In areas with a moderately humid to relatively dry climate, revegetation of newly exposed terrain is a slow process. For generations to come, therefore, deglaciated high-mountain chains will predominantly remain as areas of bare rock and debris without closed forests and mature soils (Egli et al. 2006). This will affect the attractiveness and touristic value of the respective landscape. Entire geo- and ecosystems as well as their individual parts have strongly different characteristics and time scales of response to fast climate change. This will undoubtedly lead to growing distances from conditions of dynamic equilibrium, which were able to form during the Holocene with its relatively stable climate.

One remarkable landscape element developing with continued atmospheric warming is the formation of new lakes with further glacier retreat and disintegration. Potential sites for future lake formation in over-deepened bed parts can be modeled by assuming constant basal shear stress along the central flow line, constant width-to-depth ratio of channel-type valley cross sections, and compressive flow connected with negative bed slopes. New lakes will thus most likely form where present-day low-slope ice surfaces, free of crevasses, have an enlarged width and grade into a narrower, steeper, and more or less heavily crevassed part in the flow direction (Fig. 4). Such lakes will be landforms of considerable attractiveness and, hence, to some degree compensate for the loss in landscape attractiveness from glacier disappearance. In many instances, however, they will be situated within an over-steepened and destabilized surrounding topography with enhanced periglacial-geomorphological activity. Corresponding slope stability problems would cause hazardous situations not known from the past. One example out of the number of possibilities is outlined below.

Natural hazards

Most critical stability conditions in perennially frozen rock walls are expected to be found in areas with warm permafrost (Davis et al. 2001, Noetzli et al. 2003, Gruber et al. 2004, Gruber & Haeberli 2007). Deep long-term warming of perennially frozen mountain peaks has the potential to bring steeply inclined rock layers to critical temperatures, not only over more extended vertical ranges but also to greater depths. As a consequence, the probability of large rockfalls is slowly increasing. Loss of support of steep slopes due to glacier disappearance leads to a reorientation of the stress field in adjacent slopes, and further contributes to the destabilization of rock walls above newly forming lakes. The possibility of flood waves from impacts of large rock, ice, snow or mixed avalanches must, therefore, be seriously considered.

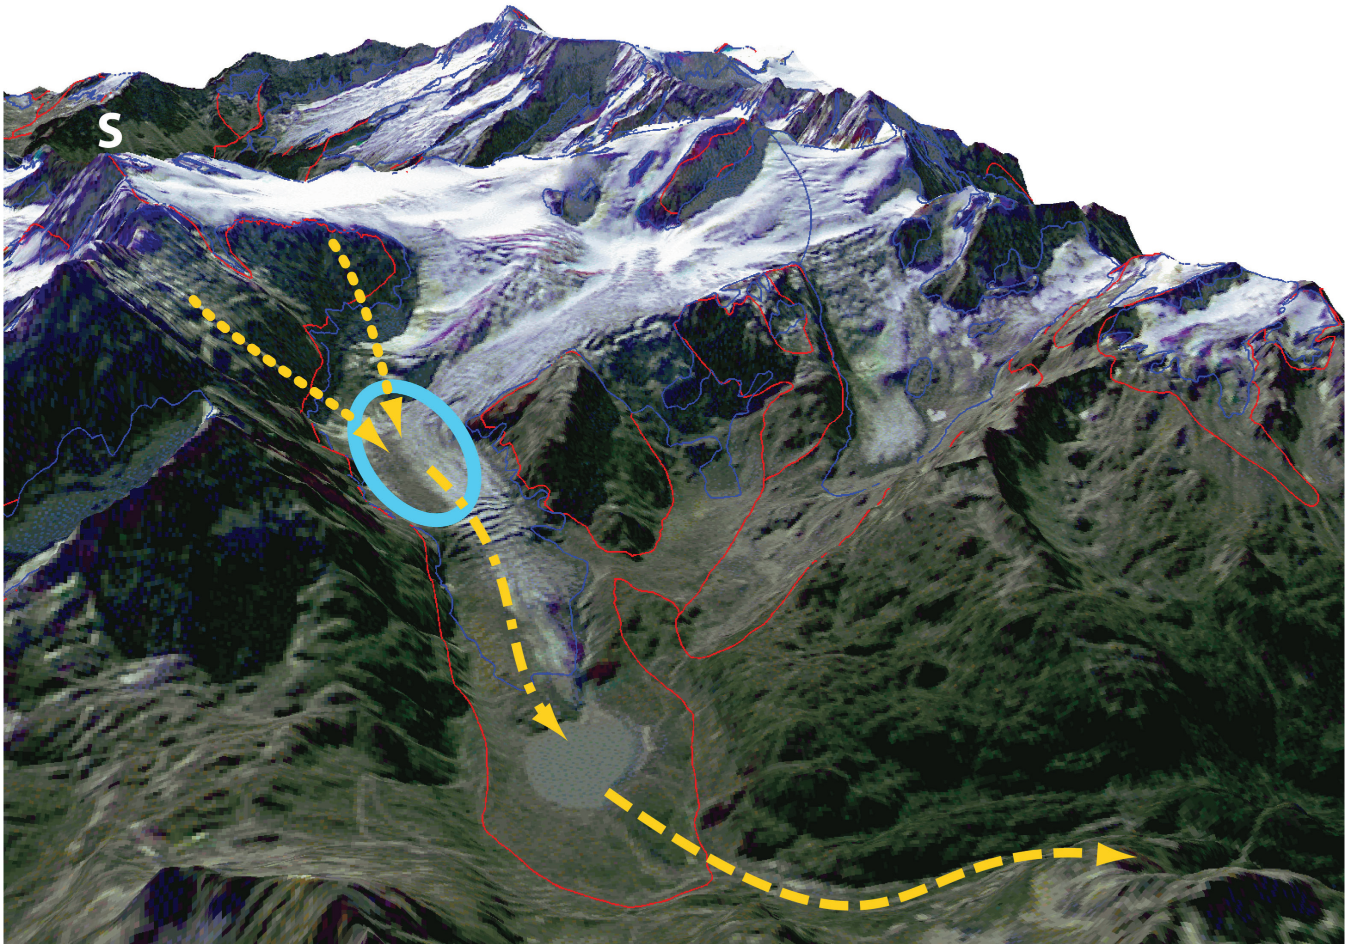

Figure 4: Modeled future development of a lake in an assumed overdeepened bed part of the Stein glacier near Sustenpass, Bernese Alps. Dotted lines indicate potential rock/ice avalanches from warming permafrost in the rock walls of Sustenhorn (S), dashed-dotted line related flood wave into the existing proglacial lake Steinsee, dashed line resulting flood wave from both lakes. Satellite image (combined SPOT/Landsat, September 1992) drawn over a DEM from swisstopo, image by F.Paul). Thin lines are former glacier margins (red 1850, blue 1973). Reproduced by permission of swisstopo (BA081042).

GIS-based models of trajectories from rock/ice avalanches can be applied for realistic assessments (Noetzli et al. 2006). The timing of the events, however, can involve long delays and is hardly predictable. The same is true, in principle, for debris flows, which can be triggered by intense convective summer precipitation events in, so far, glacier-covered starting zones with newly exposed moraine material. Examples of corresponding assessments for the Bernina group in the Upper Engadin were calculated by Rothen-Bühler (2006) within the framework of an integrative 4-dimensional geo-information system, which was built up as a tool for environmental planning in high mountain areas. Another case of a future hazard potential from flood waves caused by rock/ice avalanches from high/steep rock walls with warming permafrost into a modeled future lake replacing the now existing glacier surface is illustrated for Steingletscher/Sustenhorn (Bernese Alps) in Figure 4.

Water cycle

As a result of climate change, the maximum in river discharge will occur earlier in the year and will be less pronounced. The combined effect of increased precipitation and 0°C-isotherms at higher elevations will lead to a growing risk of winter flooding in lowlands surrounding the Alps, because greater percentages of liquid precipitation must be expected to runoff directly instead of being temporarily stored as snow. Drier summers, on the other hand, will lead to more frequent and especially more severe droughts. With conditions like in summer 2003 (stable high pressure over central Europe during several months) becoming near average in the second part of the century, the combination of missing precipitation, earlier snowmelt, and strongly reduced meltwater from disappearing glaciers could lower runoff to critical levels even in large Alpine rivers (Rhine, Rhone).

Despite the large water resources in the Alpine region, water stress could become a problem in some parts of Switzerland during the hot/dry season because of the decreasing availability of river water and its interconnection with soil humidity, water temperatures, lake/groundwater levels and aquatic ecosystems (fish, algae, etc.) and the increasing demands for domestic freshwater supply,

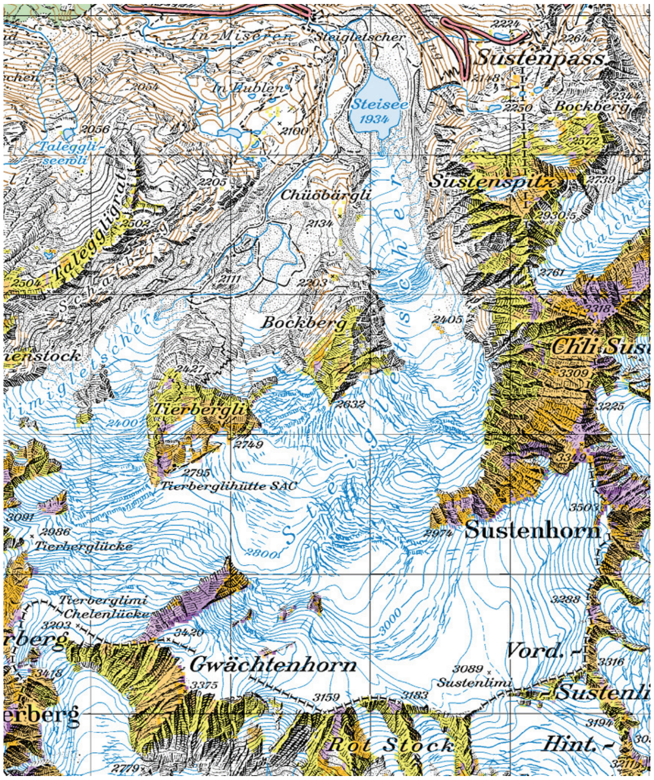

Figure 5: Detail of the map 1:50,000 with numerically simulated permafrost distribution as compiled for the entire Swiss Alps on behalf of the Federal Office for the Environment (BAFU/FOEN). The area is the same as on Figure 4. Yellow colors indicate relatively warm/thin, violet colors relatively cold/thick permafrost.

agriculture (irrigation), hydropower production, cooling of nuclear power plants, or even firefighting in desiccated forests. Conflicts about water use are likely to grow and options for adaptation—for instance, redefinition of the use of reservoirs at high-altitude (irrigation and summer power production rather than winter power production)—should be investigated as early as possible.

Conclusions and Recommendations

The "experiment with the global climate" has started. It cannot be stopped, but only be influenced. Grave consequences for cold mountain areas are unavoidable and are already developing at accelerating rates. Corresponding mitigation and adaptation measures must be planned. This primarily requires early and realistic anticipation of future developments and potential system reactions. The time scale to be considered involves several coming decades. As a consequence, rapid action is necessary. With modern digital terrain information, numerical and GIS-based models, and satellite imagery, all necessary technical means are available.

As a follow-up to the report on the climate in 2050 (OcCC 2007), a set of recommendations with respect to climate change impacts was provided to the Swiss Federal Government. Concerning Alpine glaciers and permafrost, the importance of adequate monitoring and the need for a systematic safety assessment of all existing natural and artificial lakes, as well as of all newly forming lakes, was emphasized. Perhaps the most important and most far-reaching statement, however, relates to the rights for the use of water, an aspect which may well become a central focus of living conditions and economic development in a rather near future.

At a national level, first steps have already been undertaken. The numerically modeled 1:50,000 permafrost map of the Swiss Alps, prepared on behalf of the Federal Office for the Environment (FOEN, Fig. 5), greatly helps with providing transparent information to authorities and raising public awareness. The Swiss Academy of Sciences, the Federal Office for the Environment, and MeteoSuisse, together, now definitely established the highly developed network Permafrost Monitoring in Switzerland (PERMOS), and the glacier monitoring network is being reorganized in order to integrate modern technologies and strategies according to international climate-related observing systems (GCOS 2003, 2004).

Acknowledgments

We thank all the numerous colleagues and experts who contributed to the original assessment reports. The interest, support, and excellent collaboration of the Swiss Academy of Sciences, the Federal Office for the Environment, and MeteoSuisse are gratefully acknowledged. Stephan Gruber, Jeannette Noetzli, Max Maisch, Frank Paul, and Isabelle Roer critically read an early draft of the present paper.

Abstract

Frost boils, also known as plugs or non-sorted circles, are non-sorted mineral soil centers surrounded by vegetation and occur throughout the Arctic. They influence surface albedo, soil temperature, soil stability, and consequently the distribution of vegetation; thus they are an important environmental factor in arctic landscapes. Numerous mechanisms for their initiation and maintenance have been proposed including: differential frost heave, convection cell-like cryoturbation, diapirism, and load casting; however, there are few techniques for direct observations. In this paper, we evaluate the natural, atmospheric-derived, radioactive isotope ^{210}Pb as a novel tracer of frost boil kinematics in a case study in northwestern Greenland, Pituffik Peninsula (76°N, 68°W). Once deposited, ^{210}Pb is strongly adsorbed to particle surfaces and decays with a half-life of 22.3 years; thus it is an excellent tracer for sediment motion up to approximately 80 years. Our first results confirm the usefulness of this tracer but also highlight necessary measurements and sampling strategies to fully interpret the ^{210}Pb distribution in frost boils.

Keywords: frost boil; High Arctic; patterned ground; ^{210}Pb tracer; plug.

Introduction

According to Washburn (1980:128), "Nonsorted circles are patterned ground whose mesh is dominantly circular and lacks a border of stones. The term mud-boil is frequently used in Canada for both nonsorted and sorted circles. Nonsorted circles are characteristically margined by vegetation, and occur singly or in groups…." Nonsorted circles, mudboils, or frost boils are found across the Arctic, where they are important environmental features (Walker et al. 2004). They influence microtopography, the abundance and distribution of vegetation, and therefore the temperature and moisture regime of the active layer (Roth & Boike 2001, Boike et al. 2002, Boike et al. 2007), which are important factors for the stability of permafrost as well as atmosphere-ground surface interaction. A thorough description of field observation and discussion of the diverse hypothesis of the genesis of plugs and plug circles is given by Washburn (1997).

From the 19 hypotheses for the formation of patterned ground reviewed by Washburn (1956), detailed descriptions during excavations and measurements of soil motion and soil physical parameters (Schmertmann & Taylor 1965, Washburn 1969, Nicholson 1976, Zoltai & Tarnocai 1981, Hallet & Prestrud 1986, Hallet et al. 1988, Washburn 1989, van Vliet-Lanoë 1991, Washburn 1997, Hallet 1998, Walker et al. 2004, Overduin & Kane 2006) as well as mathematical modeling approaches (Kessler et al. 2001, Kessler & Werner 2003, Peterson & Krantz 2003) indicate that cycles of freezing and thawing and of drying and wetting, inclined freezing fronts, buoyancy, and differential frost heave are the most important factors for the formation of circles, if sufficient fine soil (Goldthwait 1976) and water are present. In the case of unsorted circles (e.g., frost boils, mud boils, mud hummocks), gravity driven diapirism of water-oversaturated soil above permafrost has been suggested by Swanson et al. (1999) and Shilts (1978). Based on viscosity and density measurements, Swanson (1999) estimated that several decimeter of diapir movement could happen during a single thaw event (Swanson et al. 1999). Burial of organic rich surface material (e.g., Dyke & Zoltai 1980) along boil fringe suggests that some boils are closed systems where upward movement of soil in center causes lateral outward movement at surface and subsidence at the boil fringe (Mackay & MacKay 1976, Nicholson 1976, Dyke & Zoltai 1980, Mackay 1980, Zoltai & Tarnocai 1981, Washburn 1997). Such circulatory movement has mostly been attributed to inclining freezing front (Nicholson 1976), differential frost heave (Mortensen 1932, Hallet & Waddington 1991, van Vliet-Lanoë 1991), and freeze-thaw pumping (Mackay 1980, Veillette 1980). Dating of buried organic matter in three boils of central Canadian Arctic indicates subduction rates of organic material of ~1 mm yr^{-1} (Zoltai & Tarnocai 1981). However, even though distribution of organic material and radiocarbon dating gave indications of sediment motion, direct and detailed monitoring of sediment transport over longer (~100 years) time periods will greatly improve the understanding of the proposed mechanism.

Our study presents a new approach to trace sediment motion in frost boils using the radionuclide ^{210}Pb as tracer. ^{210}Pb is a natural product of the ^{238}U decay series and a direct daughter of ^{222}Rn ($T_{1/2}$ 3.8 d). During ^{238}U decay in the soil, part of ^{222}Rn emanates into atmosphere where it decays to ^{210}Pb ($T_{1/2}$ 22.3 y). The ^{210}Pb is scavenged by aerosols, washed out by rain and snow, and deposited on the ground surface where it is strongly adsorbed to sediment grain surfaces. These chemical and physical characteristics of ^{210}Pb make it an excellent tracer of sediment transport processes in time and space. ^{210}Pb has been used in numerous applications including sedimentation and erosion processes in lacustrine, marine, and terrestrial environments (Appleby et al. 1979, Dörr 1995, Hagedorn et al. 1999, Walling et al. 2003, Aalto et al. 2008). To our knowledge, however, it has not been used in patterned ground studies. The half-life of ^{210}Pb limits its applications to ~100 years within which surface expressions become evident based on modeling studies from Peterson & Krantz (2003) and estimates from heave and motion measurements on sorted circles in Thule NW Greenland by Schmertmann & Taylor (1965).

Study Site and Methods

The study was conducted near Thule Airforce Base in northwest Greenland (76°N, 68°W). The base is located on a ~800 km^2 ice-free peninsula between the Greenland Ice Sheet to the west and Baffin Bay to the south and east. The sampling site is in Nordfjeld (North Mountain), a high valley with average elevation of 180 m. Proterozoic sedimentary rocks (Dundas formation) dominate among glacial drift and the last glaciation was initiated around >32 Ka ago (Davies et al. 1963). A more recent glacial advance either from the fjord or ice sheet is debated (Davies et al. 1963, Kelly et al. 1999). Annual average air temperature and precipitation measured by Thule Air Base since 1978 are -11.7±3°C with July temperatures at 5.3±1°C and 124 mm$_{weq}$ precipitation of which ~40% falls as snow. For the years of sampling (2003 & 2004), the average annual air temperature was -9.2°C; average soil temperatures ranged from -9.1°C (surface) to -9.8°C (1.2 m) with a thaw depth reaching ~1.2 m in early August. Spring snow cover in 2003 and 2004 was 80 mm$_{weq}$ and 30 mm$_{weq}$, and rain was 71 mm and 106 mm, respectively.

Patterned ground at the study site is nonsorted a priori and appears as irregular stripes and frost boils. The frost boils are ~0.5 m to 2 m in diameter; they show little micro-relief during the summer and are bordered with vegetation. Some boils show slight enrichment of pebbles towards their edges, but abundance of coarse material is generally sparse. During the early summer when the surface is thawed, desiccation cracks and salt precipitates develop at the surface of the central portion of the boils. Soil of distinctive color than surface has been observed near the center of several boils and appears to be recently injected from below the surface, suggesting that soil movement can be very rapidly, which has also been suggested by Swanson et al. (1999).

The central portion of the frost boil discussed here is 1.5 m in diameter. A few pebbles rest on the surface; they are more abundant towards the fringe (Fig. 1). Near

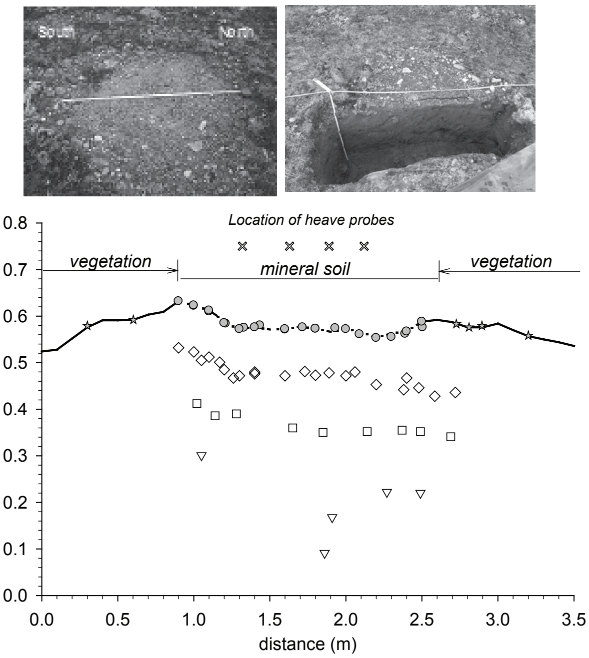

Figure 1. Upper: view of frost boil before and after excavation; note prominent crack in the image on the right developed after the excavation. Lower: detailed topography and position of samples. The different symbols refer to sampling depth in the following figures. Stars are in vegetation and dashed lines mark transition between mineral boil and vegetation. Circles with dots are measured elsewhere in vegetated areas close to frost boil. The dashed lines (Trans) mark transition from mineral soil to vegetated soil (see text). Location of boil: 78°33.241N, 68°33.596W.

the vegetated border, the mineral soil is covered with cryptogamic crust that locally forms small folds with axes paralleling the vegetation border. The center of boil consists of two apparent soil horizons: C1 (surface to 0.3 m depth) and C2 (>0.3 m depth). The C1-horizon tends to break into crumbs, shows silt caps, and has a weak platy structure. The C2- horizon has a well-developed platy structure. A few roots reach down to the frozen ground, which was at 0.69 m depth during time of excavation (June 29, 2004). A ~0.02 m O-horizon is developed in the vegetated area, and it is underlain by ~0.1 m A-horizon with weak crumb structure. A buried AB-horizon was found ~0.25 m below the vegetation. Surface samples were taken in 2003 without excavating the boil. After sampling, four heave probes were installed and left over winter, additional heave probes were installed in vegetated areas. The heave probes consist of 10 cm Plexiglas stick glued perpendicular on a 2.5 x 2.5 cm base. A Plexiglas sleeve is put over the stick and this ensemble is installed in the upper soil in the way that upper end of stick and sleeve are level with soil surface. Frost heave in upper soil will pull the sleeve up relative to the base buried deeper in the soil. The soil heave is then measured as distance between stick and outer sleeve. In 2004 the surface topography of boil was mapped and one half of boil was excavated and sampled in detail (Fig. 1). Most samples were collected undisturbed in 60 mL moisture cans to determine soil water content and bulk density gravimetrically. Dried samples were sieved to

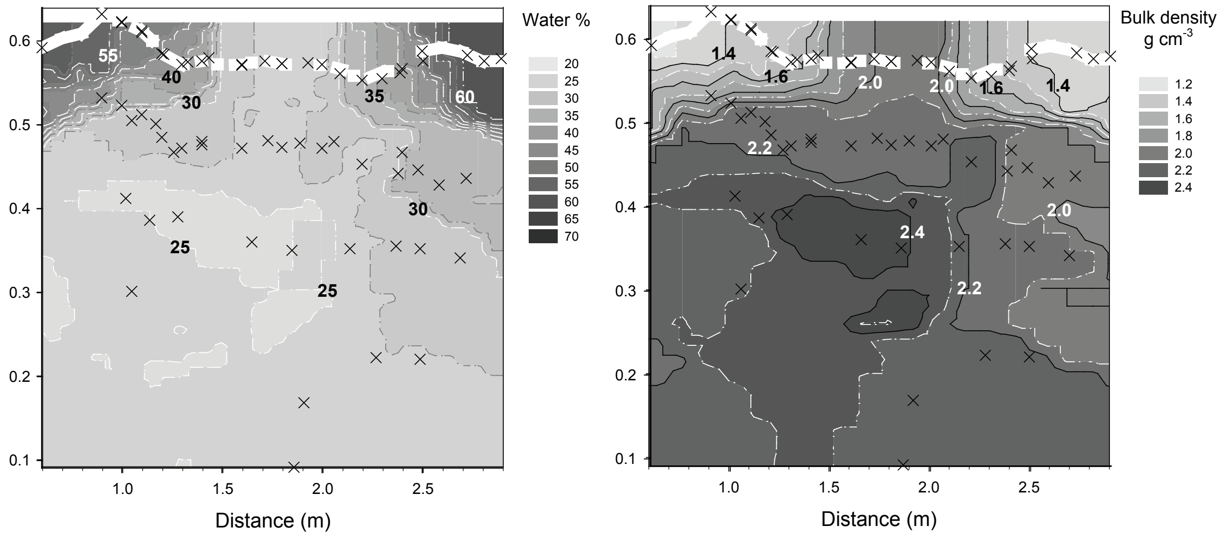

Figure 2. Vertical section through the frost boil showing contour maps of measured (A) water content and (B) wet bulk density in frost boil. Crosses mark position of measurements. The heavy white line shows the surface (topography) of the boil. Information above this line has no significance. The contours were generated by linear interpolation between nearest neighbor.

<2 mm and particle size distribution was determined by laser diffraction of the <2 mm fraction. Grain sizes of samples analyzed for ^{210}Pb were determined by Sedigraph 5100 on the <250 µm fraction. ^{210}Pb was analyzed on acid leachates of the <250 µm fraction by analyzing its granddaughter ^{210}Po using alpha spectroscopy (Aalto et al. 2008). This method only accounts for externally derived ^{210}Pb (adsorbed at grain surfaces) and the majority of it derives from atmospheric fallout. In addition to this excess unsupported ^{210}Pb, a smaller amount of supported ^{210}Pb is produced in situ by the decay of locally derived ^{222}Rn trapped in the soil atmosphere. This supported ^{210}Pb produces some background activity at depth.

Results and Discussion

Heave, grain size, and water content

Heave probes were installed in four positions (Fig. 1) across the mineral center on September 1, 2003. In addition, heave probes were also installed in vegetated areas in near proximity of the investigated frost boil. The total heave values on June 28, 2004 were 6, 12, 23, and 12 mm, while heaving rate measured in vegetated soil was <2 mm.

The grain size distribution of all samples (boil and vegetation) is loamy sand with sand: 59.5 ± 10%, silt: 30.1 ± 8.4%, and clay: 10.5 ± 4.7%. This grain size distribution is equal to low centered mud boils described by Zoltai and Tarnocai (1981) and has enough fine material to be suitable for frost heave and patterned ground formation (Goldthwait 1976). Although the frost boil appears as a nonsorted circle, there is a slight enrichment of pebbles towards the vegetated border and slight increase in the clay size fraction at depth.

The water content on June 29, 2004 is displayed in Figure 2A. It covers a range between 22 wt% and 78 wt% (on basis of wet weight) where surface samples from the center of the boil have lowest water content (22 wt% to 35 wt%). In contrast, surface samples close to surrounding vegetation are wetter (41-58 wt%) and the vegetated surfaces have highest water content (44-78 wt%). Volumetric water content calculated from bulk density and gravimetrical water content is between 13 vol% to 36 vol% indicating that soils are not water saturated at this time of the year.

The wet bulk density ranges between 990 kg m^{-3} to 2600 kg m^{-3} with lowest values below vegetation and cryptogamic crust-covered surfaces, and highest values in the bare central portion of the boil (Fig. 2A). The higher bulk density in the central portion of the boil and at depth is quite consistent with the theory that after thawing soil dries out and is compacted in center. The soil water distribution observed here is similar to water content measured in mud boils in Svalbard during and shortly after snowmelt (Boike et al. 2002). As shown by Boike et al. (2002) moisture content in these boils is quite dynamic during the season and it is difficult to draw conclusions from a single set of density/soil moisture measurements. However, using spatial distributed year-round measurements of soil moisture and soil temperature in the mud boil Boike et al. (2002) observed that moisture is transported to fringe in frozen ground and therefore leads to thawing and collapse of these regions (Boike et al. 2002). Such water dynamic seem to concurs well with freeze-thaw pumping as driving mechanism for boil development as discussed by Washburn (1997)

^{210}Pb systematics and distribution

Assuming that ^{210}Pb is deposited equally on the surface by continuous atmospheric flux, all surface samples should display the same activity if they have the same history of surface exposure. Due to its adsorption primarily on small grain sizes, lead will not infiltrate far into the ground (Stumm 1992) and therefore, surface samples collected from upper 0.1 m should contain almost all atmospheric deposited ^{210}Pb.

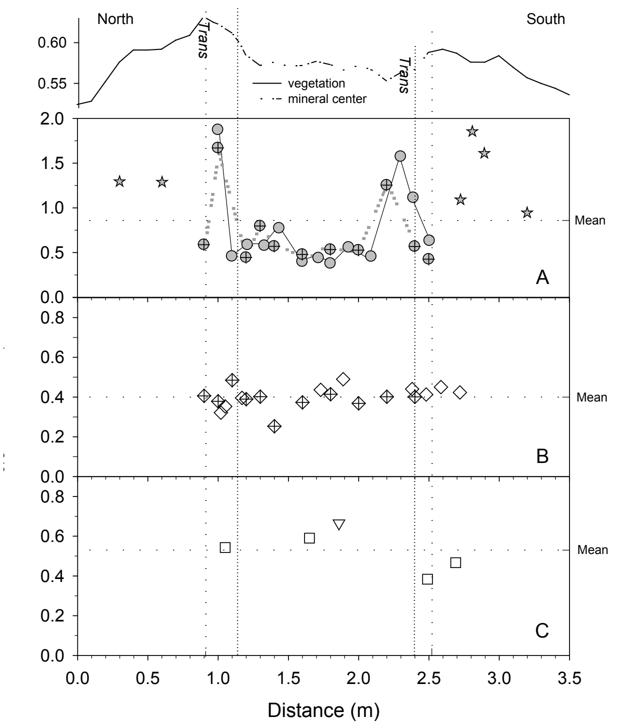

Figure 3. ^{210}Pb activity distribution in the investigated frost boil and surrounding area. The two lines delineate the transition between mineral surface and vegetation. (A) Surface samples, (B) Samples from ~0.1 to 0.15 m below surface, and (C) samples from >0.25 m below surface. Symbols refer to sampling depth (see Fig. 1); symbols with cross indicate samples collected in 2003.

If undisturbed, the ^{210}Pb activity in surface soil will begin to approach steady state conditions with ^{210}Pb deposition balanced by decay after $1/\lambda_{210}$ (τ_{210} residence time of ^{210}Pb, see Albarède (1996, p. 344 ff.)) which is 32.2 years. However, our alpha analytical techniques allow more accurate exposure determinations, or dating out to approximately $2.5/\lambda_{210}$. Hence, soil on surfaces that have been undisturbed for >80 years should closely approach the steady state ^{210}Pb activity. Furthermore, the ^{210}Pb activity at depth should be equal to background values from in situ decay of ^{222}Rn in soil atmosphere and will be lower than steady state ^{210}Pb activity at surface. Accepting that ^{210}Pb background flux is much lower than atmospheric flux, elevated ^{210}Pb values at depth indicate that surface material is transported to depth within the last 100 years and for these samples, the duration of burial can theoretically be estimated out to 80 years using the decay rate of ^{210}Pb. Following this line of reasoning, surface soil with ^{210}Pb activity lower than steady state activity has been at the surface less than 80 years.

^{210}Pb values of surface samples display a very distinct, almost symmetrical pattern with low values in center of the boil and higher values towards the vegetation border (Fig. 3A) and this pattern exists in samples collected in both years. The average ^{210}Pb activity in the inner center of the boil is 0.5 dpm g^{-1} and is much lower than the average ^{210}Pb in vegetation (1.65 dpm g^{-1}). Samples at ~0.10 to 0.15 m depth (Fig. 3B) have average ^{210}Pb values of 0.40 dpm g^{-1} with a range between 0.50 and 0.22 dpm g^{-1}. These samples do not show a systematic trend like the surface samples but scatter around the average activity. Samples collected from greater depth >0.25m (Fig. 3C) have slightly higher ^{210}Pb activity with average of 0.45 dpm g^{-1}. One sediment sample collected just above the permafrost table (triangle at ~ 60 cm in Fig. 1) has ^{210}Pb activity of 0.68 dpm g^{-1} higher than most samples at depth and higher than surface samples in the mineral center of the frost boil.

Following the ^{210}Pb systematics described above, the average ^{210}Pb activity in vegetation of 1.65 dpm g^{-1} reflects steady state. Since this surface is very stable the observed variability of ^{210}Pb activities may indicate accumulation processes due to topographic depressions or changes in plants which serve as natural sediment and dust traps.

Low ^{210}Pb activities in center part of boil suggest that sediments have recently been exposed to surface. As described above, freshly injected sediment in boil center has been observed during the thaw season on adjacent frost boils supporting the trend observed with the ^{210}Pb. Assuming that boil and its close perimeter is closed sediment system demands that the injected sediment is balanced by subduction; both motions have been assumed based on distribution of buried rocks and organic material (Dyke & Zoltai 1980) in non sorted circles. They lead to the assumption of a circulatory motion where soil subsides at boil fringe and rises from below in center of boil. According to this mechanism, the bottom of boil just above permafrost table would be replaced by material from the surface. If the circulation is fast enough (<80 years) the sediment at depth should have ^{210}Pb activity above background but lower than steady state activity. The subduction rates from Dyke and Zoltai (1980) on the order of 1 mm yr^{-1} infer that most of unsupported ^{210}Pb is decayed below a depth of 10 cm. The observed elevated ^{210}Pb activity in the one sediment sample at depth (at ~60 cm) may be due to remaining ^{210}Pb from subducted sediments and would suggest much higher subduction rates. However, elevated background activities can be reached at depth due to high moisture content which reduces ^{222}Rn diffusion out of soil and therefore, increases the in situ produced ^{210}Pb background activity. These results show the importance to accurately determine background levels of ^{210}Pb.

The fresh injected sediment in center of boil will be laterally transported towards fringe and therefore, accumulation of atmospheric ^{210}Pb with time would cause a constant increasing in ^{210}Pb activity toward the fringe. The slightly higher activity towards the northern fringe of boil could indicate lateral transport though this trend is missing in the southern part. Overall, a circularly motion in central mineral boil is not well documented by ^{210}Pb except for general low activities compared to stable surfaces which indicates that sediment has not been exposed to atmosphere for very long time and therefore, may have been injected recently from below.

In the area between stable vegetation and mineral boil, low ^{210}Pb activity in direct contact to stable vegetation also suggests injection of sediment from depth while the high

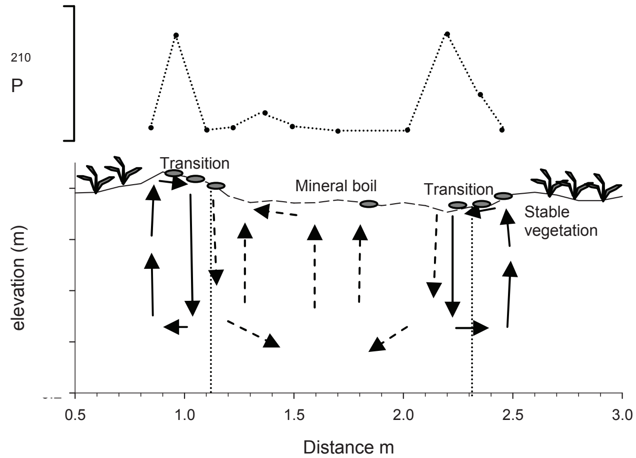

Figure 4. Schematic sketch of observed ^{210}Pb activity in surface sediments (upper) and possible sediment motion to produce observed ^{210}Pb activity trend (lower).

^{210}Pb activities in this area (Fig. 3A) indicate that sediment has been at surface for elevated time. A possible mechanism to create the observed ^{210}Pb distribution could be a circulatory cell opposite to that in mineral boil as indicated in Figure 4. The sediment is than subducted close to mineral center of boil (Fig. 4). Subduction at this location is supported by observed buried plant material (*Dryas spp.*) which was found in 12 cm depth at 1.21 m distance at north side of boil (X-axis, Fig. 3). Hallet and Prestrud (1986) proposed a similar circulatory motion ("rolling border") in the stone perimeter of sorted circles based on soil displacement measurements.

Conclusions and Outlook

The use of ^{210}Pb as a tracer for soil motion yields promising results. Compared to the radiocarbon tracer, ^{210}Pb is connected directly to sediment grains and not restricted to certain components in the sediment. It therefore can be sampled in as high resolution as needed for individual system. However, the time limit of ~80 years restricts its application to recent processes. Conclusions drawn from ^{210}Pb distribution in this study are in agreement with other field observations in this high Arctic site and with general mechanism proposed by other researchers for formation and sustainability of nonsorted circles. However, for developing this tracer to its full potential it is important to accurately determine the steady state and background ^{210}Pb activity, which are the upper and lower limits of unsupported ^{210}Pb activity within the frost boil system. Knowledge of these boundary values will allow more detailed interpretation of ^{210}Pb activities and their significance with respect to sediment motion. A way to do this would be to determine the ^{210}Pb inventory (dpm m^{-2}) by sampling continuous depth profiles rather than single points of activity. Together with boundary values sampling of continuous profiles will provide the opportunity to estimate sediment motion in time and space for the studied frost boil system.

Acknowledgments

We would like to thank Paul Overduin for his review of the manuscript, VECO, Thule Air Base for their logistical support, and A. Vigna for field assistance. This study was funded by the National Science Foundation Grant OPP-0221606 with partial support for dating by NSF EAR-0403722 and 0521774.

Abstract

The Pénestin section (southern Brittany, France) presents large diapiric deformations initially attributed to pingos by several authors. We present tectonic, petrographic and stratigraphic arguments leading to a mechanical interpretation of the deformations. The area corresponds to an upper Neogene paleoestuary of the Vilaine River, in middle terrace position, incised into a kaolinitic saprolite. There is no evidence for recent transpressive tectonics or for periglacial pingos, despite the presence of MIS 8 ice wedge casts. Shale diapirism does exist. Deformation is favoured by the liquefaction of saprolite and a seaward mass movement triggered by an earthquake around 280,000 yr. BP. This kind of deformations is common in tectonically active regions. The development of permafrost during MIS 8 (Saalian I) allowed ice segregation of the porosity in sediments, which froze younger reactivation of the shale diapirism.

Keywords: Brittany; earthquake; neotectonic; periglacial; saprolite; shale diapirism.

Introduction

Distinguishing between tectonic deformations and periglacial disturbances in the Quaternary is a prerequisite for seismic hazard assessment in former periglacial areas. Among these deformations, we discuss whether a specific “folds” succession can be related to neotectonic activity or, periglacial forms. Examples exist in the southern Pénestin section (Brittany, N.W. France, Fig. 1) and the Bovey Tracey basin (Devon, UK), where deformation was first interpreted as pingo scars (Jenkins & Vincent 1981, Rivière and Vernhet 1962) or as complex features in Germany attributed to permafrost by Eissman (1981) and Strunk (1983). Recently, these “fold trains” have been interpreted as induced by seismic shaking (Van Vliet-Lanoë et al. 2004) or as Quaternary tectonic folding (Brault et al. 2001). This paper presents tectonic, petrographic and stratigraphic arguments leading to a mechanical interpretation of the Quaternary deformation processes at Pénestin, located south of the Vilaine estuary southwest of Pénestin city. The morphologic convergence with classical deep-seated shale diapirism is explained on the basis of earthquake-induced transient transformation of a basal saprolite.

Geology

The section of “la Mine d’or” is a fluvio-marine middle terrace complex from the Vilaine River, perched about 15 m above the Hercynian basement cropping out along the shore cliff. The basement is faulted in several compartments and deeply weathered (kaolinitic saprolite). The water table is commonly above it. The section is oriented roughly north-south. At the top of the section, the topography slopes 0.5% to the north and 1% to the west (seaward).

Pénestin is located close to a southern branch of the South Armorican Shear Zone (Fig. 1). This structure is one of the major Variscan dextral strike-slip faults of the European plate (Gapais et al. 1993). The seismicity is moderately active with intensities MSK reaching VII or even VII-VIII (SIRENE database, Fig. 1). to:

- Unit B**:** Scattered blocks of sandstones observed at the contact between the saprolite and the sediments with some sandy gravel generally attributed to Oligocene deposition.
- Unit C1: A beach conglomerate, prograding from the south. At its base, it includes flat-lying blocks of Laderes sandstones and vertical frost-jacked cobbles (cryoexpulsion) stacked into the saprolite, forming cryogenic pattern ground. The truncation by abrasion of the soft but coherent saprolite, with the absence of scouring, also argues for shore face

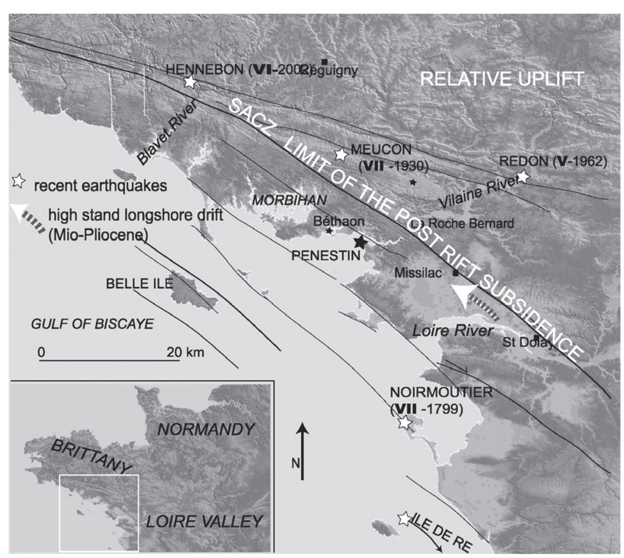

Figure 1. Location of the section.

deposition under a cold climate with block transportation by ice rafting (Van Vliet-Lanoë et al. in press). This unit yields an age of 6.7 ± 0.7 Ma by ESR. It is further locally consolidated by a hydromorphic ferricrete. This hard pan has a major impact on the deformations throughout the section by modifying the permeability and rheology above the saprolite.

- Unit C2: A prograding coarse sandy unit with an increasing charge of angular rock fragments constitutes a sedimentary progradation coming from the south. This unit is strongly rubified close to the surface by yellow-red podzolic pedogenesis. It corresponds to the top of a middle Pliocene estuarine, river-dominated braided fan formed during a major regression. It is covered by rhythmic red and grey silty clays, often wrinkled, unit C3; these tidalites represent the Gelasian/Pre-Tiglian high stand.

Unit D1: Unit C2 is eroded by a channel, consisting of fine-grained sands and clays lacking frost perturbation. This interglacial estuarine material has been dated at 445 ± 71 ka by ESR (Marine Isotope Stage 13) (Laurent 1994). The extent of the sands is visible at the base of some of the large “bowls.”. This unit is practically never deformed where it is thick, but is susceptible to stretching where it is thin and is sometimes faulted.

Unit D2: This sandy gravel belongs to a braided channel system with large blocks and covers most of the section. Blocks are ice-rafted. This periglacial river corresponds to the Pleistocene “middle” terrace of the Vilaine and is further weathered by a polygenetic red-yellow podzolic soil. The sediment has been dated at 317 ± 53 ka (MIS 10 to 8) by ESR (Laurent 1994).

Locally, Unit E1 appears. This is a loess-like khaki silt infilling wedges. These wedges are developed in specific tensional positions and post-date unit D2 and the deformations. (Van Vliet-Lanoë et al. 1997a). They correspond to ice wedge casts, which are truncated by an erosional surface, some recent loesses and heads (unit E2), and by recent dune sands (unit F), Holocene in age.

The geometry of the section revealed a paleosurface shaped at least since the Oligocene and further incised by three successive channel generations. C1 crops out as a marine strand flat, corresponding to a periglacial low stand, Late Miocene to Lower Pliocene in age. C2 is a temperate tidal channel, ending in a mud flat and coming from the south, Middle to Late Pliocene in age. D1 is a temperate tidal channel, 420 ka old. D2 is a conglomerate with more sandy layers, corresponding to a periglacial braided river, 307 ka old; it pre-dates the fold-like deformations. This stratigraphic interpretation makes the age range of the basement deformations clear. North of the bay, the weathered micaschists are truncated by a marine abrasion reaching 8 m NGF. In the middle part of the section, the substratum is weathered in bleached soft clayish silt. The main Kerfalher fault is located 50 m south of Poulante Point, the southern end of the section. A satellite fault outcrops at Poulante Point. Its orientation is roughly N120°E and it does not seem to have suffered recent slip reaching the surface.

Quaternary deformations

The wavy, fold-like deformations affecting the saprolite and the sedimentary units have been interpreted as pingo traces or as evidence for recent strike-slip faulting of the Kerfalher fault system (Brault et al. 2001). Deformations do not present a regular wavelength or strike-slip faulting. Some sectors are devoid of deformation, although others close to Poulante Point are smaller and more clustered (Fig. 2). It seems clear from our data that the more intense deformational features are almost always developed above faults affecting the basement. These pre-existing faults acted as specific water pathways to fault-controlled water migration for potential seismic pumping. Few striations have been observed along the faults. The slip movements reveal normal-sinistral kinematics, compatible with sliding toward the sea-side and incompatible with the supposed strike-slip faulting.

Deformations mostly developed in thick bleached saprolite. These are much less intense when the preserved overburden sediments are thick and more permeable. To the south, the geometry of the deformations is more or less continuous and is elongated roughly N60°E, like the basement faults. Short, often asymmetric, irregular “bowls” have developed due to the presence of the thick white saprolite below units D1 and D2 (Fig. 3a). Usually 2-3 m below the base of D1, the saprolite is undisturbed and porous. No deformation has developed where the conglomeratic ferricrete exists. The deformations are smoother and “longer” in wavelength where the saprolite is coherent (A2), larger and stronger for A3, and smaller but strong where the alluvial complex is thin. Wrinkling developed in unit C3 is related to saprolite injections and has been interpreted as due to the interaction of *P* and Rayleigh waves (Van Vliet-Lanoë et al. 2004). Deformations are thus controlled by (i) pre-existing faults; (ii) the overburden sedimentary load; (iii) the characteristics of its porosity, and (iv) the mechanical properties of the saprolite and the absence of C1 conglomeratic ferricrete.

Liquefaction can develop in clayish sands (Ruxton 2004), allowing incipient doming that stretches the overburden conglomerate cover and pinches out the flanking sandy units, simulating syn-sedimentary deformation. Locally, the D1 sand unit shows stretching with listric microfaults and bending. At the level of maximal curvature of the doming, tension gashes are injected with liquefied kaolinitic silts. Where the saprolite bursts out, load casts deform the extruded saprolite mass, with local wrinkling (Fig. 3b). At the apex of saprolite upward injection, ice wedge casts filled with khaki loess (unit E1) were later centred on tension bulges connected with the large undulations (Fig. 3c). Differential frost heaves may have deformed the structures later (Van Vliet-Lanoë et al. 2004). The clay fraction consists essentially of neoformed, silt-sized kaolinite with about 10% illite, leading to a low density and high porosity in the undisturbed saprolite. Such material has a much lower plasticity index than the other clay minerals (illite, smectite) (Skempton 1953). According to our

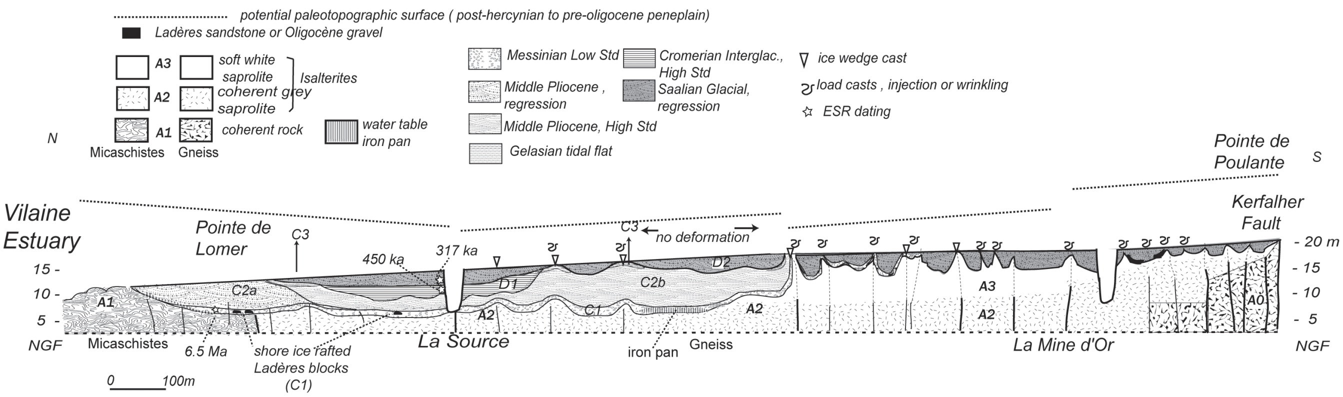

Figure 2. Global sketch of the main section at Pénestin.

laboratory data, the winter water content of unremoulded saprolite is around 23%, slightly above the water content at Atterberg plastic limit (20%, Cassagrande methodology). Liquefaction occurs above 30% in unremoulded sediment (28% at Atterberg liquid limit) where the water table seeps along most of the cliff. Shocks induced by storm waves can ease the collapse of original porous fabric of the saprolite, inducing mass wasting. The bulk density of the saprolite increases towards the surface. The undisturbed dark grey saprolite yields a 1.3 dry bulk density, which when slightly disturbed rises to 1.6, and for white, fully disturbed saprolite to 1.9. The dry bulk density of the coarse sand and the conglomerate are about 1.9 and 2.0, respectively. Cohesive kaolinitic silt is hard to liquefy in normal conditions (Skempton 1953); to destroy the fabric, we need an external trigger to induce liquefaction. To reach the liquid limit (30%) and equilibrate the pressure induced by the overburden conglomerates, we need to destroy the original porous fabric of the "light" saprolite to reach 23% water in the collapsed silt and to add at least 7% water without the possibility of water escape. The origin of this supplementary water supply is clearly connected to the basement faults. To induce mass movement, water needs to be confined in excess within the liquefied saprolite and oversaturation of the saprolite needs to be supplied with water for several days. Petrographic analysis of the saprolite is instructive, revealing no petrographic change in an undisturbed saprolite. The dense material with an unpreserved macro-fabric (A3) reveals interstitial porosity collapse. The material with a partly disturbed macro-fabric preserves most of the initial porosity, but deformed and partly crushed. At the contact with the D1 unit, the saprolite presents sliding planes, attesting to lateral movement of A3 mass with respect to D2. Other units, like C3 and D2, present late deep traces of ice lensing (paleopermafrostrelic permafrost). Frost-induced porosity usually promotes lateral drainage.

Discussion

Periglacial deformation

The deformations were first interpreted by Rivière and Vernhet (1962) as pingo scars relative to continuous permafrost, as indicated by ice wedge casts, but the clustered deformations do not fit the cone-in-cone internal fabric related to the ice-body collapse observed by De Gans (1995) and the isolated pingo. Other periglacial mounds like palsa occur in clustered locations, on wet silty or clayish surfaces, sometimes sloppy. The observed deformations do not fit those described by Pissart (1993). In pingo and palsa, scars, overturned layers exist inside the rims of the scars, sometimes disrupted by normal faults (pingo) with sedimentation or peat developed within the central depression.

Diapirs can also be induced at shallow depths with a residual thick ice cap decaying on oversaturated subglacial sediments like glacio-marine or glacio-lacustrine silts and clays (Brodzikowski & Van Loon 1980). This process is unrelated to the Pénestin paleoclimatic context, as the site is located at least 800 km from the southernmost extent of the British ice sheet. Hydrates diapirs in permafrost may also be responsible for those deformations but the section is too shallow to support this interpretation.

Liquefaction

In the southern section, liquefaction is evident from injections and the global geometry of the deposits reveals mostly a positive gradient in density with light unconsolidated saprolite overlain by dense gravely sedimentary units. However, the coarse-grained D2 unit shows mostly brittle behaviour, the sandy basal layer from D1 is stretched with brittle fracturing, and sliding planes exist close to the contact of the deformed saprolite. The occurrence of subsurface overconsolidation of the saprolite with reduction of microporosity, thin mud injection and fabric wrinkling suggests rapid deformation (Van Vliet-Lanoë et al. 2004) but the development of the large deformations with larger injections seems related to slower motion over several days. Liquefaction susceptibility reflects the relative resistance of soils to loss of strength when subjected to ground shaking. Co-seismic liquefaction is always associated with water-saturated sediments that can reach oversaturation by fabric collapse or with sediments oversaturated by co-seismic water supply (Muir-Wood & King 1993). Co-seismic liquefaction also leads to overconsolidated sediments at shallow depth, although the superficial layers are liquefied.

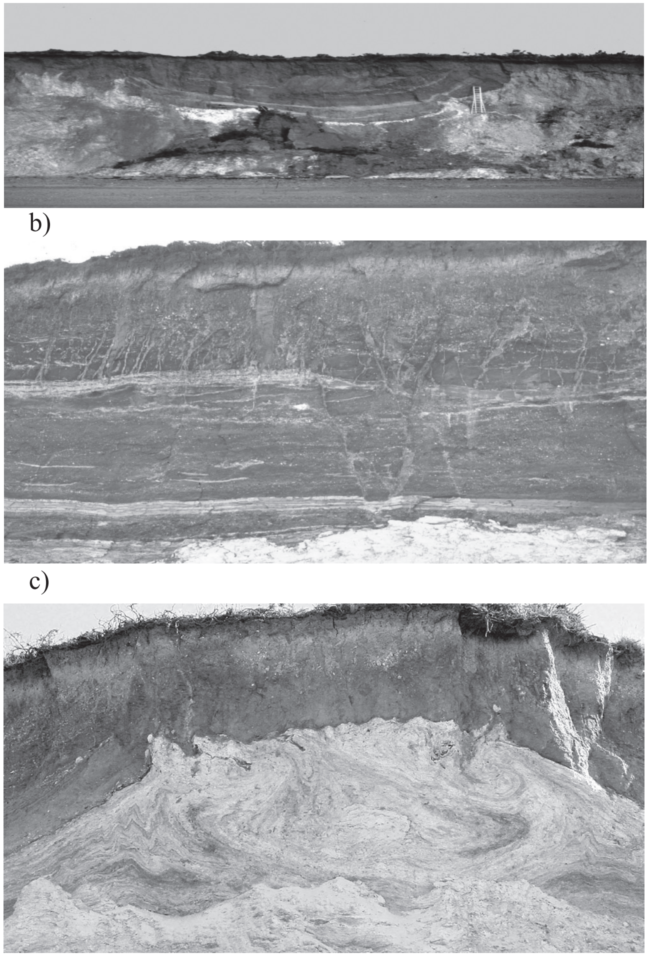

Figure 3. a): View of a "bowl" north of "la Mine d'or." Notice injection at the level of the ladder; b): Giant drop with lateral wrinkling in saprolite A3 (section height: 2 m); c): Clustered ice wedge casts above a diapir.

At Penestin, we interpret evidence of liquefaction and overconsolidation in initially cohesive sediments as resulting from fabric collapse and transient water supply. An external trigger for liquefaction and a complementary water supply is needed. As water is a non-compressible fluid, the alternating squeezing and suction from the local water table located in the faulted basement caused by P and Rayleigh waves caused a rise in excess pore water pressure in the overlying saprolite with subsequent liquefaction. This ejection of liquid mud is normally locked by overburden sediments. Here, the overburden weight of the D units is limited by erosional truncation so mud ejection was easier. Youd et al. (2004) observed that soil softening leads to a lengthening of the period of ground motion and that ground oscillation leads to a continued rise of pore water pressures after ground shaking ceases. The generated overpressure is confined at depth in the regional water table contained in a fractured substratum. An earthquake of strong magnitude can liquefy cohesive silty soils as demonstrated by recent major earthquakes. Liquefaction was also very important even on the gentle slope at the foot of the Turnagain hills with lateral spreading and sliding of a rafted suburb of Anchorage (Seed & Wilson 1967).

The remaining possible mechanisms are thus shale diapirism or folding. Tectonic transpressive folding does not fit our observations, as discussed previously. Disharmonic surface folding is difficult to apply to the geometry of deformation at Pénestin (apex of basement faults). After deformation, the whole system was truncated by a late erosional surface related to the periglacial regimes of MIS 8 and MIS 6, without younger evidence of "folding."

Shale diapirism

While often mimicking folding, shale diapirism usually develops in marine basin in association with fast sedimentation, the strong sedimentary overburden leading to water overpressure in unconsolidated sediments. Active shale diapirism occurs when the overburden layer is thinned by tension and the mobilized shales are pushed upward due to the rise in internal pressure (Vendeville & Jackson 1992). In these conditions, clay behaves as a fluid, with a very low viscosity, inducing hydraulic fracturing in the confining layer, with differential loading (Bolton & Maltman 1998). The initial diapir shape is modified by lateral or oblique upward migration of fluidized shales and may generate a network of clay dykes and sills, in the form of a ring or conical faults that help the rise of the diapir. When the hydraulic pressure drops, the diapirism stops, followed by drainage and consolidation with further collapse (Vendeville & Jackson 1992).

At Pénestin, there is no evidence of thick overburden sediments to justify confining, since sedimentation stopped at about 300 ka, prior to the main deformation. Most D1-D2 gravels behave as a confining system for the saturated saprolite. The extra pore-fluid was produced locally by seismic-induced water supply along the normal faults triggering the diapiric motion, as discussed above. This localized overpressure source induced a metric swell of the saprolite at the apex of the feeding fault, resulting in tension gashes at the apex of the bulging developed in the rigid and confining alluvial system. During the fracturing process, the inner hydraulic pressure gradient was probably involved in fracture opening, like in hydrofracturing. Nevertheless, it is difficult to determine if fracturing and fluidization were synchronous, although tension gashes were rapidly injected by the fluidised saprolite and locally extruded to the surface. The conical faulting developed further, marked and eased by injections of fluidized saprolite on the side of the diapirs; this has been confused with flower structures due to transpressive shear. In detail, shale diapirism should explain most of the deformational structures in the saprolite as well as deformation like stretching in D1 sands and sliding planes developed in the saprolite observed at the base of the bowl-like structures.

These mechanisms, co-seismic fluidization and diapiric motion, do not perfectly explain the elongation of the observed patterns and their higher frequency close to the summit of Poulante Point. The elongation develops in parallel with the main slope (E-W 1%) of the Pénestin peninsula. During the Anchorage earthquake, sliding of the whole liquefied saprolite mass (Seed and Wilson 1967) induced buoyancy and rafting of sedimentary bodies. For Pénestin, two raft models can be proposed. In the first, the sliding is orthogonal to the positive ridges that correspond to local mud diapirs in stretched areas (Fig. 4c), while in the second, the raft structures are groove-shaped and each is separated by and strikes along mud diapirs (Fig. 4d). This last model agrees with the topographic slope towards the sea (marine low stand at the time of deformation) and with the kinematics observed in NE-SW slickensides in the deformed saprolite.

Reconstitution of Pénestin event

With this succession of mechanisms, nearly synchronous, we can reconstitute the entire story. A major earthquake occurred around 280-290 ka when the climate was periglacial and the Vilaine River was prograding, but sea level was not yet too low and permafrost was absent. The regional water table was high, and during the event, fluids probably escaped along basement fault nets, locally bulging the saprolite and consequently weakening the rigid confining alluvial body. During the earthquake, water was supplied by the fractured weathered substratum, except above the ferricrete. The whole saprolite surpassed the plastic limit and, in the upper layer, the liquid limit; it began to rise, rapidly deforming the base of deposits C3, D1 and D2. This process probably continued to evolve with the continuing rise in pore water pressure after ground shaking ceased. The diapir movement probably persisted for several hours after the event and generated lateral spreading. Displacement may have been mostly south-westward, following the main slope. The sliding was groove-shaped by differential loading of the D1 gravels, parallel to the diapirs separating the various corrugations. The “folds” in the northern part of the section trace thus aborted shale diapirism.

The date of the paleo-earthquake, roughly marking the onset of a regional relaxation event after a regional compressional event (circa 430-280 ka) is somewhat disturbed by the building of major ice sheets on Britain (MIS 12 and 10; Van Vliet-Lanoë et al. 1997, 2002). After this event, the saprolite probably dried out during the Saalian I (MIS 8; 280-240 ka), by segregated ice development in the permafrost, also responsible for the development of ice wedges, and by subsequent drainage of the alluvial body when it thawed. Today, the water table is perched on the densified saprolite A3.

Such a development in a tectonically active region is basically linked to the existence of an unconsolidated clay body (sedimentary or saprolite) and to the presence of a rather shallow water table and a confining surface layer like consolidated clayish conglomerate or even a lodgement till. In formerly glaciated region, the normal load of dead ice bodies can be traced on unconsolidated mud (Brodzikowki & Van Loon 1980); seismic activity induced by glacio-isostatic rebound also provides evidence (Hasegawa & Basham 1989). Outside the glacial limits, large undulations of so-called periglacial diapirs in places like the Rhine Graben (Strunk 1983) or basins like Bovey Tracey (Devon) are more likely due to seismically induced shale diapirism.

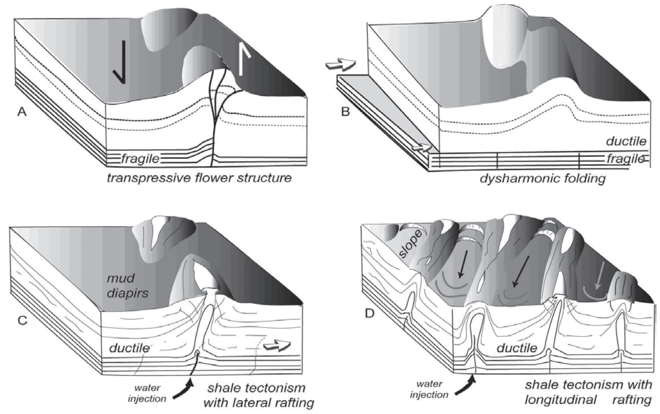

Figure 4. Hypothetic model of deformation at Pénéstin. D is the most evident from field data.

Conclusions

The deformations observed along the Mine d’or section at Pénestin represent the evidence of successive events triggered by the distant effects of an earthquake. One major deformational process is shale diapirism, initially triggered by seismic water supply, loading and lateral spreading, favoured by liquefaction of the saprolite basement that allowed the shale diapirism to develop. Traces of periglacial pingo and palsa are not observed at Pénestin, despite the presence of a paleo-relic permafrost. Neither Quaternary transpressive tectonics nor local ruptures are identified at this precise site.

During the seismic event, the phenomenon could have developed further. This whole process resulted, especially at the Mine d’or, in a liquefied mud leaded to a local mega-load cast on top of the saprolite outbursting, with lateral shortening induced by pulsated motion (wrinkling). Post-seismic relaxation, drainage and normal collapse of the stretched saprolite allowed some normal tension faulting to develop, probably also related to mass wasting, especially near “La Source.” Diapir motion probably persisted at a much lower rate for a few days or weeks, controlled by the main slope to the west, explaining the bulging of some of the diapirs exploited on the tension zone by younger ice wedge casts (260 ka), when permafrost developed and definitively blocked the motion. Seismically-induced shale diapirism seems to be frequent in active continental basins when a shallow water table is available to promote liquefaction.

The Rich Contributions of A.L. Washburn to Permafrost and Periglacial Studies

Bernard Hallet
Quaternary Research Center and Department of Earth and Space Sciences, University of Washington, Seattle

Abstract

Albert Lincoln Washburn, (1911–2007) contributed immensely to the fields of periglacial geomorphology and permafrost research through his studies, publications, leadership, and personal qualities. His deep interest in the "intimate workings of nature" is evident in his own meticulous and exhaustive field and laboratory studies of diverse types of periglacial processes, including patterned ground formation, slope movement, and ice growth in soils. This review focuses on these productive field studies in Greenland and on Cornwallis Island, and on his research in the Periglacial Laboratory at the University of Washington. Link's intense curiosity about periglacial processes and his untiring, generous effort to properly present the work and ideas of other researchers are clearly evident in his monographs and renowned books, which remain the standard references in the field decades after their publication (*Periglacial Processes and Environments* [1973], *Geocryology—A survey of periglacial processes and environments* [1979]). In addition, Link launched and directed research centers and scientific journals that have nurtured the study of cold landscapes. Significantly, his scientific legacy also includes an exceptional, more personal dimension: the emergence of the unusually cohesive and amiable permafrost/periglacial community, as it was fostered in part by Link and his wife Tahoe's warmth, generosity, and friendship, which graced many members of our worldwide community.

Keywords: active layer; frost heaving; frozen ground; patterned ground; periglacial geomorphology; periglacial processes; permafrost; upfreezing.

"To test the forefront of knowledge for even a brief period, particularly when the subject matter concerned the intimate workings of nature, provided both a motivation and challenge that ... are deep and real for me."

—From one of Lincoln Washburn's rare speeches, 1988

"Quietly content as we trotted beside the kamotik [large dog sled], I thought of some friends who would envy me, and others who would be at a loss to understand why I would wish to undergo what to them would be extreme hardship. I could not have explained my feeling to them then, nor can I do so now.… One is very close to the earth and one's companions but at the same time quite detached—an odd feeling of being free, yet an integral part of the nature of things. The Inuit know they belong to the Arctic. They are an integral part of the natural world around them. While, sadly, many of us have lost touch with it."

—From Tahoe Washburn's (1999) book relating experiences in the Canadian Arctic 1938–41

Introduction

Very sadly, Lincoln Washburn passed away on January 30, 2007, in Seattle; he was 95. He will be missed by many. We can, however, rejoice upon reflecting on his remarkably productive career.

Herein, I highlight his exceptional contributions to science and focus on his pioneering discoveries about processes shaping Arctic landscapes. I also mention his broader contributions to science, which extend well beyond his own research; they include his leadership role in the foundation of major interdisciplinary research centers and academic journals that have nurtured advances in understanding the Polar Regions, the Quaternary period, as well as permafrost and periglacial phenomena.

For more personal information about Link, as his many friends knew him, please refer to the thoughtful obituaries written by two of his long-term friends and colleagues, Steve Porter (2007) and Carl Benson (2007). Considerable material from these sources appears below.

Research Contributions: Field

Here, I focus on Link's productive field studies in Greenland and on Cornwallis Island. They comprise a wealth of detailed observations of surface exposures and excavations of diverse types of patterned ground, and extensive long-term studies of surface displacements to define quantitatively the kinematics of patterned ground activity and slope movement. It was Link's extensive fieldwork that provided the foundation and motivation for his unifying nomenclature and concept about periglacial soil patterns. He coined the term "patterned ground," provided rich and diverse examples, and summarized all ideas current at that time about their genesis (Washburn, 1950, 1956). Interestingly, "patterned ground" is now widely used not only by those working in periglacial features on Earth, but by the planetary community (e.g., Mangold et al. 2004), especially as the current stream of high-resolution images of Mars (e.g., Hi-Rise; http://hirise.lpl.arizona.edu) are revealing diverse forms of patterned ground, many of which resemble those in the hyper arid polar regions where, in contrast with Mars, the conditions and processes manifested in these patterns can be examined and monitored in detail.

Figure 1. Link and Tahoe Washburn in the late 1980s, Resolute, Cornwalis Island, Canada.

Mesters Vig

Link launched his fieldwork on periglacial processes and features near Mesters Vig in the King Oscar Fjord region of East Greenland, which he had first visited during the Louise Boyd expedition in 1937. He conducted a reconnaissance study in the summer of 1955, established instrumented sites in 1957, and made observations each year from 1957 through 1961, and again in 1964. The results of his studies are presented in three substantial monographs that appear in separate issues of the Danish journal *Meddelelser om Grønland* (Washburn, 1965, 1967, 1969). Collectively, these volumes comprise over 600 pages that record in detail his observations and measurements at more than 20 experimental sites.

His research was comprehensive in addressing a diversity of landforms and periglacial phenomena with a persistent focus on better understanding the formative processes. For example, Washburn (1969) systematically considered 11 forms of weathering, and 12 types of patterned ground. At his experimental sites, he deployed arrays of markers and established detailed photographic records that enabled him to monitor soil motion and surface changes over a period of many years. Moreover, he did not limit himself to landscape features; his outlook was interdisciplinary and included the vegetation and climate of the region, as well as its history of isostatic uplift.

Antarctica

He conducted research in Antarctica in 1957 and 1958 and was involved in planning the multinational, interdisciplinary Dry Valley Drilling Project in 1972-75, which succeeded in drilling a number of deep boreholes into permafrost, which gave revealing glimpses at the subsurface ice distribution, stratigraphy and chemistry, as well as temperature gradient over a large sector of the Dry Valleys near McMurdo. Valuable δ^{18}O data from the cores at three sites (DVDP cores 8–12) in the Taylor Valley emerged from a study led by his close colleague, Minze Stuiver, in the Quaternary Research Center (QRC, Stuiver et al. 1981). These early isotopic data and chronology continue to help fuel research within the QRC. They now render this location an ideal validation and calibration site for an ongoing effort by QRC scientists, R. Sletten, B. Hagedorn, and me, to understand the existence of subsurface ice in hyper-arid cold regions and to model the isotopic evolution of ground ice.

Resolute

His fieldwork on Cornwallis Island, Arctic Canada, in what is now Nunavut Territory, extended from 1981 to 1995. There, Link focused on solifluction and patterned ground activity. In the former, he established arrays of surface markers that he resurveyed periodically. The patterned ground work consisted of detailed mapping of extensive areas of sorted circles, establishing arrays of markers across individual circles that were repeatedly measured to monitor soil motion, and "bed-frames" that enabled him to monitor the spatial variation in surface heave and settling across a ~5 m^2 area. Washburn (1989) summarized his findings on soil displacements in sorted circles in a comprehensive paper that examines the spatial pattern of changes in position and tilt of dowels inserted in the soil surface. His research results inspired and guided much subsequent field work in diverse Arctic regions by a number of researchers (e.g., Anderson 1988a, Hallet & Prestrud 1986, Hallet et al. 1988, Hallet 1990, Hallet & Waddington 1991)

The culmination of this work is his last major written contribution, a monograph, "Plugs and plug circles: A basic form of patterned ground. Cornwallis Island Arctic Canada—Origin and implications." Washburn (1997) presents the results of years of observations and countless excavations of these soil domains, which develop spontaneously and ascend progressively through the active layer, and are likely to transform into more distinct types of patterned ground. He combines lucid, accurate descriptions with thoughtful and careful interpretations that shed light on the complexity of the principal formative processes active in the early stage of patterned ground development. Interestingly, recent numerical modeling shows sorted patterned ground initiating as plugs much like those depicted by Link (Kessler et al., 2001).

Research Contributions: Laboratory

His research in the Periglacial Laboratory at the University of Washington was focused on the effects of ice growth/thaw and frost heaving/thaw settling on solifluction, vertical textural segregation (sorting), and the development of deformational structures in layered soils. With the competent assistance of researchers, C.M. Burrous and R.G. Rein, Link Washburn used his specially designed laboratory for a comprehensive, long-term study of processes and features of the active layer, including soil deformation on horizontal surfaces and slopes. This laboratory featured a unique tilting slab capable of accommodating soil up to 1 m thick and 9 m^2 in area overlying a simulated permafrost table or an unfrozen substrate.

Next, I will describe two experiments conducted in the 1973–76 period in some detail not only because they yielded interesting sets of useful and unparalleled results, but because they illustrate the meticulous care taken in conducting the experiments in Link Washburn's Periglacial Laboratory, and in presenting the results. Unfortunately, these studies are essentially unpublished but considerable information is available in detailed internal QRC reports at the University of Washington. Two of these reports are used extensively here: "Soil deformation resulting from some laboratory freeze-thaw experiments" by A.L. Washburn, C.M. Burrous, and R.G. Rein, and "Experimental Upfreezing of Objects: Effects of Object Geometry" by C. M. Burrous. Few results from solifluction and horizontal slab experiments were published (Rein and Burrous 1980, Washburn et al. 1978).

Soil deformation, involutions

Through a number of well-designed, large-scale experiments, with thoroughly documented, simple initial conditions, Link and his co-workers were able to elucidate the rich interactions between soil texture, thermal regime, and soil deformation. Two comprehensive experiments were conducted using frost-susceptible silt on the 2.5 m by 3.6 m slab (Washburn et al. 1978). In experiment 2, for example, the slab was subdivided in plan view into 4 sectors differing in the nature of the upper 3 cm of material, but sharing the same base material, which consisted of 24 cm "clayey$_{12}$sandy$_{16}$silt$_{72}$ of predominantly eolian origin from eastern Washington" overlying 8 cm of "coarse, angular sand (Del Monte white sand) that served as a good basal aquifer. The upper 3 cm of each sector consisted, respectively, of A) clean gravel, B) silt mixed with gravel in the ratio of 6:4, C) white sand, and D) silt identical to base material. The slab was cycled through 10 freeze-thaw cycles, generally ranging from -15ºC to 15ºC while water was made available to the basal sand and remained unfrozen throughout most experiments with piezometric control at least at the onset of freezing

Figure 2 illustrates two sectors, C) with sand at the surface and D) all silt, viewed in a vertical cross-section. It demonstrates cleanly the important effect of surface soil texture on thermal behavior, and highlights the more rapid descent of the freezing front under the sand. This difference in thermal evolution, and associated surface heave, was well documented using a thermocouple probe and a displacement transducer in each sector (Fig. 3). These probes consisted of copper-constantan thermocouples spaced 2 cm apart.

The differential descent of the freezing front due to differences in soil texture results in an inclined freezing front (Fig. 4), which is important because it can induce lateral as well as vertical relative motion of relatively "large" particles in the soil. This lateral motion and inclined freezing fronts are widely recognized to be important in the development of sorted pattern ground. They also figure prominently in numerical models of patterned ground formation (Kessler et al., 2001; Kessler and Werner, 2003), and yet, with the notable exception of these poorly known results, there is a dearth of solid experimental or field data to guide the key assumptions that are required for realistic modeling of the texture-thermal feedbacks that are central to patterned ground formation.

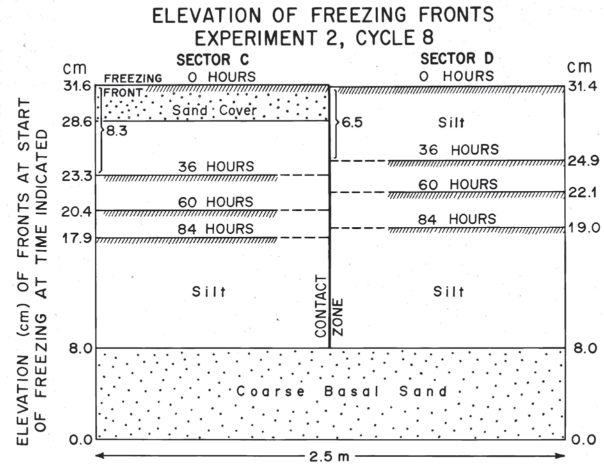

Figure 2. Initial configuration of soil in experiment 2, and descent of freezing front during a typical cooling period. After 36 hours the freezing front had descended 6.5 cm into the silt, and 8.3 cm below the sand cap. The freezing front depth was defined using temperature probes and frost tubes located in each sector, ~11 cm and 41 cm from the contact zone, respectively.

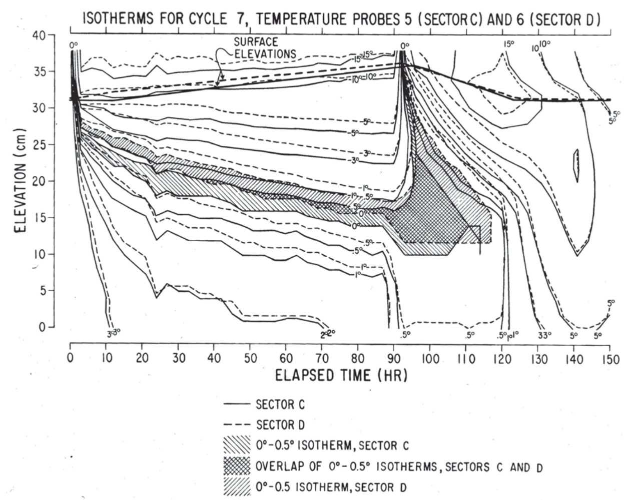

Figure 3. Contrasting thermal evolution and surface heave for the two soil sectors shown in Figure 2 through one representative freeze-thaw cycle.

Aside from important temperature data, these experiments also yielded a wealth of additional observations that were carefully described and interpreted. These are not new, but they gain importance because they arise in a system designed to be simple and uniform in terms of soil materials and moisture content at the onset, with initial conditions that are exceptionally well documented.

In a year-long study, experiment 3, Fairbanks silt, a well known frost-susceptible soil, was subjected to 32 controlled freeze-thaw cycles. The silt was underlain by 6 cm of sand that allowed for the controlled input of water at the base of the soil to fuel the ice lens growth and frost heaving. Typically, to begin freezing the surface temperature was lowered to -20ºC, while the base of the frost-susceptible soil was maintained at 2ºC. This thermal regime was maintained for 4 days, and then the soil was thawed over ~1.5 days by raising the room

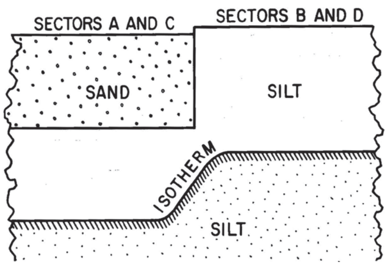

Figure 4. Hypothetical isotherm across the boundary between domains with contrasting surface materials.

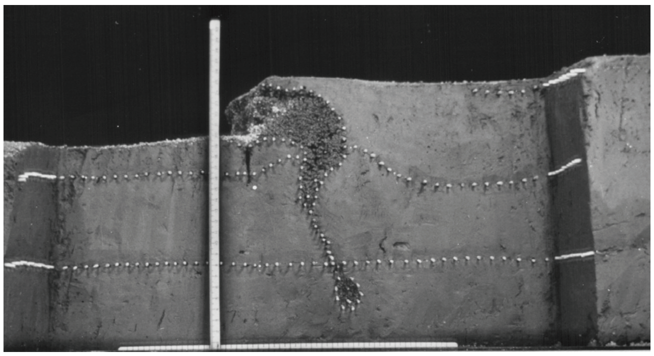

Figure 5. Vertical section at the end of 32 freeze-thaw cycles in experiment #3 highlighting a domain of sand that descended ~20 cm from the surface, a 6 cm-thick layer on the left side (removed before picture was taken). Arrays of white toothpicks delineate glitter surfaces in the soil that were initially horizontal at depths of 0.8, 8.5, and 16.6 cm. Scales are 32 cm long.

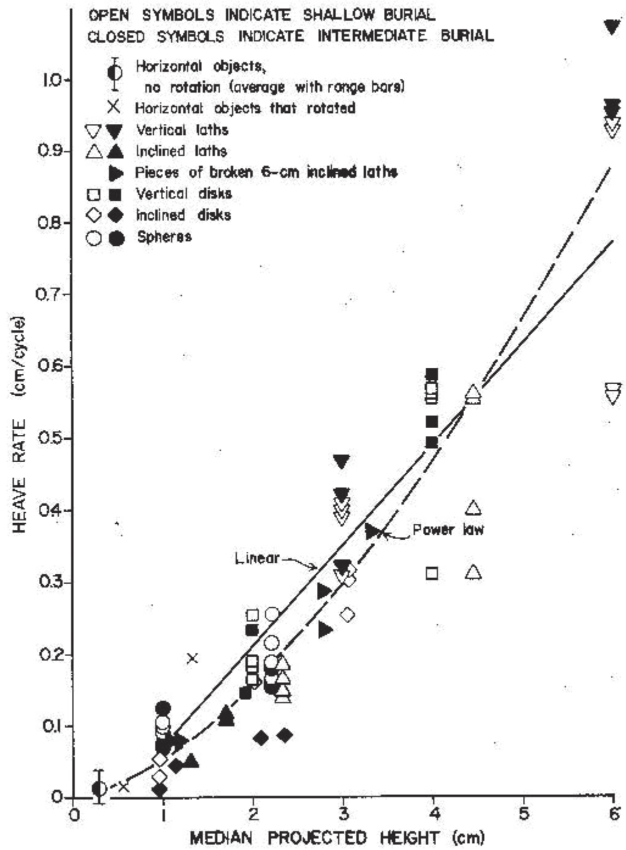

Figure 6. Combined upfreezing data as a function of median projected height of buried glass objects.

temperature and using infrared heaters above the soil surface. The silt surface generally heaved at a nearly uniform rate of 1.2 cm/day as the freezing front descended ~2.8 cm/day; the surface subsided 3.1 cm/day as it thawed. The total heave per cycle was roughly 5 cm, corresponding to a heaving strain of about 20%. Based on visual inspection, this strain is consistent with the volume ratio of visible ice lenses in cores that were taken of the frozen soil. Interesting phenomena developed largely at the boundary between domains with contrasting surface materials; they include A) involutions of sand that penetrated well below the surface, most probably during the thaw-settling phase of the experiments (Fig. 5), and B) shear displacement along a vertical surface and with limited descent of surface sand along this surface. In addition, Link and his co-workers noted details that are seldom mentioned, such as the tendency for bubbles to emerge at the soil surface near shallow up-freezing objects, and the appearance of a gleyed horizon at the silt base.

Upfreezing

Another exhaustive laboratory study examined systematically the dependence of size and shape of diverse objects on the rate at which they progressively ascend through the soil due to repeated cycles of heaving and settling. This was part of the year-long study just described, experiment 3. Prior to freezing, the Fairbanks silt was prepared carefully to permit the precise placement of 54 glass objects of different sizes and shapes (spheres, disks, and laths), with known initial position and orientation, on a 20 cm-grid at each of three levels in a silt layer ~25 cm thick.

A striking result (Fig. 6) is that the distance objects ascend through the silt per freeze/thaw cycle increases roughly linearly with their projected height. Surprisingly, the shape and orientation of the object have little effect. According to this clear result, larger stones are expected to move up toward the surface faster than smaller stones, and the upfreezing rate can be modeled as scaling with the product of the projected height of an object and the heaving strain of the soil. This powerful result inspired Anderson (1988a, b) to launch her own laboratory study of upfreezing, and guided her as she explored the role of upfreezing in sorted patterned ground. According to Figure 6, the net upfreezing of a stone with a projected height of 5 cm, for example, was ~0.6 cm per freeze/thaw cycle. This presumably resulted from an ascent of, at most, 1 cm (the product of the 20% heaving strain and the 5 cm projected height) during the freezing phase, followed by a descent of 0.4 cm during the thaw phase. Anderson (1988a) reported similar ascent/descent ratios during freeze-thaw experiments as long as the stones were well below the soil surface.

Several other findings from this study are noteworthy: 1) inclined tabular objects in these experiments rotated toward the horizontal, which was somewhat surprising in view of the common observation of steeply inclined stones emerging from the tundra that suggest a tendency for upfreezing to rotate stones toward the vertical; 2) all long (6 cm) inclined laths broke, indicating that these objects were subjected to large torques, presumably during the freezing phase; 3) for objects of the same projected height, laths heaved slightly faster than disks, which in turn heaved faster than spheres; and 4) the depth below the ground surface had little effect, which is counterintuitive because heaving strains were larger at depth due to the slower freezing while the surface heaving rate remained roughly constant; evidently greater upward heave during freezing was offset by greater settling during thaw.

Books and Monographs

Link's deep interest in periglacial processes and his untiring generous effort to present the work and ideas of other researchers properly are clearly evident in his monographs and books, which remain the standard authoritative references worldwide decades after their publication (Washburn 1973, 1979). His books are esteemed for their being thorough and for presenting the fruit of deep scholarly searches, as well as his own research findings. In contrast with most modern journal publications, Link's manuscripts are rich with lengthy presentations of multiple hypotheses and interpretations of diverse periglacial features and processes from researchers worldwide. His recent comprehensive monograph on the multitude of origins that have been proposed for the Mima Mounds in western Washington (Washburn 1987) exemplifies these qualities.

A Leader and a Visionary

Lastly, I wish to highlight Link Washburn's considerable contribution to science through his exceptional leadership and vision. He gained much recognition and appreciation while serving as the first director of the Arctic Institute (Dunbar 1952). Later, but still decades before the emergence of "earth system science" and the widespread concern about global warming, Link envisioned and launched the Quaternary Research Center at the University of Washington to promote interdisciplinary research about the global environment during the Quaternary. This fascinating period features the evolution of humans and the advent of civilization as well as massive abrupt changes in climate, sea level, global biota, and ice extent that still challenge our understanding and remind us of the difficulty of predicting climate and environmental change. Sensing the need for a scientific journal devoted to this important field, Link launched *Quaternary Research*, which appeared in 1970. "He shepherded the journal through its first 5 years, establishing for it a reputation for breadth and excellence, and making it one of the most widely cited earth science publications" (Porter 2007).

Link has been recognized and honored nationally and internationally. A few apt words by Albert Pissart (personal communication from Liège, Belgium, 2007) capture the essence of this worldwide recognition; reflecting on his deceased friend, he wrote: "j'avais conservé un culte pour ses travaux, son honnêteté scientifique, sa modestie et son extrême amabilité." Loosely translated, Albert worshipped Link's work, his scientific honesty, his modesty, and his extreme kindness. Moreover, Albert noted that with his appetite for learning and unusual fluency in German and French, he read and understood essentially all published material, and on his frequent trips to meetings in Europe between 1959 and 1985, he exchanged ideas and information freely within the European as well as the American scientific community. This exceptionally rich background contributed to his monographs and books, which were the first important syntheses of worldwide knowledge to date about periglacial processes and landforms and their connections with fossil periglacial features.

Albert also stressed that Link had received the highest scientific recognition possible in Belgium as an elected associate member of the Royal Academy. Steve Porter (2007) provides a listing of the numerous honors he received and the committees and organizations for which Link served as a directing officer, both nationally and internationally.

Summary

Highlights of Link's career include unfailing scholarship, research, administration, and careful detailed planning. His books and monographs catalyzed the emergence of periglacial geomorphology as a distinct scientific field, and solidified the field internationally by assembling and generously distilling results from a multitude of studies scattered in diverse sources worldwide, across national and linguistic boundaries. In addition to the research centers he directed and the scientific journals he launched, his rich scientific legacy includes the unusually cohesive and amiable permafrost and periglacial community, the emergence of which was fostered in part by Link and Tahoe's warmth, generosity, and friendship, which reached many members of this worldwide community.

Acknowledgments

I thank Steve Porter and Carl Benson for their thoughtful and comprehensive obituaries, sections of which I have borrowed from liberally, Ross Mackay and Albert Pissart for helpful communications, and Land Washburn for permitting use of the photograph of Link and Tahoe.

Advances in Permafrost and Periglacial Research in the Dry Valleys, Antarctica

Bernard Hallet, Ronald S. Sletten, Jaakko Putkonen
Quaternary Research Center, University of Washington, Seattle WA 98195, USA

Abstract

Extremely dry and cold conditions in continental portions of Antarctica lead to permafrost properties and periglacial processes that merit special attention because they are quite distinct from those in the Arctic, which are generally more familiar. Moreover, they resemble most closely those on Mars, providing powerful analogues that are helpful in interpreting the surface of the planet and the dominant surficial processes, as well as evidence for major recent change in the climate of Mars. Herein, we review recent studies of periglacial processes and implications for understanding the hyper-arid, cryogenic landscape typical of the non-ice covered portions of the Antarctic continent and beyond. Our review is selective as it is limited to the research we are familiar with in the Dry Valleys region; it includes 1) thermal and moisture states of Antarctic permafrost 2) factors affecting the formation, stability and longevity of ice below the ground surface, 3) nature and rates of patterned ground processes with a focus on sand-wedge polygons, 4) rates and mechanisms of permafrost creep, hillslope processes and sediment transport, and 5) specific analogues pertinent to permafrost and periglacial activity on Mars, and related inferences about Martian climate change.

Keywords: Antarctica; contraction cracks; Dry Valleys; Mars; patterned ground; periglacial; permafrost.

Introduction

In comparison with the Arctic, the Antarctic continent is very cold and extremely dry. In addition to leading to distinct thermal conditions below the ground surface, the cold and hyper-arid conditions cause major differences in permafrost properties and processes between the polar regions. The dearth of water in the Dry Valleys profoundly affects a suite of periglacial processes that are fueled by large volumetric changes associated with freezing and thawing in water-rich systems. Frost heaving is very limited, which curtails a suite of processes that are directly linked to ice lens or needle ice growth: weathering of bedrock and sediments, frost-induced sorting of material, formation of sorted patterned ground, and downslope motion of debris. On the other hand, the large seasonal temperature fluctuations, and in particular the very low soil temperatures attained in the winter because of the lack of thick insulating blanket of snow, lead to large thermal stresses in the upper part of the permafrost; the resulting thermal contraction cracks in the permafrost render polygonal patterned ground pervasive and often the dominant surface texture of extensive areas. The dry conditions also lead to two characteristics unusual in wetter cold regions: the accumulation of salts at and below the ground surface, and the importance of eolian processes in shaping the periglacial landscape. Moreover, under the cold conditions that prevail in the Dry Valleys, subsurface ice can form and persist for long periods of time, and landscape evolution can be extremely slow.

The relatively slow periglacial processes and stable landscapes typical of Antarctica merit special attention because they contrast with those in the Arctic, which are generally more familiar, and they resemble those on Mars most closely, providing an informative analogue environment that is helpful in interpreting the surface of that planet. Moreover, diverse techniques that have been developed for studying permafrost and periglacial systems in the Antarctic may prove useful in other cold regions. They include 1) analyses of cosmogenic nuclide concentrations in bedrock, sediment, soil and ice for diverse objectives: determining rates of weathering and sublimation of buried ice, ages of deposition, and duration of exposure or burial; 2) isotopic, trace and major element studies of subsurface ice to examine the origin and evolution of the ice, and 3) ground displacements using in situ instrumentation as well as space borne techniques (GPS, SAR Interferometry) to document the magnitude of thermally or gravitationally driven regolith motion.

Permafrost and periglacial process studies in the Antarctic also complement those in the Arctic in addressing questions that seldom emerge in the wetter and more dynamic frozen landscape of the Arctic. Why is there ice below the surface in this dry environment? What is the longevity of buried ice? What is the rate of sublimation of that ice? What is the origin of salts and how do they affect H_2O transport, and ionic transport and isotopic exchange in the ice? How stable is the ground surface or a landform?

Herein, we do not attempt to provide a comprehensive review but rather summarize the more substantial advances in terms of new approaches, methodology, or insight gained into key processes largely in the Dry Valleys of southern Victoria Land, near McMurdo, which contain the largest non-ice covered area on the Antarctic continent (Campbell & Claridge 2006).

Thermal Properties of Dry Valley Soils

Two primary factors distinguish the soil thermal regime in the Dry Valleys from that of a typical Arctic site: 1) soils are extremely cold in the winter, often dropping below -40ºC (Fig. 1), and 2) the near surface soil (the upper ~0–20 cm) often lacks H_2O, making the soil an effective, cohesionless

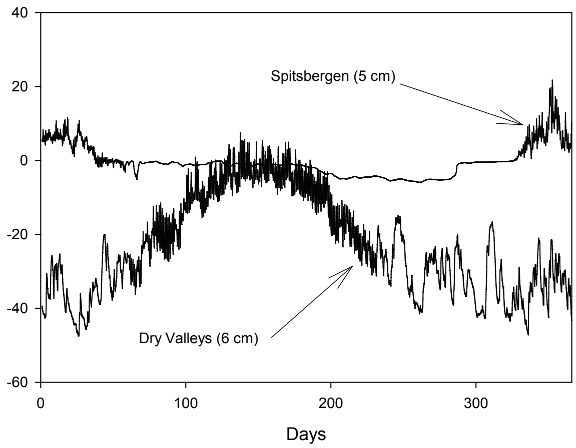

Figure 1. Soil temperatures 5 and 6 cm below the ground surface in Spitsbergen (Putkonen 1998), and in the Dry Valleys (Putkonen et al. 2003). The data span one year starting on the first of August. As the field sites are in opposite hemispheres, the summers are out of phase. Note very cold and variable conditions, and the conspicuous absence of the zero-degree curtain or other phase change effects close to 0ºC in the Dry Valleys.

insulator (Putkonen et al. 2003) with bulk soil thermal conductivities as low as 0.1–0.4 W m^{-1} K^{-1}. Laboratory measurements of typical dry surface soil samples, yield values of 0.3 W m^{-1} K^{-1} for the thermal conductivity 1000 J kg^{-1} K^{-1} for the heat capacity and 1200–1800 kg m^{-3} for the density; correspondingly, the thermal diffusivity is 0.17–0.25 x 10^{-6} m^2 s^{-1}

Such a low thermal conductivity promotes steep thermal gradients, which can reach 200 K m^{-1} near the soil surface, and limits the penetration of surface temperature variations (Putkonen et al. 2003). The dearth of near surface ice/water also eliminates all thermal effects related to the phase change of water that are characteristic of Arctic soils.

Due to the cold winters, short cool summers and low thermal conductivity of the dry soil, the active layer is thin, ranging from 30-60 cm for low altitude coastal sites to about 15 cm in the alpine valleys ~1400 m asl and about 70 km from the coast (Campbell et al. 1998, Putkonen et al. 2003). Snow may fall any time of the year, but the thin snow cover (typically less than 30 cm) lasts only days (Campbell et al. 1998, Hagedorn et al. 2007). Without the insulating snow cover, the near surface soil temperatures vary widely through the winter reflecting the large variations in atmospheric conditions.

Moisture State

Due to low precipitation and air temperatures, averaging around –20°C, in the Dry Valleys, liquid water is very limited; most snow sublimates and only a small amount melts, delivering little or no moisture to the ground (Gooseff et al. 2003, Hagedorn et al. 2007). Campbell and Claridge (1982) report that soil moisture moves mostly in the form of vapor with limited migration of snow melt. Nevertheless, salt horizons and salt crystallization beneath stones are prevalent in the Dry Valleys (Keys & Williams 1981); considering the limited solubility of the salts, these accumulations reflect significant long term fluxes of liquid water even under these extremely arid conditions.

Water persists in thin films on mineral surfaces to very low temperatures (Anderson & Morgenstern 1973, Yong et al. 1979, Fu et al. 1993) and considerable ion migration probably occurs along these films (Ugolini & Anderson 1973, Wettlaufer & Worster 1995, Claridge et al. 1996, Wettlaufer 1999, Wettlaufer 2001, Dickinson & Rosen 2003). The high solute content lowers the freezing point of water well below 0°C, and tends to increase the mobility of both water and solutes by thickening these films. To date only two studies of transport rates have been performed in the field. Using LiCl-tracers in Antarctic soils, Claridge et al. (1996) documented Li diffusion 15–25 cm into the soil and 5 m laterally in ≤ 3 years, with a strong dependence on the moisture content. Application of ^{36}Cl and ^{22}Na-labeled NaCl close to the ice-cemented permafrost in Wright Valley by Ugolini and Anderson (1973) revealed upward migration of both ions but significantly less movement of ^{22}Na than ^{36}Cl, presumably due to differences in diffusion coefficients and chemical behavior e.g., ion exchange and adsorption.

Subsurface Ice

Subsurface ice is pervasive in the Dry Valleys, where it occurs in various forms: pore ice, ice in permafrost cracks, and buried lake or buried glacial ice (Bockheim & Hall 2002, Campbell & Claridge 2006).

This ice is fundamental to diverse periglacial processes, including patterned ground activity and mass wasting, not only in Antarctica but also on Mars. Its existence within the top decimeters in soils that are 10^4 to 10^6 year old is enigmatic, however, since current models indicate that any ice within few meters of the surface would sublimate into atmosphere within several thousand years (van der Wateren & Hindmarsh 1995, Hindmarsh et al. 1998, Schorghofer 2005). Most recently, Hagedorn et al. (2007) explore mechanisms that slow or may reverse ice loss from the soil to the atmosphere, and incorporate them into a sublimation model that uses high-resolution climate and soil temperature data in Victoria Valley, where the surface is ~10 Ka old and the soil is ice cemented 0.22 m below the surface. According to this model, snow slows long-term sublimation but, due to the dearth of data on the duration and timing of snow cover, the potential of snow melt to offset vapor transport out of the soil cannot be assessed quantitatively at present. Studies of depth profiles of δD and $\delta^{18}O$ in pore ice are providing new insights into the origin and evolution of ground ice in the Dry Valleys (Hagedorn et al. 2003, Souchez & Lorrain 2006).

Massive subsurface ice occurs sporadically in the Dry Valleys. Much effort has been directed at dating and understanding the origin and longevity of this buried ice, especially in Beacon Valley where it has been interpreted as the oldest glacier ice on Earth. Such ancient ice would be of considerable interest because it may contain an unparalleled archive of paleoenvironmental conditions and lyophilized bacteria. Sugden et al. (1995) reported an 8.1 Ma volcanic ash in the sublimation till overlying this ice, and viewed it as a direct air-fall deposit. This interpretation implies slow sublimation for the survival of both the ice and the delicate layer of ash and hence, a persistent cold climate, which has broad implications about global climate stability since the Miocene. This extreme stability is not, however, consistent with independent estimates of sublimation rates of 50 m Ma^{-1} and ~10^3 m Ma^{-1}, respectively from measurements of cosmogenic nuclides in a 19-m ice core (Stone et al. 2000) and from theory (e.g., Hindmarsh et al. 1998). Moreover the use of the ash to constrain the age of the ice has been questioned by Sletten et al. (2007) who reported old tephra erratics within the sublimation till.

One way to resolve this age controversy is to decipher the history of the till overlying the massive ice from cosmogenic nuclide measurements. The till is a residue of debris-laden ice that sublimed. Ng et al. (2005) reinterpreted published ^3He depth profiles through the sublimation till in Beacon Valley, Antarctica, to derive rigorous constraints on the till-thickness history and on the amount and rate of ice loss by sublimation. The ^3He profiles show that the lower 80% of the till formed in the past 310–43 ka under sublimation rates averaging >7 m Ma^{-1}. Such rapid, recent growth of the till contradicts previous interpretations that it is older than 8.1 Ma at an adjacent site, where it encloses volcanic ash of this age, casting additional doubt on the validity of the ash in constraining the age of the ice.

Soil Distribution and Characteristics, and Weathering

Relative to many well studied portions of the Arctic, the spatial distribution of soils in the Dry Valleys region has received little attention until recently (Bockheim et al. 2007). A new soil map is being developed for selected regions of the McMurdo Dry Valleys (McLeod et al. 2007). As mentioned earlier, the active layer tends to be relatively dry and shallow (Paetzold et al. 2003); it is often ice-free particularly at the higher elevation sites near the ice sheet (Bockheim et al. 2007).

The paucity of liquid water in the Dry Valleys leads to soils sharing many characteristics with soils of arid regions with considerable salt accumulation. The dominant salts are chlorides, nitrates, and sulfate, mostly of direct marine origin (Bao et al. 2008); the latter two reflect oxidation in the atmosphere prior to deposition (Bao et al. 2000). The abundance of salts influences soil moisture (Hagedorn et al. 2007), weathering (Dickinson & Grapes 1997), and biology (Barrett et al. 2006).

The Dry Valleys Long Term Ecological Research site in Taylor Valley has served as a focus for studies of soil processes related to the soil fauna (Barrett et al. 2006, Wall et al. 2006) and to chemical weathering, which influences the chemistry of soil water, as well as streams and lakes (Lyons et al. 2002, Gooseff et al. 2007). Publications on the soils, hydrology, and biota are listed on the LTER web site (www.mcmlter.org).

The cold, hyper-arid conditions lead to some of the lowest known bedrock erosion rates on Earth. A powerful means of determining these rates has been exposure age dating using cosmogenic nuclides. Such research in the Dry Valleys area has shown that 1) the bedrock surfaces have been exposed sub-aerially for millions of years; notably they have not been buried by ice sheets or covered by water or sediments, and 2) these bedrock surfaces erode at rates of ~1 m Ma^{-1} (Nishiizumi et al. 1991, Brook et al. 1995, Summerfield et al. 1999, Smith et al. 2001, Schoenbohm et al. 2004). These bedrock erosion rates are among the lowest recorded on Earth and are 1-3 orders of magnitude slower than, for example, ~10 m Ma^{-1} in the Sierra Nevada, USA (Stock et al. 2005).

Patterned Ground

Polygonal patterned ground is ubiquitous in the Dry Valleys, even on steep hillslopes. In this and other arid, cold regions, thermal contraction cracks tend to open at the ground surface during cold periods. In contrast with regions where moisture is abundant and the cracks tend to fill with water and ice, the Dry Valley cracks fill partially with wind-blown sand and other fine-grained debris. This infilling prevents the cracks from fully closing during warm periods. During subsequent cooling periods, each crack reopens, permitting more sand infilling, thereby, incrementally forming a wedge of sand. With time, the ground surface on either side of the crack is warped upward by the growing sand wedge to form symmetrical ridges separated by a trough over the crack (Péwé 1959). These sand-filled cracks interconnect to form polygons (Fig. 2) that have received very little attention compared to the thoroughly studied ice-wedge polygons (Mackay 1971, 2002).

The progressive growth of sand-wedges can be examined by monitoring the distance between markers installed across contraction cracks. Recent measurements of 417 pairs of steel rods, which were hammered vertically into the ground on opposite sides of contraction cracks at 13 sites established in the early 1960s by Robert Black, show steady divergence across the sand-wedges of patterned ground in the Dry

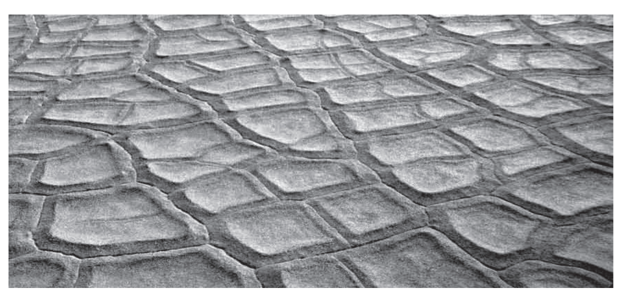

Figure 2. Polygonal patterned ground in upper Victoria Valley. These distinctive low-centered polygons form spontaneously from the recurrent opening and closing of cracks due to thermal strains, and the progressive addition of wind-blown sand into the cracks.

Valleys. Rod spacings were measured on several occasions from 1962 to 2002 (Berg & Black 1966, Black 1973, Black 1982, Malin & Rawine 1995, Sletten & Hallet 2004). Individual divergence rates between paired rods in lower Beacon Valley, for example, are highly variable, ranging from 0.1 to 1.8 mm a^{-1}. By 2002, the mean distance between rod tops increased 20–25 mm (std. dev. 16-18 mm) since their installation 39 years earlier. The rates are remarkably steady in time, and are essentially identical to those at sites recently established to continuously monitor contraction crack dynamics (Sletten et al. 2003).

The recurrent cracking and sustained addition of wind-blown sand to a depth of ~5 m generate long-term pervasive deformation in the permafrost and wedge material and net surface aggradation, or inflation, at rates of 0.05 to 0.1 mm a^{-1}. Evidence for both surface and sub-surface deformation includes the pair of ridges that commonly border each contraction crack (Fig. 2), and frozen soil layers that are often warped upward as they approach the wedge (Péwé 1959). Recent, high resolution instrumental measurements show significant thermally-induced permafrost deformation and are invaluable in studying the dynamics of this form of patterned ground (Fig. 3).

This soil deformation is complex, and constitutes a form of cryoturbation that is expected to pervasively disrupt geomorphic surfaces where sand-wedge polygons are active. The ratio of polygon size (~10 m) to typical sand-wedge growth rate (~1 mm a^{-1}) for lower Beacon Valley provides an indication of the time scale for the reworking of the ground surface, which is only ~10^4 years. Provided that the rates of wedge growth deduced from Black's data over the last few decades can be extrapolated to considerably longer time scales, they challenge the notion that similar nearby geomorphic surfaces have been stable for millions of years, as proposed by Sugden et al. (1995) and Marchant et al. (2002).

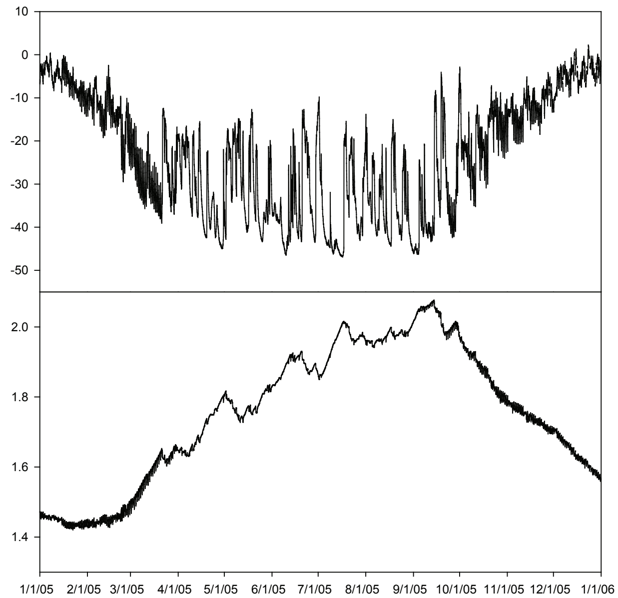

Figure 3. Air temperature (deg C) at 2 m and increase in distance between two markers (in cm) that are ~2 m apart across a contraction crack in central Beacon Valley. Displacements were measured with micrometer resolution using a linear motion transducer. Data were recorded hourly using a Campbell CR10X data logger.

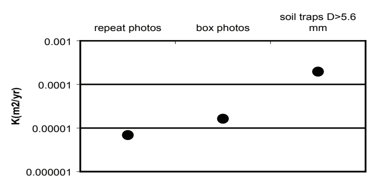

Figure 4. Mean topographic diffusivity for Dry Valleys determined using repeat photography and soil traps. These values approach the lowest known terrestrial values from hot deserts and they contrast strongly with those in the Arctic where regolith fluxes are among the highest on Earth. For additional details see (Putkonen et al. 2007).

Slope Processes

The stability of ground surfaces and preservation of deposits that record past events and environments are important to studies of the geologic and climatic history of Antarctica. Clear indications of downslope debris transport such as solifluction lobes and direct measurements of debris motion on slopes, which are common in the Arctic, are rare in the Dry Valleys; elongated polygons or sorted stripes, and solifluction terraces are uncommon. (Putkonen et al. in press).

Although the common occurrence of ancient volcanic ashes at or near ground surfaces suggests essentially perfect preservation of sedimentary deposits in the Dry Valleys (Marchant et al. 1993, Marchant & Denton 1996, Marchant et al. 1996) and negligible downslope debris motion, recent research suggests rates of downslope motion that approach those in hot deserts.

In contrast with the Arctic, all the downslope movement in the Dry Valleys is limited to the upper few centimeters of the dry soil (Putkonen et al. in press). Using repeat photographs, soil traps, and measurements of downslope displacements of rock fragments in the Dry Valleys, Putkonen et al. (2007) determined a sediment transport coefficient (topographic diffusivity) for the Dry Valleys that normalizes the debris flux per unit width of the slope for the local slope angle (Fig. 4). This contemporary diffusivity ranges from 10^{-5} to 10^{-4} $m^2 a^{-1}$; it is relatively low but approaches those previously reported from other sites worldwide (Oehm & Hallet 2005). Indirect observations in the Dry Valleys suggests that strong winds play a significant role in the downslope transport of dry debris as they can destabilize relatively large pebbles as evidenced by gravel dunes in the lower Wright valley and sediment recovered in soil traps (Lancaster 2002, Putkonen et al. 2007). The topographic diffusivities are highest in alpine valleys located farther inland from the coast, and lowest near the coast.

To determine the longer term downslope debris flux Putkonen et al. (2007) also analyzed concentrations of distinct rock fragments found downhill of eroding source boulders. These boulder trails yielded a lower limit for the

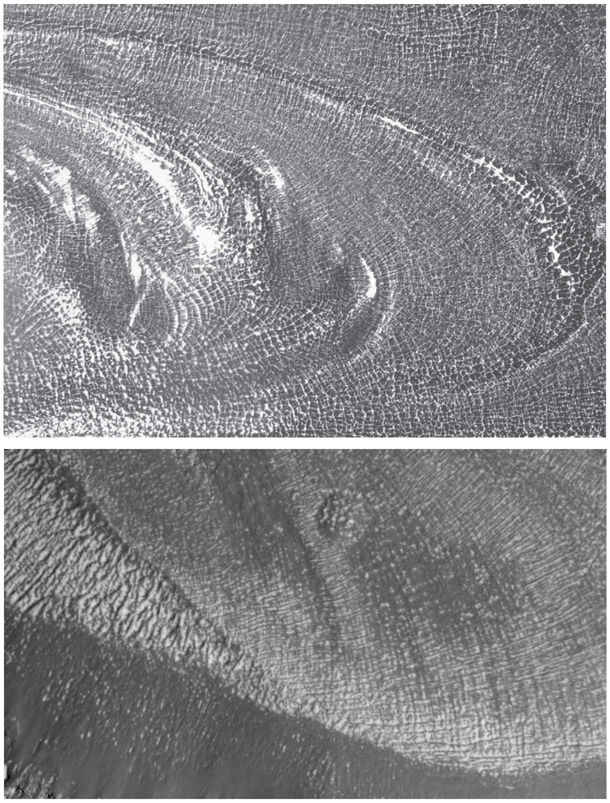

Figure 5. Upper picture shows accurate ridges and a pervasive system of near-orthogonal surface cracks on the rock glacier in upper Mullins, Valley, Antarctica. Similar terrain is observed on Mars (MOC S05-01603).

long term topographic diffusivity of order 10^{-8}–10^{-7} m^2 a^{-1}; actual diffusivities are likely much larger. Another source of information about the long-term mobility of surface debris can be extracted from braking blocks, which are partially exhumed boulders that have a typical bulge of regolith on the uphill side and a depression on the downhill side; they are ubiquitous in the Dry Valleys. Using a model of downslope motion governed by local slope, Morgan and Putkonen (2005) simulated the evolution of the microtopography toward a steady state, obtaining results resembling closely the microtopography observed in the field. They were able to assess minimum regolith transport rates; the corresponding topographic diffusivity was found to exceed 10^{-6} m^2 a^{-1}.

In conclusion, the rates at which debris moves downslope in Antarctica are generally the smallest known on earth; they strongly contrasts with those from wet Arctic that are among the highest. Despite these low rates, downslope debris transport can significantly alter landforms and disturb ancient deposits in the Dry valleys over a typical exposure time of millions of years.

Rock Glaciers – Permafrost Creep

The absence of vegetation, dearth of snow and stability of land surfaces in the Dry Valleys are ideal for the use of satellite-based Synthetic Aperture Radar studies of surface motion as the surface maintains excellent coherence of the radar returns over several years. Rignot et al. (2002) obtained a

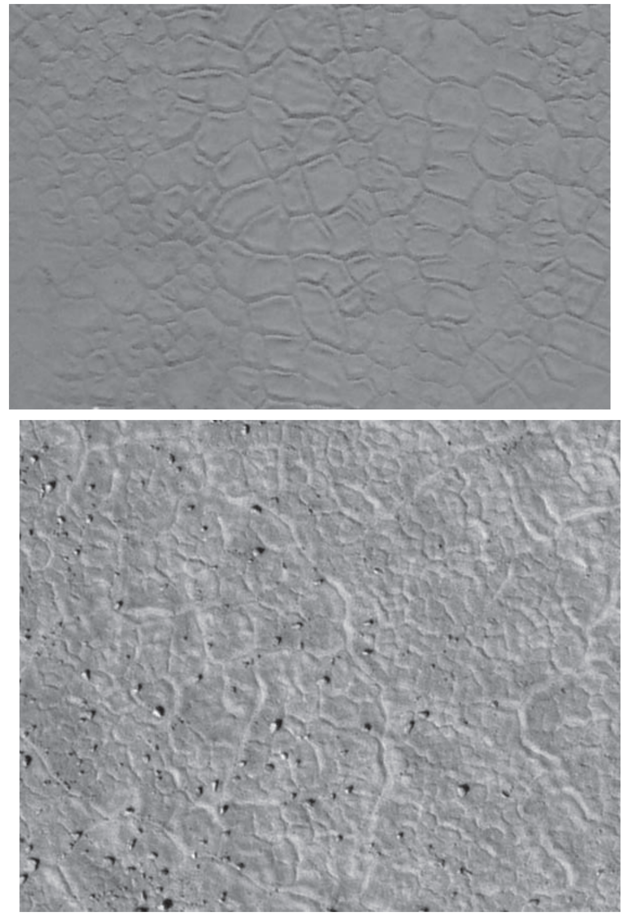

Figure 6. Aerial photograph of Victoria Valley (top) and analogous terrain on Mars (HiRise image TRA_000828_2495_IRB; illumination from the lower left). Shallow surface troughs outline polygons approximately 10–20 m across.

spatially continuous surface velocity field with a precision of fractions of a millimeter per year on rock glaciers (debris-covered glaciers) entering Beacon Valley. They found coherent velocity patterns, with peak velocities approaching 40 mm per year; these velocities are consistent with our unpublished GPS measurements of surface boulder motion.

The ice supply from these rock glaciers nourishes the central portion of Beacon Valley, where it sublimates. Interestingly, the ice supply balances the loss by sublimation provided sublimation rates are within the 0.02–0.2 mm a^{-1} range, which brackets the net sublimation rate of 0.05 mm a^{-1} obtained using cosmogenic isotopes in subsurface ice (Stone et al. 2000).

The surface of rock glaciers displays a series of features strikingly similar to those imaged on Mars suggesting the likely presence of debris-covered massive ice on Mars. Figure 5 illustrates many of these features including lobe-like forms, arcuate ridges, and complex dense patterns of surface cracks.

Studying Mars Using Antarctica Analogue

The cold and dry near-surface conditions typical of the Dry Valleys approach those on Mars. Studies of Antarctica as a useful analogue were initiated in the 1970s after the first images were taken by the Mariner and Viking spacecraft (e.g., Anderson et al. 1972). With additional successful missions and the recent acquisition of much higher resolution images, along with compelling evidence for widespread ice in the upper ~1 m of permafrost (Boynton et al. 2002), there is a considerable resurgence in interest to use the Dry Valleys as a popular natural laboratory to study landforms and processes that occur or may occur on Mars. They include rock glaciers and moraines (Head & Marchant 2003), the sublimation of subsurface ice (McKay et al. 1998, Hagedorn et al. 2007) that has much in common with the identical process on Mars (Schorghofer 2005), the formation of polygonal patterned ground (Fig. 6) and associated micro-relief (Mellon 1997, Sletten & Hallet 2003), and the occurrence and preservation of simple life forms under extreme polar conditions (e.g., Gilichinsky et al. 2007).

Acknowledgments

We acknowledge C. McKay, B. Hagedorn, D. Gilichinsky, M. Mellon and A. Gillespie for assisting us in the field and/or for informative discussions pertinent to this review. Abstract

This paper presents the results of a Spatial Point Pattern Analysis (SPPA) of small-scale polygonal terrain in Utopia Planitia, Mars, and draws comparisons with a number of terrestrial analogue sites. Utopia Planitia displays a wide variety of landforms interpreted as having periglacial origins, suggesting the past or present existence of large quantities of ground ice. Therefore, this region of Mars offers an excellent case study to assess the applicability of statistical analysis in quantifying and comparing terrestrial and Martian small-scale polygonal terrain, which in turn may yield insight about the processes responsible for their formation.

Keywords: Axel Heiberg Island; Canada; Mars analogues; polygonal terrain; spatial point pattern analysis.

Introduction

Polygonal terrain is one of the most common landscape features found in terrestrial polar environments (Mellon 1997a). These networks of interconnected trough-like depressions form through a process termed *thermal contraction cracking*—a result of complicated interactions between climatological and rheological processes (Lachenbruch 1962)—and often signify the presence of shallow subsurface ice deposits in the form of ice wedges (Mackay 1999).

Large polygonal patterns on the surface of Mars discovered by the Mariner missions were originally of great interest as they, too, were thought potentially to be implicit of ground ice deposits (Carr and Schaber 1977). However, subsequent analysis concluded that polygons with diameters ranging from 2-10km were too large to be associated with thermal contraction cracking and thus are now believed to be formed through a variety of other geological processes (e.g., Lane and Christensen 2000).

More recently, though, Mars Global Surveyor's Mars Orbiter Camera (MOC) had been used to identify and map polygons of much smaller size, revealing that these small-scale geometric networks are scattered throughout Mars' mid- to high-latitudes in both hemispheres (Kuzmin & Zabalueva 2003). With sizes ranging from 10–200 m, they are much more comparable to terrestrial polygons; as such, analysis of these features has prompted a revisiting of their analogical value.

Because polygons on Mars are often located in close proximity to other landforms thought to be representative of ground ice presence (e.g., Soare et al. 2007) and display strong visual similarities to terrestrial polygons, (Isaev and Abramenko 2003; Mangold 2005), the presence of these patterns on Mars has been used to suggest the possibility of near-surface ground ice deposits (e.g., Mellon 1997b; Seibert and Kargel 2001; Mangold et al. 2004).

Previous descriptions of polygonal terrain have tended to be qualitative in nature, and thus require some degree of subjectivity to analyze. However, by using quantitative techniques to describe polygonal geometry, it is possible to categorize various groups of networks and relate them to other factors.

Our goal for this study was to apply a statistical technique to surface patterns on the Martian surface, attempting to answer two overarching research questions pertaining to Martian polygonal terrain: "*is their geometry related to proximity to other periglacial landforms*?" and "*how similar are they to polygons found on Earth*?".

In essence, this study seeks not only to map the spatial distribution of polygonal terrain occurrence in relation to other features thought to be indicative of ground ice, but also to quantify the similarities and differences displayed between the geometry of the polygonal terrain observed on Earth and Mars.

Research Context

Terrestrial polygonal terrain and ice wedges

A detailed explanation of polygon formation via thermal contraction cracking is provided in the seminal works performed by Lachenbruch (1962), Pewe (1966), and Black (1974), summarized below. When tensile stresses due to seasonal decreases in surface and subsurface temperatures exceed the tensile strength of frozen ground, vertical cracks develop in order to relieve the stress. Over time, numerous cracks begin to join or intersect, resulting in closed polygonal geometrical shapes. As temperatures warm, the open cracks are filled with surface meltwater and groundwater that freezes when it reaches the permafrost within the crack. The vertical vein of ice that results represents the early stages of an "ice wedge."

As the surrounding climate warms later in the year, movements of near-surface soils induced by thermal expansion promote the formation of shoulder-like ridges bounding a linear depression in the ground above the wedge. Eventually, the cracks close again and the buildup of stresses due to freezing reinitiates the following winter. By repeating the process over hundreds or thousands of years, the ice wedge continues to thicken and the polygonal topographic patterns at the surface become more enhanced.

Martian polygons = ground ice?

It is conceivable that polygons found on Mars represent analogous geocryological systems to those found on Earth, based on converging lines of evidence suggesting that Martian polygons may be indicative of near-surface ground ice.

For example, it is possible that both terrestrial and Martian polygons are formed by similar processes. Mellon (1997a,b) showed that the conditions required for thermal contraction cracking could be exhibited poleward of 30 degrees latitude. Subsequently, Seibert & Kargel (2001) demonstrated that ice wedge cracking was potentially responsible for their formation.

In addition, polygons tend to be located in areas otherwise believed to be rich in ground ice. Mangold et al. (2004) noted that the majority of polygonal terrain is located poleward of 55 degrees, within the zone predicted to contain stable ice and spatially coincident with regions where Odyssey's Neutron Spectrometer detected near surface hydrogen enrichment (Boynton et al. 2002). Moreover, Langsdorf & Britt (2004) and Soare et al. (2007) showed that polygons are often found in close proximity to other landforms potentially associated with ground ice deposits (Fig. 1)

Comparing polygonal terrains on Earth and Mars

The apparent lack of quantitative comparisons between the geometry of terrestrial and Martian polygonal terrain may be a result of how polygonal ground has been categorized on either planet. On Mars, various combinations of geographical distribution, proximity to nearby landforms, and polygon size have been used to group polygonal networks (Kuzmin and Zabalueva 2003; Langsdorf and Britt 2004; Mangold 2005). On Earth, however, polygons tend not to be classified by their geometry, but rather by their relation to permafrost aggradation or degradation (Mackay 2000).

A selection of previous researchers have attempted to

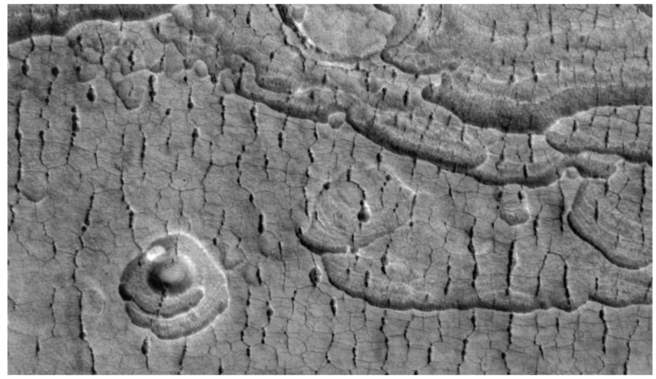

Figure 1: Example of polygons appearing within pitted and scalloped terrain (MOC image: R0301203). Image is approximately 3.5 km across.

use statistical analysis in their description of polygon morphology (e.g., Rossbacher 1986; Plug and Werner 2001; Yoshikawa 2003). Unfortunately, a universally accepted method to compare polygonal terrain on Earth and Mars has yet to be determined.

Refined statement of objectives

Through previous work, we have introduced the utility of a particular statistical method – Spatial Point Pattern Analysis – for quantifying a variety of polygonal terrain morphologies observed on Earth and Mars (Haltigin et al. 2007). We have now begun to apply the method more systematically to investigate differences in polygon morphology on a regional (rather than global) scale.

Therefore, our specific objectives for the present study are to: (1) explore variations in observed polygon morphologies displayed in the Utopia Planitia region of Mars, and; (2) compare the observed morphologies with a selection of those present in the Canadian High Arctic. By satisfying these objectives, it is possible that the inferred similarities and differences can be used to interpret some of the processes responsible for their formation.

Study Areas

Mars: Utopia Planitia

Utopia Planitia is a major topographic depression situated in the northern plains of Mars (Fig. 2). Although Odyssey's Gamma Ray Spectrometer (GRS) has revealed that this area is relatively free of hydrogen in the near-surface (Boynton et al. 2002), the large spatial resolution of GRS pixels may not be capable of identifying local ground ice occurrence.

A variety of geomorphic indicators do, in fact, suggest the presence of ground ice in Utopia Planitia. For example, small-sized polygons throughout the region and possible thermokarst features such as pitted terrain and scalloped terrain (Fig. 1) has led to the suggestion that this region contains ice-rich sedimentary deposits, whose emplacement could well be atmospheric and relatively recent (Costard & Kargel 1995; Soare et al. 2007).

Earth: Axel Heiberg Island

Fieldwork was conducted at four polygonal terrain sites near the McGill Arctic Research Station (M.A.R.S.) (79.383N, 91.067W). The region is set within a polar desert climate, having a mean annual air temperature of approximately -15°C and total annual precipitation of <100 mm (Bigras et al. 1995).

Although polygonal terrain is widespread throughout Axel Heiberg Island, the four sites near the mouth of Expedition Fjord were selected based on geomorphological considerations after a preliminary reconnaissance field campaign in 2005.

Specifically, the sites chosen display differing morphologies, but are located in extremely close proximity to each other (three of the four are separated by <1 km, while the fourth is <10 km away). Such a small geographical range removes variation in the two primary factors known to affect polygon geometry: surface age (Sletten et al. 2003) and climate (Mackay 1999).

Methodology

Data collection

(a) Mars imagery

A systematic survey of all available Mars Global Surveyor MOC Narrow Angle images was performed for the region within Utopia Planitia between 80–90E and 40–50N. Images were downloaded from the online MOC database and visually inspected for the presence of polygonal terrain. The images selected represent a broad diversity of polygon morphologies, and thus are an ideal template upon which to examine the applicability of a statistical technique to detect and quantify geometrical variation. Of the 52 images on which polygonal terrain was identified, a subset of 22 images between 80–90E and 40–45N were selected for spatial analysis.

(b) Aerial photography

Prior to aerial photograph collection, the field sites were prepared by demarcating transects on the ground with a series of Ground Control Points (GCP)—a series of brightly colored markers that are easily identifiable on the photos. Depending on the width of the area required to be imaged, four to six transects spaced 40m apart were lined with alternating brightly-colored ground markers to provide readily visible flightlines for the helicopter pilot.

Vertical aerial photographs were taken from the helicopter using a Nikon D200 digital SLR camera equipped with a 50 mm Zoom-Nikkor lens. Images taken from an altitude of approximately 300 m resulted in image widths of approximately 100 m at sub-decimeter resolution. Between 15 and 20 photos were collected per transect, totaling 75–100 individual images per site.

(c) GPS surveys

A Trimble 5700 differential Global Positioning System (dGPS) was used to measure the spatial coordinates of the GCPs and selected polygon trough intersection point using the Post-Processed Kinematic survey method (Lantuit & Pollard 2005). Standard coordinate correction algorithms were applied using Trimble's TG-Office software. Processed dGPS coordinates were subsequently used to spatially reference the aerial images (see *Data analysis* section).

Data analysis

(a) MOC image processing

Each MOC image was imported into a Geographic Information System (GIS; ArcMap 9.1) and placed within an arbitrary coordinate system (units=meters); x-y coordinates of (0.00, 0.00) were assigned to the bottom left-hand corner of the image, while the remaining three corners were scaled according to the image height and width provided in the file's metadata.

Because of temporal and computational constraints, it was infeasible to perform the spatial analysis on the entire MOC image. Therefore, an initial visual inspection was performed in order to designate a representative area of the observed polygonal terrain. Within the selected area, all discernible polygon trough intersections were manually identified and digitized. Coordinates of the digitized points were exported and used for the statistical analysis.

(b) Aerial photo processing

Individual photos were imported into the GIS to be spatially referenced. Processed dGPS coordinates were assigned to the corresponding point on the images, causing the photos to be stretched and rotated to be oriented within Universal Transverse Mercator coordinate space. By performing this "georeferencing" on all images for a given site, an oriented and scaled photo mosaic was produced. Finally, all trough intersection points were manually digitized, with the coordinates exported for spatial analysis.

(c) Spatial point pattern analysis

A full explanation of spatial point patterns is provided by Diggle (2003). Tables of x-y coordinates for both the MOC and field images were analyzed using a customized code written for the statistical software package SAS. After the analysis area was defined, the analysis yields two key outputs: (1) a range of predicted nearest-neighbor distances (NND) that would satisfy the null hypothesis of a completely random distribution, and; (2) a table of observed NND for each trough intersection point.

By plotting a cumulative frequency distribution curve of the observed NND values, it is possible to determine whether the observed spatial distribution of trough intersection points is clustered, random, or regular, and the degree to which they are so designated.

Results and Discussion

Distribution of polygonal terrain in Utopia Planitia

Locations displaying polygonal terrain are spread quite evenly throughout the area within the transition zone grading from the cratered uplands to the basin below (Fig. 3a). Although the simple *occurrence* of polygons is widespread in the entire study area, the appearance of polygons in conjunction with other thermokarst features may be a function of surface elevation.

Specifically, the majority of instances where polygons appear independently of other features are found at higher elevations (lower left portion of Fig. 3a-c), with 10 of 14 cases found well above the basin floor. Furthermore, polygons in the vicinity of scalloped terrain appear primarily at lower elevations than do those found containing pitted chains. It is unsurprising, then, that a band of images displaying *both* pits and scallops is located in the zones of intermediate elevation.

Spatial point patterns of Utopia Planitia polygons

A great variation in polygon size is displayed clearly amongst the assorted terrains throughout the study area, with median NND span from 25.5 m to 64.4 m (Fig. 3b). The overall range of NND varied greatly as well, with minimum values ranging from 15.1 m to 32.8 and maximum values ranging from to 39.6 to 154.2 m.

A diversity of morphology is also evidenced by an examination of the observed spatial point patterns. Of particular interest is the recognition that in no cases are the observed patterns clustered; rather, the sites display varying degrees of randomness and regularity (Fig. 3c).

Sites were determined to be "primarily random" if at least 50% of the observed NND fell within the envelope predicted by the spatial point pattern analysis to satisfy the null hypothesis of complete randomness. Sites were identified as "mixed" if between 25% and 50% of the observed points satisfied this requirement and "primarily regular" if less than 25% of the observed NND satisfied the requirement.

In general, the majority of sites that displayed primarily regular patterns possessed the lowest median NND values

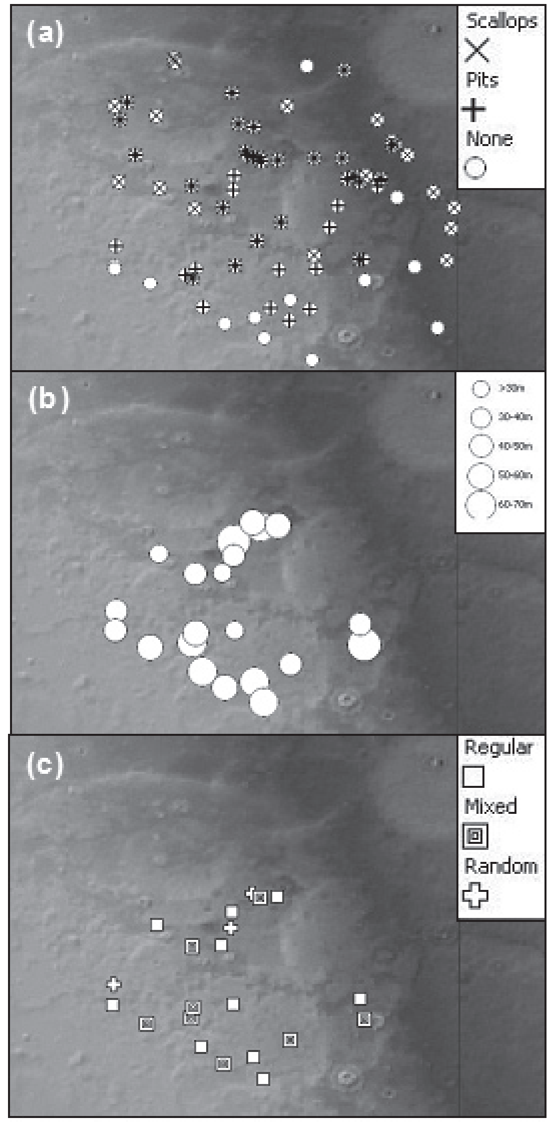

Figure 3: (a) Occurrence of polygonal terrain in relation to other periglacial features; (b) Median NND and (c) observed spatial point pattern of polygonal terrain field.

(averaging approximately 30 m), indicating that smaller polygons tend to be more regular. Conversely, the three sites determined to be primarily random had average median NND values of 40 m. Thus, a positive relationship can be inferred between polygon size and randomness of the network's geometry.

More trends emerge when comparing the observed spatial point patterns to proximity to other landforms. In particular, it is interesting to note that all three of the sites displaying primarily random geometry are found in conjunction with the pitted chains. In only one case each were pits found for sites with regular or mixed geometry, respectively. In addition, all sites that displayed scalloped terrain were found to contain regular patterning. No clear trend was apparent for sites with polygonal terrain appearing in the absence of other landscape features, having virtually an equal number of instances that were considered either mixed (5/9) or regular (4/9).

Spatial point patterns of Axel Heiberg polygons

As with the MOC images discussed above, size variation is displayed with the terrestrial polygons. It appears, though, that the terrestrial polygons are somewhat smaller. Median NND values range from 6.2 m to 19.5 m. Minimum NND values are comparable for the 4 sites, ranging from 2.2 m to 5.3 m; maximum NND values vary greatly, ranging from 15.2 m to 110 m.

Similar to the MOC images, in no cases did the terrestrial sites display a clustered distribution. However, while the MOC images tended mostly to vary between regular and random distributions, two of the four terrestrial sites were considered completely random.

It appears that a decrease in overall randomness occurs with decreasing polygon size for the field sites. Specifically, the two sites that were completely random had larger median NND than did the primarily regular sites.

Factors influencing polygon morphology

For both Martian and terrestrial polygonal terrain, spatial point pattern analysis was able to quantify variations in observed polygon morphologies. In both cases, polygons with smaller NND tended to be more regular, with increasing randomization occurring as the NND became greater. It is possible, then, that similar processes are responsible for polygon formation on both planets.

The two most well-documented factors influencing polygonal geometry are the surrounding climate (Mackay, 1999) and the amount of time that the polygons have been developing (Sletten et al. 2003). Given that the Utopia sites spanned a reasonably large range of elevation, it is evident that both climate and surface age of each site may not have been constant. As a result, it plausible that climate and age determinants may be responsible for the variations in observed polygonal size and regularity.

However, the same cannot be said for the Axel Heiberg sites. Because the polygonal terrain fields examined in this study are located so close together, climatic forcing would necessarily have been equal for each. Moreover, because their elevations are <10 m of each other, the estimated emergence age of the sites would also be virtually equal. Therefore, it is evident that some other factor must be responsible for the variation in observed morphologies.

We believe that substrate material may be as important as climate and age in determining the appearance of the polygons. Although polygonal terrain can develop in any type of ice-bonded sediment (Black 1974), varying substrate types have different rheological properties (Sletten et al. 2003). Namely, a soil's thermal contraction coefficient dictates the ground's response to thermally induced stresses (Lachenbruch 1962), and thus it will also determine the dimensions of the tension cracks and the rate and magnitude of surface sediment redistribution.

After a qualitative examination, it is possible that the sites' sediment distributions can be correlated with the polygonal morphology. In general, a decrease in maximum sediment size is associated with both a decrease in nearest neighbour distance and an increase in polygon regularity.

The use of spatial point patterns to analyze the distribution of trough intersection points may yield insight into the effects of age and substrate. As described by Lachenbruch (1962), the spacing of cracks depends on the local strength of the material and on the ground's ability to dissipate stress through the cracking process. Given that cracks initiate at local weaknesses that, theoretically, are randomly distributed throughout a particular field site, the earliest cracks to form (and thus the earliest intersections) should also be randomly distributed. Therefore, observations of random spatial distributions may indicate that the polygonal terrain under investigation is relatively young.

Similarly, point patterns may also be reflective of subsurface grain size distribution. Because cracking initiates at weaknesses, it is plausible that a more heterogeneous substrate would contain more randomly distributed points of weakness. Conversely, a more homogeneous substrate should have a more regular distribution of weaknesses. By using trough intersections as proxy indicators of the cumulative stress field that has acted over time on the site, more regular spatial point patterns may be used to infer a more uniform distribution of grain sizes in the ground.

Summary and Conclusions

The occurrence of polygonal terrain within Utopia Planitia, Mars, was characterized according to: (i) elevation; (ii) proximity to other landforms possibly indicative of ground ice, and; (iii) randomness/regularity of the spatial distribution of trough intersections.

Polygons found independently of other features tend to be located at the highest elevations, while polygons found within scalloped terrain tends to be located at lower elevations that those containing thermokarst pits. Generally, polygons within scalloped terrain are more regular than those found within pitted terrain.

Certain similarities were observed between terrestrial and Martian polygonal terrain. On both Earth and Mars, the polygons examined displayed varying degrees of regularity and randomness, but in no cases were the observed patterns considered statistically clustered.

Polygon "regularity" was found overall to have a negative relationship with polygon size. By examining the terrestrial analogue sites, a relationship was found between surface sediment size and the observed spatial point patterns. At the field sites, larger sediments were associated with larger, more irregular polygons. It is possible that similar characteristics could be evident on Mars.

The techniques outlined in this research can be applied to thousands of MOC images displaying polygonal terrain on the Martian surface, and would likely be even more effective on incoming HiRISE images. Potentially, spatial point patterns could be used to classify polygons found throughout the planet and provide a common platform by which to compare numerically the patterns observed on Mars and Earth.

Acknowledgments

Funding for this work was provided by the Canadian Space Agency's CARN program, NSERC, and ArcticNet. Logistical support in the field was provided by the Polar Continental Shelf Project (PCSP). Many thanks to Maude Oullet, Bimal Patel, and Geoff Pearce for painstakingly examining the MOC database in search of polygons. Finally, the authors acknowledge the use of the Mars Orbiter Camera images processed by Malin Space Science Systems that are available at http://www.msss.com/moc_gallery/.

Abstract

In order to clarify the effects of a tundra fire on the thermal and water conditions of permafrost and active layer, field observations were carried out on the Seward Peninsula, Alaska, between 2005 and 2007, where a 2002 tundra fire had burned up to a road that acted like a firebreak. Ground temperatures at burned sites were 4°C–5°C higher than those at unburned sites. Measurements of soil water content showed no significant tendency, increase or decrease. The depth of the active layer was significantly greater on the burned (60 cm) than the unburned (40 cm) side of the firebreak in 2005 and 2006. In 2007 the depths were 80 cm and 50 cm, respectively. The effect of fire on permafrost reaches only to the layer near ground surface, the active layer or upper part of the permafrost. Apparent electrical resistivity values up to 1 m at burned sites were relatively low. Resistivity values of unfrozen mineral soil in the active layer were calculated, and there was no significant difference of unfrozen soil between burned and unburned sites. The variation of calculated resistivity was small at burned sites, which may show the small variation of water content along the survey line due to the fire.

Keywords: active layer; permafrost; resistivity; wildfire.

Introduction

Due to its heat and disappearance of vegetation in the Arctic, wildfire affects the ground surface condition of permafrost and may cause its degradation. This degradation yields the emission of methane gas from the permafrost, which furthers global warming. Due to predicted warmer and dryer summers the area burned by tundra fire is expected to increase by as much as twice (Rupp et al. 2000), although current tundra fire activity is less frequent than the wildfires in boreal forests (Racine et al. 1985). Tundra fire disturbance and corresponding vegetation changes bring heat balance on the ground surface, and these may yield degradation of permafrost (Racine et al. 2004).

On the Seward Peninsula, large tundra fires occurred in 1971, 1997, and 2002, and a discontinuous permafrost area burned widely near the Kougarok River. In this area permafrost surveys were carried out in 2005, 2006, and 2007. The final goal of this study is to clarify effects of tundra fire on the thermal and water conditions of permafrost and active layer, and on vegetation recovery.

Study Area

Field observations were carried out in the Kougarok region, interior Seward Peninsula, Alaska (Fig. 1). There permafrost is discontinuously distributed and is considered to be sensitive to global and local climate changes. Mean annual air temperatures measured in this area range between –2.9°C and –5.5°C in 2000–2006 (Liljedahl et al. 2007).

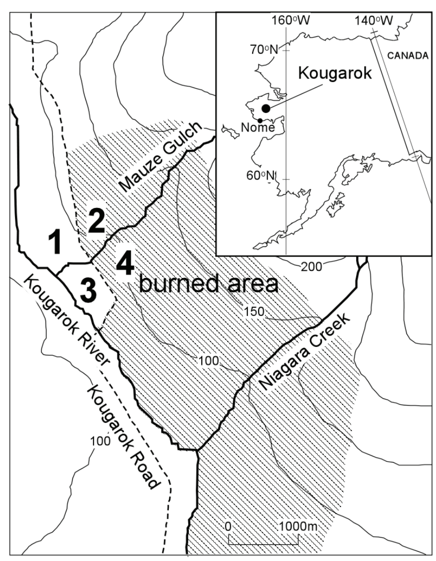

Figure 1. Location map of study sites.

In 2002, a wildfire occurred near Niagara Creek and Meuze Gulch. The fire began to burn at the east side of Kougarok Road and was stopped by the road, so the west side of the road did not burn and was considered to be undisturbed by the fire. Thus, four study sites were established near Meuze Gulch to compare the differences of thermal and moisture conditions in the active layer on the burned and unburned sides. The four sites in Figure 1 represent: unburned south-

facing (Site 1: US), burned south-facing (Site 2: BS), unburned north-facing (Site 3: UN) and burned north-facing (Site 4: BN). It is assumed that vegetation cover was similar at all sites before the fire. Unburned sites (Sites 1 and 3) are now covered by tussock-shrub tundra.

Field Observations

In order to monitor present thermal and water conditions, ground temperatures, soil water contents, and thermal conductivities in the active layer were measured by pit excavations to the permafrost table at all four sites in July and August 2005, August 2006, and August 2007. The volumetric water content was measured by the TDR method, and the thermal conductivity by the thermal probe method. Depths of active layer were also measured by using a steel rod from the ground surface. We made 50 measurements within a 10 x 10 m area at each site.

Electromagnetic soundings were carried out in order to estimate the permafrost thickness in August 2005, which was 20–30 m at north-facing sites (Sites 3 and 4), but was not detected at south-facing sites (Sites 1 and 2) due to the shallow bedrock (Sawada et al. 2005).

Electrical resistivity values of the active layer and upper part of the permafrost (1 m deep) were obtained using the DC electrical sounding method. 2D measurements were conducted at all four sites. The electrode interval, the maximum depth, and the length of survey line were set to 1 m, 5 m, and 29 m, respectively.

Observational Results

In Figure 2, typical soil profiles to the permafrost table, obtained from pit surveys conducted in August 2007 at each site, are shown. The mineral soil consists mainly of clayey soil. The thickness of the organic layer ranges widely between 0 cm and 30 cm at each site.

The significant difference between burned and unburned sites is the presence or absence of a moss layer. The moss layer is not present at burned sites due to the fire. The thermal conductivities measured in 2007 in the moss, organic, and mineral layers were 0.1–0.5 W/mK, 0.3–1.2 W/mK and 0.5–1.3 W/mK, respectively. As the moss layer has a low thermal conductivity, this layer has an important role as a heat insulator and controls the depth of the active layer.

Thus, the measured active layer thicknesses were significantly different between the burned and unburned sites, about 60 cm and 40 cm in 2005 and 2006, and about 80 cm and 50 cm in 2007 (Table 1). Statistical analyses were also made and showed the availability of data (not shown

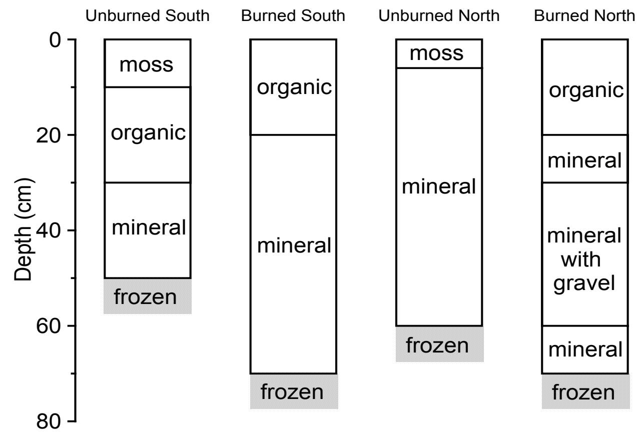

Figure 2. Typical soil profile at four sites in study area.

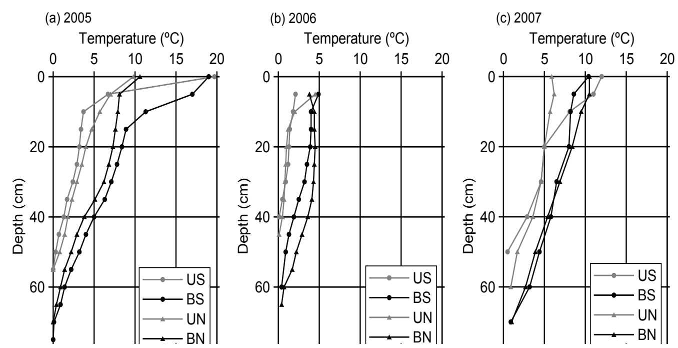

Figure 3. Ground temperature profiles in (a) 2005, (b) 2006 and (c) 2007.

here). The thickness at the burned sites was more than 20cm deeper than that at the unburned sites. This deep active layer at the burned sites was caused by the lack of the moss layer. Comparing the active layer thickness in 2005 and 2006, there is no significant increase. However, the thickness in 2007 at north-facing sites was more than 10–20 cm deeper than those in 2005 or 2006.

Figure 3 shows the ground temperature profiles measured using soil pits. The ground temperatures at the burned sites (black lines in Fig. 3) were 4°C–5°C higher than those at the unburned sites (gray lines in Fig. 3). The volumetric water contents of soil at the burned sites were higher than those at the unburned sites in 2005, but lower in 2006 (Fig. 4). The data observed in 2007 was complicated, and may have been affected by the rain fall just before the observations.

Apparent resistivity values up to 1 m deep obtained from 2D soundings conducted in 2006 are shown in Figure 5. There is an obvious difference between the burned and unburned sites. The apparent resistivity value at the burned sites was much lower than at the unburned sites.

Discussion

After the tundra fire, the thickness and ground temperature of the active layer at burned sites changed drastically due to the destruction of the surface moss layer. However, it is estimated that permafrost thickness has not changed between the burned and unburned sites (Sawada et al. 2005). These results suggest that the effect of fire on permafrost reaches only to the layer near ground surface, the active layer or upper part of the permafrost. In future, the active layer thickness may increase year by year, or the increase of active layer thickness will stop after recovery of surface vegetation. Thus, a continuous monitoring of ground temperature and a numerical calculation is needed to clarify the effect of fire on permafrost.

In 2007, the active layer thickness increased more than 10–20 cm, and this result with the other data (e.g. air temperature) should be discussed, but has yet to be. And more measurement will be needed to clarify the change of thickness of the active layer after a wildfire.

After the tundra fire, no significant tendency of change of water content was observed in this area, there was no drastic increase or decrease. As the water content is also an important factor in solving the permafrost's degradation or recovery, it is also necessary to measure water content continuously.

Here, as a resistivity value of soil depends on soil water content (e.g. Harada and Fukuda 2000), an estimation of the water condition was made using measured apparent resistivity values. Generally, an apparent resistivity value obtained from the DC sounding is produced from the combination of a true resistivity value and the thickness of the layer. In this study, relative low apparent resistivity values were obtained at the burned sites (Fig. 5). As a resistivity value of soil also depends on temperature, and the value of resistivity in the active layer or unfrozen material is conductive (e.g. Harada and Fukuda 2000), a thick active layer condition shows a low apparent resistivity value (Fig. 6). An apparent resistivity value strongly depends on the thickness of the active layer, so this apparent resistivity value does not affect the true resistivity value in the active layer directly.

In order to obtain the true resistivity value of the unfrozen mineral layer in the active layer, a simple calculation was carried out using the apparent resistivity value measured in 2006. The model used here is shown in Figure 7, and it was assumed that an apparent resistivity up to 1m, ρ_a, was produced from a resistivity value and thickness of each layer shown in Fig. 7, unfrozen organic layer, unfrozen mineral layer and permafrost,

$$\frac{1}{\rho_a} = \frac{\alpha_0}{\rho_0} + \frac{\alpha_1}{\rho_1} + \frac{\beta}{\rho_2} \qquad (1)$$

$$\alpha_0 + \alpha_1 + \beta = 1 ,$$

where ρ_0, ρ_1, and ρ_2 are true resistivity of the organic layer,

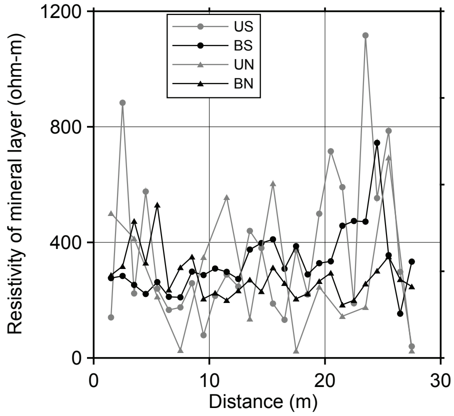

Figure 8. Estimated resistivity value of unfrozen mineral layer in 2006.

the mineral layer, and the permafrost, and α_0, α_1, and β are the thickness of each layer, respectively. Here, ρ_0 and ρ_2 were given as assumed values of 5000 and 10,000 ohm-m, respectively, and α_0, α_1, and β were given using measured thickness values were used. Then, the true resistivity value of unfrozen mineral layer ρ_1 was estimated using equation (1).

Figure 8 shows the calculated result of the true resistivity value of the unfrozen mineral layer in 2006. Comparing calculated values between the burned and unburned sites, there was no significant difference of the unfrozen mineral soil. Furthermore, the values ranged widely at the unburned sites, and a variation of resistivity was small at the burned sites. This may show the small variation of water content along the survey line due to the fire. In the future, a calibration between soil water content and resistivity will made, and this model will be developed to monitor the ground water content using the DC electrical sounding method.

Conclusions

Permafrost surveys were carried out in order to monitor the permafrost conditions after a wildfire at the discontinuous permafrost area on the Seward Peninsula, Alaska.

After a 2002 tundra fire, thermal conditions of the active layer at the burned sites changed drastically due to the destruction of the surface moss layer. The measured active layer thicknesses were significantly different between the burned and unburned sites, by more than 20 cm. There is no obvious increasing of the thickness between 2005 and 2006, however, the thickness in 2007 at north-facing sites was more than 10–20 cm deeper than those in 2005 or 2006.

The effect of fire on permafrost reaches only to the layer near ground surface, the active layer, or the upper part of permafrost.

The ground temperatures at the burned sites were 4°C–5°C higher than those at the unburned sites. Measurements of soil water content show no significant tendency, increasing or decreasing.

Measured apparent resistivity values at the burned sites show a lower value than those at the unburned sites, which was caused by the thick active layer. Using the estimation model, the true resistivity value of the unfrozen mineral layer was calculated, and there was no significant difference between burned and unburned sites. The resistivity values ranged widely at unburned sites, and the variation of resistivity was small at burned sites, which may show the small variation of water content along the survey line due to the fire.

Acknowledgments

We would like to express our sincere thanks to Prof. L. Hinzman, R. Busey, A. Liljedahl, and K. Yoshikawa of the University of Alaska Fairbanks for their support with the fieldwork. This research was financially supported by the Japan Aerospace Exploration Agency.

Abstract

As boreal and arctic regions of North America have been undergoing considerable warming since the 1950s, a key question remains as to the fate of permafrost and carbon over this important time period. We used ^{137}Cs as an age constraint for soil carbon that has accumulated since the first occurrence of ^{137}Cs in 1954. We tested this approach by comparing profiles of $\Delta^{14}C$ to ^{137}Cs for soils of different plant communities near Delta Junction, central Alaska. Both isotopes indicate upward accumulating, organic systems that have little evidence for mixing or leaching. We then used inventories of these isotopes to normalize the C storage between frozen and thawed site-pairs. To date, we identified a net loss of carbon from a tundra-forest transition in northern Alaska. We measured net increases of C resulting from forest-bog and forest-fen transition in Alaska and Canada.

Keywords: boreal; carbon storage**;** discontinuous permafrost zone; peat; permafrost; soil carbon; thermokarst.

Introduction

Boreal regions in general and central Alaska in particular, encompass a broad range of ecosystems that are underlain by permafrost. There is an abundance of upland terrain with sporadic or discontinuous permafrost. Lowland terrain is also underlain by discontinuous permafrost, often with thicker peat deposits and ice-rich permafrost. Further nested within these landscapes are highly patchy vegetation and soil conditions that result from frequent fires. In central Alaska, recent results indicate that 7% of the landscape has undergone thermokarst, 47% has permafrost, 27% is unfrozen without a recent permafrost history, and 19% of the area has an uncertain thermal status (Jorgenson et al. 2005).

Permafrost degradation has been observed for the past decades when remotely-sensed and field observations have noted associated changes in vegetation (Vitt et al. 2000; Camill et al. 2001, Jorgenson et al. 2001, Turetsky et al. 2002, Christensen et al. 2004). Changes in air temperature, ground ice content, winter snowfall, and fire contribute to stabilization and destabilization of near-surface permafrost (Osterkamp & Romanovsky 1999). Discontinuous permafrost in Alaska may by particularly sensitive to climate warming in areas where soils are not blanketed by loess and ice-rich seasonal frost (Swanson 1996). Since 1949, thermokarst in the Tanana floodplain of Interior Alaska has increased by 21% and may result in the disappearance of permafrost in these landscapes (Jorgenson et al. 2001).

Thawing of near-surface permafrost has been associated with changes in patterned ground (Osterkamp et al. 2000) and conversion of forests to wetlands (Osterkamp et al. 2000, Jorgenson et al. 2001, Jorgenson & Osterkamp 2005). Permafrost thaw can also lead to the development of an open talik, or drained soil layer, involving shifts toward drier landscapes and ecosystems, for example, from moss- to lichen-dominated ground covers (Burn, 1998, Schuur et al, 2007).

Recent changes in northern climate systems have led to a piqued awareness of carbon stocks residing in near-surface permafrost and of their vulnerabilities to climate change. Since the 1960s, significant changes in air and surface temperatures have been documented for northern regions (see http://www.gtnp.org/pdf/icoppostergtnp). Upon significant warming, permafrost degradation can lead to either net accumulation or loss of carbon via shifts in ecosystems and C processing, and it is likely that both effects occur concurrently, yet heterogeneously, across the landscape. Evidence for net increases in carbon resulting from thermokarst, for example, include wetlands (Turetsky et al. 2007). Conversely, in systems that are becoming drier, there is the potential for aerobic respiration to reduce terrestrial carbon stocks.

Detecting changes in C storage using trace gas exchange requires long-term monitoring to decipher interannual variations from significant trends (Dunn et al. 2007). CO_2 budgets are particularly problematic because sources of respiration are numerous, and because detecting small changes in decomposition relative to large signals of

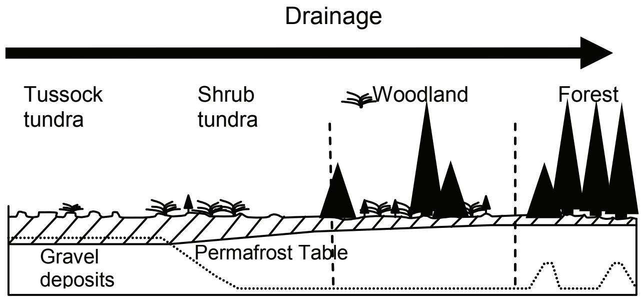

Figure 1a. Schematic drawing of permafrost degradation leading to drainage. Active layer in tundra on floodplain terrace deepens and leads to drainage of water through gravel deposits. Based on Wilmking et al. 2006.

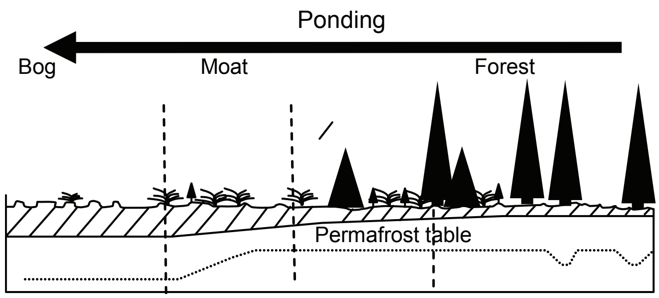

Figure 1b. Example of permafrost degradation leading to ponding. Based on Meyers-Smith et al. 2007.

respiration is difficult. Detecting changes in the solid carbon phase (e.g., vegetation and soil) is also challenging, owing largely to long-term variations in frozen ground, plant cover, and fire history (Harden et al. 2000).

Significantly, the recent warming trend in northern latitudes has been accompanied by atmospheric labeling by radiocarbon and radiocesium as a result of aboveground weapons testing. Such labeling of organic matter lends itself to assessments of carbon that has been fixed in recent decades. In context of landscape changes, such assessments can help to decipher the fate of carbon in the recent phase of northern latitude warming.

Approach

In Interior Alaska, the fate of terrestrial carbon over the next few decades likely will be determined by shifts in hydrology following permafrost thaw. Water plays a critical role in governing C cycling processes, including plant production (NPP), combustion (F), decomposition (kC or Rh), and leaching (DOC). Our goal is to test this hypothesis at the site scale, using radioisotopes of carbon and cesium to identify carbon stored in the past 50 years.

We examined a variety of ecosystems in Interior Alaska and northern Canada, including black spruce forests, tussock tundra, *Sphagnum* bogs, and a rich fen. We paired sites according to our interpretations of their near-surface permafrost and histories of thermokarst, and analyzed soils for radioisotopes.

Site scale measures of C stocks and isotopes are particularly helpful at establishing C accumulation rates over the last 50 years. ^{137}Cs is a product of uranium fission produced by weapons testing. The first significant atmospheric fallout occurred in 1952 with the maximum delivery occurring between 1963 and 1964. It can be used as a tracer for soil materials if the following conditions are met: (1) total cesium inventories are conserved in the soil, and (2) there is no significant movement of ^{137}Cs. These conditions are examined for a variety of soils before testing our hypotheses.

Radiocarbon was also produced by weapons testing and has been used as a tracer for carbon turnover in soils (Trumbore 2006). The main differences between Δ^{14}C and ^{137}Cs are: (1) Whereas fallout of ^{137}Cs declined precipitously after 1963, fallout of Delta^{14}C declined slowly owing to terrestrial C exchange with the atmosphere and fossil fuel emissions, And (2). Whereas ^{137}Cs is conserved in soil and sediment, Delta^{14}C can be retained via slow decomposition or effective stabilization or lost via rapid decomposition or combustion. ^{137}Cs in the atmosphere is generally bound to particulates, whereas Delta^{14}C in the atmosphere is present in gas phase. Isotopes of Cs and C therefore have different input mechanisms to the land surface.

Methods

In order to test the feasibility of using these isotopes to estimate recent changes in C storage, we first examined variations in soil ^{137}Cs and ^{14}C for patterns of storage, remobilization, and accumulation. Four sites were located in Interior Alaska near Delta Junction. Vegetation at all sites contained black spruce, but varied in tree density and abundance, owing mainly to variations in soil moisture and temperature (for more detail see Manies et al. 2004). Groundcover varies from a feather moss/lichen mix to feather moss.

In order to interpret the response of C storage to thaw, we sampled organic soils at sites with and without near-surface permafrost, interpreting sites as pairs of frozen and thawed landscapes. In Manitoba, Canada a frozen palsa was found adjacent to a collapse bog, a collapse fen, and a rich fen (Bubier et al. 1998, Trumbore et al. 1999). We assumed that the collapse fen originated as part of the palsa complex based on new collapse features on the side of the palsa that slumped into the fen. There was no direct evidence that the bog or rich fen had formed directly from the palsa, but cores at 2m depth were composed of *Sphagnum* peat and woody peat.

In Alaska, we sampled organic soils at permafrost/thawed pairs of soils in two locations. In the case of sites near the Kugururok River near treeline, sites from a tundra and a forest site (Wilmking et al. 2006) were used as frozen and thawed pairs. These sites were separated by shrub and shrub tundra ecosystems that were invaded by trees over the past 40 years; a deepening active layer along the tundra-forest transition indicates a transition from moderate to well-drained soil conditions (Fig. 1a). In the case of sites along the Tanana River near Fairbanks, a forest system underlain by permafrost was directly observed to burn and within a year to collapse into a wetland bog in 2001 (Myers-Smith et al. 2007). Environmental reconstructions from charcoal and diatoms indicated previous cycles of fire-induced collapse.

We used ^{137}Cs and $\Delta^{14}C$ to identify organic matter that accumulated since about 1964, a time when atmospheric enrichment from aboveground weapons testing reached a maximum. Radiocarbon was measured on bulk organic matter at the UC Irvine W. M. Keck Carbon Cycle AMS facility (KCCAMS) and at the Lawrence Livermore Laboratory following correction and calibration procedures (Trumbore et al. 1999). Splits of the same samples were analyzed for ^{137}Cs, total ^{210}Pb and ^{226}Ra activity by gamma spectrometery at the USGS Sediment Radioisotope Laboratory in Menlo Park (Fuller et al. 1999). ^{210}Pb data is not presented and is being evaluated as a chronometer for these profiles.

For samples from both Manitoba and Alaska, we calculated inventories of radiocarbon and Cs to compare C stocks and accumulation rates represented in the upper layers of the organic soils. Inventories were calculated as:

$$\Sigma(i{*}fC{*}\ BD{*}\ th)_{horizons} \qquad (1)$$

where i is the concentration of isotope in fraction modern (^{14}C) in soil; fC is the fraction organic C used for FM only; BD is bulk density (g m^{-3}); and th is the thickness of each horizon (m).

Soil horizons labeled by bomb-enriched concentrations of isotopes are defined by concentrations >0.04 pCi/g for ^{137}Cs, which represents the detection limit of the instrument, and concentrations >FM 1.0 for radiocarbon, where FM = Delta^{14}C/1000 + 1. In the case of Alaska samples, we assumed that the bomb-enriched layers were 50 years old (sampled in 2004; enriched by fallout since 1954). In the case of Manitoba samples collected in 1994, we used radiocarbon peak 1963 to estimate peat ages of 30 years (Trumbore et al. 1999). Inventories included only organic soil horizons.

Results

Depth profiles of both isotope profiles reach maximum and pre-bomb values at approximately the same depths in each core. Maximum values in both isotopes likely represent the time around 1963, when weapons testing reached peak-output to the atmosphere (Fig. 2). Deep soil horizons with radiocarbon values <1.0 FM likely indicate pre-bomb ages. These layers are essentially free of ^{137}Cs (Fig. 2), likely indicating that Cs was not re-mobilized from shallow to deeper layers. It also is possible, but unlikely, that ^{137}Cs and radiocarbon could have mobilized in tandem.

Mean ^{137}Cs inventories were 3.3 +/- 1.3 pCi/cm2 and mean $\Delta^{14}C$ inventories were 0.6 +/- 0.2 Delta^{14}C /cm^2 (data not shown). Variability in inventory of fallout materials among ecosystems in a given region ranged from 40 to 30% of the mean inventory for ^{14}C and Cs, respectively.

C inventories in bomb-labeled soil layers

Based on the site pairing where thermokarst led to drainage, there was a 64% loss of C in the near-surface soil (Table 1, example 1). Based on the examples where thermokarst led to ponding and formation of wetlands, there was a mixed response. In Manitoba, thaw resulted in -70% (loss) to +80% (gain) in C stocks in which fens accumulated C and the bog lost C (Table 1, examples 3–7). In Alaska, C stocks increased by 11% .Based on inter-site variations in Cs stocks (above), changes less than 30% are likely not significant.

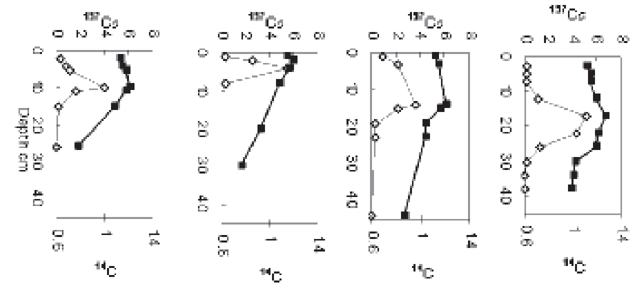

Figure 2. Radiocarbon (closed symbols) and radiocesium (open) concentrations versus basal horizon depths from 4 soils of differing ecosystem settings from the area around Delta Junction, Alaska. From left to right, profiles correspond to mature forest stands, sites DFTC6 (well-drained), DFTC23 (well-drained), DFCC15 (permafrost at ~50cm), DFDC1 (permafrost at 41 cm) from Manies et al. 2004. Samples collected in 2002. Cs measured in 2006.

C inventories of total soil profiles

Changes in total carbon stocks for the full soil profiles showed a net decrease in C stock where thermokarst led to drainage, and a net increase in C stocks where thermokarst resulted in wetlands.

Discussion

Based on Cs and C isotopes, it appears that either isotope may be used as labels for C that has entered the soil since about the 1950s when above-ground weapons testing introduced significant sources of ^{137}Cs and $\Delta^{14}C$. We interpret depth profiles of these isotopes (Fig. 2) as evidence for "upward accumulating" systems with little or no vertical mixing. As noted above, the soils from Delta Junction showed little or no sign that Cs was mobilized in the soil profile based on the agreement in depths where (1) peak values and (2) pre-bomb values of both ^{137}Cs and Delta^{14}C occurred. However, data from the Fairbanks site (Myers-Smith et al. in press) did show signs of remobilization in the deepest organic layers, based on a comparison to radiocarbon ages.

Albeit a preliminary finding with no replication, we found that soil C was lost (C source) where thaw water was drained and that there was a mixed response for C where thaw water was ponded. It is likely that drainage of thawed water resulted in aerobic decomposition, which outweighed plant production and resulted in a C source to the atmosphere. By contrast, where thaw resulted in ponding, changes from frozen state to anaerobic conditions for decomposition and changes in plant production may result in a mixed response, resulting in a C sink or C source.

There are at least three important limitations of this isotopic approach that limit our ability to constrain changes in carbon storage. First, mobilization of either radiocarbon or radiocesium would impact results of this approach. Input and decomposition of organic matter into and out of the soil layers causes most of the depth variations, because peaks and attenuations of both isotopes are coincident for 4 very different soil types. Nevertheless, some amount of both isotopes could move together through the profile via leaching or mixing. Second, any estimates of recent net carbon accumulation are overestimates, because C loss via decomposition of deep soil layers is not accounted for by this approach. Based on assessments by Rapalee et al. (1998), this overestimate may be quite small because decomposition rates are very slow in saturated systems. By the same logic, recent carbon losses resulting from thermokarst are underestimated, again because deep decomposition is not accounted for in this approach. Where systems are converting frozen and large C stocks to aerobic decomposition, such underestimates could be quite large. For example, turnover time in well-drained soil of 100 years applied to a carbon stock of the tundra soil of 10000 gC m^{-2} amounts to 100 gC m^{-2} yr^{-1}. Third, the time of initial thermokarst formation is not known for any of these sites. Therefore, if rates of C accumulation change over time-since-thermokarst, C accumulation rates should not be compared directly without finding a way to stratify the data according to post-thaw successional age.

In order to address these important limitations to our labeling approach, we recommend that C stocks be assessed for post-bomb labels, particularly in newly-formed thermokarst features of known age. Moreover, C inventories should be replicated for a variety of ecosystems. Methods also should be developed to account for the contribution that deep decomposition may make to offset near-surface accumulations of C. Owing to its powerful greenhouse potential and sensitivity to the water table, the role of methane in the trace gas budget of these systems will vary according to the fate of water upon thaw. For example, saturated collapse scars have significantly higher CH_4 emissions than palsas or non-permafrost wetlands (Wickand et al. 2006, Turetsky et al. 2002). As permafrost wetlands are dominant sources of CH_4, yet make up a small proportion of the total landscape, quantifying total green house gas emissions from remote sensing is a challenge that must be met for these boreal regions (Bubier et al. 2005).

Conclusions

Detection of change

Cesium and radiocarbon inventories lead us to expect 30 to 40% variability, respectively, in fallout inventories within a given region. Therefore, C stocks need to be >50% different from the control or baseline in order to be a significant detection of change. During the time period since the 1950s when the atmosphere warmed significantly, it is likely that significant soil C losses accompanied conversion of tundra to forest in our study site in Interior Alaska. By contrast, significant soil C uptake accompanied the conversion of black spruce forest to wetland in our study site in northern Manitoba.

Abstract

Here we present a review of recent ground thermal data derived largely from the continent-scale network of instrumented boreholes within mountain permafrost established between 1998 and 2001 by the European Union PACE project. More recently, networks of intermediate and shallow boreholes in Switzerland, Norway, and Iceland have been added. A large number of complex variables determine permafrost temperatures, including altitude, topography, net radiation, and snow distribution. Thus, modeling the above-ground climate signal from observations of permafrost temperatures and coupling downscaled climate models to assess future permafrost thermal responses to climate forcing remain major research goals. Boreholes drilled in areas of steep mountain topography may penetrate complex three-dimensional thermal fields, making interpretation of thermal profiles in terms of changes in the upper thermal boundary extremely challenging. However, in the lower relief settings of the Scandinavian and Svalbard PACE boreholes, observed warm-side deviation in thermal profiles strongly suggests a period of sustained surface warming in the latter half of the 20th century and in the early 21st century. The significance of short-term extreme thermal events is illustrated with reference to the record-breaking summer of 2003 in the Alps and the anomalously warm winter-spring-summer period in 2005–2006 in Svalbard. It is concluded that such events may initially be more significant than the longer-term underlying trends in climate. Permafrost thermal responses to climate change occur at markedly different time scales, with changes in active layer thickness being more or less immediate, modification of thermal profiles below the depth of zero amplitude taking decades or centuries, and basal melting associated with progressive permafrost thinning requiring millennial time scales. However, as illustrated here by the example of Icelandic permafrost, where the frozen ground layer is thin and warm and the geothermal heat flux rates are high, permafrost decay and disappearance may be much more rapid.

Keywords: borehole monitoring; climate change; Europe; permafrost temperatures.

Introduction

In the present paper we review current evidence for permafrost warming within the European sector. In the mid-latitude high relief setting of the Alps, ground temperatures are only a few degrees below zero and permafrost may be thin near the lower permafrost boundary. Permafrost warming in alpine mountain slopes increases the risk of landslides, debris flows, and rockfalls (Noetzli at al. 2003, Gruber & Haeberli 2006). However, predicting the thermal response of mountain permafrost to climate change is challenging because of spatially complex topography and substrate properties (e.g. Hoezle et al. 2001). In contrast to the Alps, permafrost is continuous in the Arctic archipelago of Svalbard, outside the glaciated areas. Ocean-atmosphere coupling results in the climate being particularly sensitive to variations in sea-ice cover (Benestad et al. 2002, Isaksen et al. 2007b). Observed and predicted reductions in sea-ice (Stroeve et al. 2007, Serreze et al. 2007) suggest the onset of a rapid climate transition, with increasing frequency of anomalously high temperatures (Christensen et al. 2007, Isaksen et al. 2007b). The thermal response of permafrost may therefore exceed recent historical experience. Finally, the maritime setting of Iceland results in permafrost being restricted to higher elevations, and here geothermal heat flux increases the sensitivity of permafrost to changes in the upper boundary condition (Farbrot et al. 2007). This diversity of permafrost settings within Europe provides a background for this paper.

European Borehole Monitoring

A major stimulus to European permafrost research was provided by the PACE project (Permafrost and Climate in Europe), which commenced in 1997 (see Harris et al. 2001), and much of the more recent research reported here is a legacy of this program (Harris et al. submitted). Primary data have been collected through instrumented permafrost boreholes; the main borehole network of six instrumented bedrock boreholes drilled 100 m or more in depth was established between 1998 and 2001 through the PACE project (Fig. 1). The longest continuous European permafrost temperature time series is from the 32 m deep Murtèl Corvatsch borehole in Switzerland (Fig. 1) which was drilled in 1987, in an ice-rich rock glacier (Vonder Mühll and Haeberli 1990, Hoelzle et al. 2002). This borehole has been incorporated into the PACE network.

Over the past decade, the number of intermediate and shallow (less than 25 m) depth monitoring boreholes has increased steadily, particularly in Switzerland, where permafrost monitoring is coordinated by the PERMOS programme (Vonder Mühll et al. 2004, 2007). In Norway and Svalbard the IPY project "Thermal State of Permafrost" (TSP) (Christiansen this volume) has also instigated a

program of permafrost monitoring through shallow boreholes. A total of 66 boreholes are listed from the European sector in the GTNP database (http://www.gtnp.org/); 31 of these are in Switzerland, 18 in Norway and Svalbard, and between 3 and 6 in Iceland, Italy, Spain, and Sweden. Not all are continuously monitored, and many have only short time series.

Instrumentation generally utilizes automatic logging of thermistor strings within cased boreholes. Recommendations on instrument specification, spacing, and logging frequencies may be found in the PACE Manual (see Appendix B, Vonder Mühll 2004), but all thermistors should be retrievable to allow periodic recalibration. In most PACE boreholes a second 15–20 m deep borehole was drilled adjacent to the deeper hole to allow more detailed higher frequency monitoring of the near surface (Isaksen et al. 2001, 2007a, Gruber et al. 2004c). In other borehole monitoring programs, a multimeter may be used to record thermistor temperatures periodically, or the borehole may be equipped with single-channel miniloggers, which are retrieved annually for downloading. Alternative approaches to monitoring the thermal status of permafrost include active layer thickness (e.g., the Circumpolar Active Layer Monitoring (CALM) program), and measurement of the Bottom Temperature of Snow (BTS) (e.g., Vonder Mühll et al. 2004, 2007).

Permafrost Geothermal Profiles

Since heat advection by ground water or air circulation is often negligible, permafrost geothermal profiles are primarily a function of heat conduction from the Earth's interior and heat fluxes at the ground surface. The annual ground surface thermal cycle penetrates to 15–20 m (the depth of zero amplitude), but larger perturbations of longer periodicity may penetrate much deeper and take much longer to do so (e.g., Lachenbruch & Marshall 1986). Perturbation of the thermal gradient below the depth of zero annual amplitude may provide direct evidence of thermal trends at the permafrost table during preceding decades or centuries (e.g., Cermak et al. 2000, Osterkamp & Romanovsky 1999). Where permafrost is thin (<100m), such thermal perturbation may extend to the base, causing basal melting, but in thicker permafrost, deeper penetration of climatically forced thermal cycles is likely to require millennial time scales.

In mountain permafrost, the thermal field is often strongly three-dimensional (Noetzli et al. 2007) and the thermal offset between mean ground surface temperature and mean permafrost table temperature reflects spatial heterogeneity in active layer composition and snow distribution, the latter also being subject to large inter-annual variations (Gruber et al. 2004c). Thus, modeling the above-ground climate signal from observations of permafrost temperatures, and coupling downscaled climate models to assess future permafrost thermal responses to climate forcing, remain major research goals (Harris et al. submitted). The greater altitudinal range and more complex topography in the Alps lead to greater variability in permafrost temperatures recorded by Swiss boreholes than those in Scandinavia and Svalbard. Figure 2 shows ground temperature profiles from PACE boreholes recorded in April 2005.

Ground temperatures in the Alpine boreholes Stockhorn and Schilthorn are highly disturbed by topography. Gruber et al. (2004c) have shown that for Stockhorn, marked differences in thermal gradient occur over short distances in response to a strongly three-dimensional temperature field. At Schilthorn, permafrost temperatures are very close to 0ºC and are influenced by latent heat effects and convective heat transfers by water as well as topographic effects. In contrast, the three Nordic boreholes have low relief within 100–200 m of the monitoring sites, relatively uniform bedrock and thin snow cover, suggesting that the climate signal dominates the observed geothermal gradients (Isaksen et al. 2007b). At greater depths than the boreholes, the effect of larger-scale relief may be significant and may in part explain

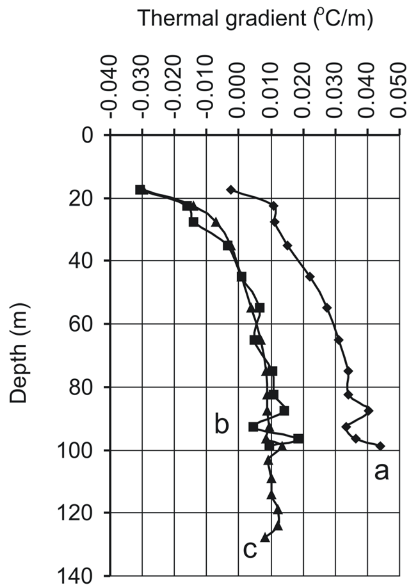

Figure 3. Thermal gradients at (a) Janssonhaugen, (b) Tarfalaryggen, (c) Juvvasshøe, calculated from profiles presented in Figure 2.

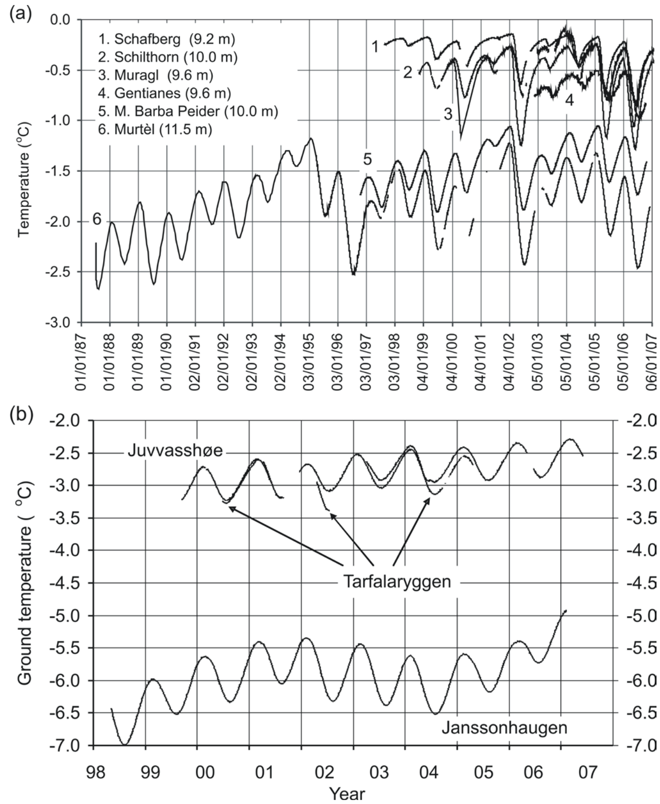

Figure 4. Permafrost temperature time series from around 10 m depth. (a) selected Swiss PERMOS boreholes. (b) Nordic PACE boreholes. For locations of boreholes, see Figure 1.

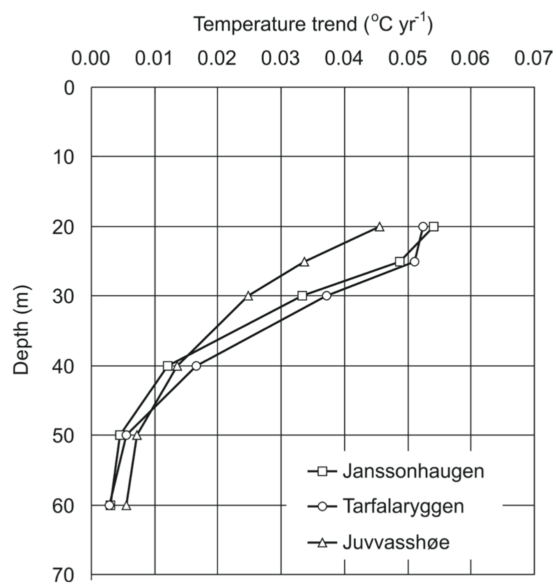

Figure 5. Observed linear trends in ground temperature as a function of depth. Time series at start in 1999 at Janssonhaugen, 2001 at Tarfalaryggen, and 2000 at Juvvasshøe, and they last for 6, 4, and 5 years, respectively.

the low thermal gradients observed at Tarfalaryggen and Juvvasshøe (Fig. 3). All three boreholes show a significant warm-side deviation in their thermal profiles to 70 m depth, with marked increases in thermal gradient with depth. Just below the depth of zero amplitude, gradients are negative (Fig. 3). These characteristics probably reflect surface warming since the mid 20th century (Harris et al. 2003, Isaksen et al. 2001, 2007a) and extrapolation to the surface of temperature gradients between 30–20 m depths and 70–100 m suggests surface warming of ~1.4°C, ~1.1°C and ~1.0°C for Janssonhaugen, Tarfalaryggen, and Juvvasshøe respectively.

Recent Trends in Permafrost Temperatures

Permafrost temperatures at depths of around 10 m in Swiss and Norwegian boreholes are illustrated in Figure 4(a) and (b). At Murtèl-Corvatsch in Switzerland, marked warming was recorded between 1987 and 1995 (Vonder Mühll & Haeberli 1990, Vonder Mühll et al. 1998, 2002, 2007, Hoelzle et al. 2002), but this was reversed in the winter of 1995–96 and more markedly so in 1996–97. Since then, at Murtèl and other Swiss boreholes, no marked overall warming trend is apparent, with periods of rising ground temperatures being cancelled out by marked winter cooling in 2002–03 and 2006–07. Harris et al. (2003) showed that snow-poor early winter periods rather than markedly lower atmospheric temperatures were largely responsible for these ground cooling events.

In the three Nordic boreholes, deflation maintains relatively thin snow cover in winter, so that ground temperatures are strongly coupled to atmospheric temperatures (Isaksen et al. 2007a). At Janssonhaugen especially, temperature records at 10 m depth show pronounced fluctuations and large inter-annual variability, making identification of longer-term trends more difficult. However, recorded ground temperature changes below the zero annual amplitude provide direct evidence of thermal trends at the ground surface during recent decades. At all three sites a clear trend towards warming ground temperatures is detected (Fig. 5). For instance, at 30 m depth, present warming rates are in the order of 0.025 - 0.035°C yr^{-1}. Isaksen et al (2007a) demonstrated that statistically significant ground warming may be detected to 60 m depth, the rate of warming being greatest at Tarfalaryggen and Janssonhaugen (Fig. 5).

The Significance of Extreme Events

Climate warming in the 20^{th} and 21^{st} centuries is likely to increase active layer thicknesses. However, an associated increase in frequency of high-temperature anomalies with sustained higher than normal temperatures may well dominate active layer evolution. Two examples of such extreme periods are discussed below: summer 2003 in the Alps, when temperatures during June, July, and August were approximately 3°C higher than the 1961–1990 average (Gruber et al. 2004c) and Svalbard in 2005–6 when anomalously high winter spring and summer temperatures caused significant permafrost warming (Isaksen et al. 2007b).

At the bedrock borehole of Schilthorn, Switzerland, active layer thickness ranged from around 4.4 m to around 4.9 m in the five years prior to 2003, but increased to nearly 9 m (Fig. 6a) during the 2003 extreme summer. In subsequent years the thickness has been around 4.8 m. At Stockhorn the active layer increased from around 3 m in the previous few years to 4.27 m in 2003. Numerical modeling has shown that in 2003 Alpine active layers were thicker than in the previous 21 years and were probably the greatest for several centuries (Gruber at al. 2004b). Rapid warming and thawing of bedrock containing ice-bonded joint planes led to a marked increase in rockfall events (Keller 2003) particularly on north-facing slopes where the effects of elevated atmospheric temperatures are greatest, and permafrost most widely distributed (Gruber et al. 2004b, Noetzli et al. 2007). The sharply increased depth of thaw during the summer of 2003 far outweighed the direct effect of gradually rising temperatures on the stability of the uppermost few metres of rock in most Alpine rock walls (Gruber et al. 2004c, Gruber & Haeberli 2006).

In contrast, active layer thickness changed much less dramatically at the ice-rich rock glacier of Murtèl-Corvatsch (Fig. 6b) in Switzerland where latent heat demand during thaw at the permafrost table provides an effective heat sink, limiting the active layer thickening. The general trend since 1987 has been towards increasing active layer thickness and in 2003 it reached 3.51m, around 11 cm thicker than in the previous summer and the greatest value since monitoring began in 1987. However, once thawed, meltwater drains away, leaving a thicker active layer with much lower ice content and therefore latent heat demand than the underlying permafrost. Thus, despite a much cooler summer in 2004, the active layer reached the same thickness as in 2003, and in 2005, which was cooler again, thaw penetration was only a few cm less than in 2003 (Vonder Mühl et al. 2007).

The winter-spring-summer period in 2005–6 on Svalbard provides a remarkable example of extreme atmospheric temperatures. The mean air temperature between December and May 2005–2006 was as high as −4.8°C, which is 8.2°C

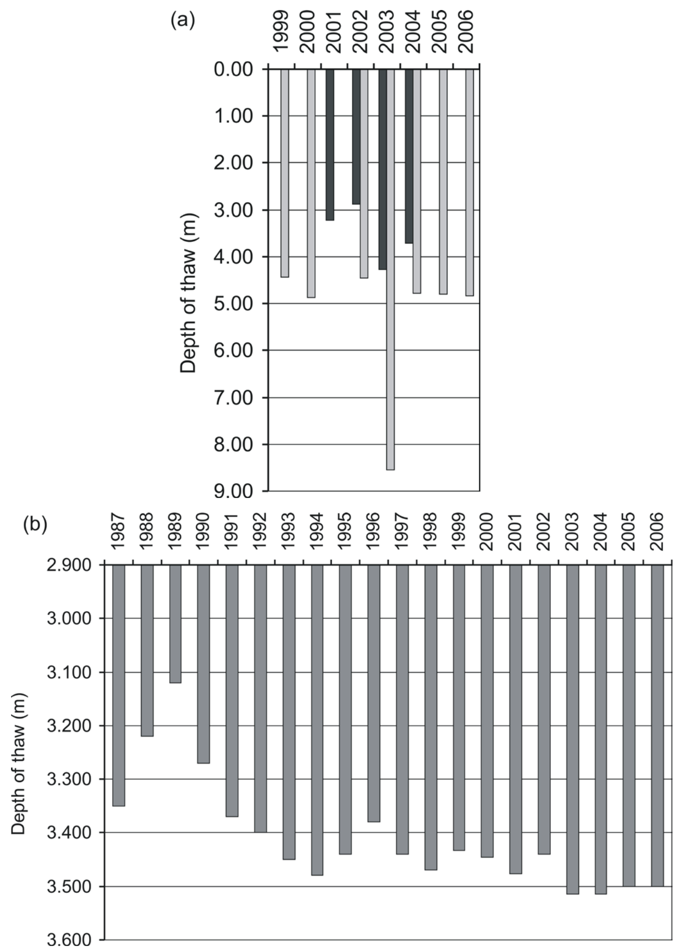

Figure 6. Active layer thickness: (a) Schilthorn (light bars) and Stockhorn (dark bars); (b) Murtèl-Corvatsch.

above the 1961–1990 average and 2.8°C higher than the previous record from 1954, amounting to an offset of 3.7 standard deviations from the mean (Isaksen et al. 2007b). The anomaly coincided with a marked reduction in sea-ice cover and an unusually large extent of marine open water around Svalbard during winter, spring, and summer 2005–2006. The warm winter was followed by warmer than average summer temperatures, which were around 2°C above the 1969–1990 normal. For calendar year 2006, the cumulative negative ground temperature at the permafrost table in the Janssonhaugen borehole (2 m depth) showed a 40% reduction compared with the average of the previous six years.

The effect on permafrost temperatures at Janssonhaugen is most clearly captured by considering the 12-month period from 1 December 2005 to 30 November 2006 (Isaksen 2007b). Plotting mean ground temperatures over this period, for instance the uppermost 3 meters, shows temperatures at the permafrost table 1.8°C above the 1999–2005 average, with the thermal anomaly traceable to a depth of at least 15 m. The start of active layer thawing was the earliest in the 8-year record and active layer thickness was 1.8 m, exceeding the mean of the previously recorded years by 0.18 m (an 11% increase).

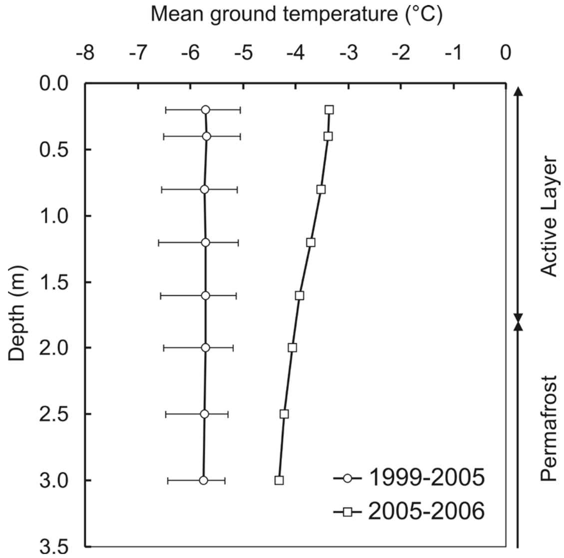

Figure 7. Mean ground temperature profile at Janssonhaugen for 2005–2006 compared with the mean for 1999–2005. Horizontal bars show the absolute variations of the previous years.

In order to place this anomaly into the context of climate change, Isaksen et al. (2007b) compared the accumulated degree day air temperature curve for 2006 at Svalbard airport with equivalent curves derived from empirical-statistical downscaling based on the multi-model World Climate Research Programme (WCRP) Coupled Model Intercomparison Project (CMIP3) of the most recent Intergovernmental Panel on Climate Change (IPCC) assessment in which atmospheric CO_2 reaches 720 parts per million by 2100. The 2006 accumulated degree day curve lay well within the range of the predicted scenarios for 2071–2100. Since 1999, accelerated warming has been observed at Janssonhaugen, the calculated rate at the top of the permafrost being in the order of 0.6–0.7°C/decade (Isaksen et al. 2007a). Thus the extreme temperatures of 2005–2006 were superimposed on a significant warming trend. If the frequency of such high temperature anomalies increases, then near-surface permafrost warming will be irregular rather than gradual and punctuated by rapid warming events such as that in 2005–2006.

Sensitivity to Geothermal Heat Flux

In Iceland, maritime conditions give cool summers and mild winters. The MAAT for 1961–1990 is around 4°–5° C in the south, and 2°–3°C in the north in lowland areas (Farbrot et al. 2007). Extensive non-glaciated mountain areas have MAAT below -3°C, indicating a potential for permafrost where snow cover is thin or absent. A regional model, calibrated against borehole thermal data and rock glacier inventories, suggests the presence of permafrost above around 800m a.s.l. in the north and above 1000m in the south (Etzelmüller et al. 2007, Etzelmüller et al. 2008), with the thickness of snow strongly modulating permafrost distribution.

Four monitoring boreholes in central and northeastern Iceland were established in 2004 (Farbrot et al. 2007,

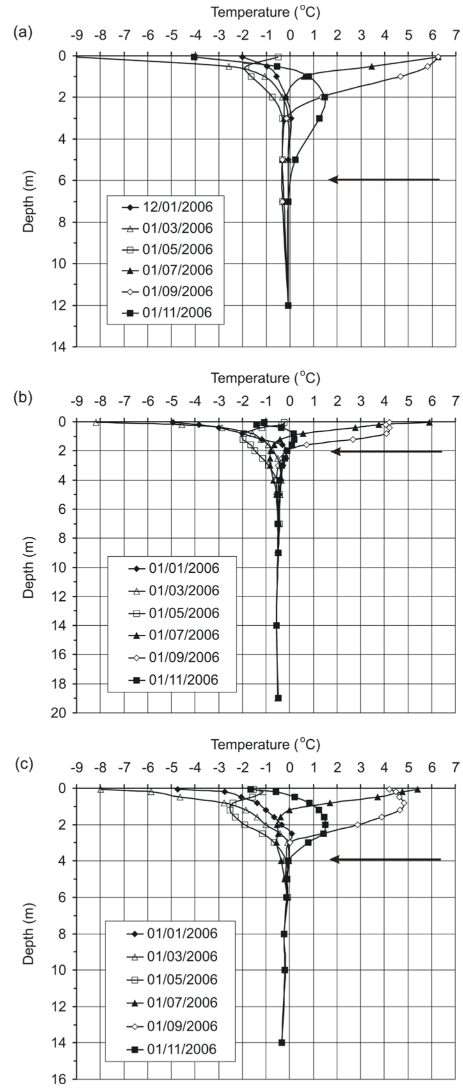

Figure 8. Temperature profiles in boreholes during 2006: (a) Hágöngur, (b) Snæfell, (c) Gagnheiði. Active layer thickness during the 2006 summer season indicated by arrows.

Etzelmüller et al. 2007, Etzelmüller et al. this volume), at altitudes of between 890–930 m a.s.l. (Fig. 1b). All boreholes are shallow (12–22 m deep) and penetrate thin sediment into basaltic bedrock. Permafrost was absent at the Vopnafjörður site due to excess snow cover, but at Snæfell and Gagnheiði it was estimated to be 30–35 m thick (Fig. 8b, c), with active layers around 2 m and 4 m respectively. At the Hágöngur borehole, permafrost was thin and the active layer thick (around 6 m) and permafrost temperatures close to zero degrees C (Fig. 7a). Meteorological data indicate that mean annual ground surface temperatures for the past few years in Iceland have been 0.5–1°C higher than those for the 1961–90 period (Etzelmüller et al. 2007). At the Gagnheiði and Snæfell boreholes, temperature profiles show warm-side deviation from steady state, suggesting recent rises in the upper boundary temperature (Fabrot et al. 2007).

Using a one-dimensional thermal model, Farbrot et al. (2007) showed that increases in mean daily surface air temperatures of (a) 0.01°C a^{-1} and (b) 0.03°C a^{-1} would cause permafrost to disappear at Snæfell in 160 and 100 yr respectively and at Gagnheiði in 125 and 75 yr respectively, the slower thermal response at Snæfell reflecting higher ice contents. Modeled temperature evolution since 1955 suggested that the present-day permafrost thicknesses reflect cooling in the late 1960s/early 1970s. This rapid permafrost thermal response is in part a reflection of the shallowness of the permafrost layer, but it is also due to the influence of high geothermal heat fluxes, which at Snæfell are around 170 mW m^2, approximately five times the values at the Scandinavian PACE borehole sites.

Conclusions

The spatial complexity of European mountain permafrost makes the representativeness of data from the small number of monitored boreholes extremely difficult to assess. The time series of borehole temperatures are mainly less than 10 yr, apart from Murtél-Corvatsch.

The addition of new boreholes provides the opportunity to sample a wider diversity of terrain and substrate character. However, prediction of permafrost distribution and response to climate change in European mountains requires further progress in physically-based numerical modeling coupled with remotely sensed data on relief, ground cover, and substrate characteristics.

PACE boreholes in Norway, Sweden, and Svalbard provide firm evidence for significant and accelerating ground warming. In addition, the importance of short-term extreme thawing events is emphasized. These have included the three-month period of sustained high temperatures during summer 2003 in the Alps, when active layers thickened significantly in bedrock sites and, in Svalbard, the anomalously warm year of 2005–6 when marked warming of permafrost occurred. Comparison of 2006 air temperatures in Svalbard with downscaled model scenarios of warming associated with enhanced greenhouse gases in the 21st century indicates that 2005–6 was well within the range predicted for the period 2071–2100, suggesting that the Svalbard archipelago may be in a critical location, with potential for particularly rapid climate change.

Given the variability of climate in the past and evidence for continued and possibly accelerated change in the future, permafrost is clearly in a transient state. More or less immediate response to extreme annual temperature variations may be anticipated in active layer thickness, while thermal profiles extending to several decimeters below the depth of zero amplitude reflect changes over many decades or centuries. Permafrost warming and basal melting are, however, likely to take several millennia, except where permafrost is thin and — as is the case in Iceland — where geothermal heat flux is unusually high.

Abstract

In this paper we present data from one typical cycle of freezing and thawing, derived from a 17-cycle full-scale experiment to simulate solifluction processes associated with two-sided active layer freezing and one-sided seasonal ground freezing. Two adjacent 12° slope models, each 5 m long, 1.5 m wide , and 35 cm thick were constructed using the same silt-rich natural soil. In the one-sided freezing model, the slope was formed above a sand substrate in an open hydraulic system, and the slope thawed completely between freezing cycles. The second model was constructed on a refrigerated plate that maintained permafrost in the lowermost 5 cm of soil and promoted bottom-upward soil freezing in addition to the top-down freezing induced by air temperature cycles. In the two-sided freezing model, downward moisture migration during the thaw period resulted in ice segregation immediately above and within the permafrost table. In the seasonally frozen slope model, ice segregation was greatest in the near-surface zones and decreased with depth. This contrasting distribution of soil ice caused marked differences in patterns of heave, thaw settlement, timing and style of downslope soil movement.

Keywords: one-sided freezing; physical modeling; solifluction; two-sided freezing.

Introduction

Here we present preliminary results from a three-year full-scale simulation experiment designed to investigate the influence of the distribution of segregation ice on the style and timing of periglacial solifluction (gelifluction and frost creep). These experiments form part of a larger program in which physical modeling coupled with field monitoring will provide detailed validation and calibration data for numerical modeling of solifluction processes (see also Kern-Luetschg et al. 2008).

Although the literature on periglacial solifluction is extensive, it is largely focused on areas with seasonally frozen ground or warm permafrost, where freezing takes place from the surface downwards. Field measurements (e.g., Washburn 1967, Benedict 1981, Smith 1988, Kinnard & Lewkowicz 2005, Jaesch et al. 2003) and laboratory simulations (Coutard et al. 1988, Harris et al. 1995, 1997) have shown that in seasonally frozen frost-susceptible soils, winter frost heave is followed by solifluction movements during summer thaw consolidation. Ice contents often decrease with depth, as do rates of soil movement. In cold permafrost regions, two-sided active layer freezing is observed, with freezing from the bottom upwards and the top downwards (Mackay 1981, Cheng 1983, Lewkowicz & Clark 1998, Schur 1988, Shiklomanov & Nelson 2007), and this commonly leads to a zone of ice segregation at the base of the active layer and top of the permafrost, termed the "transient layer" by Schur et al. (2005).

In Garry Island, Canada, Mackay (1981) described late summer plug-like solifluction, associated with displacement over the ice-rich zone at the base of the active layer. He showed that ice within this basal zone forms by early winter upward advance of a freezing front from the permafrost table, augmented by ice lensing in late summer as water migrates downward across the thaw front and into still-frozen basal active layer and upper permafrost. Similar observations of slow, annual downslope active layer movement over a deforming basal zone are reported by Lewkowicz & Clark (1998) and Matsuoka & Hirakawa (2000). Thaw consolidation may reduce the unfrozen thickness of this basal deforming zone, and resulting shear strains, accumulated over many annual freeze-thaw cycles, have been implicated in the reduction of local soil shear strength over time, promoting active layer detachment slides during anomalously warm summers (Harris & Lewkowicz 2000).

Table 1. Average test soil properties. *PL* is Plastic Limit, *LL* is Liquid Limit, c_v is coefficient of consolidation, and *k* is permeability.

% clay	% silt	% sand	PL %	LL %	ø degrees	c_v m^2/yr	k m/sec
25	65	10	22	33	26	18.4	4.4×10^{-8}

An early experiment to investigate the significance of ice distribution within the thawing active layer was reported by Rein & Burrous (1980), who used a tilting box containing a 25 cm thick layer of frost susceptible silt-loam. Two experiments were conducted, first with high ice contents in the mid profile, second with high ice contents at the base. Thaw consolidation and solifluction were shown to be concentrated within these ice-rich layers, with little shear strain occurring elsewhere in the profile. In the present paper we seek to test the hypothesis that similar processes of soil shear strain occur close to the surface in seasonally frozen ice-rich soil and at the base of the active layer in permafrost regions where two-sided freezing is associated with an ice-rich basal layer.

Experimental Design

Two identical 12° slope models were constructed adjacent to each other within a 5 m square freezing chamber, using the same frost susceptible soil (Fig. 1). Models were 5 m long, 1.5 m wide, and 35 cm thick. Soil properties are similar to those of many solifluction soils reported in the literature (see, for instance, the review by Harris, 1982) and are summarized in Table 1. Air temperatures were lowered to between -8°C and -12°C to simulate winter freezing, and were subsequently raised to between +15°C and +20°C to simulate the summer thaw period.

The two-sided freezing model was constructed above a refrigerated plate that maintained a 5–6 cm thick permanently frozen layer (permafrost) at the base of the model, with basal temperatures around -2.5°C during simulated summer conditions. Freezing was from the bottom upwards and the top-down (two-sided) during simulated winter cycles. Since the maximum thaw depth was only around 30 cm, active layer thickness was much less than in most field situations. When the active layer had reached its full thickness, water was added at the surface via a fine spray. Downward moisture migration led to basal ice segregation, simulating summer frost heave (e.g., Mackay 1983) and increasing the basal ice content. The one-sided freezing slope model was formed above a sand substrate in an open hydraulic system (basal water supply). Moisture contents prior to initiation of winter freezing averaged around 25% by weight in the two-sided freezing model, but were slightly higher in the one-sided model.

In this paper we present results of one freeze-thaw cycle from the final sequence of 8 cycles and contrast the soil response in the two-sided model with that in the one-sided model.

Figure 1. Two parallel slope models, far side, two-sided freezing model, near side, one-sided freezing model. Cross beams support pairs of LVDTs which form fixed base triangles, the apex of which is attached to a Perspex footplate embedded in the soil surface.

Instrumentation

Data were collected at half-hourly intervals via a PC-based data logging system. Instrumentation was similar to that used in earlier experiments (see Harris et al. 1997). Temperatures were measured using an array of stainless steel thermistor probes measuring to within ±0.38°C, (supplied by Campbell Scientific Ltd.) located at the surface and depths of 0 cm, 5 cm, 15 cm, 25 cm, and 35 cm in the central zone of each slope model. Pore water pressure monitoring used Druck PDCR 81 miniature pore pressure transducers consisting of stainless steel cylinders of diameter 6 mm and length 12 mm with a porous stone tip. Transducers were filled with low viscosity silicon oil and had a range of 350 mb, combined non-linearity and hysterics of ±0.2%, and thermal sensitivity of 0.2% of reading per °C. Pore pressure data are not included here but will be fully discussed in later papers.

Soil surface motion was recorded using pairs of longstroke (300 mm) captive guided armature linear variable differential transformers (LVDTs) with spherical end bearings supplied by RDP Electronics Ltd, UK. Pairs of LVDTs formed a fixed base triangle mounted on a slotted track parallel to the slope above each model, supported by a beam (Fig. 1). Both LVDTs were connected to an 8 cm square Perspex footplate embedded in the soil surface, forming the apex of the triangle. Frost heave, thaw consolidation, and downslope displacements of the soil surface were registered by changes in LVDT length and were resolved as orthogonal vectors perpendicular and parallel to the soil surface. Soil displacement profiles were observed through re-excavation of Rudberg columns.

Results

Soil temperatures

Typical responses of both slope models to cyclic freezing and thawing are illustrated below by reference to Cycle 16, between 20 April and 7 June 2007. For convenience, all soil depths are given here for the equivalent unfrozen soil. When frozen, soil depths increase as a result of frost heave, but this varies from one cycle to another. Contrasting thermal

regimes were observed during the freezing phase, reflecting the presence of permafrost in the two-sided freezing model, but its absence in the one-sided model (Figs. 2a, b). The basal temperature in the two-sided (permafrost) model was maintained at around -2.5°C, and active layer thickness was around 26 cm until air temperatures were lowered to approximately -10°C on May 10th. Winter freezing occurred over the next three days, with freezing fronts advancing from the permafrost table upwards and from the surface downwards. In the one-sided model downward freezing from the surface was initiated by the fall in air temperatures on May 10th and lasted some 5 days.

Frost heave and thaw settlement

A fall in surface temperatures of around 6°C on April 20, 2007, coupled with the addition of 5 litres of water sprayed across the entire surface, initiated the first phase of basal freezing in the two-sided freezing model and 18 mm of "summer heave" was recorded by April 26th (Fig. 3a). Further surface cooling on May 3rd, and the addition of 5 liters of water caused a second phase of ice segregation at the base of the active layer with an additional 6 mm of summer heave. Finally, the phase of two-sided freezing from May 10th–13th was associated with approximately 25 mm of frost heaving.

Surface downward frost penetration in the one-sided model, initiated on May 10th, led to a uniform rate of heaving with approximately 28 mm of surface frost heave recorded by May 16th (Fig. 3b) after which heave virtually ceased. The freezing front had penetrated to an unfrozen depth of between 15–20 cm by May 16th, so that little heave occurred during freezing of the lower 15 cm of the model. This was due to closure by freezing of the basal water supply tubes at the top of the model.

Thawing in both models was initiated by raising air temperatures to around 20°C on May 20, 2007. In the two-sided model the rate of thaw penetration increased through the uppermost 5 cm, was at a maximum between 5 and 15 cm depth, and then progressively decreased (Fig. 4a). Average thaw penetration rates are shown in Table 2. In the one-sided model, thaw penetration accelerated through the thaw period (Fig. 4b, Table 2) and was complete some 12 days before the maximum thaw depth was reached in the two-sided model.

By coupling the rate of thaw penetration with the rates of surface thaw settlement, and assuming that surface settlement during a given period was due to consolidation of the layer that thawed in that period, we were able to reconstruct ice contents within the thawing models (Table 2). Average heaving ratios (HR defined as frost heave divided by frozen thickness) were calculated from the amount of settlement recorded over a given soil depth range, divided by the frozen thickness. In the two-sided model, ice content was lowest within an ice-poor zone between unfrozen depths of 5 cm and 15 cm (HR 0.03), and highest in the basal zone between unfrozen depths of 25 cm and 26 cm (HR 0.66). In contrast, segregation ice was concentrated between 0 cm and 5 cm unfrozen depths in the one-sided freezing model, where the average heaving ratio was 0.25, and decreased to virtually zero in the lowermost 10 cm of the model.

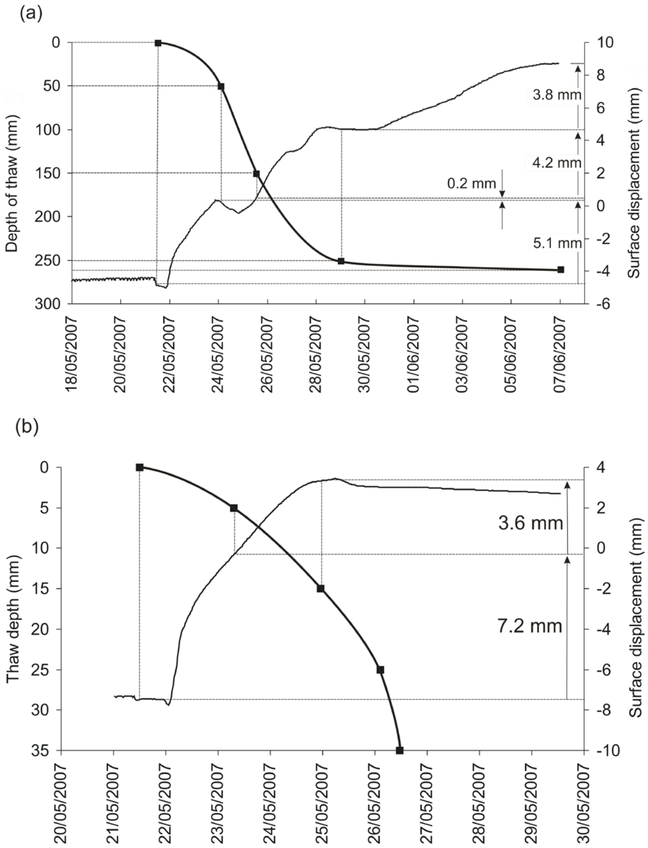

Figure 4. Rate of thaw penetration (heavy line) and measured surface downslope displacements. (a) Two-sided freezing model. (b) One-sided freezing model.

(b) synthetic model derived from thaw penetration and displacement data (Figure 4[a]). Labels show levels of layer boundaries (surface, 5 cm, 15 cm, 25 cm and 26 cm) in frozen (1–4F) and thawed (1–4T) states.

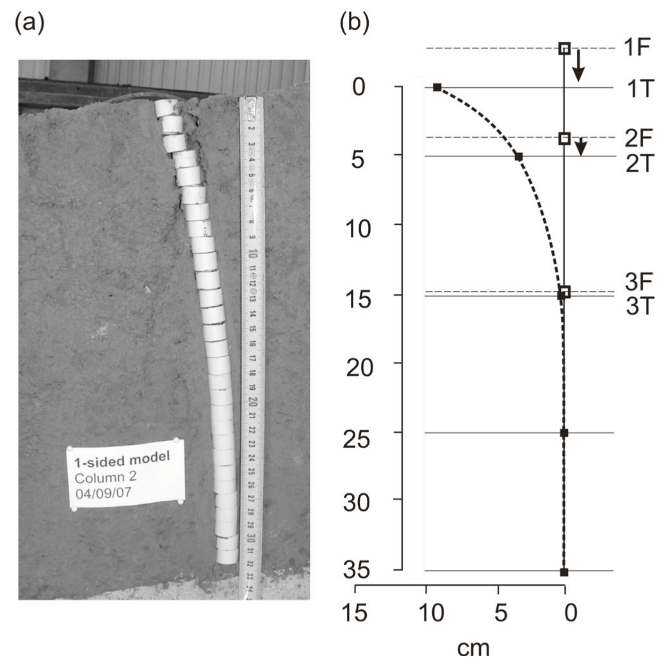

Figure 6. Soil displacement profiles one-sided freezing model. (a) observed displacement profile after 8 cycles of freezing and thawing. (b) synthetic model derived from thaw penetration and displacement data (Figure 4[a]). Labels show levels of layer boundaries (surface, 5 cm, 15 cm, 25 cm and 26 cm) in frozen (1–4F) and thawed (1–4T) states.

Downslope soil displacement

The distribution of soil shear strain within each model was assessed for the single thaw phase described here by attributing measured surface downslope surface displacement over a given time period to shear strain within the layer of soil that thawed over the same time period. In Figure 4(a) and (b), downslope surface displacement is plotted on a common time axis with the penetration of the thaw front. In the two-sided model, thawing of the upper 5 cm unfrozen thickness of soil was associated with some 5.1 mm downslope displacement, but thawing of the ice-poor region between 5 cm and 15 cm unfrozen depth caused virtually no net downslope movement, the recorded displacements probably reflecting changes in moisture status of the already thawed soil layer. As the thaw front penetrated to below 15 cm unfrozen depth, surface movement was again recorded, continuing over the prolonged period when the very ice-rich zone between 25 cm and 26 cm (unfrozen depths) thawed. In contrast, surface displacement in the one-sided model occurred only as the uppermost 15 cm of the model thawed, with displacement of 7.2 mm during thaw of the upper 5 cm, and 3.6 mm during thaw between 5 cm and 15 cm unfrozen depths.

Synthetic displacement profiles were generated for each model on the basis that the measured surface movements were attributed to the corresponding thawing soil layer. For clarity, displacements are multiplied by 8, to give the synthetic profiles that would arise following eight identical cycles of freezing and thawing in each model. These are compared with observed displacement profiles from excavated Rudberg Columns following the last eight freeze-thaw cycles of the

Table 2. Details of model freezing and thawing.

Model	Unfrozen depth mm	Unfrozen thickness mm	Frozen thickness mm	Thaw settlement mm	Heaving Ratio	Time to thaw hr	Thaw rate mm/hr

modeling program (Figs. 5, 6). Clear similarities are revealed between synthetic profiles and observed profiles.

Discussion and Conclusions

The thaw consolidation theory of Morgenstern & Nixon (1971) and Nixon & Morgenstern (1973) provides a theoretical basis for prediction of pore water pressures induced during thawing of ice-rich soils, and in our experiments, maximum shear strains were observed within the ice-rich layers where thaw consolidation was greatest. However, since the rate of thaw penetration was governed largely by soil ice contents (which determined latent heat required for phase change), thaw consolidation ratios (R) were actually highest where ice contents were least and thaw penetration fastest (central active layer zone, two-sided freezing experiment, $R = 0.37$ and basal zone, one-sided experiment, $R = 0.26$). Conversely, the slower thaw penetration in the ice-rich layers in both models resulted in the release of more meltwater and induced more soil deformation, but was reflected in lower thaw consolidation ratios.

Although the model of two-sided active-layer freezing did not strictly represent the annual cycle of the lower thermal boundary, we were able to successfully simulate segregation ice distributions. The distribution of segregation ice within the two-sided freezing model was similar to field observations in natural permafrost active layers. For instance, Mackay (1981, Fig. 15, p. 1674) clearly illustrated a desiccated central zone within the active layer in Garry Island very similar to that observed here. In addition, continuous monitoring of a permafrost slope in Svalbard during 2005–2006 (Harris et al. 2006) has also demonstrated an ice-poor zone in the central part of the active layer, with very little thaw settlement or downslope movement being recorded as this layer thawed. As in the experimental results discussed here, the majority of movement at the Svalbard field site occurred during thaw of the ice-rich basal zone. Progressive soil freezing from the surface down and from the permafrost table upwards forms a closed hydraulic system within the central zone of the active layer, both in the field and in our model. Water migration towards the respective freezing fronts reduces moisture contents in the central zone, and pore water suction increases effective stress and hence unfrozen shear strength.

In this paper we have presented initial results from one freeze-thaw cycle in a series of 17 such cycles undertaken during a three-year laboratory simulation of solifluction processes. More detailed papers are in preparation in which data from all cycles will be considered and recorded pore water pressures discussed. The initial hypothesis was that solifluction-induced shear strain results from thaw consolidation of ice-rich soil, and that the distribution of segregation ice within a frozen profile largely determines where greatest thaw strain will occur. Continuous monitoring of heave, settlement, and surface displacement of identical slope models subjected to contrasting thermal regimes has provided compelling evidence, supporting the initial hypothesis and confirming that thawing of the basal ice-rich zone within the permafrost model generated basal shearing and "plug-like flow" similar in character to field observations.

Abstract

In a joint project of computer- and geo-scientists, wireless sensor networks (WSNs) are customized for permafrost monitoring in alpine areas. In this paper, we discuss requirements for a rugged setup of such a network that is adapted to operation in a difficult environment. The experiences with a first deployment at Jungfraujoch (Switzerland) show that, beside hardware modifications of existing WSN platforms, special emphasis should be given to the development of robust synchronization and low-power data routing algorithms. This results from the fact that standard software tools are not capable in dealing with the high-temperature fluctuations found in high-mountains without compromising the power consumption and the network topology. Enhancements resulted in a second deployment at Matterhorn (Switzerland), from where we expect results in the near future. Once the technology of WSNs is a science-grade instrument, it will be a powerful tool to gather spatial permafrost data in near real-time.

Keywords: measurement; permafrost; PermaSense project; wireless sensor networks.

Introduction

Spatially distributed measurements of permafrost parameters over long periods are time consuming in deployment and maintenance, vulnerable to environmental impacts, and create inhomogeneous data sets, as no standard and easy applicable measurement devices exist. The project *PermaSense* addresses the development of a new generation of monitoring equipment for remote and harsh environments (Fig. 1). In this paper, we present the design and implementation of a wireless sensor network (WSN) to measure temperatures, dilatation, and diverse hydrological parameters in rock faces of alpine permafrost.

A WSN generally consists of distributed *network nodes* with attached sensors that communicate by local UHF radio within each other and that are up-linked by one (or several) *base stations* via mobile communication (e.g., UMTS, GPRS), internet, or other data transfer systems to a *data sink server* (Fig. 2). Each node contains a microprocessor, a radio transceiver, a sensor interface, some local memory, and an independent power supply. The network topology depends on the radio connectivity between the nodes. If data is transmitted via intermediate network nodes to the base station, this is called *multi-hop,* while a pure star-topology around the base station is called a *single-hop* network. Compared to existing logging systems using single radio-connected measurement devices, WSNs are designed to adapt their network topology dynamically according to the connectivity constraints, allowing observation of a larger area with multi-hop connection. While the dataflow is generally out of the network through the base station into the data sink, commands, network parameters or even executable programs can potentially be pushed into the network.

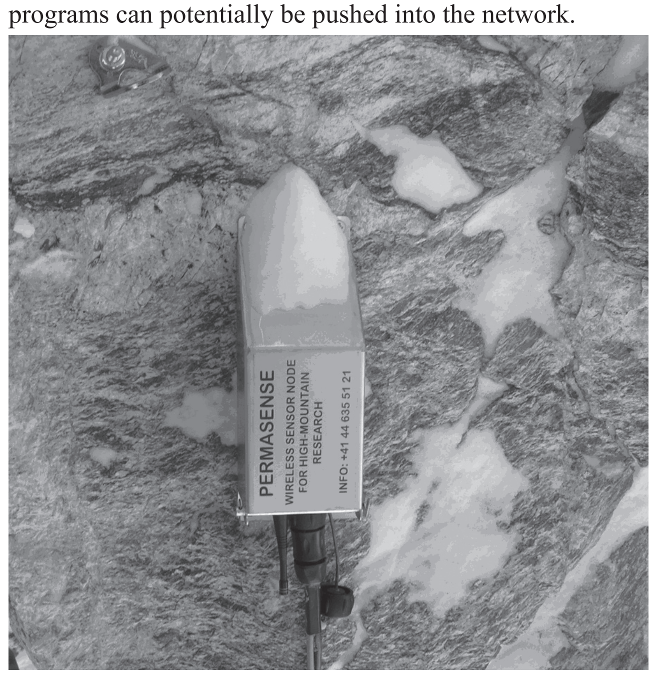

Figure 1. Network node at the field site Matterhorn – Hörnligrat.

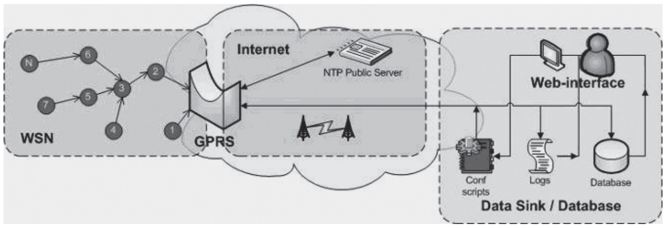

Figure 2. Framework of a WSN as used in our field deployments and test bed.

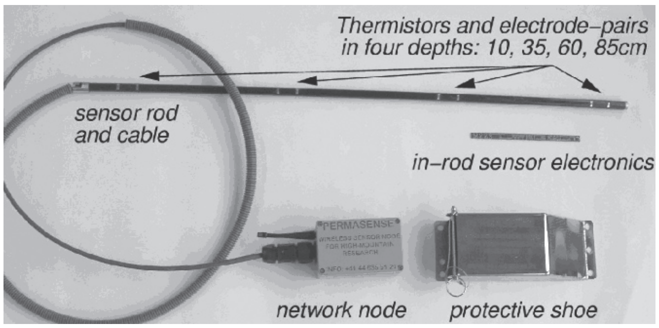

Figure 3. First-generation network node and customized sensor rod that measures temperatures and DC-resistivity as an indicator of liquid pore water at four different depths; the electronics and battery (lithium-thionyl) of the network node are mounted in a waterproof aluminum housing (125x80x57 mm) and protected from icefall and rockfall with a steel protective shoe. Measurement electronics are in the tip of the sensor rod to minimize temperature fluctuation errors.

Based on experiences with our first deployment on Jungfraujoch (3500 m a.s.l., Swiss Alps) during winter and spring 2006/2007, we specify requirements for yearlong stand-alone monitoring. WSN concepts and requirements for environmental use, and challenges for the implementation as well as the experiences from a second deployment generation are presented and discussed in this article.

Application of WSNs for Permafrost Research

Environmental WSNs

Environmental applications of WSNs have emerged in the past years following the general developments in mobile communication (Hart & Martinez 2006). Depending on the monitored variables and processes, the sensor networks differ in node size (e.g., from weather station to the futuristic "smart dust") as well as in spatial and functional extent of the network. In permafrost process research we are mainly interested in so-called localized multifunctional sensor networks. These systems are able to measure multiple parameters within an area of special interest. Despite the fast progress in the field of WSNs, only a limited number of application projects exists so far. The Projects *Glacsweb* (Martinez et al. 2004), *SensorScope* (http://sensorscope.epfl.ch/index.php), or the *Volcano monitoring project* (Werner-Allen et al. 2006) are such examples. A larger overview of existing environmental sensor network projects is given by Hart & Martinez (2006).

Potential of WSNs

For permafrost research and other remote environmental applications of WSNs, we identify the following potential:

- Once installed, maintenance and data acquisition is less time-consuming with WSNs than with standard logging systems, particularly at difficult accessible locations. The nodes inform the operator about battery level and functioning.
- Data is available all year-round at near real-time on a user interface. This is not only relevant for research, but can be very valuable for hazard monitoring.
- The data can be stored with redundancy, and not only locally on the logger. In case of destruction or loss of a sensor node, the data measured until this event is saved.
- Measurements are synchronous and arrive at one central database. No extensive manual post-processing and homogenization of the data is needed.
- Interval and mode of measurements do not require being statically predefined. They can be controlled by remote commands from the user interface or can be context-sensitive to other measurements of the network.

The project PermaSense

Wireless sensor networks have not yet been established for reliable, yearlong operation under cold climate and high alpine conditions. In PermaSense, computer- and geo-scientists upgrade in close cooperation the WSN platform *TinyNode* for permafrost research. Software for power-efficient operation of an adaptive multi-hop network topology is currently under development and being tested. Robust and reliable deployment hardware was designed, sensor interface hardware was developed, and software integration of sensors is being implemented. Customized sensors were manufactured, and compatible commercial sensors were evaluated and connected (Fig. 3). A detailed description of the network software of our first deployment, based on TinyOS, is given by Talzi et al. (2007).

Requirements for a permafrost WSN

Similar to standard logging systems for permafrost purposes, a WSN requires the following main features: Stable operation over a wide temperature range from -40°C to 40°C during at least one year or season, respectively (battery capacity). For analog measurements, a 12-bit analog-digital conversion (ADC) is generally sufficient, as the resulting resolution for temperature measurements over the indicated range is 0.02°C (a corresponding measurement accuracy can be reached with a zero-point calibration around 0°C). If pressure sensors are applied, a vibration wire (VW) compatible ADC, or frequency counter is of use. One or several digital interfaces (RS 232, RS 485, or SDI-12) for commercial sensors, allows the integration of diverse sensor types into the network. For power-intensive measurements (e.g., ERT), an incoming power supply line or solar panel control should be considered. All incoming and outgoing lines of this sensor interface should be lightning protected if the system operates at exposed locations.

As permafrost parameters typically change with slow rates, a temporal resolution of the measurements of some minutes to hours is required. Rarely, continuous measurements are needed (e.g., acceleration sensors), which is not further considered in this article. The mechanical setup should correspond to the operating conditions (e.g., Fig. 3).

WSN-specific requirements:

- The scale of the spatial extent ranges from decameters up to several hundred meters (depending on WSN limitations). To provide connectivity in complex alpine topography, a *multi-hop* system is preferable.
- Network topology is established automatically. A predefined topology is not applicable in practice and cannot adapt itself to a temporal lack of connection caused by snow cover, for example, of the devices.
- Connectivity through snow and ice is better with lower radio frequencies (<1GHz).
- Ultra low-power operation is supported. Sleeping cycles of the radio receiver, and consequently synchronization of the wake periods, are required.
- The measurements of different nodes are taken synchronically (in most cases, an accuracy of seconds is sufficient) and time-stamped.
- Nodes with no connectivity to neighbors store measured data locally on the node (capacity: 6 months).
- Data transmission capacity considers payload of the measured data with some margins to catch up data transmission from temporally invisible nodes. Generally, measured data does not exceed 2 kB per day.
- A *deployment mode* allows checking radio interconnectivity within the network during installation.
- A small form factor of the network node and a pluggable sensor interface ease the logistic effort for system maintenance.
- System health parameters (battery level, node temperature) inform the operator about network conditions and optimize the time of battery change.
- Command propagation into the network or context sensitivity allows to monitor periods of special interest in high resolution and to save power during less interesting periods.
- Data is stored in a database that provides metadata and has a safe backup strategy.
- A user interface supports the network maintenance (see above) and the database management.

Field Deployments

Energy balance models to estimate permafrost distribution and condition have recently been applied successfully to high-mountain topography (Gruber et al. 2004). Especially for steep and compact rock faces with little snow cover, modeling results correspond well with surface temperature measurements. Also mean annual subsurface temperature distribution and permafrost bodies are simulated satisfyingly with a 3D heat-conduction model (Noetzli et al. 2008). However, in such models processes of nonconductive heat transport are not considered despite their relevance for thawing depth and rate along fractures in the bedrock. The aim of our measurement site at Jungfraujoch is to quantify the spatial variability of thawing processes and heat transport in the near-surface layer.

First deployment: Jungfraujoch, winter 2006/2007

The influence of surface characteristics, fracturing, and meltwater availability is measured by eight of the above described sensor rods in gently steep (40°–70°) and fractured rock faces (general case in high alpine areas) around the Sphinx observatory at Jungfraujoch (ca. 3500 m a.s.l., Figs. 4, 5). Additionally, two thermistor chains are installed into the bordering ice faces.

The monitoring site consists of north and south faces of a ridge, which divide the network into two clusters with limited connectivity between them and differing thermal regimes (Fig. 4). Resulting from this topology, the thermal clock drift requires synchronization algorithms that let the node times converge even with such temperature deviations.

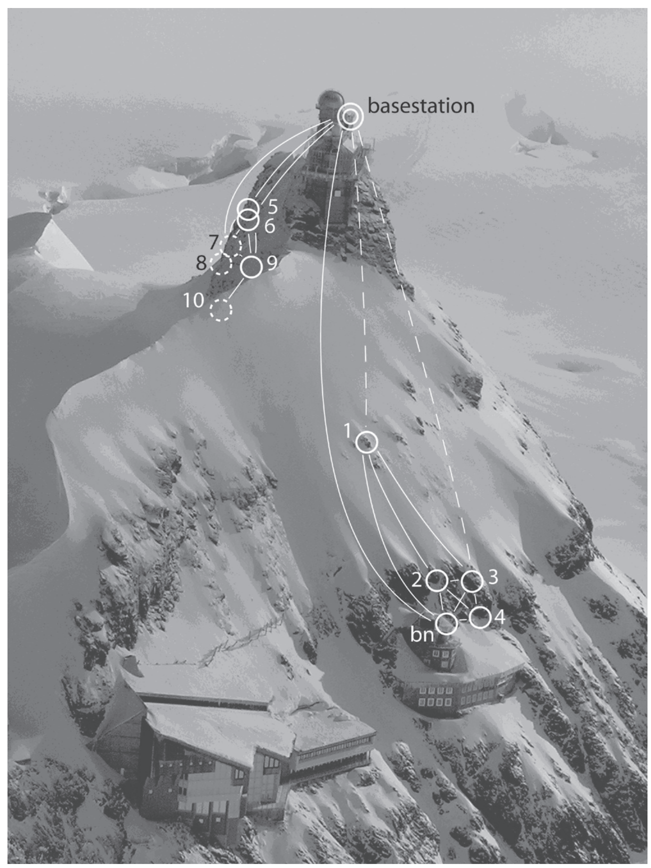

Figure 4. Deployment on Jungfraujoch (3500 m a.s.l., Swiss Alps) consisting of 10 sensor nodes with network topology; the base station is mounted on the Sphinx observatory. Each circle depicts a network node with its corresponding number. Lines indicate good radio connectivity between nodes; dashed lines indicate unstable connectivity; dashed circles are hidden nodes; and *bn* is a bridge node introduced to provide stable connection to the base station. The network is divided into to two clusters on the north-facing (left) and the south-facing (right) slopes of the ridge.

The initial installation of the sensors took place in fall 2006 after four months of system design and hardware production. We set up the first network at the same time, which, however, has not been successful due to the short development time and insufficient testing of the network software and hardware. In addition, a stability problem of the measurement values appeared under field conditions. After a debugging and testing phase over the winter of 2006/2007, first valid data could be gathered in April 2007 (Fig. 6). Yet no data transmission could be maintained over a period of more than two weeks. At this point, an extension of the project with the integration of network into a test bed prior to deployment was already planned for the second deployment in fall 2007. We decided to momentarily leave the network in a mode where data is stored locally to the node memory, and enhance and test the system for the second deployment.

Figure 5. Network node #4 and cable to the sensor rod, which is drilled one meter into the rock perpendicular to the surface. The network nodes can be easily exchanged and attached to the sensor by a waterproof plug.

Second deployment: Matterhorn "Hörnligrat" (3400 m a.s.l., Swiss Alps) in October 2007

Although public and research interests increased significantly following the hot summer of 2003, frost dynamics and natural hazards research in alpine permafrost areas has been discussed already a decade ago (e.g., Haeberli et al. 1997, Wegmann 1998). Frost weathering and rockfall activity is subject to yearlong field observations and measurements (e.g., Matsuoka & Sakai 1999, Matsuoka 2001) and lab experiments (Murton et al. 2006). These lab experiments have shown that ice segregation takes place also in solid (but porous) rock. Field data gave clear evidence for the contribution of temperature fluctuation and water to near-surface weathering and pebble fall. However, a direct physical linkage between temperature and rockfall disposition has not yet been demonstrated in the field. Different concepts of this linkage are discussed in Gruber & Haeberli (2007). The second deployment of PermaSense addresses this issue, to gather data of cleft ice and rock stability interaction.

The installation containing 13 sensor nodes with 6 sensor types, 2 bridge nodes, and 1 base station was made on the

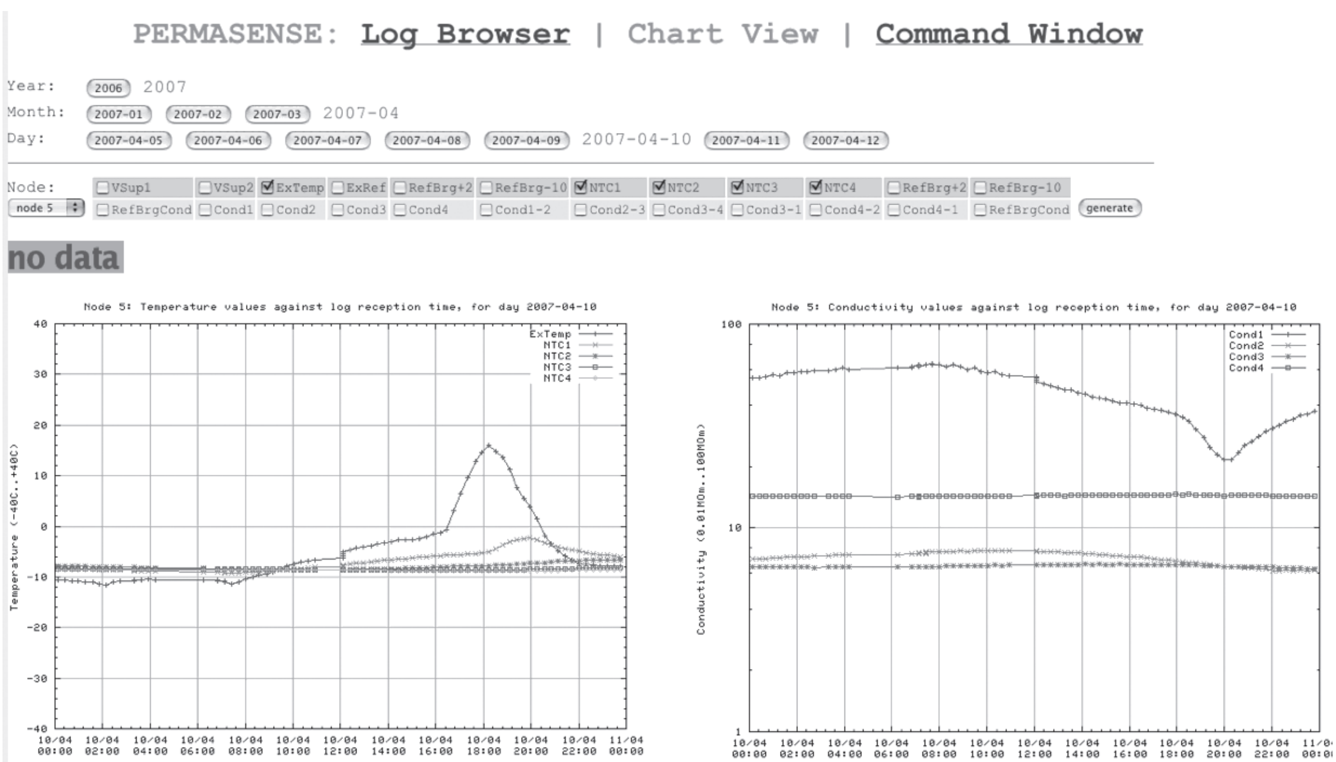

Figure 6. Screenshot of the user interface; direct visualization of one day of measurements from sensor rod #5 in the north-facing slope of the Sphinx. On the left, temperatures of the sensor rod thermistors (NTC1–NTC4) and the node temperature are plotted; the right diagram shows the corresponding rock resistivities. At the near-surface level (NTC/Cond 1), the temperature signal is clearly visible in the resistivity values.

northeast ridge of the Matterhorn at Hörnligrat in October 2007 (Fig. 7). At this site, a rockfall of some 1000 m^3 occurred in July 2003. Massive ice was observed at the surface of the detachment zone (Fig. 7) just after the event. This indicates the presence of stability-relevant ice-filled clefts in this area.

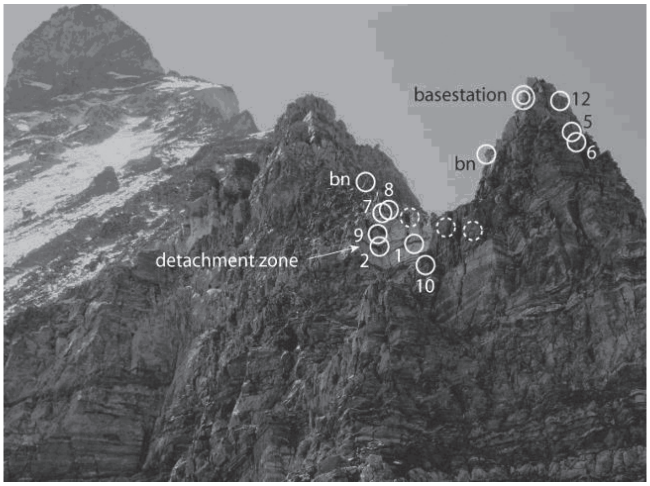

Figure 7. Deployment at Hörnligrat of the Matterhorn. Circles with numbers mark sensor nodes; dashed circles are sensors on the back (northwestern) side of the ridge; *bn* indicates bridge nodes.

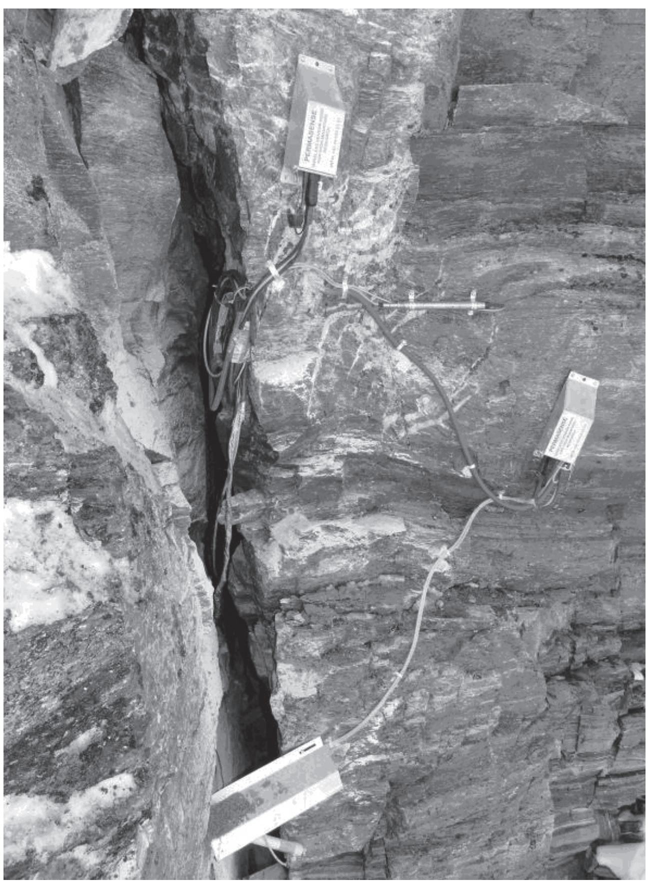

Figure 8. Installation site with multiple sensors: At the bottom, two crack meters measure dilatation. Within the cleft, potential water pressure and ice stress, as well as temperatures at different depths, are measured. The tube between the two nodes is the reference air pressure measurement.

In addition to the sensors used on Jungfraujoch, we integrated commercial sensors with a newly designed *sensor interface board* (SIB) into our network. With these sensors we measure crack dilatation, water pressure, ice pressure, and water movements in the clefts. Thermistor chains are mounted into clefts to measure temperature profiles together with the mentioned parameters. One node and SIB has a combination of this sensors attached resulting in a multiple sensor network node. The installation of more than one network node at one spot allows a flexible combination of sensors adapted to the situation in the field (Fig. 8).

Discussion of Experiences and Challenges of PermaSense

In the initial phase of PermaSense until April 2007, diverse problems were critical for the function of the WSN and the subject of debugging. The quality of the measurements and the instable operation of the base station are two examples of early-stage and hardware-related problems. Other system parts, such as the mechanical setup or the battery type, appeared well adapted to the conditions met in the field over the winter and spring 2006/2007.

The network setup at Jungfraujoch at the end of April 2007 and the subsequent test runs at the test bed in Zurich showed two main topics remaining critical for stable, long-term operation:

1. Time synchronization of the nodes.
2. Stability and power efficiency of the data routing.

As described above, the conditions in the field make time synchronization challenging due to large temperature fluctuations and deviations between installation spots. Short radio receiving slots compared to the sleeping intervals due to power limitations require a high quality of synchronization. The fact that the clock quartz are generally optimized for 25°C and have high drifts at negative temperatures makes a precise synchronization of a permafrost WSN even more challenging. Software-based temperature-drift compensation could be a possible solution, but needs extensive testing before application.

The currently used statically predefined data transmission slots, the radio communication as a power intense component, are used in a rather inefficient way. To optimize power consumption and consequently increase battery life-time, a dynamic organization of the data transmission slots is promising. This could also increase the data transmission capacity in areas of the network where it is required and, as a consequence, support more stable data routing as well.

Conclusions

Based on the experience gained from technology development and two high-mountain deployments, we can draw the following main conclusions for the application of WSNs in mountain permafrost research:

For a successful application of WSNs in permafrost research and in other environmentally challenging situations, an adapted software design and extensive testing of the network under realistic but well-monitored conditions are essential.

Due to large temperature fluctuations and large lateral temperature gradients, in combination with complex network topologies and power limitations, synchronization of the nodes is a very challenging task. Major algorithmic work, as well as specific testing, is needed here.

The power efficiency and the duration of operation without battery exchange in the field can be increased significantly with further software development.

Once we succeed in overcoming the current major problems, WSNs have the potential to become a powerful technology to gather spatially distributed field data in near-real time for permafrost research.

Acknowledgments

We would like to thank Sandro Schönborn, Roman Lim, and Mustafa Yücel for their contribution to PermaSense. The project is partly financed by the Swiss Federal Office for the Environment (FOEN) and the National Competence Center for Research – Mobile Information and Communication Systems (NCCR-MICS). We also acknowledge the helpful technical advice of Hansueli Gubler, ALPUG, in the initial phase of PermaSense.

A Four-Phase Model to Quantify Subsurface Ice and Water Content in Permafrost Regions Based on Geophysical Data Sets

Christian Hauck
Institute for Meteorology and Climate Research, University of Karlsruhe/Forschungszentrum Karlsruhe, Germany
Mathias Bach
Geophysical Institute, University of Karlsruhe, Germany
Christin Hilbich
Geographical Institute, University of Jena, Germany

Abstract

The indirect nature of geophysical soundings requires a relation between the measured variable (electrical resistivity, seismic velocity) and the rock/soil, water, air, and ice contents. In this contribution we present a model which determines the volumetric fractions of these four phases from tomographic electrical and seismic data sets. The so-called 4-phase model is based on geophysical mixing rules for electrical resistivity and seismic P-wave velocity. Observed resistivity and velocity data are used as input data on a two-dimensional grid; in the general case a porosity model has to be prescribed. First results confirm the good model performance, especially concerning the detection and quantification of ground ice as well as the detection of air cavities in the blocky surface layer. In addition, differences in ice content from time-lapse data can be determined. Examples from permafrost and non-permafrost sites with different morphologies (e.g., high mountain bedrock plateaus, scree slopes, moraines) are presented.

Keywords: electrical resistivity; four-phase model; geophysics; ice content; refraction seismics; water content.

Introduction

Based on the observational evidence of climate change in permafrost regions in recent years (e.g., Kääb et al. 2007, Marchenko et al. 2006, Fukui et al. 2007), it is now recognised that a detailed knowledge of the material composition of the subsurface in permafrost regions is required for (1) modeling of the future evolution of the ground thermal regime in permafrost areas, (2) a physically-based assessment of the hazard potential due to degrading permafrost, and (3) an optimal design of hazard mitigation measures. The important material properties in this context include the ice content, the unfrozen water content, and the porosity. The relative proportions between ice, water, and air content determines the thermal conductivity of the frozen material (e.g., Lachenbruch et al. 1982) which is needed for modeling of future thermal conditions of permafrost. Due to the commonly remote location of permafrost areas and corresponding logistical and financial difficulties in obtaining these properties from borehole logs, knowledge about the exact material composition of the subsurface in permafrost areas is scarce.

In frozen ground subsurface material may consist of four different phases: two solid phases (rock/soil matrix as well as ice), a liquid (unfrozen pore water), and a gaseous phase (airfilled pore space and cavities)(see Fig. 1). Except for laboratory and borehole data, the composition of the subsurface material can only be inferred through indirect geophysical investigations. Due to the complexity of the subsurface, a combination of complementary geophysical methods (e.g., electrical resistivity tomography and refraction seismic tomography) is often favoured to avoid ambiguities in the interpretation of the results (Maurer & Hauck 2007).

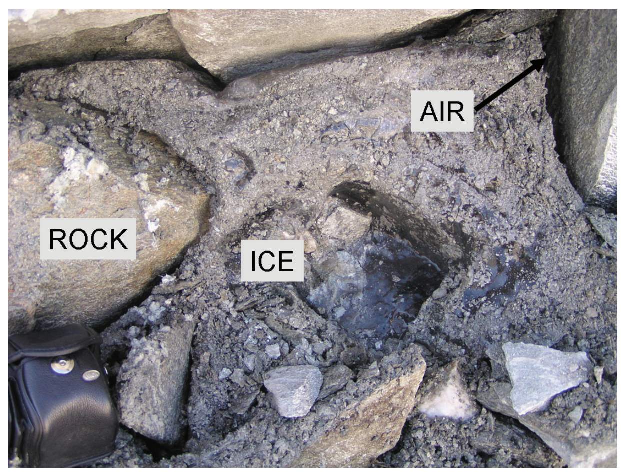

Figure 1. Photo of an ice-air-rock mixture within a rock glacier in the Swiss Alps. The camera in the lower left corner illustrates the scale.

However, the indirect nature of geophysical surveys requires a relation between the measured variable (electrical resistivity, seismic velocity) and the respective parts of the material composition (rock, water, air, ice). Such relations have been developed for the electrical properties; for example, the well-known relation between the electrical resistivity of the bulk material, the pore-water resistivity, the porosity and the saturation known as Archie's Law (Archie 1942), and for the elastic properties such as the mixing law for seismic P-wave velocities by Timur (1968).

In permafrost studies, quantitative combinations of electric and seismic data sets were introduced by McGinnis et al.

(1973) who used resistivity data for calculating the increase in seismic P-wave velocity due to the frozen layer. Oberholzer et al. (2003) used an index based on the ratio of resistivity and seismic P-wave velocity to differentiate between frozen and unfrozen morainic material in the Swiss Alps. However, up to now no physically-based relation between parameters commonly measured in surface geophysical surveys and the four phases present in permafrost material exists for practical applications in permafrost studies.

In the following a so-called 4-phase model (FPM) for explicit prediction of three of the four phases is presented which is based on two-dimensional tomographic electrical and seismic measurements. Results from the application of the 4-phase model to several periglacial morphologies will be shown to illustrate the performance of the model. In a further step the model is applied to time-dependent resistivity and seismic velocity data to determine the temporal change of ice and unfrozen water content between two measurement dates.

It is believed that the FPM serves as a useful tool for improved interpretation of geophysical data sets in frozen regions, and that it can be applied for determining quantitative information about the ice content and its temporal evolution.

Theory

The 4-phase-model is based on the well-known geophysical mixing rule for electrical resistivity (Archie 1942) and on an extension of the time-average formula for seismic P-wave velocities (Timur 1968) (Eqs. 1, 2):

$$\rho = a\rho_w \Phi^{-m} S_w^{-n} \tag{1}$$

$$\frac{1}{v} = \frac{f_w}{v_w} + \frac{f_r}{v_r} + \frac{f_i}{v_i} + \frac{f_a}{v_a} \tag{2}$$

where ρ and ρ_w are the electrical resistivities [in Ωm] of the bulk material and the pore water, respectively, Φ is the porosity, S_w is the saturation, n, m, and a are empirical constants, f_w, f_r, f_i, and f_a are the volumetric fractions of the water, rock, ice, and air content, and v, v_w, v_r, v_i, and v_a are the seismic P-wave velocities [in m/s] of the bulk material, water, rock, ice, and air, respectively. Under the condition

$$f_w + f_r + f_i + f_a = 1 \tag{3}$$

and using $\Phi = 1-f_r$ and $S_w = f_w/\Phi$, equations for the ice, water, and air content can be derived as a function of the rock content (1-porosity):

$$f_i = \frac{v_i v_a}{v_a - v_i}\left[\frac{1}{v} - \frac{f_r}{v_r} - \frac{1-f_r}{v_a} + \left(\frac{a\rho_w(1-f_r)^n}{\rho(1-f_r)^m}\right)^{1/n}\left(\frac{1}{v_a} - \frac{1}{v_w}\right)\right] \tag{4}$$

$$f_a = \frac{v_i v_a}{v_i - v_a}\left[\frac{1}{v} - \frac{f_r}{v_r} + \frac{1}{v_i}(f_r - 1) - \left(\frac{a\rho_w(1-f_r)^n}{\rho(1-f_r)^m}\right)^{1/n}\left(\frac{1}{v_w} - \frac{1}{v_i}\right)\right] \tag{5}$$

$$f_w = \left(\frac{a\rho_w(1-f_r)^n}{\rho(1-f_r)^m}\right)^{1/n}. \tag{6}$$

Equations (4), (5), and (6) allow then to explicitly compute ice, air, and unfrozen water content for each model block on a 2D-grid from seismic P-wave velocity and electrical resistivity data if a suitable porosity model can be prescribed. In the absence of ice or if the ice and rock content are considered as one (solid) phase, Equations (1) to (3) can be rearranged to determine the porosity. The seismic velocities for air (330 m/s) and ice (3500 m/s) are known—further material properties such as the P-wave velocity of the host rock material, the resistivity of the pore water, or the so-called cementation exponent m and the saturation exponent n have to be specified. Whereas the former two parameters can be measured in the field, the latter are often assumed to equal 2 for many rock materials (e.g., Archie 1942, Keller & Frischknecht 1966). In a further step these model parameters can be determined by a Monte Carlo approach, the results of which are used additionally as indicator for the reliability of the model results (Bach 2008).

The model was tested using electric and seismic data sets from two active rock glaciers in the Swiss Alps, where borehole data were available to verify the performance of the FPM. Sensitivity studies indicate a strong dependence of the quantitative model results on the pore water resistivity, which should be measured directly in the field, wherever possible.

Data Sets

Seismic and ERT data sets from various field campaigns on different periglacial morphologies were used to test the model performance and evaluate the applicability of the FPM to different rates of ice, water, air, and water within the subsurface. The geophysical data stem from a number of different projects, including the EU PACE project (Permafrost and Climate in Europe) and the geophysical monitoring network within PERMOS (Hilbich et al. 2008) and are described in the respective publications (Table 1). Data inversions were performed using the geoelectric Res2DINV software and a seismic inversion algorithm by Lanz et al. (1998). In the following we will present data from an ice-rich, coarse-grained moraine material from the South-Shetland Islands, Maritime Antarctica (further details can be found in Hauck et al. 2007), poor-ice bedrock slope with superficial fine-grained material on Schilthorn, Swiss Alps (described in Hauck 2001), frozen and unfrozen bedrock material from a long gentle slope in Jotunheimen, Norway (Hauck et al. 2004) and a low-altitude, cold-ventilated scree slope in the Black Forest, Germany (Hauck & Kneisel 2008). Examples of rock glaciers will be discussed in detail in a companion paper and will not be repeated here. Finally, a monitoring data set comprising measurements along the same survey line observed at two different times from the frozen bedrock plateau at Stockhorn, Swiss Alps (Hilbich et al. 2008) will be presented. The characteristics of the field sites are summarised in Table 1.

Four-Phase Model Results

Figure 2 shows inversion results for P-wave velocity and specific resistivity as well as the FPM results for the

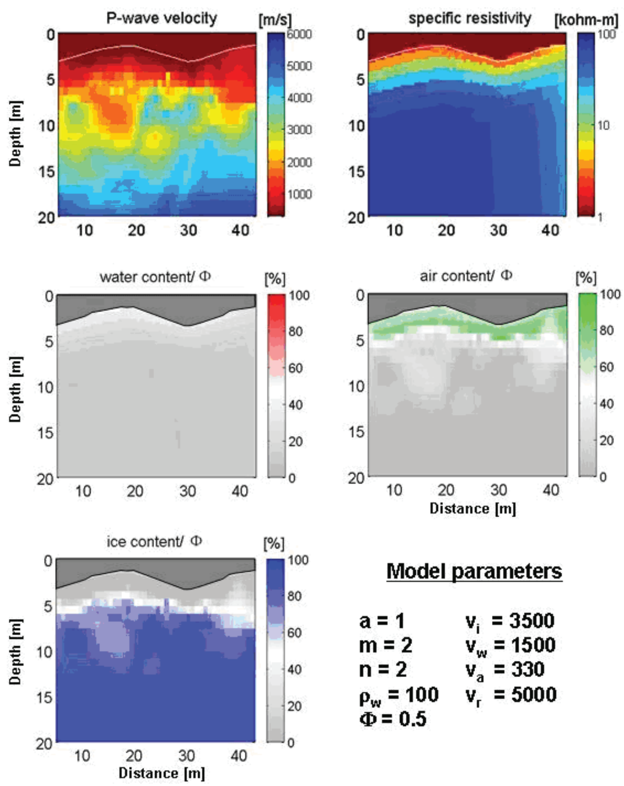

Figure 2. P-wave velocity and specific resistivity inversion results for the ice-cored moraine on Livingston Island, Maritime Antarctica. Ice, water, and air content are displayed relative to the available pore space of 50%.

volumetric contents with a prescribed constant porosity model of 50% for a blocky moraine on Livingston Island, Maritime Antarctica. Ice, water, and air contents are normalised by the porosity showing the percentage of the pore space which is filled by the respective material. Resistivities are high below the uppermost 2 metres, and seismic velocities show a low-velocity zone in this region, indicating an active layer without any frozen material. Consequently, the result for the ice content shows values up to 100% below the uppermost 2 m meaning that 100% of the pore space is filled with ice below the active layer. Within the active layer, mostly air and only little water is present within the available pore space. The results indicate clearly that the moraine is ice-cored—similar results were obtained for the ice-rich rock glacier Murtèl in the Swiss Alps (not shown here).

Figure 3 summarises the results for the other landforms, i.e., the frozen bedrock sites at Schilthorn and Juvvasshøe, the unfrozen bedrock slope 600 m below the top of Juvasshøe, and the low-altitude scree slope at Präg. All examples except Schilthorn were computed with different but constant porosity models, which may limit the significance for interpreting absolute values, but which can be used as indication to what extent the pore space is filled with the respective material. Based on results from a drilling in 1998 (Vonder Mühll et al. 2000), a porosity model that decreases with depth was used for the Schilthorn site. Table 2 provides an overview of the model parameters used for the different field sites.

The results for the frozen bedrock at Juvvasshøe show high ice contents below a 4 m thick active layer, which is mainly "filled" with air but only little water. The sharp transition between active layer and permafrost at 4 m can be seen both in the resistivity and in the seismic data. The permafrost layer consists almost completely of rock and ice with only little air and water. These results agree well with borehole logs and borehole temperatures from this site (Isaksen et al. 2001, Harris et al. 2001).

In contrast, the results for the frozen bedrock at Schilthorn indicate a much lower ice content relative to the available pore space and a significantly higher unfrozen water content (see also Noetzli et al. 2008, Hilbich et al. 2008). These model results are caused by the much lower resistivity values

Note, that the scales for seismic P-wave velocities and resistivities are different for the various sites.

yielding higher unfrozen water contents through Equation (1). Significant ice contents are found below a depth of 5 m, which agrees well with the observed active layer depth at the time of the measurements (Hauck 2001).

Blocky and ventilated scree slopes are known to sustain permafrost thermal regimes including substantial ground ice occurrences (Delaloye & Lambiel 2005). In the absence of excavations and boreholes, usually no indications are given as to whether ground ice is present or whether "dry permafrost conditions" prevail (Hauck & Kneisel 2008). Although the model results for the low-altitude scree slope at Präg indicate total ice contents of up to 25% (half of the available pore space of 50%) at around 10 m depth, this result has to be treated with care, as the model results for water and air show that the modeled ice-bearing zone is located right between the air-filled top layer (uppermost 7–10 m) and the ground water table at 12–15 m depth. Inversion results with a slightly deeper low-velocity top layer or a low-resistivity bottom layer reaching to slightly shallower depth would lead to a vanishing intermediate ice layer. Such inaccuracies in modeled layer depth are well within the uncertainty range of geophysical inversion models.

The unfrozen Juvvass slope is located along the northern slope of Juvvasshøe summit, but at an altitude where joint thermal and geophysical measurements proved the absence of permafrost (Hauck et al. 2004). The FPM results correctly predict no ice occurrences within the uppermost 10 m, where air is predominantly found in the upper 2 m with partly

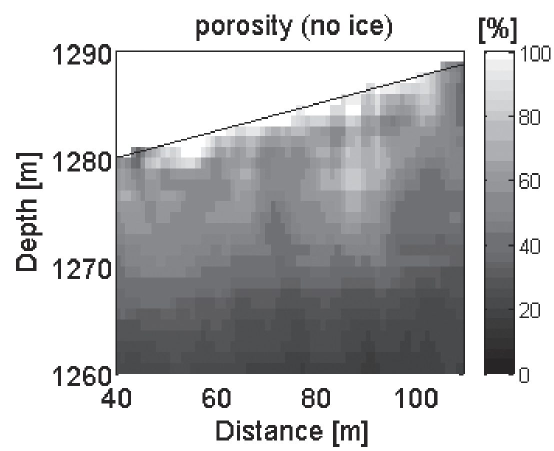

Figure 4. Calculated porosity for the unfrozen bedrock slope at Juvvass/Jotunheimen, Norway, under the assumptions of no ice and n = m = 2.

saturated conditions below. However, below a depth of 10 m modeled ice content values are increasing with depth. This obvious discrepancy to the thermal evidence has its causes in the increasing velocity and resistivity values measured at greater depth, which most probably corresponds to the bedrock layer. Assuming an ice content of zero and using the simplifications of n = m = 2, Equations (4)–(6) can be reformed to compute the porosity distribution over the model domain. In Figure 4 porosity values >50% are predicted for

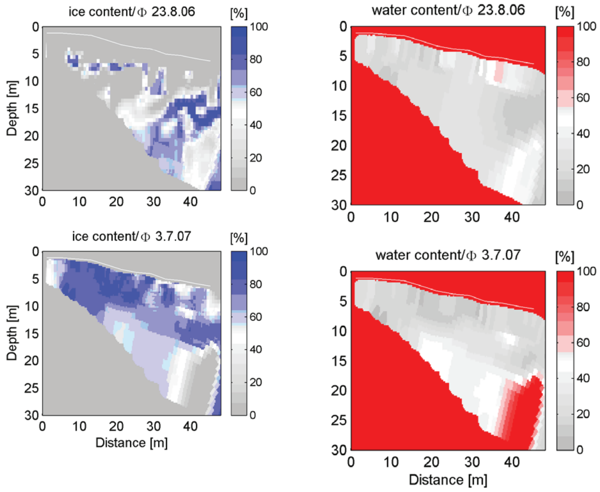

Figure 5. FPM Monitoring results for ice and water content at the bedrock plateau Stockhorn, Western Swiss Alps, for two measurement dates in summer 2006 and 2007.

the bouldery surface layer with decreasing porosity values below, indicating the more and more compacted rock material at greater depths. This much more probable scenario (no ice and decreasing porosity with depth as opposed to constant porosity and increasing ice content with depth) illustrates the main deficiency of the FPM in cases of low ice contents and unknown porosity distribution. Because rock and ice can exhibit similar seismic P-wave velocities and similarly high resistivity values, the differentiation between bedrock and ice occurrences is sometimes difficult, especially if no geological or glaciological *a priori* data are present.

Monitoring Results

The full potential of the FPM becomes evident for applications with time dependent data sets. Figure 5 shows the FPM results for two measurements at Stockhorn, Western Swiss Alps, where geoelectric and seismic measurements are regularly conducted within the geophysical monitoring network of PERMOS (Permafrost Monitoring Switzerland, see Hilbich et al. 2008). Due to different resolutions of seismic and ERT data sets, the coinciding model domain is triangular in this case.

Measurements were obtained in late summer 2006 and early summer 2007, representing different phases of the seasonal thawing of the active layer. The much higher ice contents in the uppermost 5 m in July 2007 compared to the ice-free conditions at the end of August 2006 are clearly visible in Figure 5. Furthermore, ice contents at greater depth (>15 m) are larger in August 2006 than in the beginning of July 2007, which may resemble the phase lag of winter temperatures. Corresponding water contents are generally low with maximum values near the surface in August and at greater depth in July. The saturated water anomaly in the lower right corner originates from a consistently occurring low-resistive anomaly in the ERT monitoring results, the cause of which has not yet been determined.

Table 2. Model parameters used for FPM calculations at the different field sites. In all cases the following values were used: $a = 1$, $m = 2$, $n = 2$, $v_i = 3500$ m/s, $v_a = 330$ m/s, $v_w = 1500$ m/s.

Conclusion

A new model for quantifying subsurface ice, water, and air contents in permafrost regions has been presented. The so-called 4-phase model (FPM) is based on tomographic specific resistivity and seismic P-wave velocity data sets and combines well-known petrophysical relationships of electric and elastic properties of the material on one hand and the relative phase fractions within the subsurface on the other hand. Field cases from a series of different permafrost sites were presented to evaluate the model performance. Key results from this study include:

- The model correctly delineates the ice, air, and water contents in cases of large ice occurrences such as ice-cored moraines and rock glaciers.
- Internal layers, especially the active layer, can be delineated because of strong contrasts in the vertical ice and air distribution. These contrasts can become more pronounced in the FPM results than in the original geophysical data, which facilitates the interpretation.
- Unfrozen water contents are generally low, except for the Schilthorn site, where modeled water content values are higher than the corresponding ice contents.
- In its present form, the absolute model results are strongly biased by the prescribed porosity model. As a consequence, phase fractions are shown relative to the available pore space. In a further step the free model parameters (including porosity) will be determined using a quasi Monte Carlo approach yielding more realistic porosity distributions.
- Deficiencies of the FPM have been found for cases of low ice contents in combination with an unknown porosity distribution. As rock and ice may exhibit similar seismic P-wave velocities and similar high resistivity values, the differentiation between bedrock and ice may become difficult, especially if no geological or glaciological *a priori* data are present.
- Promising results were obtained for geophysical monitoring data, where porosity remains unchanged and resistivity and velocity changes can unambiguously be related to changes in ice, air, and water content.

Acknowledgments

We would like to thank all field crews participating in the geophysical surveys, H. Maurer for providing the seismic inversion code and M. Böttcher for her contribution in developing the FPM. Fieldwork was partly financed by the EU-PACE, PERMOS (BAFU, Switzerland) and Permamodel (Spanish Antarctic Program and University of Zürich) projects.

Rationalizing Climate Change for Design of Structures on Permafrost: A Canadian Perspective

Don W. Hayley
EBA Engineering Consultants Ltd., Canada
Bill Horne
EBA Engineering Consultants Ltd., Canada

Abstract

The design engineer is challenged by uncertainty when determining how a plethora of published trends indicating a warming arctic climate can affect future permafrost stability. A process was developed in Canada in 1998 for screening projects in an attempt to rationalize the effects of climate change. Two case histories from the authors' files are used to illustrate the screening process. One project is a government building with complex foundation conditions but a defined service life. The second example is a site reclamation project that relies on permafrost for stability. Reclamation requires confirmation that the risk of thaw can be managed to an acceptable level over the long term. Climate change trends for structures on permafrost with a defined service life can reasonably be predicted from historical climate data and climate normals developed over a period of years (30 years). Global Climate Models (GCM) can be a better choice when longer term analyses are required. Both methodologies have limitations that must be balanced with appropriate risk assessment. A geothermal analysis that includes appropriate climate trend input, coupled with a failure modes and effects analysis, can provide a useful tool for evaluating alternatives where long term environmental risks must be managed.

Keywords: Canada; climate change; GCM; permafrost; site reclamation; thermal analysis; thermosyphons.

Introduction

Concern about global warming has added a new layer of uncertainty to the current practice of cold regions engineering. Recent studies have clearly shown that climatic warming trends are more severe at higher latitudes, and regional data from northern Canada has identified that the mean annual air temperatures are most affected by warmer than normal winter conditions. Structures that rely on properties of permafrost and ice for long-term stability can be at risk if design processes do not recognize and rationalize future uncertainty from changing climatic conditions. It is no longer an accepted procedure to adopt historic thirty-year climatic normals as design parameters in regions of permafrost.

This paper describes a risk-based process for screening projects sensitive to climatic warming that was developed in 1998 for application in Northern Canada. In this paper, the process is described in general terms, and two representative projects are used as case histories to illustrate the strengths and limitations of the process.

Project Screening Process

Engineering projects in the north usually depend on permafrost as a structural material for foundation support, seepage retention or as a barrier for contaminant flow. The ability of the frozen ground to carry out these functions depends on site conditions and meteorological parameters that sustain the permafrost. Environment Canada initiated a three year study to review and document the factors that require consideration when designing new structures on permafrost in 1995. The author was a contributor along with a number of government scientists and university researchers with permafrost interests. The product was a report titled "Climate Change Impacts on Permafrost Engineering Design" (Etkin et al. 1998). The report is no longer available in print but can be provided by the authors in .pdf form on request.

The report is ten years old and much has changed in our understanding of how climate change is affecting our practice. The value in the 1998 report is the recognition that not all structures are exposed to the same risk level. The process requires the designer to systematically consider the sensitivity of the site and type of structure to damage resulting from changes to the permafrost regime. Each project is screened to categorize its site sensitivity and the consequences of failure resulting from permafrost warming or thaw following the schematic in Figure 1. The probability and consequences feed into a risk table, Figure 2, where the risk level, identified as a scale with four levels, is used to determine a reasonable level of analyses appropriate for the project.

The analyses range from non-concern through application of professional judgement to detailed quantitative analyses using state-of-practice numerical models. A simple classification system for relating soil type and initial ground temperatures to site sensitivity is shown in Figure 3. A table of consequences linked to potential failure modes is included in Figure 4.

Project Examples

Application of the process can be illustrated with two projects from the authors' files. The first project has been chosen to illustrate a complex foundation design for a new municipal building with a defined service life. The

second project involves site reclamation that must address the implications of changes to the permafrost regime over the very long term. In both cases, the project cycle is well advanced such that they can be considered realistic case histories.

Inuvik Hospital

The Government of the Northwest Territories initiated replacement of the hospital in Inuvik with a new Regional Health Centre in the late 1990s. The chosen site was on the fringe of municipal development. The Inuvik area is typically covered with glacial materials with a high proportion of ground ice prevailing in continuous permafrost. The hospital site underlain by a granular soil with a relatively low ice content. Inuvik was developed as a new townsite in the 1950s, and the challenges of building on ice-rich permafrost were met at that time by establishing a procedure for installation of timber piles frozen into steamed holes (Philainen 1959). The construction could then proceed above the surrounding ground to provide a cold crawl space to allow natural air convection. These designs have functioned well but are now generally architecturally unacceptable for municipal and industrial buildings. The new hospital required its main floor to be on grade, with a crawl space excavated into permafrost soils. A thermosyphon heat exchange system was chosen to allow below grade foundation design.

The guideline screening process identified that Inuvik is a region of high sensitivity to climate warming and that the consequences of thaw-settlement on a structure of this type would be severe. Moreover, the lower Mackenzie Valley, in close proximity to the Beaufort Sea, is recognized as a “hot spot” for climatic extremes. An appropriate framework for design analyses was therefore state-of-practice geothermal modelling to select a thermosyphon configuration that would sustain the permafrost foundation soils. This must be coupled with consideration of the potential for future deformations attributed to permafrost warming. The building had a designated design life of thirty years; therefore, it was necessary to look forward to the year 2030 for climatic input to design analyses and to consider the probability that extreme events could upset the ground thermal regime during the thirty years of operation.

The building is a steel frame structure on concrete footings set below grade with a warm crawl space. The underlying permafrost is protected from thaw with a thick layer of rigid polystyrene insulation underlain by a horizontal looped thermosyphon system. Figure 5 shows the structure at the open foundation and framing stage in October 2001, and a foundation schematic is shown in Figure 6.

The thermal design requirements were to develop a combination of granular pad thickness, insulation thickness and thermosyphon spacing that would satisfy the design life requirements of preservation of the permafrost and minimal warming from initial ground temperatures. The design was based on two-dimensional finite element geothermal analyses that have been configured to include heat flux to a horizontal plane of thermosyphons (Hwang 1976). Heat is

Figure 5. Inuvik Hospital – open foundation and framing stage, October 2001.

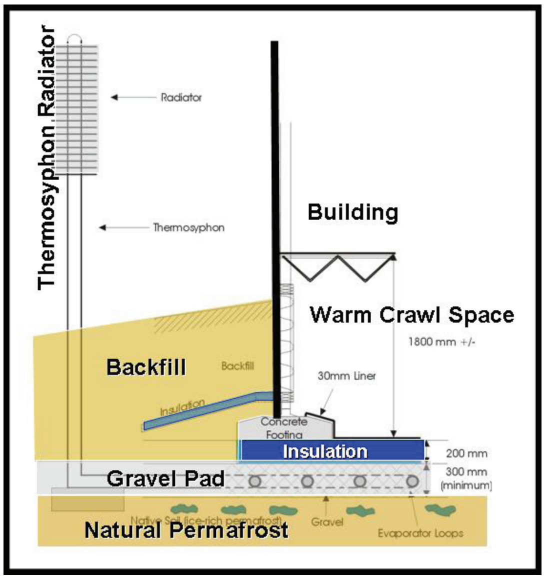

Figure 6. Foundation schematic.

removed from the foundation soils and dissipated to the air at the above-ground radiators whenever the air is colder than the ground below the building. The overall heat balance, therefore, becomes dependant on the outside air temperature and the efficiency of heat extraction process. That efficiency is expressed by a coefficient that can be determined from the literature (Haynes and Zarling 1988) or adapted from similar projects where performance records are available. The greatest uncertainty is the outside air temperature and wind velocity and how that might change in response to microclimatic effects from construction or macro-climatic effects from climate warming trends.

The foundation system was configured to satisfy thermal design criteria based on historic air temperature records for each of the following conditions:

- Five consecutive 1 in 5 warm years followed by a 1 in 100 warm year,
- Ten consecutive 1 in 5 years, and
- A linear warming trend over the life of the structure.

It was necessary to use the historical database to construct hypothetical annual air temperature inputs that were representative of each of the above conditions. A probabilistic analysis was carried out to determine the mean monthly temperatures representative of both the 1 in 5 and 1 in 100 return period warm years. The freezing and thawing indices for each of the years from 1957 to 2000 were calculated and ranked with a "best fit" linear regression on probability paper. The 1 in 5 and 1 in 100 warm indices were chosen and normal monthly air temperatures were scaled upward by the ratio of the respective freezing and thawing indices to their normals. These constructed new mean monthly air temperature annual cycles were considered representative of conditions with the chosen return periods.

The influence of a potential global warming trend was evaluated by starting at the mid-point of the thirty year Canadian Climate Normals available at the time (1961 to 1990) and ramping the mean annual temperatures upward in a linear function over the period from 1975 to 2030. The Environment Canada Report provided guidance for selecting either a best estimate case or a high sensitivity case global warming scenario and amplifying the effects based on season, and latitude. Inuvik lies at about 70°N latitude where the winter amplification increases the seasonal increase by a factor of 3 and the summer increases are attenuated by a factor of 0.5. The annual cycle is divided into four seasons of three months each and the air temperature increase applied for each month by cycle expressed as degree-C/month/decade was: Winter 0.95, Spring 0.66, Summer 0.16, and Fall 0.18. This allowed construction of a mean monthly air temperature representative of each year as the temperatures continued to increase in a linear fashion. The overall trend for the high sensitivity case chosen as a design basis could be expressed as a ramp increase in mean annual air temperature of 0.47°C/decade with most of the warming applied during the winter and spring months.

The resultant climatic design input is shown in Figure 7. The analyses and design were carried out in early 2001 using the best available information at that time. It is used here to illustrate a process rather than quantify climatic design parameters for the community of Inuvik. If the work were undertaken today, the most current data would be used. Figure 7 also shows mean annual air temperatures recorded in Inuvik since the design and construction was completed. The limited data suggests that with some excursions, the climate continues to warm following a near linear relationship that fits the extrapolated best fit line for the entire 50 year data set. That line falls slightly above and is parallel to the values chosen for design.

The ground temperatures below the warm crawl space under the structure have been monitored. Initial ground temperatures at a depth of 5 m were in the range of -2.6°C to -3.7°C and were predicted to rise slowly to -2.2°C over the thirty year term. Post-construction ground temperatures are reported elsewhere in these proceedings by Holubec et al, 2008. Performance has been better than design predictions for the first seven years of operation as the ground has been cooled by the thermosyphon system. There have been no movements reported for the foundations, although some water has migrated into the crawl space forming ice mounds under the insulation, and there has been some distress in the thermosyphon pipe attributed to manufacturing defects that are unrelated to the system design.

Reclamation of arctic military sites

Reclamation of decommissioned military defense sites across North America has been ongoing for the past twelve years. The most active program in Canada has been the Distant Early Warning (DEW) line of radar surveillance camps that stretched along the high arctic coastline from Baffin Island to Alaska. The sites typically lie about 69 degrees North Latitude where mean annual air temperatures range from -9°C to -15°C and corresponding ground temperatures range from -5°C to -12°C. The reclamation process often requires construction of secure landfills where contaminated soil is encapsulated in geomembrane liners and permafrost soils.

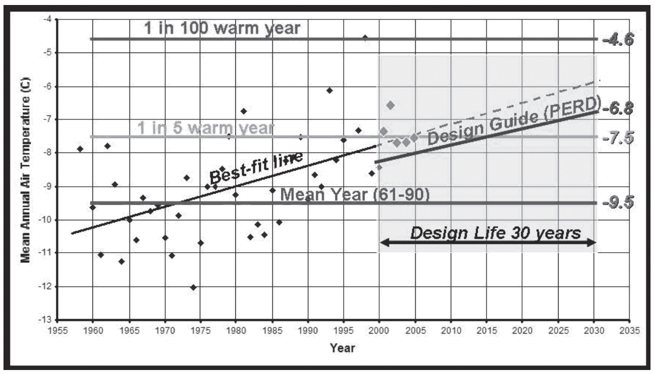

Figure 7. Mean annual air temperatures in Inuvik.

Unlike the Inuvik Hospital, these waste containment structures do not have a defined life but must function in perpetuity at a level of environmental risk that is acceptable to aboriginal people who use the nearby land for subsistence. Regulatory processes in the arctic require detailed technical review of all designs and consultation to ensure that best management practices are followed. Climatic uncertainty is therefore an important component in the design of waste containment structures that interface with permafrost. Stringent requirements must be met to achieve approvals.

A typical design developed jointly by EBA Engineering Consultants Ltd. (EBA) and UMA Engineering Ltd. for containment of contaminated soil is shown in Figure 8. The first defence against loss of contaminated pore fluid is a geomembrane liner. The second line of defence is the underlying ice-saturated permafrost soil. A final soil cover is configured to retain the active layer within the cover.

The screening process identifies most of these remote sites as moderate permafrost sensitivity; however, failure consequences could range from minor to major, depending on proximity to sensitive receptors. The risk posed from climatic warming is that the active layer thickness will increase with time allowing thaw to penetrate into the waste. A hypothetical worst-case failure mode could see the permafrost slopes supporting the liner thaw and slump,

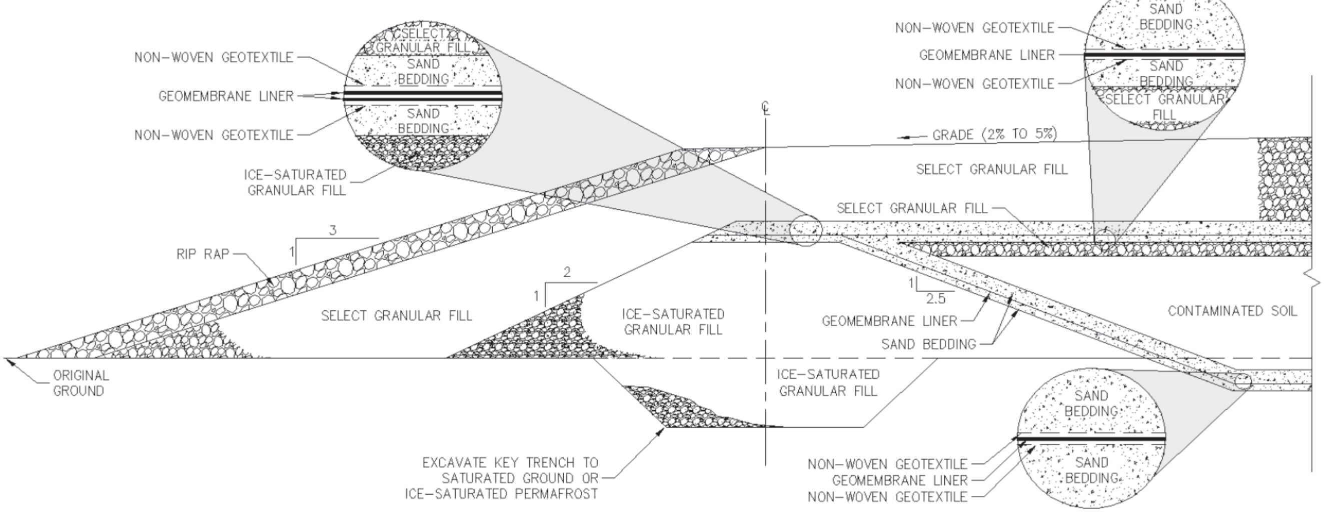

Figure 8. Design of soil containment landfill.

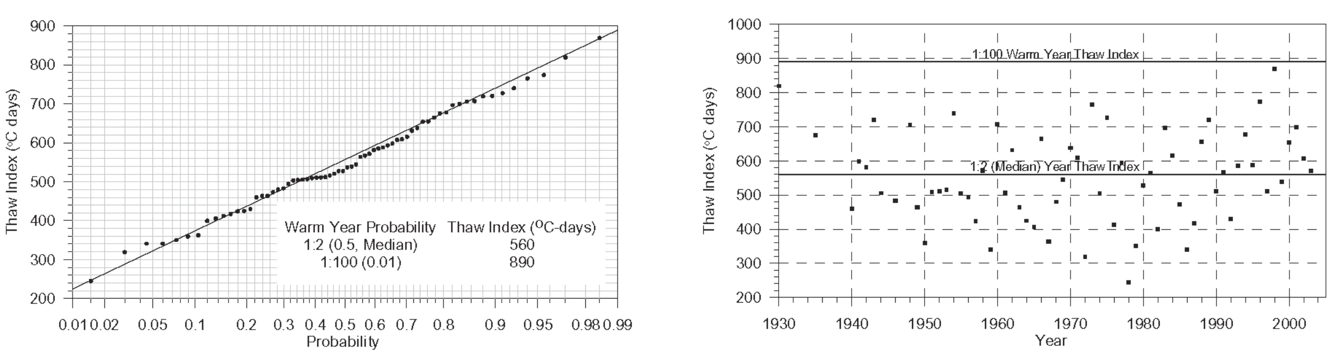

Figure 9. Historical thaw index probability.

resulting in failure of both the primary and secondary containment.

Geothermal analyses are required to substantiate the use of permafrost as a containment system for the landfills. Analyses are carried out to predict the short-term and long-term ground temperatures to determine the following:

- Length of time for landfill freezeback;
- Short-term thermal regime in the landfill;
- Long term thermal regime including an estimated amount of climate change; and
- Depth of annual thaw (active layer) in the cover material.

Geothermal analyses are carried out for each landfill using GEOTHERM, which is a proprietary two-dimensional finite element computer model developed by EBA. The model simulates transient, two-dimensional heat conduction with a change of phase for a variety of boundary conditions. The heat exchange at the ground surface is modelled with an energy balance equation considering air temperatures, wind velocity, snow depth, and solar radiation. The thermal analysis is calibrated to measured temperatures and/or observed active layers thicknesses.

Climatic data required for the thermal model include monthly mean air temperature, wind speed, solar radiation, and snow cover. Weather stations were maintained at the sites; therefore, climatic records dating back to the mid-1950s are available. The landfills are designed for mean conditions, warm conditions and long-term climate change.

Statistical analyses are carried out to determine mean monthly temperatures representative of a 1 in 100 warm year using the process described for the Inuvik Hospital. A historical thaw index probability analysis of a site is shown in Figure 9.

The influence of climate change on the landfill ground temperatures and active layer is evaluated by carrying out thermal analyses for a period of 100 years. The change in air temperature is estimated using a similar method, described in ACIA 2005. The air temperatures are estimated from Global Circulation Models, or GCMs. The GCMs are mathematical representations of the atmosphere, land surfaces, and oceans that have been developed to predict future climate behavior in response to changes in the composition of the atmosphere. Several scenarios have been developed to estimate the likely range of future emissions that may affect climate (IPCC 2000). Different GCMs have been developed, resulting in different degrees of projected climatic warming.

The outputs from various GCMs are posted on the web by the Canadian Climate Impact Scenario project (http://www.cics.uvic.ca/scenarios/index.cgi). Seasonal temperature changes are posted for the "B21 scenario" from four GCMs: a) CGCM2 (Canadian Centre for Climate Modelling and Analysis, Canada); b) GFDL-R30 (Geophysical Fluid Dynamics Laboratory, United States); c) ECHAM4 (Max-Planck Institute of Meteorology, Germany), and d) HadCM3 (Hadley Centre for Climate Prediction and Research, United Kingdom). Average seasonal changes in temperatures from the four GCMs for a central arctic site (69°N, 83°W) are listed in Table 1.

Table 1. Mean air temperature change (°C) over 110 years.

	December January February	March April May	June July August	September October November	Annual
Average of Four GCMs	6.4	4.2	3.8	5.1	4.9

Table 2. Predicted long-term maximum depth of thaw penetration into secure soil disposal landfills at a central arctic location.

Air Temperature Conditions	Predicted Active Layer Thickness (m)
After ten consecutive mean years	1.7
After one 1:100 warm year following ten mean years	2.2
After ten consecutive 1:100 warm years	2.4
After 100 years of global warming (average of four GCMs)	2.7
After 100 years of global warming plus one 1:100 warm year	3.3

The thermal analysis indicates that the permafrost remains during a 100-year period. The active layer depth continues to increase with time. Typical active layer thicknesses for a central arctic site are listed in Table 2 for the various climate conditions. The values are site specific. Thermal analysis are carried out for individual sites to take into account the local soil properties, ground temperatures, and climate.

The performance after 100 years becomes rather hypothetical because estimates of climate change scenarios seldom extend beyond 100 years. Longer term performance can only be bracketed by a range of climate potential climate extremes between 100 and 200 years. The project team has evaluated the following three alternatives:

- Air temperatures reach a stable condition and remain constant after 100 years;
- Warming rate continues on a linear ramp function similar the first 100 years; or
- Warming rate reduces to 50% of the 100 year warming rate.

Thermal analysis indicates that the permafrost at central arctic sites will be retained below a thickened active layer if the warming rate continues at a constant rate for a period of 200 years. The ground temperature warms at a rate similar to the air temperature at these sites. Degradation of the permafrost may begin to occur at sites that initially have warmer air and ground temperatures.

A failure modes effects analysis (FMEA) can be carried out to evaluate the effects climate change as well as other failure modes. Methods of FMEA are described by Nahir et al. 2005, and Roberson and Shaw, 2005. The FMEA considers the effects of retrogressive thaw of permafrost at a predicted rate on the performance of the landfill, including the potential for physical instability and contaminant flux out of the landfill. The potential consequences of these releases to the surrounding environment can then be considered.

The consequence of failure can be ranked as low, minor, moderate, major or critical, relative to financial costs, ecosystem impact, and health and safety of the local population. Each proposed design must provide a balance between potential long term environmental impacts and legal obligations with the overall site remediation costs.

A geothermal design that includes a conservative climate change scenario coupled with an FMEA analysis will provide a basis for a rational decision on adoption of a landfill construction plan at a particular site.

Limitations and Conclusions

The screening process described in this paper has no official status as an adopted guideline in Canada. Nevertheless, it has received reasonable acceptance by Canadian regulators as an appropriate framework for identifying projects where climate change effects on permafrost can put the environment at risk. The study is now ten years old and has been tested with operating structures such as complex buildings, dams reliant on permafrost and industrial site reclamation. The process has been shown to add value to projects and streamline regulatory assessments. The inputs to the process must, however, evolve with time as scientific knowledge pertaining to the magnitude of warming trends matures.

The design engineer's toolbox comprises historical air temperature data and output from a range of GCMs that simulate hypothetical changes to the composition of the atmosphere. The application of these parameters as inputs to engineering analyses must be kept in perspective with the risks involved. Straight line extrapolation of historic air temperature data is not realistic beyond a thirty-year climate normal period and should never be used beyond the length of the period of record.

The failure of GCMs to predict current climate on a regional scale is a significant drawback to the use of these models for engineering analyses. All numerical models used by design engineers must be rationalized at the input stage by calibration to existing known conditions. The failure of many models to calibrate effectively sheds doubt on their use as predictive tools. At the current time, a practical option is to establish initial conditions at remote sites from limited site data and use the future trends predicted by GCMs with appropriate judgement.

It becomes a design engineer's unprecedented challenge to look more than 100 years into the future to establish climate change trends. Science seldom provides projections deep into the next century, and linear extrapolation from current conditions into that grey zone can have a serious adverse effect on decision-making for arctic resource development. Those projects must be based on best practices for risk assessment. That requires a coupling of appropriate ground thermal analyses with failure modes and effects analyses. We must always be prepared to weigh the consequences of a long term retrogressive system failure against general landscape degradation that could accompany many of the worst-case climate change scenarios that are currently being contemplated.

Abstract

We selected a north-south transect in the Tibetan Plateau, comprised of six alpine tundra ecosystems underlain with permafrost, to examine the terrestrial carbon dynamics with the Terrestrial Ecosystem Model (TEM) for the period from 1967 to 2000. We find that the ecosystems act as a carbon small source in the most northern site, Wudaoliang (-0.87 g C m^{-2} a^{-1}), while the other five sites act as a carbon sink at 0.31, 2.49, 5.19, 5.35, and 4.21 g C m^{-2} a^{-1} at Naqu, Tuotuohe, Anduo, Dangxiong, and Gandansi, respectively. From north to south, the number of months with carbon sink increases along the temperature and precipitation gradient. Due to warmer and wetter soil conditions, all sites in the transect acted as a carbon sink in the 1990s. The future warming climate may enhance ecosystem carbon sequestration due to increase of soil temperature and moisture associated with permafrost thawing in the Tibetan Plateau.

Keywords: net ecosystem production; permafrost; Tibetan Plateau; transect.

Introduction

The Tibetan Plateau, the largest geomorphologic unit on the Eurasian continent, almost covers an area of 2.6 million km^2, with an average altitude more than 4000 m above sea level, and accounts for 26.8% of China's landmass (Zhang et al. 2002). From the southeast to northwest, supplies of heat and water decrease gradually, and forest, meadow, steppe, and desert ecosystems are developed (Zheng 1996). Meanwhile, there exists the largest area of mountainous permafrost worldwide with an area of 1.5 million km^2 in the plateau. Climatic warming on the plateau in past decades has been evident from meteorological observation and ice core records (Liu & Chen 2000, Thompson et al. 2000). It has been shown that the annual mean temperature of the Tibetan Plateau has risen at a rate of 0.26°C per decade in the last 40 years, which was much higher than those of whole china and the world (Du 2001); the winter temperature rose about 0.32°C per decade from 1955 to 1996 (Liu & Chen 2000). Consequently, the region experienced widespread permafrost degradation, and the thickness of the active layer has increased in the last few decades. Future warming will likely result in an even more extensive and rapid permafrost degradation in the region. Thus, the knowledge of ecosystem responses to the changes of permafrost and active layer depths in the past will help understand the contribution of regional carbon dynamics to global carbon cycling. However, few studies have been conducted to quantify the inter-annual variations and changing trend in carbon fluxes for the terrestrial ecosystems in the plateau. On the plateau, heat and moisture increase gradually from north to south, and these gradients provide a good opportunity to examine the variation pattern of net ecosystem production (NEP) during the past decades. In this study, we select a north-south transect in the permafrost region in the plateau, including six field sites dominated by alpine tundra (Wudaoliang, Tuotuohe, Anduo, Naqu, Dangxiong, and Gandansi) to examine the terrestrial carbon dynamics during the past few decades with the Terrestrial Ecosystem Model (TEM), which is coupled with a permafrost model (Zhuang et al. 2001, 2002, 2003). Our aims are (1) to explore whether the terrestrial ecosystems in the permafrost region are sequestering or releasing carbon, (2) to examine the temporal trends of NEP for each site along the transect and their relations with soil temperature and moisture, and (3) to provide information for simulating the response of alpine tundra ecosystems to projected climate variability across the range of permafrost region on the plateau.

Methods

Data preparation

The six sites with high altitudes are located in plateau permafrost region (Fig. 1) with heat-moisture gradients from north to south (Table 1). To drive the TEM, the monthly temperature and precipitation data for each site are calculated from the nearest meteorological station. Considering the elevation differences between the field site and the nearest meteorological station site, we have recalculated the monthly temperature using the month-specific elevation lapse rate of temperature (Fang 1992). As for precipitation, we haven't done any recalculations and used meteorological data directly. The cloudiness data are extracted from the gridded data of the Climatic Research Unit, University of

Norwich, U.K. (http://www.cru.uea.ac.uk/) based on the sites' geographic location. To parameterize model TEM, we have measured the net primary production (NPP), C in vegetation and soil, total N in vegetation and soil, and soil texture at Wudaoliang site (Luo et al., 2002a, b, 2004). We use the annual atmospheric CO_2 concentration data from Mauna Loa station (Keeling & Whorf 2005).

Model parameterization and simulations

As a process-based ecosystem model, the terrestrial ecosystem model (TEM) uses spatially referenced information on climate, elevation, soils, and vegetation to estimate the spatial and temporal distribution of major carbon and nitrogen fluxes and pool sizes at continental scales, and can be used to describe mechanistic processes of ecosystem carbon and nitrogen cycle and their dynamic responses to changes in environmental conditions. It was first applied to estimate the NPP of potential vegetation in South America (Raich et al. 1991) and then widely used in evaluating responses of terrestrial ecosystems to historical and projected changes in atmospheric CO_2 and climate for different spatial scales (Kicklighter et al. 1999, Tian et al. 2000, Schimel et al. 2000, Clein et al. 2000, McGuire et al. 2000, Clein et al. 2002), and modeling the carbon dynamics and emission of greenhouse gas in Alaska tundra ecosystems (Zhuang et al. 2007). In this study, we use version 5.0 of the model to quantify carbon dynamics for each field site along the north-south transect on the plateau permafrost region. We first parameterize TEM with the observations of vegetation and soil carbon and nitrogen and NPP for the alpine tundra ecosystem. The specific data used to parameterize the model

are described in Table 2. The tundra parameterization of soil thermal dynamics in Alaska from our previous study is used for alpine tundra ecosystems in this study (Zhuang et al. 2003). The parameterization of carbon is verified with the observed data of NPP. Third, we simulate the monthly NEP from 1967 to 2000 for those six sites. Finally, we analyze the relationships between NEP, annual air temperature and precipitation, the averaged soil temperature in top 20 cm depth, and soil moisture.

Results

Temporal variation in simulated NEP

From 1967 to 2000, simulated annual NEP for Wuadaoliang, Tuotuohe, and Dangxiong decreased from -1.5, -11.3, and 13.2 to -3.3, -18.3, and 5.1 g.C.m^{-2}.a^{-1}, respectively. In contrast, annual NEP for Anduo and Gandansi increased from 3.3 and -10.2 to 30.9 and 16.4 g.C.m^{-2}.a^{-1}, respectively

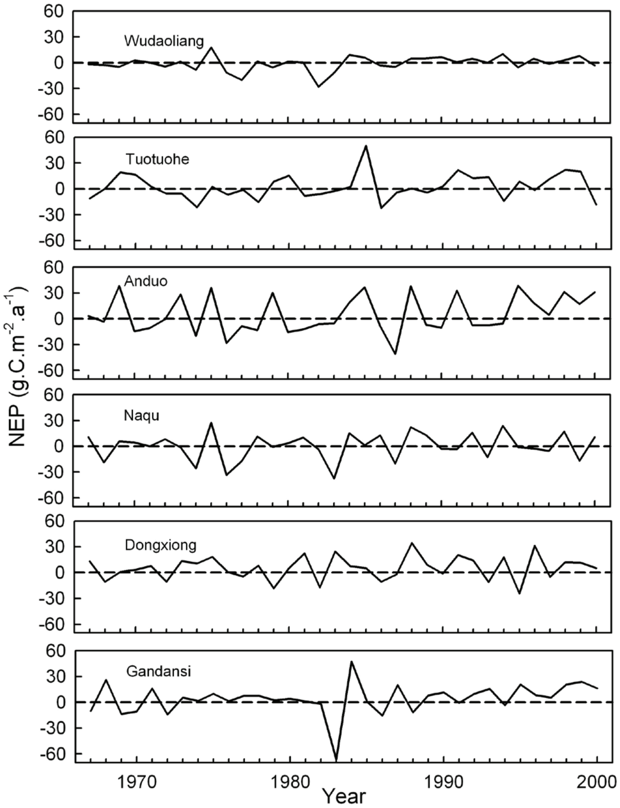

Figure 2. Changes in net ecosystem production (NEP) for the six sites along the north-south transect as simulated by the Terrestrial Ecosystem Model (TEM) during the period from 1967 through 2000.

(Fig. 2). During the past three decades, simulated NEP at the six sites differs in variation pattern, with small interannual variations in Wudaoliang and large variations in Anduo and Gandansi. The terrestrial ecosystem in Wudaoliang is a very weak carbon source with the average value of -0.87 $g.C.m^{-2}.a^{-1}$, while the terrestrial ecosystem in Naqu acts as a very weak sink with the value of 0.31 $g.C.m^{-2}.a^{-1}$. From north to south along the transect the terrestrial ecosystems in other the four sites are carbon sinks with values of 2.49, 5.19, 5.35 and 4.21 $g.C.m^{-2}.a^{-1}$ in Tuotuohe, Anduo, Dangxiong and Gandansi, respectively.

Monthly variation in NEP

We calculate the mean monthly NEP from 1990–2000 and compare the seasonal variation patterns in NEP among the six sites (Fig. 3). From January to May, most sites along the transect act as a carbon source, except that Dangxiong and Gandansi are weak sinks in May with the values of 1.37 and 0.26 $g.C.m^{-2}.month^{-1}$, respectively. The NEP for all sites has switched from a net source to a net sink in June except for Tuotuohe. In October, the NEP for all sites has switched from a net sink to a net source except that Gandansi acts as a sink with the value of 5.99 $g.C.m^{-2}.month^{-1}$. From north to south along the transect, the number of months with carbon sink increased gradually from three months in Wudaoliang (from June through August) and Tuotuohe (from July through September), four months in Anduo and Naqu (from

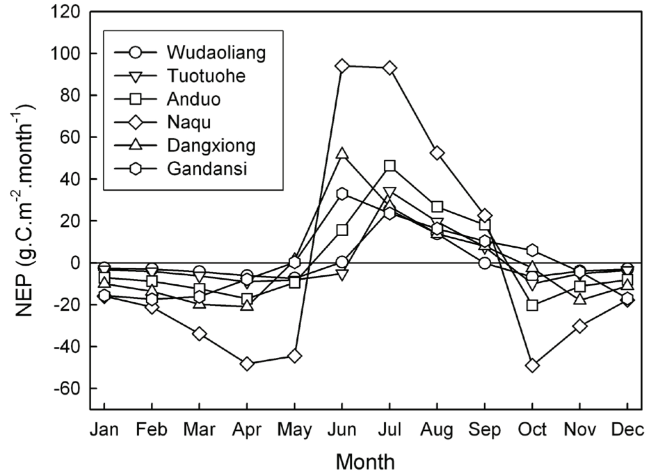

Figure 3. Mean monthly NEP values for the six sites along the north-south transect as simulated by the Terrestrial Ecosystem Model (TEM) during the period from 1990 through 2000.

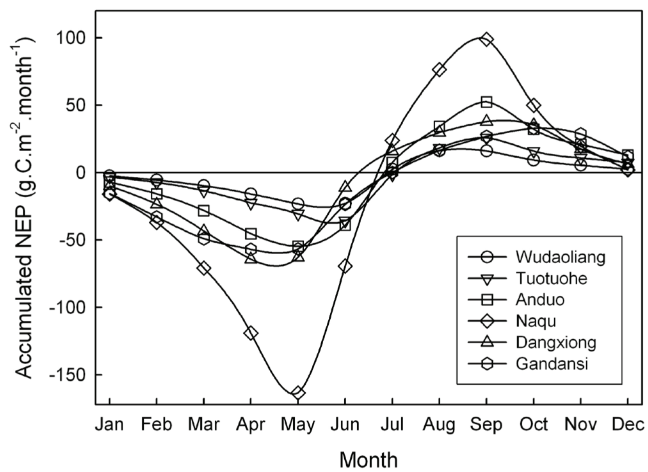

Figure 4. Accumulated mean monthly NEP values for the six sites along the north-south transect as simulated by the Terrestrial Ecosystem Model (TEM) during the period from 1990 through 2000.

June through September), five months in Dangxiong (from May through September), to six months in Gandansi (from May through October) due to water-heat increase trend from north to south along the transect. The mean NEP in months with sink increases from 13.18 $g.C.m^{-2}.month^{-1}$ in Wudaoliang to 65.59 $g.C.m^{-2}.month^{-1}$ in Naqu and then decreases to 14.97 $g.C.m^{-2}.month^{-1}$ in Gandansi. For the inter-annual variation pattern, the estimates of monthly NEP for Naqu vary between -49.02 $g.C.m^{-2}.month^{-1}$ in October and 94.13 $g.C.m^{-2}.month^{-1}$ in June, and demonstrate considerably more variation than for other five sites. As for the inter-annual variation in accumulated NEP values (Fig. 4), the alpine tundra ecosystem in all sites has offset the amount of carbon released to atmosphere and sequestered carbon from atmosphere in July except for Tuotuohe, which begin to store carbon in ecosystem until August. In all sites, the ecosystem sequestering carbon activities occurred first in Dangxiong (Fig. 4). Similar to the intra-annual variation pattern in monthly NEP, the accumulated monthly NEP for

Naqu also shows considerably more variation than for the other five sites.

Temporal responses of NEP to climate

There are different temporal responses of NEP to temperature, precipitation, soil temperature, and moisture among the six sites. In general, climate in growing season (from May to September) plays a more important role than annual climate in affecting NEP in alpine tundra ecosystems (Table 3). For trends in annual climate during the past three decades (Table 3), simulated annual NEP and annual soil temperature within 20 cm depth are uncorrelated across six sites, and meanwhile simulated annual NEP and annual temperature and precipitation are also uncorrelated for all sites except for Gandansi. NEP trends are negatively correlated with annual soil moisture in Tuotuohe and Anduo. As for the relationships between NEP and climate in growing season (Table 3), estimates of annual NEP are positively correlated with the mean air temperature and soil temperature from May through September for Wudaoliang, Anduo, and Naqu. Mean soil moisture from May through September is negatively correlated with NEP for Anduo and positively with NEP in Gandansi. From the 1970s to the 1990s, mean temperature in growing season increased for all six sites (Fig. 5). In comparison to the 1970s, precipitation in growing season increased in the 1990s for all sites except for Tuotuohe in which the precipitation decreased by 36.32 mm. When both temperature and precipitation are considered, during the growing season five sites experienced warmer and wetter conditions over the three decades, and only one site (Tuotuohe) became warmer and drier (Fig. 5). In response to climatic change, NEP increased for all sites during the past three decades (Fig. 5). In the 70's, only two sites (Dangxiong and Gandansi) acted as a carbon sink, three sites (Tuotuohe, Naqu, and Dangxiong) became carbon sink in the 1980s, and all sites became carbon sink in the 1990s with the highest decadal NEP value of 11.20 in Gandansi.

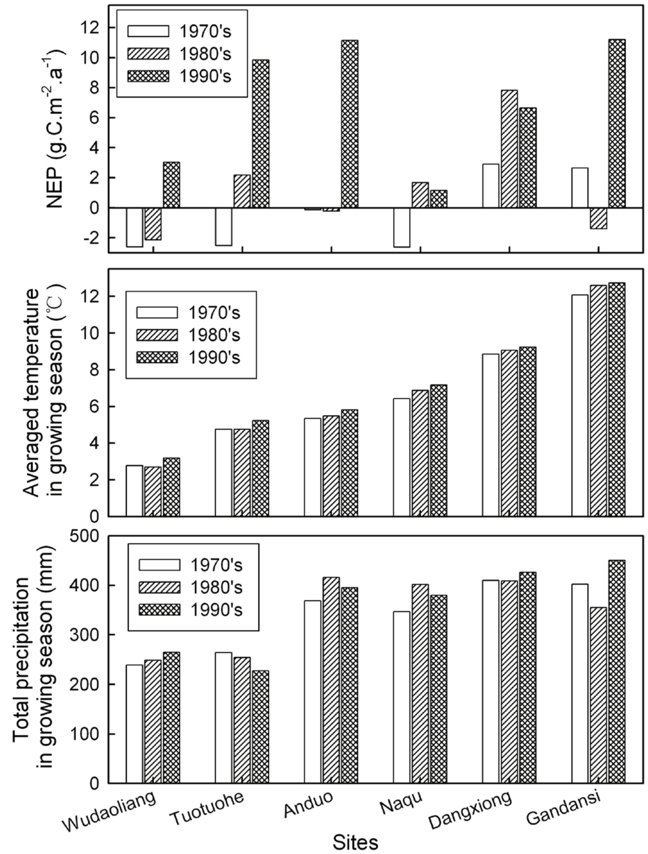

Figure 5. Mean NEP, averaged temperature and precipitation in growing season (May–September) in the 1970s, the 1980s and the 1990s for the six sites along the north-south transect.

Discussion

Using the TEM, we evaluate the NEP variation patterns in six sites dominated by alpine tundra in Tibetan permafrost region during the period from 1967 to 2000. Our results indicate that the alpine tundra ecosystems in the permafrost region mostly act as a carbon sink over the last three decades, which is consistent with the finding based on carbon flux measurements (Xu et al. 2005a, b, Zhao et al. 2005) and static closed chamber measurement data (Zhang et al. 2005) in other sites on the Tibetan plateau.

In the alpine shrub tundra ecosystem in Haibei of northeastern Tibetan plateau (101°19′E, 37°37′N, 3200 m), CO_2 flux observation data show that net CO_2 influx occurred from June to September, and net CO_2 efflux occurred from January to May and October to December with peak influx in August and peak efflux in April (Xu et al. 2005a, b). Our simulated NEP values show similar monthly variation pattern as that in Haibei. In our results, most sites along the transect acted as a carbon sink from June to September and had the lowest NEP in April and the highest NEP in June or July (Fig. 3). In comparison to the observation data in Haibei, our simulated mean NEP values during the 1990s for all sites, varying between 3.03 and 11.2 $g.C.m^{-2}.a^{-1}$ (Fig. 5), were less than 61.91 $g.C.m^{-2}.a^{-1}$ for alpine shrub ecosystem

(Xu et al. 2005a, b) and 76.91 $g.C.m^{-2}.a^{-1}$ for alpine meadow ecosystem, close to 14.45 $g.C.m^{-2}.a^{-1}$ for alpine shrub meadow ecosystem, and much higher than -130.36 $g.C.m^{-2}.a^{-1}$ for alpine swamp meadow ecosystem (Zhao et al. 2005) in Haibei. These differences in NEP values may be due to higher altitude, lower temperature, shorter growth period, and different plant species in the transect. Our simulated mean NEP during the 1990s is also less than the value of 71.12 $g.C.m^{-2}.a^{-1}$ for alpine grassland ecosystem, calculated from the empirical model between CO_2 emission amount and soil surface temperature in Pangkog (90.01°E, 31.23°N, 4800 m) on the Tibetan plateau (Zhang et al. 2005). This difference suggests that spatial variability in climate, soil, and vegetation is important in determining patterns of ecosystem NEP. Compared to the arctic tundra ecosystem, our estimates of mean NEP during the 1990s for Tuotuohe (9.85 $g.C.m^{-2}.a^{-1}$), Anduo (11.14 $g.C.m^{-2}.a^{-1}$), and Gandansi (11.20 $g.C.m^{-2}.a^{-1}$) are very close to the mean annual NEP of Pan-Artic (10 $g.C.m^{-2}.a^{-1}$) and substantially less than the value for moisture tundra in the Kuparuk River Basin, which fluctuated around 25 $g.C.m^{-2}.a^{-1}$ (McGuire et al. 2000).

In the Pan-Arctic, simulated NEP in moisture tundra is more correlated with soil moisture than with air temperature (McGuire et al. 2000), and the same relationships are also found in Tuotuohe and Anduo in our study. For tundra in northwestern Alaska, NEP trends during 1981–2000 are negatively correlated with air temperature trends and positively correlated with precipitation trends (Thompson et al. 2005). In contrast, we didn't find the same correlations in this research. The results from Thompson et al. (2005) indicated that NEP for tundra in northwestern Alaska decreased in warmer and drier conditions or warmer and wetter conditions while in colder and wetter conditions, NEP would increase. In this study, the alpine tundra ecosystems in five sites experienced warmer and wetter conditions over the three decades and one (Tuotuohe) experienced warmer and drier conditions (Fig. 5). However, in comparison to the values in the 1970s, NEP increased for all sites during the past three decades (Fig. 5). Contrary to the results of Thompson et al. (2005), our study indicates that the warmer climate states result in increases in NEP, rather than decreases. Future warming will result in an even more extensive and rapid permafrost degradation in the permafrost region. The warmer and wetter condition in the Tibetan Plateau will likely enhance its carbon sequestration in the terrestrial ecosystems.

Conclusion

In this study, we evaluate the terrestrial carbon dynamics for six sites in permafrost region from 1967 to 2000 with the biogeochemistry TEM. We find that the alpine tundra ecosystems in most sites act as a carbon sink varying between 5.35 $g.C.m^{-2}.a^{-1}$ in Dangxiong and 0.31 $g.C.m^{-2}.a^{-1}$ in Naqu during the past three decades. As for the seasonal variation patterns in NEP among the six sites, from January to May, most sites along the transect act as a carbon source. The NEP for all sites switches from a net source to a net sink in June except for Tuotuohe. In October, the NEP for all sites switches from a net sink to a net source except for Gandansi. Moreover, there are different temporal responses of NEP to changes of air temperature, precipitation, soil temperature, and moisture among the six sites. Generally, climate in the growing season (from May to September) plays a more important role than annual climate in affecting NEP in alpine tundra ecosystems. In comparison to the 1970s, precipitation in the growing season increases in the 1990s for all sites except for Tuotuohe. So the alpine tundra ecosystems in five sites experienced warmer and wetter conditions over three decades, and one site (Tuotuohe) experienced warmer and drier conditions. In response to climatic change, NEP increased at all sites during the three decades. In the 1970s, only two sites (Dangxiong and Gandansi) acted as carbon sinks, three sites (Tuotuohe, Naqu and Dangxiong) became carbon sinks in the 1980s. All sites became carbon sinks in the 1990s. Our analysis suggests that the changes of soil temperature and moisture conditions due to changes in permafrost conditions have significant effects on terrestrial ecosystem carbon dynamics. The future quantification of carbon budget in the Tibetan Plateau should consider the NEP spatial variability induced by changes of soil temperature and moisture associated with permafrost dynamics.

Changes of Permafrost and the Cold-Region Environment in Northeastern China

Ruixia He, Huijun Jin, Lanzhi Lü, Shaopeng Yu, Shaoling Wang, Dongxin Guo
State Key Laboratory of Frozen Soils Engineering, Lanzhou, China 730000

Abstract

Extensive air-temperature inversions in the winter affect the development and distribution of permafrost in the Xing'anling Mountains, Northeastern China. Permafrost is thicker and colder in lower topographic positions. Wetlands and permafrost are interdependent. Permafrost conditions are closely related to surface coverage conditions. The cold-region environment has been greatly affected by climate warming and human activities during the past 50 years. Permafrost has been degrading as evidenced by the deepening active layer, thinning permafrost, rising ground temperatures, expanding taliks, disappearance of patches of permafrost, and the significant northward shift of the southern limit of permafrost. Under the projected climate warming, there would be significant degradation of permafrost and resultant environmental changes. In particular, degradation of permafrost would lead to land desertification on the Hulun Buir Plateau at the west flank of the Da Xing'anling Mountains and on the northern edge of the Songnen Plain, adversely affecting the regional sustainable development.

Keywords: assessment; cold-region environment; engineering projects; permafrost; urbanization; Xing'anling Mountains.

Introduction

Systematic geocryological studies in Northeastern China began in the early 1950s. Several important projects were conducted in the 1960s and 1970s, and the distribution and evolution of permafrost became better understood. In the 1970s, field expeditions, observations, and monitoring which focused on the development and distribution of permafrost, ground temperature, and ground ice were organized and sustained. The first map of permafrost (1: 3,000,000) was compiled based on engineering explorations, investigations, and climatic data (Guo et al. 1981, NECPRT 1983).

During the period from 1979 to 1980, the southern limit of permafrost was studied in detail through correlations of climatic variables and through field investigations along the delineated southern limit of permafrost from the correlations. From 1989 to 1992, the impact of forest fires on permafrost was observed and analyzed. The impact of climate warming on permafrost and its environmental effects also were investigated preliminarily. From 1990 to 2004, permafrost study was initialized to meet the needs for building civil infrastructures and because of increased environmental concerns. Since 2004, permafrost research has been re-activated by the Third-Term Knowledge Innovative Project of the Cold and Arid Regions Environmental and Engineering Research Institute, Chinese Academy of Sciences. The need for better understanding the frozen-ground conditions for the construction of the China-Russia crude-oil pipeline project from Skovorodino, Russia, via Mo'he, China, to Daqing, China, and the Mo'he Airport provided further incentive and funding for geocryology.

At present, the research mainly focuses on relationships among climatic and environmental changes in permafrost regions, interactions of permafrost, forested wetland and snow cover, and the changes of land use in the northern part of Northeastern China. This paper reviews the changes of permafrost and the cold-region environment in Northeastern China, in which the latest data obtained during the surveys and studies of permafrost conditions for the China-Russia Pipeline and Mo'he Airport projects, and field investigations on permafrost and periglacial phenomena in July–August 2007 are incorporated. It also includes the interactions between permafrost and human activities.

Although the degradation of permafrost in Northeastern China has been of considerable concern during recent decades, the research on the mechanisms and the processed-based modeling and prediction of permafrost degradation and its impacts on the cold-region environment are not well established. The Xing'anling Mountains contain the largest cluster of forests and wetlands and, consequently, the habitats and national reserves of many endangered species particularly sensitive to changes of permafrost, climate, and anthropogenic disturbances. Several national key construction projects, including the China–Russia crude-oil pipeline, Hei'he to Dalian Expressway, high-speed railway from Harbin to Dalian, require further investigations on frozen-ground engineering to provide a timely scientific base for frost hazard mitigation. Therefore, the studies on the degradation, mechanisms, trends, and environmental impacts of permafrost in the mountains under influences of climate warming and anthropogenic activities can provide scientific bases for regional environmental management and societal and economic development.

Study Region

Permafrost in Northeastern China is located on the eastern margin of the Eurasian Continent. The Xing'anling Mountains are located in the northern and western parts of Northeastern China (Fig. 1). The elevation of the Da Xing'anling Mountains ranges from 500 to 600 m in the northern section to 1,000 to 1,400 m in the middle section, and further to more than 2000 m in the southernmost section, with its highest peak (Huanggangliang Mountains) at 2029

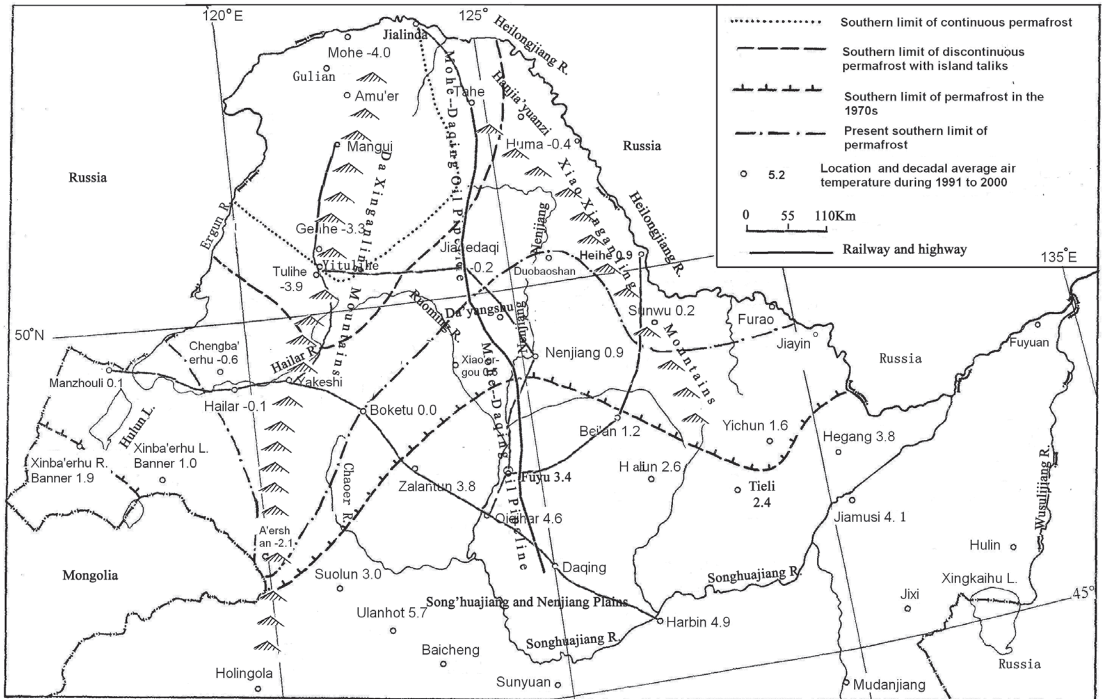

Figure 1. Study area map showing permafrost distribution and changes of the SLP in the Xing'anling (Hinggan) Mountains (revised from Jin et al. 2007a, with permission from the John Wiley & Sons, Ltd.).

m. In contrast, the Xiao Xing'anling Mountains are gentler in topography, with meandering river channels, elevations of 500 to 600 m, and few peaks higher than 800 m.

The mountains are comprised of Late Palaeozoic granites, and Cenozoic volcanic formations, with sporadic Paleozoic metamorphic and sedimentary rocks. Since the onset of the Quaternary, the mountains have been slowly and differentially uplifting, and have been subjected to long-term erosion and leveling. The slope deposits on the upper parts of the mountains are predominately angular gravel or sandy clay with gravel, generally only 1–2 m in thickness, and with a layer of humic topsoil 0.1–0.2 m in thickness. However, in piedmont areas, intermontane basins and valleys, deposits from debris flows, fluvial, and slope processes are as much as 10–15 m thick. In typical soil profiles, peat and humic soil are underlain by clayey sand and sandy clay with sand and gravel (Zhou et al. 2000).

The region is characterized by a temperate continental monsoonal climate with long, cold winters and short, hot summers. Mean annual air temperatures range from 0~+1°C in the south to -5~-6°C in the north. The average annual precipitation ranges from 500–700 mm in the southeast to less than 200 mm in the northwest. Rainfall in summers accounts for 80–90% of the annual precipitation. The Siberia high pressure in winter causes an extensive air temperature inversion which strongly affects the development and distribution of permafrost. A large part of the region is covered with dense forests, or shrubs, or wetlands.

The Hulun Buir Plateau is at the northwestern flank of the Da Xing'anling Mountains. It is gentler in topography with low relief and surrounded by hills. As a main body of the plateau, the Hailar platform is located in the central part. Loose Quaternary strata are widely distributed along the Hailar, Hui, and Wu'erxun Rivers. The upper part of soil profile is composed of silt and sand, generally its thickness varies from 20 to 50 m. The lower part consists of gravels, with thicknesses of 30–60 m. The landscape changes from forest to steppes to the west of the Yimin River.

Evidence of Permafrost Degradation

Although the features of permafrost are largely controlled by latitude, elevation, and longitude, they vary greatly within a relatively small area. The extensive air temperature inversion in winter greatly affects the development and distribution of permafrost. As a result, permafrost is thicker and colder in lower topographic positions than at higher elevations (Lu et al. 1981, Guo et al. 1981). Although the thickness of permafrost gradually increases northwards and northwestwards, it is further complicated by local geology, geography, snow cover, and vegetation. In addition, permafrost has been remarkably affected by anthropogenic activities.

Evidence of permafrost degradation

During the last few decades, permafrost has been remarkably affected by climate warming and increasing human activities. Permafrost degradation is shown by the deepening active layer, thinning permafrost, rising temperature, expanding taliks and the disappearance of permafrost patches (Zhou et al. 1996, Jin et al. 2006). The southern, or lower limit of permafrost has shifted significantly northward and upward (Jin et al. 2006, 2007a).

Northward shifts of the southern limit and areal reduction

Because of its marginal nature, permafrost in Northeastern China is very sensitive to external disturbances. Formation and degradation of permafrost has happened many times during the Pleistocene and Holocene (Guo & Li 1981). The main body of existing permafrost was formed during the Last Glaciation Maximum. There is a very statistically significant correlation between the mean annual air temperatures and the southern limit of permafrost (Guo et al. 1981). Based on the average air temperatures during 1991–2000, and extensive ground-truthing, the southern limit of permafrost has shifted evidently northwards, as much as 50–120 km in some areas (Jin et al. 2007a). The area of permafrost was reduced by 35%, from 390,000 km^2 in the 1970s (Lu et al. 1981) to 260,000 km^2 in the late 1990s (Jin et al. 2006, 2007a).

Deepening active layer and disappearing permafrost patches

The permafrost table has been lowering. The depths of maximum thaw have been increasing. For example, the depth of the active layer in the Amu'er area in the northern Da Xing'anling Mountains was less than 0.8 m during the 1970s. By 1991, it had increased to 1.2 m (Gu et al. 1994). Some patches of permafrost identified in the 1960s and 1970s have disappeared. For example, a permafrost island with the permafrost table at 1.7 m was observed near Jiagedaqi during railway construction in 1964, but by 1974 permafrost was absent under the rail roadbed. Many patches of permafrost from Dayangshu to Wuerqi, and even to Jiagedaqi, have disappeared according to the latest investigations and surveys in 2007.

Thinning and warming of permafrost

Borehole 14 at the former Yituli'he Permafrost Observatory is located in an undisturbed meadow on the first terrace of the northern bank of the Yituli'he River. The mean annual soil temperatures at shallow (<20 m in depths) have warmed as a result of the combined influence of rapid urbanization, disturbance from road construction and use, urban heat-island effects, and climate warming. Ground temperatures at 13 m increased by about 0.2°C between 1984 and 1997 (Jin et al. 2006). Permafrost degradation also has led to the change of its thermal stability types and the expansion of taliks. Some periglacial processes, such as thermokarsting and thaw-slumping, have been enhanced.

Factors Affecting Permafrost Degradation

Climate change

The main reason for extensive degradation of permafrost is climate warming (Gu et al. 1994, Jin et al. 2007). During the past century, the average temperature in Northeastern China had increased by 1.7°C. The mean annual air temperatures of the Da Xing'anling Mountains were increasing from 1954 to 1989 (Yan 1994). During the past 120 years, the mean annual air temperature in Heilongjiang Province has increased by 1.4°C; with the maximum increase in winter and spring (Pan et al. 2003). The warming during 1971–2000 was 1.4°C more than during the 30 years from end of the 19th century

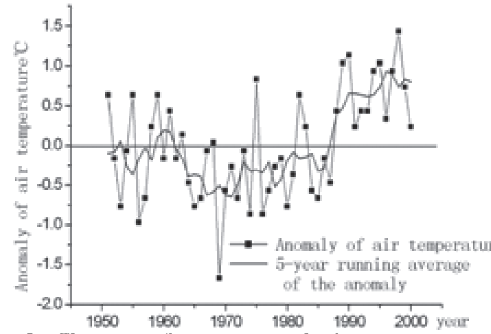

Figure 2. Changes of mean annual air temperature of the Da Xing'anling Mountains during 1961–2000.

to the early 20th century (Pan et al. 2003). Observations at 33 local stations confirmed a similar trend. The mean annual air temperatures during 1971–2000 were 0.9~2.2°C higher than those in the 1960s (Fig. 2) (Jin et al. 2007a). The intensity of warming in the north is more prevalent than that in the south, and the largest warming occurred in the northern Heilongjiang Province and eastern Inner Mongolia, where the mean increase rate was 0.08°C/year.

Increasing anthropogenic activities

There were few human activities in Northeastern China before the 19th century, and the natural environment was not significantly disturbed before the 20th century. During the 1930s to 1940s, the natural environments were devastated because of the Japanese occupation. Since the 1950s, the forest farming in Xing'anling Mountains has increased significantly. Town buildings, forestry, traffic, and transportation were constructed and expanded. In the late 1960s, large amounts of forests were felled for building the Nenlin Railway and the subsequent rapid expansion in population. Establishment and growths of new towns necessitated further deforestation. Long-term, illogical exploitation of forest resources has significantly reduced the forested areas, and remarkably and extensively changed the natural environments. The forested belts retreated northwards by as much as 150–200 km compared to those in the late 19th century. According to a forestry bureau in the Xiao Xing'anling Mountains, the percentage of local forest coverage decreased from 94% in 1957 to 10% in 1980 (Zhou et al. 2000). The extremely serious forest fire in May to June 1987 also changed the albedo of the ground surface and subsequent radiation balance, air and soil temperatures, and soil moisture, resulting in a significant change in the distribution and thickness of permafrost in the Da Xing'anling Mountains (Zhou et al. 1993).

There were about 20,600 people in the 1950s. This number increased to 540,000 by 1994 (Zhou et al. 2002). The population growth necessitated the construction of more infrastructures, such as railways, roads, and buildings. Engineering construction inevitably introduced disequilibrium in the thermal balance and temperatures of permafrost, resulting in various thawed zones, deepened active layers, and accelerated permafrost degradation. For example, in Yakeshi, Jiagedaqi, and Dayangshu near the southern limit of permafrost, there were patches of permafrost everywhere in the early 1950s and 1960s when the towns were

Table 1. Comparison of decadal average air temperature at the Gen'he (50°47′N, 120°30′E, 717 m) and Tuli'he (50°29′N, 120°04′°E, 733 m) meteorological stations during 1961–2000.

Station	Decadal average air temperature (°C)			
	1961–70	1971–80	1981–90	1991–2000
Gen'he	-5.5	-5.0	-4.0	-3.3
Tuli'he	-5.4	-5.0	-4.3	-3.9

Note: The average ground surface temperature at two stations from 1960–1980 was -4.1°C.

Table 2. Comparison of average of mean annual air temperature (AMAAT) and average ground-surface temperature (AGST), maximum frost depths (MFD), and date of thaw completion (DTC) at Gen'he and Tuli'he meteorological stations during 2000–2004.

Station	AMAAT (°C)	AGST (°C)	MFD (cm)	DTC
Gen'he	-3.4	-1.8	260	Late June
Tuli'he	-4.1	-2.6	300	Late July

booming. After 20–40 years of human activities, permafrost has been difficult to find. Urbanization and its "heat-island" effect on permafrost degradation were recognizable. The Gen'he and Tuli'he Forestry Bureaus were set up in 1953, in the discontinuous permafrost zone with natural *larch* forest. The mean annual and decadal average ground temperatures were little changed before 1980s. The Gen'he Forest Bureau had a population of 70,000 in the early 1990s. After the Gen'he City was founded in 1994, the population increased to 180,000 in an area of 19,929 km^2 (Zhou et al. 2002). The city dimensions are 3–4 times those of Tuli'he. It is apparent that the average temperature of Gen'he was 0.6°C higher than that of Tuli'he during 1991–2000 (Table 1). The depth of maximum seasonal frost penetration in Gen'he is 40 cm shallower than that in Tuli'he, and the completion of thawing of the seasonally frozen layer is 1 month ahead (Table 2).

Degradation of Permafrost and Environment

During recent decades, the rapid degradation of permafrost has led to a series of changes in local environments. The major impacts include wetlands degradation, grassland desertification, and shifts of forest types.

Permafrost degradation and changes in wetlands

Freshwater marshes and shallow lakes in Northeastern China, with a total area of 67,378 km^2, account for 17.5% of the total wetlands areas in China (Wang & Du 2006). Coexisting with permafrost, the wetlands in the Da Xing'anling Mountains, with a total area of 8,245 km^2, are mainly located in river valleys, on gentle slopes, and on divides of watersheds. The wetlands in the Xiao Xing'anling Mountains are mainly distributed in the wide valleys and the gulches adjacent to the watershed divides, more on the northern slopes than on the southern slopes.

The wetlands have been gradually shrinking due to the persistent climate warming and drying, permafrost degradation, deforestation, land reclamation, and other anthropogenic activities such as engineering construction and operation, urbanization, overgrazing, and land reclamation. According to a survey report, the area of rivers, marshes, and shrub wetlands in Wuma Forestry Bureau had decreased by 17.4 km^2 in 2001 compared to 1989 (Dai 2007). Further reduction in areal extent of herbaceous swamps was projected under climate change scenarios in the future.

Among the many factors contributing to the changes of wetland ecosystems in the Da Xing'anling Mountains, the single most important one was probably permafrost degradation . In permafrost regions, wetlands are developed in the active layer, which is the interactive interface for mass and heat transfers between permafrost and the external environments. The marsh vegetation layer and the underlying peat layer possess unique thermal properties for insulation and water conservation (Jin et al. 2007b). As a result, they facilitate the formation of permafrost and protect it.

At the meantime, the permafrost layer effectively withholds the downward infiltration of water into soil strata, resulting in ponding at ground surface. A variety of nutrients leached from the active layer enriched here is conducive to the growth of marsh plants. It again facilitates water collection on the surface and formation of an anaerobic environment with slow and decreased decomposition of organic matter.

The freeze-thaw processes have controlling effects on the development, distribution, and degradation of wetlands (Jin et al. 2007b). In recent decades, with the rapid degradation of permafrost, the frozen layer gradually has become thinner. When permafrost is less than 40 cm in thickness, it will be thawed by mid- to late April, before the marsh plants sprout in early May; the soil moisture quickly infiltrates and the ensued physiological drought of plants will adversely affect the swamp development (Zhao & Du, 1980). As a result, the degradation of permafrost inevitably leads to the shrinkage of wetlands, which degrades permafrost (Wang 1983).

Relationship between permafrost degradation and deterioration of the grassland ecosystem

The Hulun Buir Plateau consists of grasslands, wetlands, lakes, and deserts in a transitional zone between patchy permafrost and seasonally frozen ground. Located to the west of the Da Xing'anling Mountains, the Hulun Buir Sandy Land has an annual precipitation of about 350 mm but with good vegetation coverage. It is still considered one of the best pastoral areas in China. However, three sandy belts have developed and are expanding, eroding into the grasslands (Sun & Liu 2001).

According to the 3rd Grassland Resources Investigation, the total grassland area in the Hulun Buir was 112,980 km^2 during 1981–1985, in which the Aeolian-desertified area was 20,970 km^2. By the end of 2002, the area of existing grasslands was 100,878 km^2, with the sandy area of 38,828 km^2. About 12,102 km^2 of grasslands, or 10.7%, were lost during the past 20 years. The aeolian-desertified area increased from 20,970 km^2 (18.6%) in the 1980s to 38,828 km^2 (38.5%) in 2002 (Huang et al. 2003). A survey on desertification on the Hulun Buir Grassland indicates that the total area of aeolian-desertified land has been expanded, to 11,413 km^2, which is about 3.3% more than that in the 1990s (Nie et al. 2005).

The deterioration of the Hulun Buir grassland ecosystem is attributed not only to natural causes, such as climate warming and permafrost degradation, but also to human activities, such as over-exploitation of water, land, and biological resources, among which the degradation of permafrost may have played an important role in the deterioration of the grasslands ecosystems.

Permafrost degradation could lead to deeper freezing and thawing, and resultant thermokarst, solifluction, and thaw-slump. Freeze-thaw cycles weaken soils structurally, and strengthen the frost weathering and mineralization of organics, resulting in intensifying damages to soil surfaces. The bare soil surface becomes material sources for desertification and is conducive to soil erosion. Permafrost degradation causes the reduction of soil moisture at the plant roots layer, drying of surface soils and wetlands, rising ground temperatures, and changes in soil structures and composition, facilitating grassland degradation. Therefore, permafrost, to a certain degree, constrains and impacts the trends and intensity of changes in the grassland eco-systems. In the permafrost zone, when vegetation coverage is reduced, surface heat absorption increases, ground temperatures rise, and depths of seasonal thaw penetration increase, accelerating permafrost degradation.

Changes of forest ecosystem

The Xing'anling Mountains are the northernmost and largest forested areas in China, with an area of 84,600 km^2. As the representative of bright-leaved taiga in Northern China, it belongs to the taiga area characterized by cold climate and simple forest structure, which mainly includes *Larix gmelinii*, *Pinus sylvestris var. mongolica,* primeval *Betula platyphylla* forests, and secondary forests and other underwood, and underherb (Zhang et al. 1995).

In the Da Xing'an Mountains, where about 81% of frozen ground has Xing'an *larch* forests, is the largest continual coniferous forest in China. Permafrost is necessary for the natural evolution of the Xing'an *larch*, which relies on the suprapermafrost water to keep growing in a shallow-rooted pattern over a long time, and to store freshwater with permafrost, forming a typical frost-forest environment.

Natural forests in permafrost regions are controlled by a frozen-ground environment. However, the degradation or disappearance of permafrost can result in ground subsidence, drunken forests, or dead woods. In a forest farm of Gen'he Forestry Bureau, 6,000 m^3 of woods fell and the thermokarstic subsidence hollow expanded at a rate of 10 m/year, resulting in the losses of woods (Zhou et al. 2003).

The degradation of permafrost and shifts in the southern limit of permafrost can cause a change of vegetative distribution and types (Tan & Li 1995). Patchy permafrost used to exist in Dayangshu in the 1960s, but it had disappeared by 1978. Primeval Xing'an *larch* forests disappeared gradually and were replaced by secondary *Populus davidiana* and *Betula platyphylla* forests, and further became *lespedeza* and *hazelnut* forests (Zhou et al. 2003). The enhanced air and ground temperatures had an impact on forest. As a result, the Xing'an larch forest belt moved northwards. For example, the Xing'an larch used to be common in Yakeshi in the west, but it is seldom sighted. In Nenjiang in the south, primeval forests have already been replaced by secondary forests (Tang & Li, 1995).

At present, the degradation of permafrost is accelerating. As a result, the areal extent of forests in permafrost regions is shrinking, and the vegetation system of the original Xing'an *larch* is being threatened because of human activities such as tree felling, land reclamation, mine exploitation, road construction and operation, anthropogenically-enhanced occurrences of forest fires, and influences of climate warming and permafrost degradation.

Conclusions

1. Due to the pronounced climate warming and increasing anthropogenic activities, permafrost has been degrading rapidly in Northeastern China as evidenced by the deepening active layer, thinning permafrost, rising ground temperatures, expanding taliks, and disappearance of permafrost patches.
2. A series of cold-region ecological and environmental changes were observed, some with adverse consequences.
3. It was estimated on the basis of changes in mean annual air temperatures, and partially verified by field investigations, that the southern limit of permafrost in Northeastern China has shifted significantly northwards, as much as 50–120 km in some areas, during the last 30 years. However, most of the surveys were made along major linear engineering corridors, which may have been more impacted by construction and operation of engineering infrastructures and other human activities.
4. Cold-region ecological environments have changed noticeably, such as vanishing wetlands, deforestation, desertifying grasslands and wetlands, and enhanced water and soil erosion.
5. Human activities, typically represented by rapid urbanization and engineered infrastructures, have cast significant influences on permafrost and the cold-region environment in Northeastern China, as many more people were supported there that other permafrost regions on earth.
6. The key to the study of environmental management and protection in the northern part of Northeastern China is to understand permafrost dynamics and the changes of permafrost environments under a changing climate and intense anthropogenic activities. Long-term, in-depth, and integrated research should be conducted to manage, protect and rehabilitate the damaged ecological environment, in order to healthily sustain the socio-societal and economic development in the cold region in the northern Northeastern China.

Abstract

An Electrical Resistivity Tomography (ERT) monitoring network has been installed in different permafrost landforms in the Swiss Alps. Repeated ERT measurements yield information on changes occurring in the physical properties of the ground with changing temperature and time. Because the sensitivity of electrical resistivity to temperature is mainly due to the amount of unfrozen water in the pore space of the subsurface material, temporal resistivity changes can be related to freezing and thawing processes. The combined analysis of borehole temperature and ERT monitoring data is used to determine temporal changes of ice and unfrozen water. Key results from this approach include (a) the determination of site-specific total resistivity ranges (as a function of ice content) and amplitudes of seasonal resistivity changes, (b) the demonstration of 3D-topography effects on resistivity distribution in ridge situations, and (c) the identification of depth dependent resistivity-temperature relationships as a function of depth related unfrozen water contents.

Keywords: electrical resistivity tomography; monitoring; mountain permafrost; PERMOS; temperature.

Introduction

Within the context of climate change, the European Alps are affected by greater average warming than commonly projected for Europe as a whole (Beniston et al. 1997). The consequences of global warming for permafrost have been investigated and observed in polar regions for many years (e.g., Osterkamp et al. 1983, Nelson et al. 2001, Frauenfeld et al. 2004, IPCC 2007). In contrast to mainly flat polar lowlands, mountain permafrost is strongly influenced by topographic factors (aspect, slope angle, altitude) affecting net solar radiation and snow cover distribution (Hoelzle et al. 2001). Spatial and temporal heterogeneities of these factors cause complex permafrost distribution patterns that are complicated by heterogeneous subsurface material compositions (bedrock; fine- and coarse-grained debris). Consequently, also the ice content differs markedly between different permafrost landforms.

In addition to temperature, ice content is one of the most critical parameters for the evaluation of the impact of global warming on rockwall stability. Direct observations of ice content are scarce and difficult to obtain. Indirect information from Electrical Resistivity Tomography (ERT) has great potential for detecting the presence of ice, because the specific resistivities of frozen and unfrozen material are markedly different. With repeated ERT measurements under constant general conditions, temporal changes of resistivities are assessed and can be related to freezing and thawing processes (Hauck 2002, Hilbich et al. 2008).

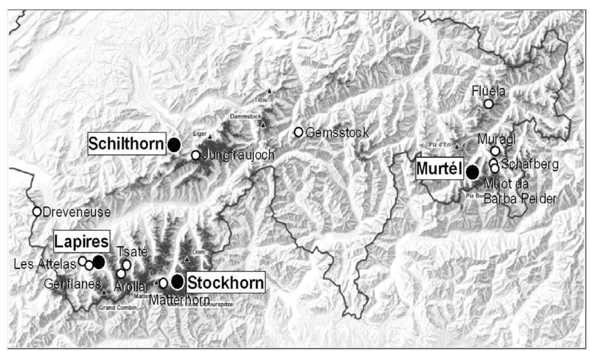

Figure 1. The PERMOS network in the Swiss Alps with borehole temperature monitoring sites (white dots) and combined borehole and ERT monitoring sites (black dots) (Map: BAFU 2007).

However, reliable and quantitative conclusions concerning climate-related changes in ice content can only be drawn when resistivity changes related to external water input (e.g., from precipitation, snowmelt, or lateral water flow) can be excluded (or distinguished from ice melt).

The newly installed ERT monitoring network within the Swiss permafrost monitoring network PERMOS (Fig. 1) provides a unique data set that facilitates study of the relations between measured resistivities and borehole tem

peratures in different permafrost landforms. Sites in the network include the *Schilthorn* (Bernese Alps) permafrost site, which has the longest (>8 years) record of ERT measurements (Hilbich et al. 2008). In this paper we analyze the potential of coupled ERT and temperature monitoring to improve resistivity-based estimates of total amounts and temporal changes of ice content in permafrost regions.

Theory and Methods

Borehole temperatures

In existing European and Swiss permafrost monitoring networks (PACE21, PERMOS (Harris 2001, Vonder Mühll et al. 2004)), subsurface temperature data are obtained in a network of shallow and deep (down to 100 m) boreholes. The PERMOS programme started in 1999 and involves 16 permafrost borehole-monitoring sites with the longest time-series at rockglacier *Murtèl* (Upper Engadine), recording since 1987. However, long-term climate-related degradation processes in terms of thawing phenomena cannot necessarily be identified by thermal permafrost monitoring alone, as the ice content depends on temperature evolution, and also on the availability of unfrozen water during the freezing period (Hilbich et al. 2008).

Electrical Resistivity Tomography (ERT)

The electrical resistance of the ground can be determined by passing a current between two electrodes and measuring the resulting potential difference between two other electrodes coupled to the ground. Repeating this procedure along an electrode array for a number of different 4-electrode combinations (quadrupoles) with different center points and spacing reveals a two-dimensional distribution of electrical resistances within a subsurface section. By multiplying a geometric factor representing the distance between the four electrodes, the apparent resistivity ρ_a is obtained for each data point of a certain multi-electrode configuration. Using the software package RES2D-INV (Loke & Barker 1995), a 2D model of specific resistivities ρ_s, i.e., the true resistivity distribution of the subsurface section, can be calculated from ρ_a by an iterative tomographic inversion process. All ERT data presented in this contribution were measured with the WENNER configuration, and the robust inversion scheme (Clairbout & Muir 1973) of the software RES2DINV was applied.

ERT monitoring

Within the ERT monitoring network a fixed electrode array was installed at four characteristic permafrost sites in the Swiss Alps. All electrodes of one array are permanently connected via cables to a contact box, which serves as an adaptor to a resistivity meter and can be accessed throughout the year (described in detail in Hilbich et al. 2008). Measurements can be carried out by only one person, even in winter, when the electrode array is covered with snow. ERT monitoring started in 1999 at the *Schilthorn* site, in 2005 at the *Murtèl* and *Stockhorn* sites, and in 2006 at the *Lapires* site (see section "Field Sites") and comprises roughly 10 measurements per site to date, except for *Schilthorn* with more than 100 measurements.

Dependence of resistivity on temperature

According to an empirical relationship called Archie´s Law, the resistivity of a medium (consisting of a rock or soil matrix and pore water) can be related to the resistivity of the water, the porosity, and the fraction of the pore space occupied by liquid water (Telford et al. 1990).

The sensitivity of electrical resistivity to temperature arises from different effects, above and below the freezing point. At positive temperatures, the resistivity of the pore water increases with decreasing temperature as a consequence of increasing viscosity of the pore water, which, in turn, decreases the mobility of the ions in the water. This can be quantitatively described as a linear function of the resistivity ρ_0 measured at a reference temperature T_0 and the temperature coefficient of resistivity α, which has a value of about 0.025 K^{-1} for most electrolytes (Telford et al. 1990):

$$\rho = \frac{\rho_0}{1+\alpha\,(T - T_0)} \qquad (1)$$

Below the freezing point, resistivities increase exponentially due to successive freezing of the pore water with decreasing temperatures. The subzero relationship between resistivity and temperature is given by:

$$\rho = \rho_0\, e^{-\,b(T)} \qquad (2)$$

where ρ_0 and b (in K^{-1}) are constants (e.g., Hauck 2002). The factor b controls the rate of decrease and can be determined from Equation (2) if resistivity data for different subzero temperatures are available.

Repeated ERT measurements therefore yield information on the changes occurring in the physical properties of the ground with changing temperature and time (Fortier et al. 1994). Plotting ground temperatures from boreholes (interpolated to the depths of the model blocks of the tomograms) against ρ_s extracted from ERT data at borehole positions (marked in Figs. 4–6) then allows comparison of the relation between T and ρ_s for different sites.

Field Sites

ERT monitoring sites have been chosen to represent different permafrost landforms, different climatic regions in the Swiss Alps, and with respect to the availability of deep boreholes (≥20 m). The landforms include the north-facing rock slope of *Schilthorn* (Bernese Alps), the rock plateau *Stockhorn* (Valais), the talus slope *Lapires* (Valais), and the active rock glacier *Murtèl* (Upper Engadine) (Fig. 1). All ERT profiles were placed close to at least one borehole to enable a calibration of the indirect geophysical measurements with direct observations of the subsurface material composition as made during drilling, and subsurface temperature records of the boreholes. A detailed description of the test sites is given in Table 1.

Results and Discussion

Eight-year ERT monitoring at Schilthorn

The ERT monitoring at *Schilthorn* started in September 1999 and comprises more than 100 datasets, making it the

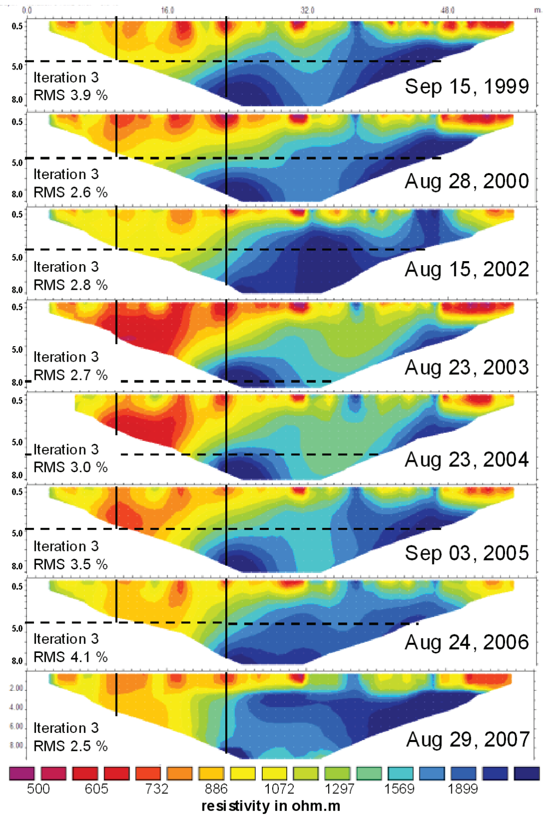

Figure 2. ERT monitoring results of Schilthorn: interannual comparison of late summer resistivity distribution (modified after Hilbich et al. 2008).

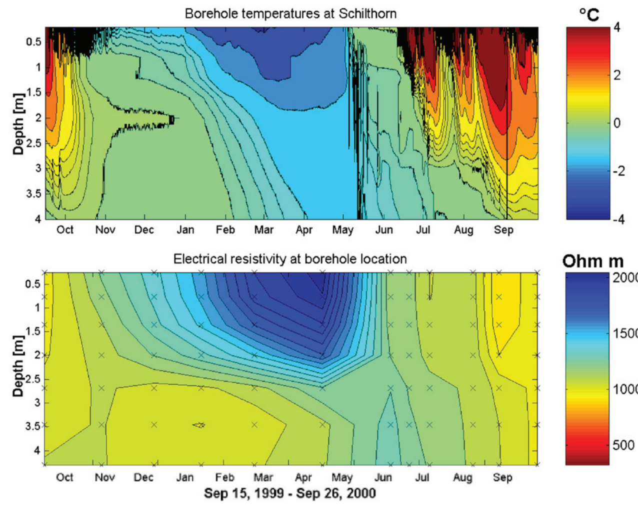

Figure 3. Comparison of temperatures (top) and interpolated resistivities at borehole location (bottom) for September 1999–September 2000 at *Schilthorn*. Resistivity data points used for interpolation are shown as black crosses.

longest ERT monitoring record in mountain permafrost research. A comprehensive analysis of this time series is given in Hilbich et al. (2008). Figure 2 shows the interannual changes between measurements in late summer for each year except 2001.

One of the most prominent features of the dataset is the effect of the extraordinarily hot summer of 2003 on mountain permafrost in the European Alps. According to the borehole temperatures, the summer of 2003 caused an immense deepening of the active layer to almost twice the depth of the years before (horizontal dashed lines in Fig. 2). But, in contrast to the subsurface temperatures, which returned rapidly to almost "normal" conditions in 2004, measured resistivities took about 4 years to recover to pre-2003 conditions. As stated before, temporal resistivity changes are assumed to be caused by freezing and thawing processes that are themselves controlled by temperature. The close relation between temperature and resistivity is evident from Figure 3, where borehole temperatures and specific resistivities at the borehole position are shown for the upper four meters and for a one year period (September 1999 to 2000).

ERT monitoring at different landforms

First results from ERT monitoring in different permafrost landforms reveal pronounced differences in total resistivity values and the amplitude of seasonal resistivity dynamics. The first is due mainly to site-specific material characteristics (lithology, pore volume, fractions of pores filled with air, ice, and unfrozen water, etc.), but the latter can have different causes. Besides local climatic effects controlled by altitude, aspect, snow regime, etc., such morphological characteristics as differences in substrate, active layer thickness, thermal conduction in the active layer, etc. play an important role for the amount to which seasonally variable atmospheric forcing is transferred into the ground. This becomes evident not only from the site-specific subsurface temperature regime but also from the resistivity changes throughout a year. Figures 4, 5, and 6 show tomograms with typical summer (top) and winter (bottom) resistivity distributions for the bedrock (*Stockhorn*), rockglacier (*Murtèl*) and talus slope (*Lapires*) sites. From the qualitative comparison, the most important site-specific characteristics are discussed qualitatively in the following paragraphs:

Stockhorn

The Stockhorn profile is located on a plateau between the steep (>80°) northern rock face, and the steeply inclined southern slope. Permafrost distribution is therefore assumed to be affected by 3D topography effects as described by Gruber et al. (2004) and Noetzli et al. (2008). Three-dimensional effects become evident in the ERT monitoring data by pronounced active layer freezing (increasing resistivities during winter) in the northern part, while similar characteristics are missing in the southern part. This corresponds well with observations of the snow cover, which is usually thicker and persists longer in the northern part. In general, the site is exposed to pronounced resistivity changes in the whole subsurface section (to about 20 m depth), which is attributed to 3D topographic effects of the ridge, influencing radiation and turbulent heat transfer to the ground.

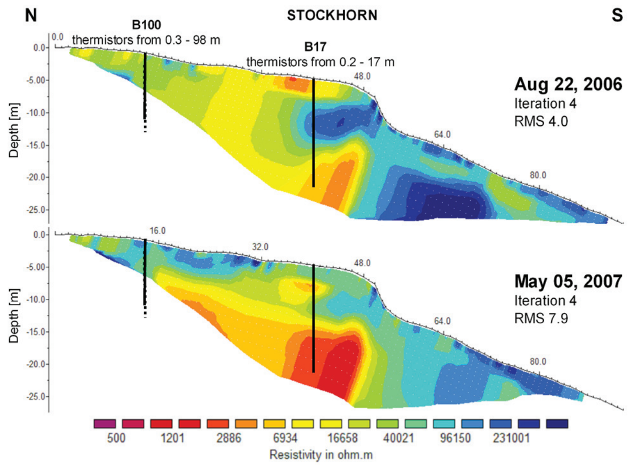

Figure 4. ERT tomogram for typical summer (top) and winter (bottom) conditions at rock plateau *Stockhorn*.

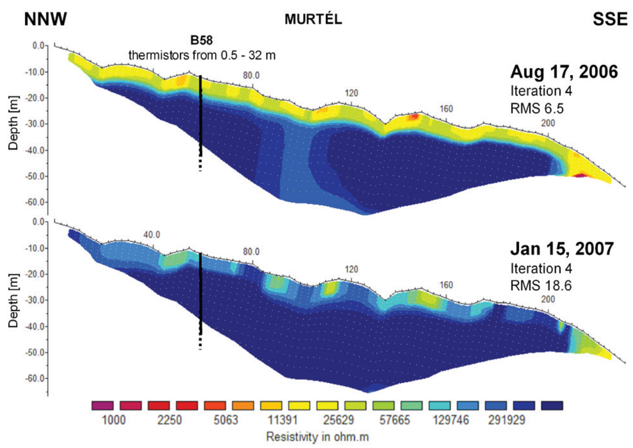

Figure 5. ERT tomogram for typical summer (top) and winter (bottom) conditions at rockglacier *Murtèl*.

Murtèl

Rock glacier Murtèl is generally characterized by extremely high resistivities (300 kΩm to > 2 MΩm) in the interior part caused by the large volume of massive ice. The air in the blocky top layer effectively isolates the ice core from summer heating. Consequently, seasonal resistivity changes are only observed in the active layer (ca. 3–3.5 m) and the tongue. Although changes in the inverted resistivities of the ice core can be quite high (not resolved by the color scale), no systematic seasonal change or trend can be observed from the monitoring data so far. Due to a limited sensitivity of the inversion model to high resistive zones at greater depth, spatial or temporal variations of such high resistivities on the order of MΩm should not be over-interpreted (Marescot et al. 2003). An exception concerns the slightly less resistive vertical zone below the depression at 100–105 m horizontal distance, which is observed in all ERT data (see upper panel in Fig. 5). In summer this resistivity contrast is usually more pronounced than in winter. Due to the uncertainties mentioned above, this zone with decreased (but still very high) resistivities is difficult to interpret but may be an indication of a slightly higher amount of unfrozen water (under subzero temperature conditions), possibly indicating water flow or a zone of higher debris content.

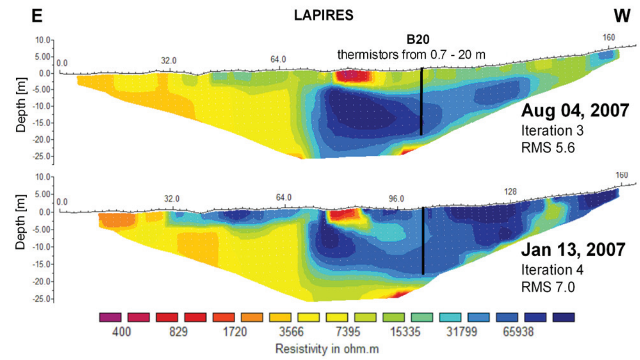

Figure 6. ERT tomogram for typical summer (top) and winter (bottom) conditions at talus slope *Lapires*.

Lapires

The *Lapires* site can be characterized as a talus slope thermally influenced by internal ventilation with a special pattern of permafrost and ground ice occurrence partially reflecting of this internal air circulation (reported in detail by Delaloye & Lambiel 2005). The highly resistive feature in the central part of the tomogram indicates the zone where ground ice is likely to be present. In general, such high resistivities (here >40 kΩm) can be caused by high amounts of ice or air within the pore space of the blocky talus slope (Hauck & Kneisel 2008). ERT monitoring results reveal substantial seasonal changes in resistivities within this zone, possibly indicating a change in material properties over the course of the year. In combination with direct observations during drilling of the borehole and subsurface temperature records, decreasing resistivities at the bottom of this feature during winter and increasing resistivities in summer appear to be related to the air circulation. This may indicate ice formation in summer and thawing processes in winter, but the process remains difficult to understand physically. However, the resistive anomaly can also be influenced by the presence of a cable car pylon in the middle of the profile, represented by very low resistivities in the upper few meters. This low resistive anomaly may cause a low confidence of the resistivity measurement and the inversion process beneath. Further tests are necessary to judge the significance of resistivity changes as indication for changes in material properties.

Active layer freezing during winter (up to 4 m) is, however, clearly evidenced at this site.

Resistivity-temperature relationships

Resistivity-temperature (ρ-T) relationships are plotted for all four test sites in Figures 7 and 8. Figure 7 shows the results for *Schilthorn* (active layer from 0–4.3 m depth), where the largest data set is available. For temperatures above the freezing point results agree well with theory (Eq. 1) with slightly but continuously increasing resistivities with decreasing temperature.

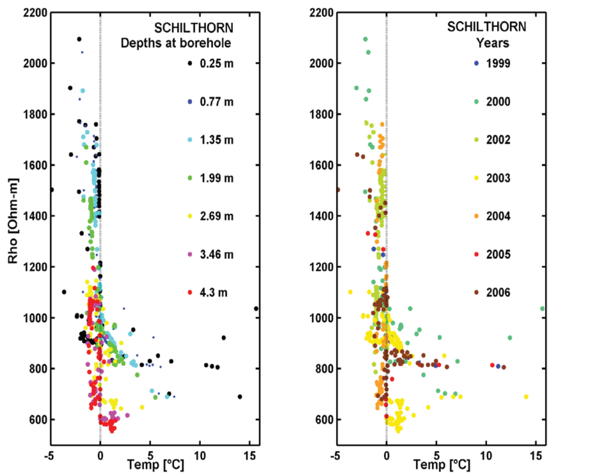

Figure 7. Resistivity at borehole location against subsurface temperatures for the 8-year *Schilthorn* dataset. Colors highlight depths (left panel) and years (right panel). Note that temporal resolution and number of measurements per year are not regular.

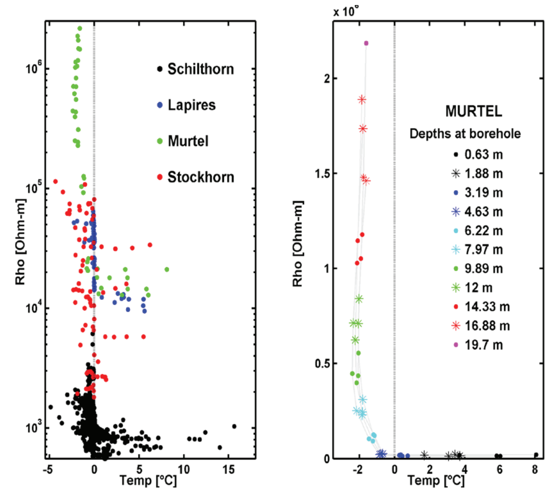

Figure 8. Left panel: comparison of amplitudes of resistivity-temperature relationships for all sites. Right panel: ρ-T relation for 4 different measurement dates at *Murtèl* with colors highlighting different depths. Note that temporal resolution and number of measurements per year are not regular.

At subzero temperatures the reverse effect is visible at all sites: starting at temperatures slightly below the freezing point; resistivities increase exponentially while temperature decrease is almost negligible. Comparing the ρ-T relationship for different depths it is apparent that although the shape of the curves is similar the resistivities are decreasing with depth, indicating higher amounts of unfrozen water at greater depths of the active layer (according to Archie's Law). During freezing unfrozen water contents remain higher in the deeper parts represented by the still lower resistivities (Hauck 2002). Analyzing the same data set with respect to different years, the exceptional low resistivity values of 2003 and the following years become evident as being completely below the main part of the ρ-T curve, again confirming the hypothesis of substantial ground ice degradation at *Schilthorn* in the summer of 2003.

Figure 8 shows the data from all monitoring sites. The amplitude of the resistivity increase for subzero temperatures differs significantly between the sites. While values approximately duplicate at *Schilthorn* from ca. 800 Ωm in unfrozen state to 1600–2000 Ωm in frozen state, they rise over more than an order of magnitude from <100 kΩm to >2 MΩm at *Murtèl*. Unfrozen values at *Lapires* and *Stockhorn* are similar to *Murtèl*, reflecting the blocky active layers, but frozen values are significantly lower due to the lower ice contents. Unfrozen resistivity values of *Stockhorn* cover a wide range due to high variations between dry and wet surface conditions.

The right panel in Figure 8 shows the ρ-T relationships for different measurement dates (lines) and depths (colors) at *Murtèl*. In contrast to *Schilthorn*, values are constant over time, showing almost the same relationship at all temporal reference points. This high degree of repeatability highlights the thermally inert role of the rockglacier and further confirms the reliability of the ERT monitoring approach, even on blocky and highly resistive terrain. A striking feature is the clear dependence of the ρ–T relation on depth. At *Murtèl* (and also at *Stockhorn* and *Lapires*, not shown here) the reverse pattern of *Schilthorn* is visible: Values increase with increasing depths. In contrast to *Schilthorn* (Fig. 7), values in Figure 8 mainly represent conditions below the permafrost table and are therefore interpreted as being due to decreasing unfrozen water contents with depth. However, also decreasing intensity of weathering, higher density and less pore space with depth may be contributing parameters.

Conclusion

Results from an ERT monitoring network at four sites in the Swiss Alps are presented and analyzed in combination with borehole temperature data. Key results from the landform-specific approach can be summarized as follows:

- Both total resistivity ranges and amplitudes of temporal resistivity changes differ markedly for the observed landforms. This is due to site-specific differences of material properties (lithology, pore volume, contents of air, ice and unfrozen water within the pore space, etc.), seasonal dynamics, temperature ranges and the hierarchy of dominating factors.
- Three-dimensional topographic effects influence radiation and turbulent heat transfer to the ground in ridge situations and complicate the pattern of resistivity distribution and seasonal changes, as shown by the example of the rock plateau *Stockhorn*.
- Small seasonal changes are recorded at the *Murtèl* site due to thermally inert characteristics of rockglaciers as opposed to high seasonal dynamics at the other sites as a consequence of internal ventilation (*Lapires* talus slope), high unfrozen water and low ice contents (*Schilthorn*) and 3D effects (*Stockhorn*).
- From the ρ-T relationships a significant dependence on depth becomes evident, with opposite behavior observed

in the active layer (at *Schilthorn*) and below the permafrost table (*Stockhorn*, *Lapires*, *Murtèl*) due to differences in unfrozen water content.

A long-term continuation of the ERT monitoring in the scope of PERMOS is intended and aims at a site-specific assessment of climate related ground ice degradation.

Abstract

A 150-km^2 area near Barrow, Alaska, was monitored at hourly intervals between 2001 and 2005 using ~70 data loggers recording air and near-surface soil temperature as part of the Barrow Urban Heat Island Study. Data records for the winter period were used to calculate site-specific *n-factors*, the ratio between seasonally cumulated degree days at the ground surface to those at standard screen height at corresponding locations. Winter n-factors have similar magnitudes between sites and across years, with typical averages of 0.65-0.70. However, n-factor magnitudes are generally lower and their spatial variability much higher near the urbanized area, owing to heterogeneous snow accumulation and the effects of drifting snow.

Keywords: Alaska; air temperature; n-factor; permafrost; snow cover; urbanization.

Introduction

The surface energy balance in Arctic tundra is highly variable over relatively short distances owing to the localized effects of snow, vegetation, soil moisture content, and substrate properties. These variables affect the amount of heat conducted to depth and therefore have considerable influence on the soil thermal regime. In permafrost terrain, energy inputs in summer develop the active layer, which itself exhibits a high degree of spatial variability. One method to parameterize the surface energy balance and simplify calculations over longer time periods is the *n-factor*. Originally proposed by Carlson (1952), this is a simple ratio of seasonal degree days (°C-days) at the ground surface to seasonal degree days in the air over the same time period (Lunardini 1981). The n-factor's geographic variability has been analyzed at a variety of spatial scales. Shur & Slavin-Borovskiy (1993) examined summer n-factor patterns in western Siberia across more than 25 degrees of latitude, and noted a general increase in n-factors poleward. At the local plot scale, Klene et al. (2001) observed significant variation in summer n-factors between natural landscape-vegetation types, but relative consistency within the units.

This study was conducted at an intermediate scale, and uses a relatively dense network of temperature-measurement sites to map winter patterns of the n-factor. The purposes are to (1) quantify the degree of regularity in seasonal n-factor magnitude and spatial patterns between different years; and (2) identify conditions that influence winter n-factors at the scale of the study.

Study Area and Background

Barrow is a coastal village on the Chukchi Sea at 71.3°N, 156.5°W. With a mean annual temperature of -12.0°C (National Climate Data Center [NCDC] 2003), the area lies in the continuous permafrost zone, with permafrost thickness extending to depths of nearly 400 m. Active-layer thickness averages around 35 cm (Hinkel & Nelson 2003), but is highly variable between landscape types (Klene 2005). The snow cover is typically established by mid-September and averages about 40 cm in depth at the end of winter.

Barrow has a population of around 4600, with an urban settlement pattern typical of the U.S. Building density is relatively high in the older village center, while suburban-style housing of lower density dominates recent developments around the village's periphery and extends as a band along the coast for several km.

Most buildings are single-story and built atop piles driven into the underlying permafrost. The local road network consists of gravel berms elevated 1-2 m above the natural terrain. The urbanized area constitutes an artificial topography that exceeds the natural relief of the surrounding coastal plain and has significant impacts on snow-drift patterns, snow depth, and retention of water at the surface. Each of these factors, in turn, influences the n-factor.

As part of a larger study concerned with evaluating the impact of Barrow's urban heat island on soil temperatures and permafrost stability, HoboPro® data loggers were installed across a 150-km^2 area beginning in 2001. Fifty loggers were deployed in 2001, and by 2003 the network had expanded to nearly 70 loggers. About half were deployed in urban settings, with the remainder dispersed across the hinterland in a loose grid pattern (Hinkel et al. 2003, Hinkel & Nelson 2007). The two-channel loggers have an accuracy of ±0.2°C and precision of 0.02°C at the freezing point. Loggers were mounted on an instrument mast with one thermistor inside a radiation shield at standard screen height (1.8 m) to measure air temperature, and the other thermistor positioned 5 cm below the ground surface to measure near-surface soil temperature. Loggers were synchronized to record hourly measurements. The rate of instrument attrition was around

10% yearly, owing primarily to animal activity and logger failure.

Methodology

Because the date of snowmelt in spring and snow cover development in autumn varies between sites and years, it was first necessary to define seasonal boundaries. For each site, the mean daily air and soil temperature traces were plotted. Using these records in combination with graphs of daily soil temperature range, we defined the winter snowcover period as 15 Sept to 15 May (243 days; 244 days on leap year).

For each site with a complete record for the seasonal period, average daily air and soil temperatures were cumulated. The n-factor was then calculated for each site, summary statistics generated, and seasonal maps produced using a simple kriging algorithm (Golden Software 2002) to interpolate site values over the study area.

Sites were defined as urban or rural depending on whether they were within 30 m of any building, road, or other "built" structure.

Results and Discussion

In a region of relatively even and continuous tundra vegetation such as Barrow, winter n-factors can initially be treated as a homogenous group for analysis. N-factors near unity indicate close coupling between the soil and air temperature. Conversely, lower magnitudes indicate relatively warmer soil temperature in winter that reflects the insulating effects of the snow cover. Strong decoupling is induced by deep snow, with n-factors falling toward zero.

Annual summary statistics

Summary winter air temperature statistics are given in Table 1. The number of sites used in the calculations varied between winters owing to lost or partial records. Winter 2002-03 was about 2°C warmer than other years; this is also apparent in Figure 1, which shows the distribution of the daily air and soil temperature averages by winter period. There is limited variation in average daily air temperature in all winters, as can be expected within such a relatively small area. By contrast, the variability in near-surface soil temperature is substantial, and is related to local edaphic, vegetation, and snow conditions.

Summary n-factor statistics are given by winter period in Table 2, and the range of n-factors by year is shown in Figure 2. Winter n-factors have very similar measures of central tendency (0.65-0.69 for mean and medians), indicating little interannual variation. Winter snow-cover depth, measured each year at the 121 grid nodes of the ARCSS/CALM 1-km^2 grid within the study area, was consistently around 31 cm, except during the winter of 2003-04 when it averaged 38 cm. The thicker snow cover does not appear to impact the mean, median, or range of n-factors in that year, although values appear somewhat more clustered around the median (Fig. 2). Direct interannual comparison is difficult, however, because the number of operational sites varied between years.

Annual spatial patterns

Maps of the winter n-factor are shown in Figure 3. The winter pattern of n-factors demonstrates relatively consistent geographic patterns with (1) higher magnitudes (>0.70) near the coast, especially in the vicinity of Elson Lagoon; (2) lower magnitudes (<0.55) near the urban center, and (3) much higher spatial variability near the urbanized areas. This last point can be best appreciated by separating the urban and rural sites, and calculating summary statistical parameters of n-factors (N=164) for the two groups (Table 3). The urban sites have a lower mean and median n-factor (by about 0.10), and vary more around the measures of central tendency; the range is wider and the standard deviation is greater by a factor of two. A plot of the histograms for the two groups of sites (Fig. 4) verifies this interpretation and clearly illustrates the tight clustering of rural n-factors around the mean and median centered on 0.7.

In Barrow, strong winter winds (averaging ~11 knots or 5.5 m s^{-1}) are consistently from the NNE and snow drifting is common. Deflation of snow by wind on the northeastern

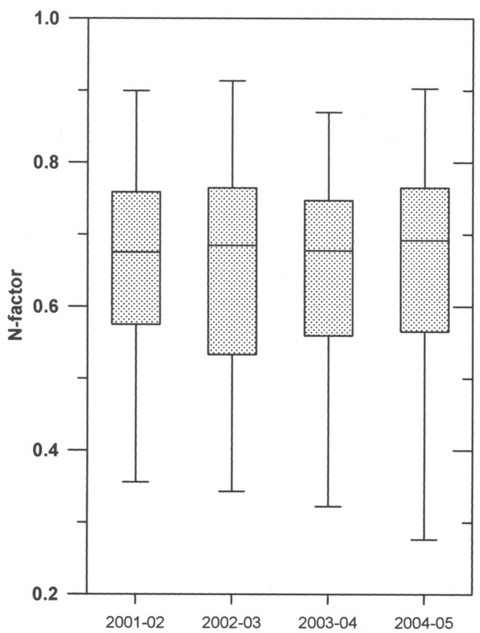

Figure 2. Box-and-whisker plots of winter (15 Sept-15 May) n-factor by year.

coast would tend to increase the winter n-factor at affected sites. Conversely, relatively large accumulations of snow in the lee of buildings, plowed roadways, and snow fences (Hinkel & Hurd 2006) reduce the magnitude of the n-factor and promote spatial variability. Because the number of sites used to construct these maps differs substantially, more detailed comparison is not prudent.

Forcing factors

During winter, snow depth and thermal properties have been found to be the dominant factors determining ground temperature in rural and urban environments (e.g., Gold 1967, Goodrich 1982, Woo & Debreuil 1983). In some environments, this is closely tied to vegetation, which traps snow in the canopy layer (Sturm et al. 2001). In Barrow, however, the relatively short tundra vegetation (seldom more than 20 cm and usually much less) reduces the importance of this factor. This study found snow to be the main determinant of winter soil temperatures and n-factors, with the artificial topography inducing snow accumulation and drifting, thus impacting the magnitude and variability of winter n-factors in the urban setting. Other urban factors that may complicate

the ground thermal regime include changes in subsurface soil water flow caused by construction of permafrost-stabilized road berms. Particularly in the newer subdivisions of Barrow, roads form a grid pattern that inhibits lateral meltwater runoff in spring and causes ponding. This results in such intensive flooding that tanker trucks proceed from block to block, pumping water to be dumped elsewhere. Other urban factors, such as the effects of dust on snow albedo (Dutton & Endres 1991), can also have an impact in this environment. Separation of n-factor regimes by rural and urban regions provides a useful first-approximation explanation.

Compared to results from previous studies, the rural values reported here are somewhat higher than those found by Taylor (1995), Karunaratne & Burn (2003, 2004) and Kade et al. (2006). Taylor (1995), for example, reported winter n-factors of 0.12–0.45 for forested sites in the Mackenzie River Valley. Karunaratne and Burn (2003) examined winter n-factors at several sites in the Yukon (forested, burned, meadow, snow fence, and cleared) between 1997 and 2000. They reported winter n-factors at the cleared sites (0.5) that were similar to those observed in the forested site, while the burned and snow fence sites had n-factors of ~0.3 and the meadow site had an intermediate value. Kade et al. (2006) examined n-factors in barren nonsorted frost circles and vegetated tundra along a climate gradient consisting of three sites in northern Alaska. They calculated tundra n-factors of about 0.3, 0.6, and 0.9 at Happy Valley, Franklin Bluffs, and Howe Island, respectively. This generally shows the impact of reduced snow depth, vegetation height, and soil organic layer thickness as one moves poleward from the Arctic Foothills towards the Arctic Ocean. Carlson (1952) calculated winter n-factors of 0.25-0.33 for three sites of differing land-covers (trees, shrubs, vegetation removed) with an undisturbed snow cover. At "urban" sites that were cleared of snow, he found n-factors of 0.62-0.76 at sites with a gravel surface and n-factors of 0.65–0.84 associated with concrete and asphalt surfaces. The high n-factors observed at Barrow likely reflect the effects of the relatively thin snow cover and tundra vegetation.

Conclusions

This study of n-factor magnitudes and spatial patterns is somewhat different from those conducted in the past in that (1) the analysis was performed at a spatial scale intermediate between the plot- and regional-scale studies reported in the literature; (2) it utilizes a relatively dense network of data loggers; and (3) the study took place over several years to examine the annual variability of winter n-factors. The spatial and temporal consistency of n-factors over a series of winters has been demonstrated empirically in the rural environment.

Conversely, individual sites within the urban environment were of lower magnitude and show greater variability. The anthropogenic impact on snow accumulation and drifting patterns induced by buildings, plowed roads, and snow fences is the likely cause. This indicates that n-factors may exhibit high variability across short distances in natural terrain of high relief, and merits further investigation. Other studies may focus on the impact of engineered structures or climate-induced vegetation changes. Spatial and temporal analysis of summer n-factors would likely require implementing a land cover classification scheme to fully understand the complex patterns (Klene et al. 2003, Hinkel et al. 2004).

Abstract

A series of environmental studies have been carried out in the northern foothills of the Brooks Range and the Arctic Coastal Plain in the Kuparuk River Basin, Alaska, to develop a better understanding of the physical and climatic dynamics of an arctic ecosystem. As part of these studies, soil temperature and snow depth measurements along a transect from near the Beaufort Sea coast across the Coastal Plain to the Brooks Range foothills were made continuously at three locations. Summarized here are trends observed in soil temperature spanning the last 15 years in this area. Soil temperature measurements were made in the active layer and permafrost to depths exceeding 10 meters. Data collection began at these sites in 1993. These datasets are of sufficient temporal length and quality to begin showing long-term trends in arctic soil temperature and the relationship between snow depth and winter soil temperature. All locations within the permafrost show a warming trend (average annual temperature) over the period of observations (depths greater than 50 cm at Franklin Bluffs and Sagwon Hill and 90 cm at Imnavait Ridge). Maximum soil temperatures in the active layer above the permafrost, however, show a slight cooling trend at all three sites. Minimum soil temperatures in the permafrost at each site are increasing as are average annual soil temperatures; maximum annual temperatures in the permafrost are mixed with Sagwon Hills decreasing. There is no significant overall trend in snow water equivalent (SWE) at the three sites. There is considerable variation in SWE and snow depth from year-to-year, which clarifies the dependence of the soil thermal regime on snow. The hydrologic cycle in these catchments has yet to show any response that can be documented.

Keywords: active layer; Alaska; climate change; hydrology; permafrost; soil temperature.

Introduction

Since 1985, continuous hydrologic research studies have been ongoing on the North Slope of the Alaskan Arctic (Fig. 1) in watersheds within and adjacent to the north-flowing Kuparuk River Basin (Kane et al. 2000). The hydrologic response of these basins is related to the major physical properties of the basin such as topography, soils, vegetation, and thermal state In this case the thermal state is probably the most important, as the area is underlain by continuous permafrost 250 to >600 m deep. It is clear from the published papers that the environment of this region is transitioning to a warmer climate (Serreze et al. 2000, Hinzman et al. 2005, and others). Heat and mass water fluxes in any environment are closely intertwined. Therefore, if the climate is warming, the hydrology of these Arctic basins will also be impacted. One could foresee greater precipitation with less spatial and temporal sea ice extent (sources of precipitable water increasing); perhaps increased evapotranspiration (ET) from land surfaces with increases in precipitation and air temperature; and the runoff response is debatable, depending upon what happens with precipitation. One of the major controversial areas is what will happen to the active layer and vegetation, as this has long-term implications to the hydrologic cycle of the Arctic.

Two decades ago, Lachenbruch and Marshall (1986)

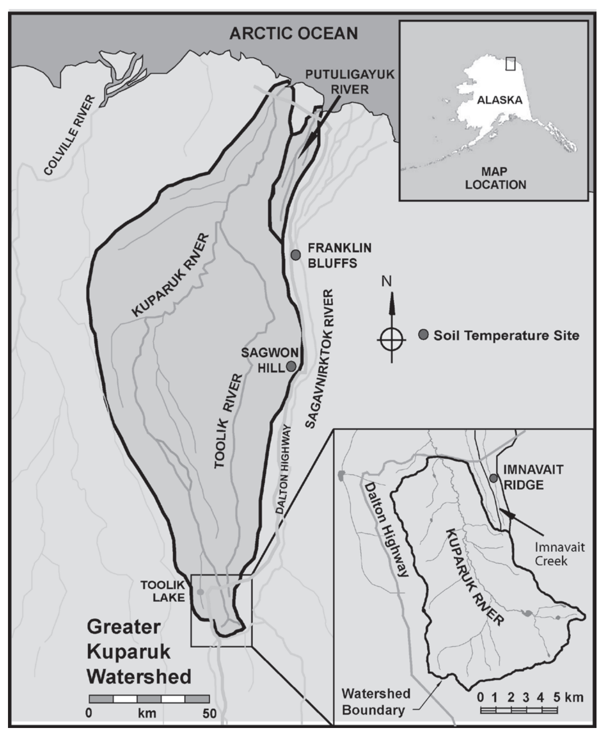

Figure 1. Map of the monitored watersheds and the borehole observations sites on the North Slope of Alaska, USA.

showed that permafrost on the North Slope of Alaska was warming. Clearly it took thousands of years for the permafrost to form, and it is not going to totally disappear for some time (except where it is quite warm and thin, but that is not the case in northern Alaska). Presently, the active layer in the Kuparuk basin is on average about 40 to 60 cm deep (Hinzman et al. 1998), greater in well-drained sites, and shallower in poorly drained sites. There is evidence, however, that change is ongoing near the ground surface. Sturm et al. (2001) described the increase in shrubs in the present tundra environment on the North Slope of Alaska; hydrologically this has implications for trapping snow, ET and soil moisture, and possibly runoff. A warmer climate should result in a deeper active layer initially, though there are some who would argue that shrubs will invade and provide ground shading and thus lower ground surface temperatures. It is more complex than this, however, as different plant communities have different soil water demands (drier soils typically have deeper active layers because less energy is needed for phase change). Overduin and Kane (2006) have shown that over a three-year period, no increase in the active layer thickness was observed for a site on the North Slope of Alaska from relative depth measurements at summer's end. However, more detailed analyses showed that areal ground surface subsidence rates of 2 to 5 cm/yr were due to the melting of ice at the base of the active layer, although not detected in simple active layer depth measurements relative to the surface with a probe.

Presented here are the results of 15 years of borehole data collected at sites on a north-south transect in the Kuparuk River basin. Most of the discussion will concentrate on three sites: Franklin Bluffs, Sagwon Hill, and Imnavait Ridge. At these three sites, measurements were made at depths greater than 10 m. Several thermistor strings were also installed at numerous other sites in the shallow active layer.

Setting

Four nested watersheds on the North Slope of Alaska, USA (Fig. 1), are instrumented with hydrologic and meteorological stations that support hydrologic and related process studies and data to complete water balance computations (Kane et al. 2004, Lilly et al. 1998, Kane et al. 2008a). These studies were initiated in 1985 in Imnavait Creek (2.2 km^2), 1993 in the Upper Kuparuk (142 km^2) and entire Kuparuk River (8,140 km^2), and in 1999 in the Putuligayuk catchment (471 km^2). The U.S. Geological Survey (USGS) started gauging the entire Kuparuk River near Deadhorse in 1971, and the record is continuous. They also started gauging the Putuligayuk River in 1971; however, in the 1980s some years of data are missing, and then they switched it to a crest gauge. During the early years of gauging by the USGS, there was very little complementary hydrologic data collected until this study was initiated.

The north draining Kuparuk basin transitions the northern extremities of the Brooks Range, through the foothills and finally into the Arctic Ocean after crossing the low-gradient Coastal Plain. The permafrost thickness increases from 250 m in the headwaters to 600 m along the coast. The active layer is generally about 40 to 60 cm deep, although it is quite variable, depending upon slope, aspect, soils, organic cover, etc. Vegetation is essentially continuous over the area, starting with alpine communities in the headwaters, tussock tundra in the foothills, and sedges and grasses on the Coastal Plain. Shrubs (~1 m high) can be found throughout the basin except at the high elevations and the northern extremes. More detailed description of these basins can be found in Kane et al. (2000).

Results

Franklin Bluffs is located approximately 25 miles south of the Arctic Ocean coastline in the Coastal Plain (Fig. 1). The terrain is low gradient and poorly drained. The daily soil temperatures are plotted since 1993 in Figure 2 (there is one gap in the dataset). Soils at this site displayed a cooling of the summer maximum annual temperature in the active layer and a warming of the permafrost soils (Fig. 3, Table 1). The winter minimum annual soil temperature showed a cooling trend for active layer soils and a warming trend of permafrost soils (Fig. 4). Overall the average annual soil temperature (Fig. 5) demonstrated a trend of cooling of the active layer soils and a warming of permafrost soils. With cooling of the active layer and warming of the permafrost, there was a convergence of the average annual temperature at each depth. Three winters had above-average SWE (Fig. 6) at this site after 2000; this would decrease deep winter cooling and delay ablation in the spring, thus possibly shortening summer.

The Imnavait Ridge site is located in the Imnavait Basin in the upland of the foothills of the Brooks Range near Toolik Lake (Fig. 1). The site is located on a well drained ridgeline on a gentle west facing slope.

Discussion

It is clear that the hydrology of the Kuparuk River Basin is dominated by deep continuous permafrost. First, the permafrost acts as an aquitard, and there is no hydraulic connectivity between the surface and the subsurface permafrost groundwater (Yoshikawa et al. 2007). In some neighboring watersheds, there are springs of subpermafrost groundwater origin that have apparently been flowing for thousands of years. The thick, ice-rich permafrost severely limits subsurface storage to just the active layer, where the volume of storage is quite close to the average total precipitation for just one year. Because of this limited storage, runoff ratios for these basins are much higher than found in more temperate climates (Kane & Yang 2004) for both snowmelt and rainfall

Kane et al. (2003a) discuss the impact of surficial permafrost features on the runoff response of arctic catchments. In general, these features (polygons, thaw lakes, strangemoor ridges, beaded drainage, etc.) reduce the hydrologic runoff response of these watersheds. However, as an example, the conversion of low-centered polygons to high-center polygons

Table 1. Trend line slopes (1993 to 2007) of annual maximum, minimum, and average temperature at two depths in boreholes on the North Slope of Alaska. *P*-values are in parentheses. The *p*-value represents a decreasing index of the reliability of a result (Brownlee 1960). The lower the *p*-value, the more we can believe that the trend line is significantly different from zero. A *p*-value of 0.01 implies the slope of the trend line is significantly different from zero at the 99% confidence level.

could significantly increase the hydrologic runoff response of a watershed, including sediment yield. This process has been observed in several areas by the authors along the Dalton Highway outside the studied basin. McNamara et al. (1999) hypothesized that headwater drainages (water tracks) in the Arctic are immature channels that have not fully developed because of the underlying permafrost. The suggestion that permafrost is limiting channel maturity has many implications to the hydrologic response of arctic catchments in a changing climate, including runoff response and sediment (suspended and bed) yields.

In response to some imposed disturbance, such as a tundra fire or climatic warming, massive ice-rich permafrost may differentially thaw, creating irregular surface topography. Depressions forming on the surface soon form ponds, accelerating subsurface thaw through lower albedo and additional heat advected into the pond through runoff. In time, a talik (a layer of unfrozen soil above the permafrost and below the seasonally frozen soil) may form below such ponds as the depth of water becomes greater than the amount that can refreeze during the winter. If the talik grows to a size that completely penetrates the underlying permafrost or connects to a subsurface layer that allows continued drainage, the pond may then begin to drain. Over the past three to five decades, increased pond formation and shrinking have been observed in Alaska (Yoshikawa & Hinzman 2003, Jorgensen et al. 2001), Canada (Smol & Douglas 2007), and Siberia (Smith et al. 2001).

Summary

The general trend of the thermal regime at the three research sites is one of overall warming; this is in agreement with other studies (Romanovsky et al. 2002). The warming was strongly statistically significant at the 850 cm depths for the minimum annual temperatures at all three sites. The deeper temperature probes (>400 cm) displayed significant warming in average, minimum, and maximum annual temperatures at Imnavait Creek and Franklin Bluffs, but was not consistent at Sagwon. To date, we do not see measurable responses of arctic hydrology to climate change in the form of changes in precipitation, runoff, soil moisture, storage, and ET. Clearly the permafrost is warming, thermokarsting is evident, and

thawing of the top of the ice-rich permafrost is ongoing. In an area of the world where frozen ground plays a dominant role in the physical structure of a watershed, this should be viewed ominously. Why do we not presently see this impact on arctic hydrology? First, it may not be extensive enough to reach a threshold value at the watershed scale. Second, changes in the hydrology will not be evident until the soil has progressed from frozen to thawed. Although warming is occurring, it appears that the small amount of thawing that has occurred at the base of the active layer has not significantly increased the available storage due to subsidence concurrent with thawing. Third, there is considerable natural variability in these hydrologic processes, plus we still struggle to make accurate estimates of hydrologic fluxes and stores. The natural variability in hydrological variables may be much greater than the subtle differences induced by a warming climate. We hypothesize that continued warming of the permafrost will bring significant changes to the hydrology of this region as we presently know it.

Abstract

The aim of this study was to determine the environmental factors controlling the diversity of periglacial landforms on the landscape scale. The study was performed using an empirical dataset of periglacial landforms from an area of 600 km^2. Both distribution and abundance of landform diversity were modeled. The utilized statistical method was generalized linear modeling (GLM). A total of 40 different periglacial landform types and subtypes were identified. The number of different types in the 25-ha modeling squares varied from zero to nine. Based on GLM, the diversity of periglacial features increased with increasing moisture variability and altitude. Moreover, slope angle was an important correlate with cubic term; the diversity was highest on flat ground sites (0–2°) and on rather steep slopes (8–12°). The employment of GLM proved to be a useful approach to estimate the role of environmental factors in determining the periglacial geodiversity.

Keywords: generalized linear modeling (GLM); geodiversity; periglacial geomorphology; prediction; subarctic.

Introduction

Periglacial domain covers different features from large pingos to small sorted circles (French 2007). On a regional scale, the variety of periglacial phenomena can be substantial including several tens of features (e.g. Åkerman 1980). While the diversity of periglacial landforms is a well-known issue, rather few have studied the environmental factors behind the feature variability. One potential reason for the lack of research may be the difficulty in analyzing complex processes in extensive regions. The recent developments in combining the Geographic Information System (GIS), remote sensing (RS) data, and statistical techniques have improved the possibility of surveying extensive regions and studying different aspects of periglacial geomorphology (Luoto & Hjort 2005, 2008, Etzelmüller et al. 2006, Brenning et al. 2007, Hjort & Luoto, in press).

It would be profitable to develop spatial analysis techniques to map the sites of high geodiversity, because knowledge on the variability of geomorphological processes and landforms is important to conservation managers, engineers, and scientists (Walsh et al. 1998). Furthermore, in the context of geodiversity, the interest in variability on non-living nature has risen recently (e.g., Gray 2004). The concept of geodiversity is less well-appreciated in geomorphology, but is now developing momentum of its own. Geodiversity conservation is increasingly seen as important in its own right and as an essential support to biodiversity and cultural conservation programs (Gray 2004).

Here we examine the applicability of GIS-based datasets and generalized linear modeling (GLM) in determining the factors controlling the diversity of periglacial landforms on the landscape scale (Luoto & Hjort 2004, Hjort et al. 2007). The study is performed using an empirical dataset of periglacial landforms from an area of 600 km^2 at a 25-ha resolution (n = 2249). This rather coarse resolution was chosen based on data exploration and attempts to reduce the potential problems of spatial autocorrelation in statistical modeling (McCullagh & Nelder 1989). Both distribution (high- vs. low-diversity sites) and abundance (number of different types) of landform diversity were analyzed. Especially, we seek answers to the questions: (i) can we spatially predict the diversity of periglacial landforms and (ii) which environmental factors control the diversity in subarctic Finland on the landscape scale?

Study Setting

Background: factor-process-landform relationship

The complex relationship between environmental factors affecting the activity and presence of periglacial processes is presented in Figure 1A. In general, the most important environmental drivers are climate, topography, material, moisture conditions, snow and ice cover as well as vegetation (Washburn 1979, French 2007). Climatological conditions affect, for example, freeze-thaw cycles and moisture distribution and thus, all periglacial processes (Fig. 1B). Moreover, the wind has a significant role in snow redistribution, which affects ground temperatures and moisture conditions. Soil moisture, along with temperature, is one of the most important determinants of frost processes (e.g., Matthews et al. 1998). Soil material affects the moisture distribution and activity of periglacial process. Topography, snow cover, and vegetation influence the processes through the main factors: temperature and soil moisture (Fig. 1). However, topography directly affects slope phenomena, and vegetation on the slope as well as aeolian processes. Most of these environmental factors have a positive relationship with the process activity. Nonetheless, some factors (e.g., soil moisture) may reduce the activity of periglacial processes (e.g., aeolian phenomena).

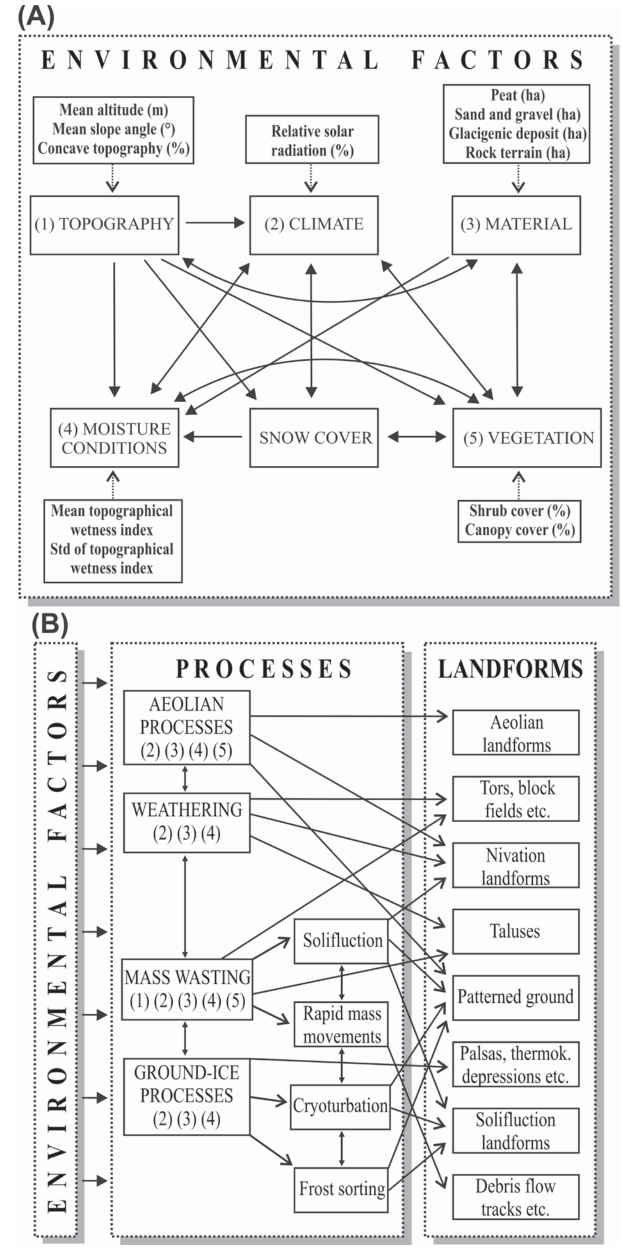

Figure 1. (A) The main interactions between environmental factors affecting periglacial processes and landforms on a regional scale. The environmental predictors and surrogates of factors used in this study are shown in outermost boxes. (B) Simplified conceptual model of the relationships between environmental factors, periglacial processes, and periglacial landforms commonly found from northern Fennoscandia (e.g., Lundqvist 1962, Harris 1982, Seppälä 2005). The main factors affecting processes are indicated with numbers (1 = topography, 2 = climate, etc.).

Study area

The study area is located in the northernmost Finnish Lapland within the zone of discontinuous permafrost (Fig. 2). The landscape of the area is characterized by rather rounded fells with elevations ranging from 110 to 641 m above sea level. The bedrock (ca. 1.9 billion-year-old) is covered by glacigenic till and peat, as well as sand and gravel deposits (Meriläinen 1976). Moreover, silty sediments are prevalent in the wide flat-bottomed valleys. The climate of the area is subarctic: the mean annual air temperature is -2.0°C, and mean annual precipitation ca. 400 mm (*Climatological Statistics in Finland 1961–1990* 1991). The vegetation of the area is characterized by subalpine mountain birch forests (*Betula pubescens* ssp. *czerepanovii*) and alpine heaths (*regio alpina*).

Modeling data

Periglacial landforms. The landforms were mapped and converted to grid-based modeling data in four steps (for details see Hjort 2006). First, a detailed stereoscopic interpretation of black-and-white aerial photographs (1:31,000) was performed to identify the potential sites of periglacial features. Second, the features were mapped utilizing pre-mapping results and a Global Positioning System (GPS) device (Garmin eTrex personal navigator with an accuracy of ca. 10 m) in the field during the summers of 2002 and 2003. Third, the field-mapping results were digitized in a vector format on orthorectified aerial photographs (ground resolution = 1 m) utilizing GIS software. Both active and inactive landforms were grouped together because the determination of activity of some feature types would have been a complicated task without several year-round field measurements. Finally, the created geomorphological database was used to produce two types of response datasets at the 25-ha resolution. In the first case, the datum was divided to the sites of high (coded 1) and low (coded 0) diversity using threshold values from 4 to 6 (e.g., high diversity ≥4 landform types present in the modeling square, low diversity <4 types present). In the second case, landform diversity was determined based on the number of different landform types in the modeling squares. The first type of datum was used to model the occurrence of high and low sites of diversity (distribution modeling) and the second type was used to analyze the intensity of diversity (abundance modeling).

Explanatory data. Taking into account the study aims, modeling resolution, and the complex relationships between environmental factors, periglacial processes, and periglacial landforms (Fig. 1), the explanatory variables (i.e., predictors) were compiled from commonly used and accessible information sources, namely a digital elevation model (DEM) (20-m grid size) (Hjort 2006), biotope database (Anonymous 2002), and digital soil map (Hjort 2006). Six topographical parameters (mean altitude, mean slope angle, mean and standard deviation of topographical wetness index, proportion of concave topography, and relative solar radiation), 4 soil-type variables (glacigenic deposit, sand and gravel, peat, as well as rock terrain cover), and 2 vegetation factors (shrub and tree cover) were computed using Arc/Info GRID at the 25-ha resolution (Fig. 1).

Data split. The final modeling data included 2249 squares, which were randomly divided into model- calibrating (50%, n = 1125) and model-evaluation sets (50%, n = 1124) (Guisan & Zimmerman 2000). A total of 151 squares were excluded due to the abundant water cover and deficiency in the explanatory data.

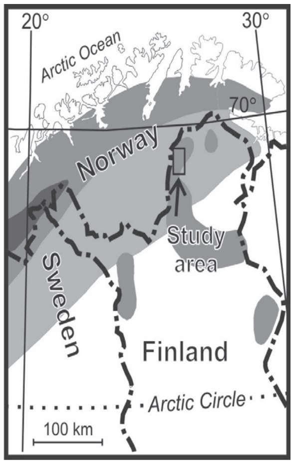

Figure 2. Location of the study area in northern Fennoscandia. Permafrost conditions are indicated with shades of gray: continuous (darkest), discontinuous, and sporadic (modified after Brown et al. 1998).

Generalized linear modeling

Generalized linear models (GLMs) are mathematical extensions of traditional least square (LS) regression models that do not force data into unnatural scales; they allow for nonlinearity and nonconstant variance (heteroscedasticity) structures in the data (McCullagh & Nelder 1989). In this study, the model calibration was performed utilizing the statistical package R version 2.3.0, with standard GLM function. The probability of curvilinear relationships between the explanatory and response variables was examined by including the quadratic and cubic terms of the predictors in the models (Crawley 1993). The variables were selected using a statistically focused backward elimination approach (see Crawley 1993). Elimination was based on a strict criterion ($p < 0.001$) for variable exclusion. The percentage of deviance explained [(null deviance – residual deviance / null deviance) * 100] was calculated for the final GLMs to gain an overall picture of the success of the fitting (for details see Hjort 2006).

Model evaluation. The distribution models were assessed utilizing evaluation data and the area under the curve (AUC) values of a receiver operating characteristic (ROC) plot (e.g., Pearce & Ferrier 2000). The AUC values range from 0.5 for models with no discriminative ability to 1.0 for models with perfect discrimination. Swets (1988) proposed a rough guide for classifying the AUC measures of the models: 0.50–0.70 = low model accuracy, 0.71–0.90 good model accuracy, > 0.90 = high model accuracy. The predictive ability of the abundance model was assessed by calculating Spearman's rank correlation coefficient (R_s) between the predicted and observed diversity using evaluation data (Guisan & Zimmermann 2000).

Results

Periglacial landforms

A total of 40 different periglacial landform types and subtypes were identified (Table 1). The most common landforms, if calculated by occupied modeling squares, were earth hummocks (n = 1636), peat pounus (n = 702), sorted nets (n = 631) and sorted sheets (n = 431). The rarest features were non-sorted lobes (n = 10), slushflow tracks (n = 4) and braking blocks (n = 4), respectively.

Table 1. Periglacial landforms mapped from the study area and their prevalence at the 25-ha modeling resolution (x = not determined).

Periglacial landforms	Present squares (%)
Palsas (4 subtypes)	134 (5.4%)
Thermokarst ponds	69 (2.8%)
Circles	
- convex non-sorted circles	229 (9.2%)
- stony earth circles	245 (9.8%)
- earth hummocks	1636 (65.4%)
- peat pounu	702 (28.1%)
- sorted stone circles	81 (3.2%)
- stone pits	252 (10.1%)
- debris islands	38 (1.5%)
Polygons	
- non-sorted polygons	18 (0.7%)
- sorted polygons	50 (2.0%)
Nets	
- sorted nets	631 (25.2%)
Boulder depressions	73 (2.9%)
Steps	
- non-sorted steps	111 (4.4%)
Stripes	
- non-sorted stripes	36 (1.4%)
- sorted stripes	198 (7.9%)
Debris flow slopes	17 (0.7%)
Slush flow tracks	4 (0.2%)
Solifluction features	
- non-sorted terraces	275 (11.0%)
- non-sorted lobes	10 (0.4%)
- ploughing blocks	15 (0.6%)
- braking blocks	4 (0.2%)
- sorted sheets (2 subtypes)	431 (17.2%)
- sorted terraces	74 (3.0%)
- sorted lobes	68 (2.7%)
- sorted streams	244 (9.8%)
Talus slopes	19 (0.8%)
Block fields	34 (1.4%)
Tors	127 (5.1%)
Nivation sites	x
Stone pavements	15 (0.6%)
Sand dunes (3 subtypes)	99 (4.0%)
Deflation sites (2 subtypes)	295 (11.8%)

The number of different periglacial landform types in the 25-ha modeling squares varied from 0 to 9 (Fig. 3). A total of 247 (9.9%) squares were without any periglacial features and 2253 (90.1%) sites were occupied by at least 1 landform type. Squares with only 1 landform type were commonly occupied by extensive fields of earth hummocks, peat pounus, palsas, or sorted nets. Considerably many of the modeling squares included 2 to 4 different landform types, which is mainly caused by the presence of feature continuums. Over 6 landform types were observed from only 58 (2.3%) squares.

Diversity GLMs

The results of the diversity modeling are summarized in Table 2. In distribution modeling, the amount of explained deviance varied between 16% and 18%. The abundance model was able to explain 21% of the deviance change. In model evaluation, the AUC measures of the distribution models ranged from 0.76 to 0.78, indicating fair discrimination ability between the sites of high and low diversity. The abundance model was moderate in predicting the number of different periglacial landforms present in the analysis squares (R_s = 0.52).

The number of the environmental factors varied from 2 to 4 in the final GLMs (Table 2). The most important correlates for both the distribution of high-diversity sites (≥4 landforms present) and abundance of landform types were mean altitude, mean slope angle, and soil moisture variability. The slope angle variable was included in 3 of the 4 models with cubic term, indicating that the diversity was highest on flat ground sites (0–2°) and on rather steep slopes (8–12°) (Fig. 4). Moreover, canopy and peat cover were shown to be connected to the diversity (Table 2).

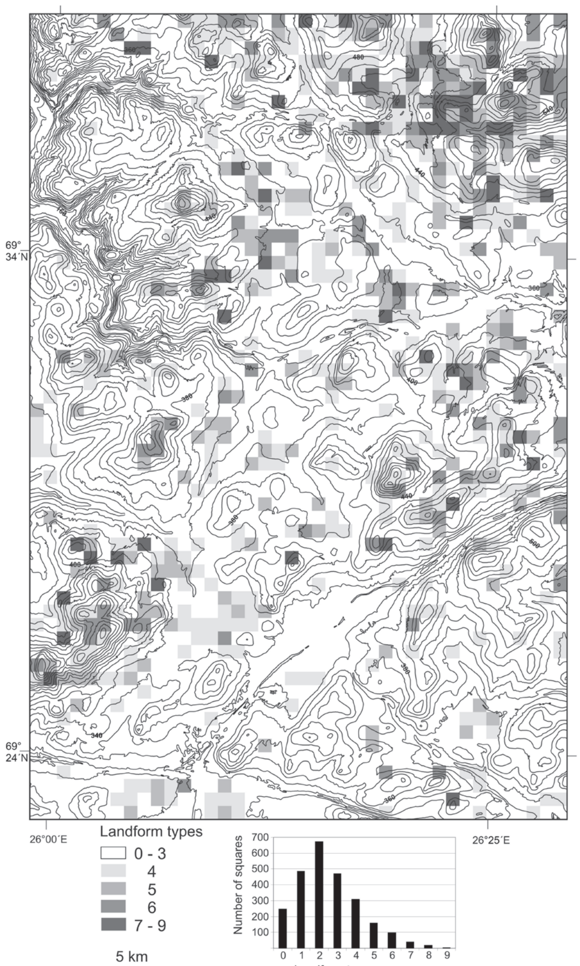

Figure 3. Number of different periglacial landform types at the 25-ha modeling resolution. The vertical interval of contours is 20 m (© National Land Survey of Finland).

Discussion

In general, knowledge on the diversity of geomorphological phenomena could be useful for academic, applied and economic applications (Gray 2004). In the context of global change, spatial models of geodiversity could be used to assess the impacts of changing environmental conditions on periglacial processes (Fronzek et al. 2006, Johansson et al. 2006). One would expect that declining frost conditions would decrease the feature variability, but the short-term effects of climate change on periglacial processes are rather unclear. For example, increasing temperature decreases frost severity. However, increasing precipitation could increase frost activity because moisture availability has shown to be one of the most important determinants for the occurrence

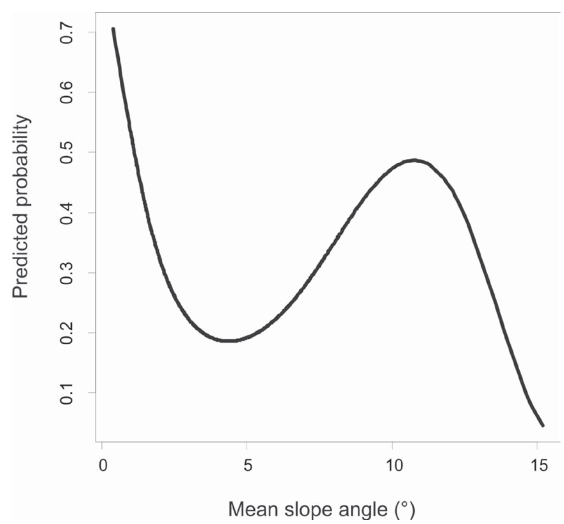

Figure 4. Relationship between diversity of periglacial landforms and slope angle. The predicted probability of diversity is derived from the distribution GLM (threshold value = 4) relating slope variable separately to the response variable.

Table 2. Summary of the final distribution (D_x) and abundance (A) models (x indicates the utilized threshold value in distribution modeling).

GLM	Mean altitude	Mean slope angle	Std of wetness index	Mean canopy cover	Peat cover	AUC cal / eval *$R_{(s)}$ cal / eval*
D_4	↗	− + −	↗	↘		0.79 / 0.76
D_5	↗	− + −	↗			0.78 / 0.76
D_6	↗		↗			0.79 / 0.78
A	↗	− + −	↗		∩	*0.48 / 0.52*

The direction of the effect of environmental factor ($p < 0.001$) is indicated with symbols (↗ = positive correlate, ↘ = negative correlate, ∩ = second-order correlate with a humped response curve, − + − = third-order correlate with a recumbent S-shaped response curve). The area under the curve (AUC) values and Spearman's rank correlation coefficient (R_s) were calculated with the calibration (cal) and evaluation (eval) data.

and activity of frost processes on a local (e.g., Matthews et al. 1998) and regional (Luoto & Hjort 2004) scale. Moreover, climate warming will probably increase the vegetation cover in sparsely vegetated arctic and subarctic regions (e.g., Liston et al. 2002). This would affect the periglacial processes, because feature occurrences have shown to be connected to shrub abundance, both positively and negatively, depending on the process type (Hjort 2006).

Periglacial phenomena have been mapped from numerous cold climate regions, but environmental factors controlling diversity have not been analyzed statistically previously (e.g. Lundqvist 1962, Karte 1979, Åkerman 1980, Harris 1982, Hjort 2006). Based on the modeling conducted in this study, the diversity of periglacial landforms was connected to altitude and soil moisture variability on the landscape scale. Moreover, the most diverse sites were either flat areas (0–2°) or rather steep slopes (8–12°). Different patterned ground features occur on flat topography, whereas moderate slopes are covered by sorted and non-sorted solifluction landforms. In proportion, gentle slopes are less suitable for most of the observed periglacial feature types (cf. Washburn 1979, French 2007).

The prediction and explanation power of the models were only on a moderate level (cf. Brenning & Trombotto 2006, Hjort et al. 2007). This is partly due to the complex process-environment relationships when landforms of different origin are grouped. Several different processes are responsible for the genesis of the observed periglacial landforms, and it is a challenging task to generate spatial datasets of causal factors of periglacial processes (Luoto & Seppälä 2002). Moreover, the correlation between environmental factors and periglacial landforms may be blurred by the fact that an environmental factor may be a positive or a negative correlate, depending on the feature type. On the other hand, the employment of a multivariate method and GIS-based data helped to draw a conclusion of factors affecting periglacial geodiversity, an issue that may be a complicated task using traditional descriptive methods.

Despite the fact that the prediction and explanation abilities of the models were rather low, the models were robust and gave parallel results. Therefore, the inferences of important environmental factors lie on fairly solid ground. However, the data-related limitations and method-based weaknesses may bias the modeling results, and the model outcomes should not be interpreted uncritically. In the context of geomorphological modeling, these important issues have been discussed, for example by Guzzetti et al. (1999) as well as Luoto & Hjort (2006).

Conclusions

The employment of GLM and GIS-based data proved to be a useful way to estimate the role of environmental factors in determining the diversity of periglacial features. However, the prediction and explanation power of the models were comparatively low due to the complex process-environment relationships when landforms of different genesis were grouped. Thus, there remains considerable room for further improvements in modeling the diversity of periglacial geomorphology. Improved models could be applied in geodiversity and environmental change studies.

Stephan Gruber
Glaciology, Geomorphodynamics & Geochronology, University of Zurich

Abstract

In Switzerland, several boreholes are monitored within the framework of the Permafrost Monitoring Switzerland (PERMOS). Three of these boreholes, at Murtèl, at Schilthorn, and at Stockhorn, are at least 60 m deep. In addition, a number of shorter boreholes (c. 6 m deep) were drilled in other projects and have been continuously observed over several years. Results on long- and short-term behavior of these boreholes are presented and compared to standard meteorological components, such as air temperatures and snow cover, measured directly at these borehole sites or nearby. First analyses show the importance of the snow cover duration and thickness; more important on a local scale are different surface and subsurface characteristics influencing heat transfer by conduction and heat capacity. The concept of different offsets between atmosphere and lithosphere is discussed, and data reflecting these offsets are presented for typical alpine conditions.

Keywords: alpine permafrost; borehole temperatures; meteorological measurements; surface offset; thermal offset; total offset.

Introduction

Climatic and microclimatic factors control the surface temperature. In turn, the surface temperature is one of the major factors influencing the ground thermal regime. Usually, once the surface temperature regime is known, the thermal regime in the ground, provided it is homogenous, can be analyzed without further consideration of climate. However, snow cover as well as ground thermal properties that depend on surface and near-surface characteristics often strongly modify heat and energy fluxes in the ground (Brown & Péwé 1973, Harris & Brown 1978).

Since the early 1980s, climate–permafrost relationships in high-alpine areas have been in the focus of Alpine permafrost research (cf. Keller 1994, Haeberli et al. 1998, Hoelzle et al. 1999, Hoelzle et al. 2001, Hoelzle et al. 2003, Mittaz et al. 2000, Stocker-Mittaz et al. 2002). In recent years, mountain permafrost research has developed considerably. Main efforts are concentrated on improved modeling and attempting to couple regional climate models with local scale models (Salzmann et al. 2006, Noetzli et al. 2007, Salzmann et al. 2007). There is, however, still a considerable lack in process understanding of the complex interactions between atmosphere and lithosphere in high- mountain areas. This is mainly caused by the complex topography and the high variability of the spatial and temporal influences of snow and surface characteristics (Gruber et al. 2004, Hanson & Hoelzle 2005). The model-concept describing the offset between mean annual air temperature (MAAT) and temperature at the top of permafrost (TTOP) has been developed by several authors (Burn & Smith 1988, Smith & Riseborough 1996, Smith et al. 1998, Henry & Smith 2001, Riseborough 2002) and is a useful simplification to overcoming the problem of physically coupling the atmosphere and the ground. However, snow and surface/subsurface conditions in alpine areas differ quite strongly from the ones in the Arctic. First attempts to apply the concept of TTOP to mountain areas were made by Herz et al. 2003 and Juliussen & Humlum 2007. In the concepts of Lachenbruch & Marshall 1986, Burn & Smith 1988, and Smith & Riseborough 1996, the total offset between MAAT and TTOP is often expressed first by a surface offset between MAAT and the mean annual ground surface temperature (MAGST) and MAGST and TTOP. In reality, the surface offset consists of two separate offsets: one between MAAT and the mean annual surface temperature (MAST) and one between the MAST and MAGST. These two offsets are often treated as one, because they are hardly ever separately measured. The MAST can be expressed as the radiative surface skin temperature, which can be measured by an IR thermometer (see Table 1) measuring the thermal infrared radiating temperature of the ground surface in its field of view. This temperature is measured always at the variable current surface of the corresponding season; e.g., in winter mainly the snow surface and in summer mainly the bedrock surface.

Until today, no reliable information about long-term values of these offsets for alpine areas have been available that are based on long-term measurements. The long-term measurements presented in this paper should help to provide first approximations of the various offsets and a description of the general relationship between MAAT, snow depth, MAGST, and TTOP. This study also reveals the importance of long-term monitoring to improve our process understanding, which is required to develop useful but simple model concepts.

Measurements at Murtèl-Corvatsch and Schilthorn

Meteorological measurements at Murtèl-Corvatsch

The Murtèl-Corvatsch and Chastelets borehole sites are located northwest of the Murtèl cable car station within the ski area Silvaplana – Piz Corvatsch. The area is situated in the Upper Engadine (Eastern Swiss Alps). A steep northwest-facing rock wall surrounds the area, and the slopes below the rock walls are covered by several meters of loose debris. Several rock glaciers and protalus ramparts are situated at the foot of the slope below the ridge. The area is inside the periglacial belt with strong weathering intensity on the headwalls resulting in a large amount of debris feeding the active rock glaciers below.

One of these rock glaciers is the Murtèl rock glacier (46°26´N, 9°49´E), which has been well-investigated over many years (Hoelzle et al. 2002). A borehole was drilled in 1987 and has provided a ground temperature data record since then. In 1997 a first micrometeorological station was installed at the Murtèl-Corvatsch site (Mittaz et al. 2000). Such long-term micrometeorological studies at the borehole locations (Harris et al. 2003) are needed for process understanding, model development, and calibration (Hoelzle et al. 2001). They provide data on heat fluxes between the atmosphere and the active layer, and between the active layer and the underlying permafrost. Therefore, they have been included in the concept of the permafrost monitoring network Switzerland (PERMOS).

Air temperature, radiation, and wind speed among others have been measured directly at the borehole site on the rock

Table 1. Sensors used in this study.

Variables	Sensors (Company)	Sensor Type	Range	Accuracy
Air temperature	MP-100A (Rotronic)	RTD PT-100 1/3-Din ventilated	-40 - +60°C	±10 %
Snow height	SR50 (Campell)	Ultrasonic Electrostatic Transducer	0.5 – 10 m	±0.01 m
Surface temperature	Infrared thermometer	IRt/c.5	-35 – 10°C	±1.5°C
Ground temp. Murtèl-Schilthorn-Stockhorn boreholes	YSI 44006 Yellow Springs Instruments	NTC-Thermistors	-20 - +40°C	±0.02 °C
Ground temp. Active layer	UUB31J1 Fenwal	NTC-Thermistors	-20 - +40°C	±0.02 °C
Chastelets boreholes	YSI 44006 Yellow Springs Instruments	NTC-Thermistors	-20 - +40°C	±0.02 °C
Rocklogger	M-Log Geoprecision	PT1000	-55 - +85°C	±0.01°C

glacier since January 1997. In addition, there is a meteorological station on the summit cable car station that has been run by MeteoSwiss since 1983. With the help of this meteorological station the air temperature at Murtèl-Corvatsch was reconstructed from 1997 back until 1987, which is when the ground temperature measurements started. The same reconstruction is made for the surface temperature measurements, which have been recorded since 2001 by an IR thermometer. Since 1972, snow depths have been continuously measured in winter (October to May) at the middle station of the Corvatsch cable car by the Snow and Avalanche Research Institute in Davos. These data are compared and adjusted to the direct measurements made at the Murtèl-Corvatsch station, which allowed a continuous reconstruction of snow depth for the period 1988ñ2007. These reconstructions were necessary to have a continuous data record directly at the measurement site of the Murtèl borehole.

The micrometeorological station measures air temperature, wind speed and direction, humidity, snow depth, as well as all components of the radiation balance every 10 minutes which is logged every half-hour as a 30-minute mean (cf. sensor description in Table 1). Meteorological measurements in high-alpine environments are difficult because of the harsh climatic conditions. This results in many periods without data. Such periods are caused by lightning, avalanches, rime-ice, or burying of the instrumentation by snowfall.

Ground temperature masurements at Murtèl-Corvatsch

The Murtèl borehole from 1987 was drilled down to 58 m, but in this study only the uppermost thermistors, down to 6 m, are analyzed. The measuring interval is 24 hours.

Seven thermistors were placed in the uppermost 90 cm of the active layer less than 2 m from the microclimate station and in close vicinity of the borehole. Five thermistors are placed 5 cm deep in the boulders, while two thermistors are hanging in cavities between the boulders, thus measuring the ambient air temperatures. They are described in detail by Hanson & Hoelzle 2003, 2004. Temperatures were registered every minute and logged as a 5-minute mean. All thermistors were calibrated before their placement and are annually indirectly calibrated by the zero curtain in spring.

In the Chastelets area, five boreholes were drilled in the year 2002. These boreholes are described in detail by Hanson & Hoelzle 2005. The boreholes were selected using the criteria that aspect and climatic conditions should be the same and that only the surface characteristics are different, such as, for example, coarse debris or bedrock.

Meteorological measurements at Schilthorn

The study area in the Schilthorn massif is situated at the transition between the Prealps in the north and the principle chain of the Bernese Alps, which exceed 4000 m a.s.l. The Schilthorn summit reaches 2970 m a.s.l. and is located at 46°34′N, 7°50′E.

Today, only perennial snow patches can be found, which have been shrinking considerably as a consequence of the warm 1980s and 1990s (Imhof 2000).

Due to its geographic situation (exposed to moist western winds), the climate in the Schilthorn massif is of almost maritime alpine character; i.e., with fairly abundant precipitation, showing a distinct summer maximum. The mean annual accumulation in Lauterbrunnen (valley floor) is 1234 mm, whereas about 2700 mm were estimated on the highest summits, where about 90% of the precipitation falls as snow (Imhof 2000). Consequently, the surface is snow-covered for longer than in most of the comparable regions of the central Alps.

The microclimatological station was installed about 100 m to the northwest of the Schilthorn summit at 2900 m a.s.l. in 1998.

Ground temperature measurements at Schilthorn

Also in 1998, a 14-m deep borehole was drilled into bedrock a few meters to the northwest of the climate station and equipped with a thermistor chain. Two additional boreholes were drilled in the year 2000: a vertical one with a depth of 100 m and a horizontal one with a depth of 92 m. The borehole data show that the active layer reaches, in general, to a depth of about 5 m, and that the MAGT at 14 m depth is around -0.5 to -0.7°C. Thus, permafrost is present at the drill sites but is rather warm.

Results

Meteorological measurements at Murtèl-Corvatsch and Schilthorn

Tables 2 and 3 show the mean monthly values for the three variables (1) air temperature, measured 2 m above the ground, (2) snow height, and (3) ground temperature at 3.6 m and 5.0 m below surface at the top of permafrost.

As ground temperature data for Murtèl-Corvatsch exist from 1987 onwards, air temperature and snow depth were reconstructed as needed.

Schilthorn meteorological and ground temperature data recording started in 1998/99. The mean ground temperature at 3.6 m depth represents the TTOP. Air temperature has an annual peak amplitude at Murtèl-Corvatsch of 15.4°C and at Schilthorn of 13.5°C. Mean snow depth at Schilthorn is approximately double that of Murtèl-Corvatsch.

These values indicate that Murtèl-Corvatsch has a more continental climate than Schilthorn. Schilthorn is situated around 300 m higher than Murtèl-Corvatsch. Despite this elevation difference, the ground temperatures at Murtèl-Corvatsch are by far -1.2°C colder.

TTOP at Schilthorn is at a depth of around 5 m; however, in the year 2003, the active layer thickness increased to around 9 m. This was caused by the heat wave of 2003 which lead to warmer TTOP temperatures than normal. This can also be recognized in Figure 2.

Time series of air temperature, snow depth, and ground temperatures at Murtèl-Corvatsch

Figure 1 displays the continuous mean monthly data set from 1988 to 2007 for air temperature, snow depth, and ground temperature at TTOP 3.6 m below surface. The time series illustrates the influence of snow cover on the TTOP. The winters 1993/94, 1996/97, 2000/01, and 2002/03 had snow depths that far exceeded normal conditions. As a result, the TTOP were very warm, even in the year 2002/03 which had very cold winter air temperatures. In contrast, the winters 1988/89 and especially 2001/02 had below-average snow conditions, which resulted in very cold TTOP. An exception was the winter 2006/07, which had the lowest snow depth since the beginning of the snow measurements in 1972. It did not result in the coldest TTOP, because winter air temperatures were the warmest ever recorded at the meteorological stations in the Corvatsch area.

Table 2. Mean monthly values of different meteorological measurements at the Murtèl-Corvatsch site from 1988 to 2006.

Monthly mean 1988-2006	Air temperature [°C]	Snow height [m]	Borehole temperature (depth = 3.6 m) [°C]

December	-7.88	0.88	-0.08
Average	**-2.77**	**0.81**	**-0.35**

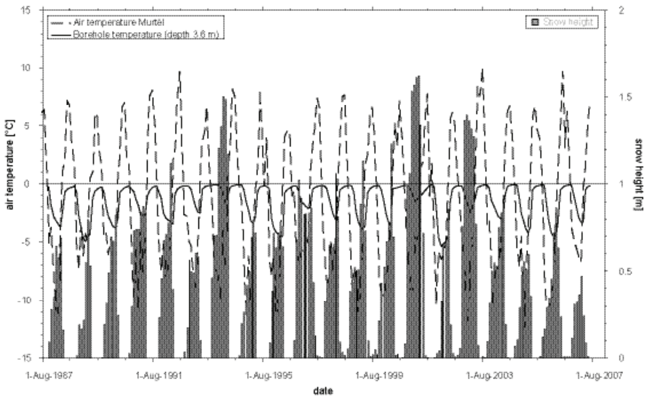

Figure 1. Monthly air temperature, snow depth and ground temperature at TTOP in 3.6 m depth at Murtèl-Corvatsch (borehole 2/87).

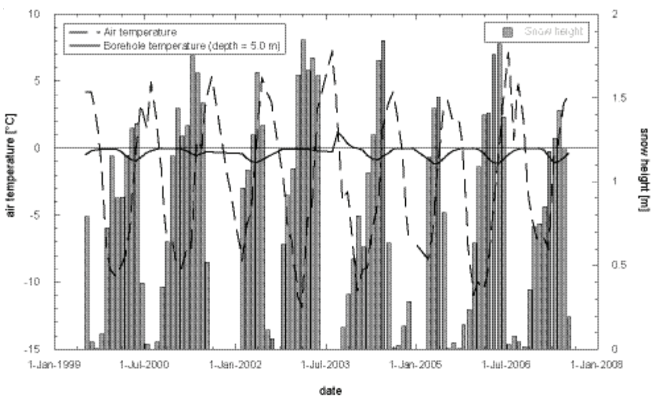

Figure 2. Monthly air temperature, snow depth and ground temperature at TTOP in 5.0 m depth at Schilthorn (borehole 51/98).

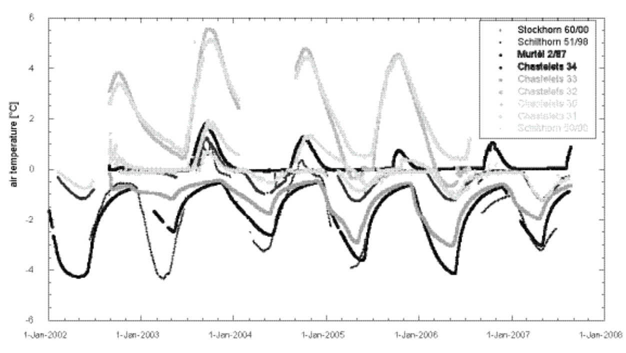

Figure 3. Daily ground temperatures in all boreholes at 5 m depth.

Time series of air temperature, snow depth, and ground temperature at Schilthorn

Figure 2 shows the mean monthly data set from 1999 to 2007 for air temperature, snow depth, and ground temperature at TTOP in a depth of 5.0 m. The time series from the Schilthorn does not reflect the influence of the snow cover on the TTOP temperature as well as the Murtèl-Corvatsch series does. The winter snow cover at Schilthorn shows less variability than at Murtèl-Corvatsch.

In general, winter snow cover at Schilthorn starts earlier and reaches greater snow thicknesses than at Murtèl-Corvatsch. This results in stronger warming than at Murtèl-Corvatsch. Additionally, the surface layer at the Schilthorn is composed of fine-grained material containing more unfrozen water and resulting, therefore, in reduced cooling because of latent heat effects.

Table 4. Surface offset (temperature at 0.5 m depth – air temperature) and total offset (including thermal offset) 1) temperature at 2.5 m depth – air temperature; 2) temperature at 4.5 m depth – air temperature) for different boreholes and years. The rows in grey show the values for the permafrost boreholes.

Borehole	Measurement period	Surface offset	Total offset 1	Total offset 2
Murtèl 2/87	1997/98	1.50	0.33	-0.12
Murtèl 2/87	2001/02	0.26	-0.33	-0.50
Murtèl 2/87	2002/03	1.33	0.02	-0.37
Murtèl 2/87	2003/04	1.40	0.73	0.28
Murtèl 2/87	2004/05	0.41	0.10	-0.37

Stockhorn 60/00	2002/03	-1.28	4.98	3.72

Time series of different ground temperatures at all investigation sites

Figure 3 shows the temperature development since 2002 within all boreholes investigated in this study. After the very warm summer 2003, a slight cooling trend is observed within all boreholes. This effect can mainly be attributed to less winter snow (see also Fig. 1).

Offset data at all sites

Table 4 shows the surface offset and total offset for several years and borehole sites. These selected data only include years that have less than 10% data gaps. The data show that at most permafrost sites the surface offset is less than at permafrost-free sites. The range of surface offset at the permafrost sites varies from less than 0 up to 2.9°C, but between 3.41 and 4.6°C at permafrost-free sites. Borehole 34 lies in between and should be treated as a special case, because this site is at the edge of a rock glacier within fine material and the lowest temperature sensor at 6 m depth is close to 0°C, indicating permafrost below but not in this borehole.

In Figures 4 and 5, the surface offset and thermal offset, including the offset between MAAT and MAST, are shown as an average over the whole measurement period for Murtèl-Corvatsch (Fig. 4) and Schilthorn (Fig. 5). The offset data reveal that the mean difference between MAAT and MAST is 1.12°C at Murtèl-Corvatsch and 1.24°C at Schilthorn, respectively. The offset between MAST and MAGST is 3.62°C at Murtèl-Corvatsch and 3.99°C at Schilthorn.

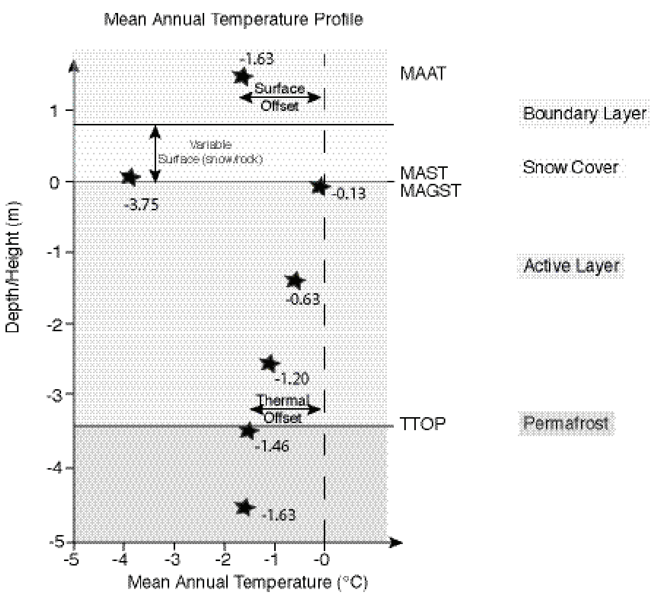

Figure 4. Different offset values shown from the mean data measured at the Murtèl-Corvatsch.

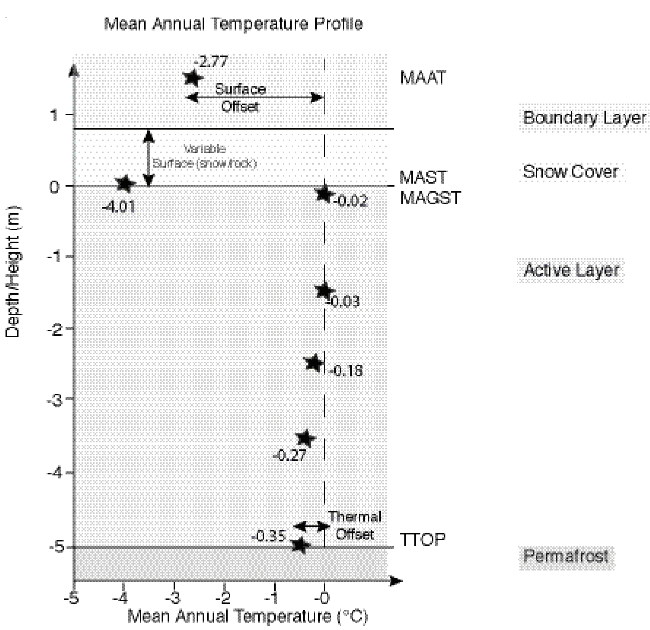

Figure 5. Different offset values shown from the mean data measured at the Schilthorn.

The offset usually called *surface offset* (MAGST – MAAT) is 1.50°C at Murtèl-Corvatsch and 2.75°C at Schilthorn. The offset usually called *thermal offset* (TTOP –MAGST) is 1.53°C at Murtèl-Corvatsch and 0.33°C at Schilthorn. The total offset (TTOP – MAAT) at Murtèl-Corvatsch with a value of 0.17°C is considerably smaller than at Schilthorn with 2.42°C.

Discussion and Conclusions

The long-term data sets collected in the last 20 years within the monitoring project PERMOS, together with the additional data, form a unique archive that is becoming more and more valuable. The time series at Murtèl-Corvatsch and Schilthorn not only reveal how the TTOP are related to snow cover and air temperature, but they also show the different behavior at the different investigation sites mainly caused by variable surface and subsurface characteristics.

However, the variability of the offsets between the permafrost sites is high. As an example, the surface offset at Murtèl-Corvatsch is more or less compensated by the thermal offset in the ground, which results in a very small total offset of only 0.17°C. In contrast, at Schilthorn the surface offset is dominating and the thermal offset is very small, resulting in a larger total offset of 2.42°C.

In the future, the concept of working with different offset values, based on long-term measurements, may help to better understand the processes between atmosphere and mountain permafrost and, therefore, will help to build up simple relationships for modeling mountain permafrost (Noetzli et al. this volume) and to better interpret the development of temperature and related ice content in the ground (Hilbich et al. this volume).

Abstract

This paper examines the response of tundra systems to more than a decade of experimental warming, using International Tundra Experiment (ITEX) open-top chambers (OTCs) in wet and dry vegetation types near Barrow and Atqasuk, Alaska. The magnitude of chamber warming varied by site and changed over time. Maximum thaw depth varied little between OTC and control plots, except in recent years. To understand how vegetation controls air-soil heat exchange, we denuded the vegetation to bare ground in two chambers and added the removed vegetation to adjacent chambers to provide enhanced thermal insulation. Soil temperatures were coolest in chambers to which litter had been added. The difference between air and soil temperatures was similar between the chambers with added litter and chambers that had been in place for nine years. This experiment indicates that changes in vegetation due to a warmer climate may result in cooler soils.

Keywords: experimental warming; ITEX; open-top chamber, soil temperature; thaw depth; tundra; vegetation.

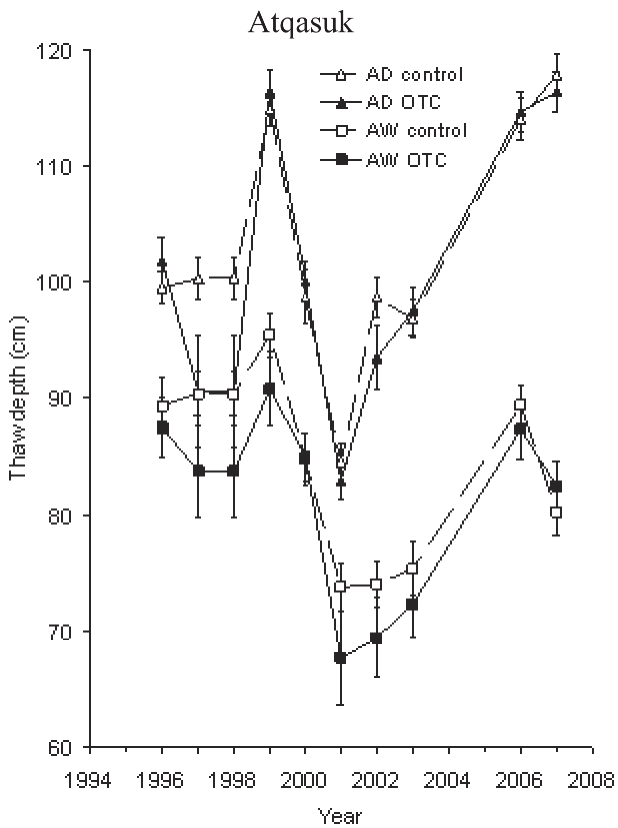
Introduction

Open Top Chambers (OTCs) have been used by the International Tundra Experiment (ITEX) since the early 1990s to simulate warmer snow-free growing conditions, which are expected to occur in the Arctic with climate change (Henry & Molau 1997, Arft et al. 1999, Hollister et al. 2005a, Walker et al. 2006). Recent studies have shown that the effect of OTCs on air and soil warming varies across sites of differing vegetation type (Marion et al. 1997, Hollister et al. 2006). Related studies document increased plant growth, changes in plant species composition and abundance, and an accumulation of leaf litter in response to warming (Hollister 2003, Hollister 2005a, b, Walker et al. 2006). This study aims to understand how changes in vegetation can alter the air-soil heat exchange properties of warmed plots and potentially explain the differential response of some vegetation types to OTCs.

We manipulated vegetation by removing the canopy and adding the clipped plant matter to adjacent plots to directly explore the impact of the plant canopy on air-soil heat exchange in a manner similar to Ng and Miller (1977). The relationship between air and soil warming is driven by soil type and vegetation (Gross et al. 1990, Walker et al. 2003). While dead plant litter is not a true substitute for a denser living plant canopy, it is easily manipulated and may provide insights into the insulating effect of the vegetation on soil temperature.

Study Area and Methods

Study sites were established in different years (see Table 1) in wet and dry plant communities near the villages of Barrow (71°18′N, 156°40′W) and Atqasuk (70°29′N, 157°25′W), Alaska. Barrow and Atqasuk are on the coastal plain of Alaska's North Slope and lie within the zone of continuous permafrost. Seasonal thaw varies with landscape position and is generally less than 1 meter (Nelson et al. 1998, Hinkel & Nelson 2003). Atqasuk is 100 km south and inland from Barrow and is on average 5^{o}C warmer in July than Barrow (Haugen & Brown 1980). The Barrow dry (BD) site lies on a former raised beach ridge. The soil is a moderately well drained xeric pergelic cryaquept underlain with fine silt, sand, and gravel. The vegetation is a dry heath dominated by prostrate shrubs and lichens. The Barrow wet (BW) site lies on the edge of a drained thaw lake basin. The soil is a poorly drained histic pergelic cryaquept underlain by fine silt. The vegetation is a wet meadow dominated by graminoids and mosses. The Atqasuk dry (AD) site lies on a raised rim of a drained thaw lake basin. The soil is a well drained pergelic cryopsamment underlain with aolian sand. The vegetation is a dry heath dominated by lichens and prostrate shrubs. The Atqasuk wet (AW) site lies on a pond margin. The soil is a poorly drained histic pergelic cryaquept underlain with aolian sand and silt. The vegetation is a wet meadow dominated by mosses and graminoids.



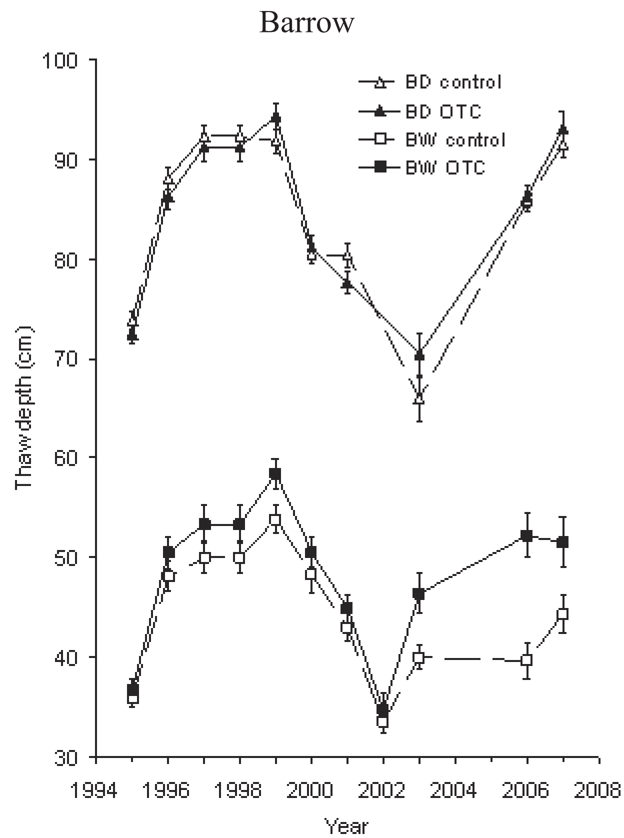


Figure 1. Mean annual maximum depth of thaw below OTC plots (filled symbols) and control plots (open symbols) at Atqasuk (left) and Barrow (right). Note the change in scale between locations; lines between readings for each year to allow for ease of delineating sites and treatments. Data were not collected in 2004 and 2005. Error bars represent the standard error of the mean and most sample sizes were 24.

Figure 2. Mean July temperature (°C) of air at +13 cm (circles) and soil at depths of 10 cm (triangles) and 45 cm (squares) in OTC plots (filled symbols) and control plots (open symbols) at the four study sites. Error bars represent the standard error of the mean (n=2). Missing data are represented by an M; a dot above and below the value to represent missing error bars.

Table 1. Years that sites were established, temperature and thaw measurements were initiated, and number of years in operation. Sites of 24 OTC and 24 control plots were established in different years. Plots where temperatures were recorded were established in the same year.

Site	Established		No. years	
	Site	Temp	Temp	Thaw
Atqasuk dry (AD)	1996	1998	9	11
Atqasuk wet (AW)	1996	1998	9	11
Barrow dry (BD)	1994	1998	9	13
Barrow wet (BW)	1995	1998	9	12

Each of the study sites consists of 24 OTC and 24 control plots in which standardized annual measurements, such as summer thaw depth, are made. The hexagonal OTCs are constructed of Sun-Lite HPTM fiberglass (Solar Components Corporation, Manchester, New Hampshire) to passively warm study plots. Chambers are approximately 35 cm high, 103 cm across at the base, and 60 cm across at the top (Molau 1993, Hollister 2003). The OTC and control plots cover an area of approximately 1 m^2. The magnitude of warming in the OTCs is driven by solar intensity and wind conditions (Marion et al. 1997, Hollister et al. 2006). For example, on calm sunny days the passive OTCs can warm the plant canopy up to 10°C above the ambient temperature. OTCs were installed soon after snowmelt and removed in mid to late August at the end of each field season. The length of the growing season and snow depths were not altered by the experimental manipulation. Additional plots for destructive sampling and sensor installation have been set up since the sites were established.

At each site two plots per treatment were established in 1998 to provide more detailed information on the effects of the OTCs on the air and soil microclimate. Since 1998 soil temperature has been measured at depths of 0 cm , 10 cm, and 45 cm using TP101M temperature probes (Measurement Research Corporation, Gig Harbor, Washington) connected to Campbell Scientific CR10X dataloggers. Prior to 2005, aerial sensors were housed in radiation shields placed within the plant canopy at approximately 13 cm above the ground surface and connected to HOBO® or StowAway™ loggers (Onset Computer Corporation, Pocasset, Massachusetts). In 2005 air temperatures were measured with Campbell 107 temperature probes connected to the CR10X at each site. The accuracy of each probe varies with temperature but is generally within 0.2°C. Temperatures were measured every 10 to 80 minutes. Averages and standard errors were calculated by averaging values for each plot and then comparing plots.

To explore the influence of the plant canopy on OTC performance between sites, two new treatments with two replicates each were established in 2007 at each site. In one treatment the plant canopy was removed down to bare ground in a 20 cm diameter circle in the center of the plot during late June. The removed vegetation was added to adjacent plots, forming a loose layer of litter that mixed in the existing plant canopy. This additional material may generally be considered as litter because the plants were unattached, although it contained lichens, mosses and vascular plants that remained green and appeared vigorous. These two new treatments of OTC plots were in place for one field season. Temperature was monitored in these plots at +13 cm, -1 cm, and -10 cm using StowAway™ loggers.

Depth of thaw was measured to the nearest cm by inserting a graduated metal rod into the ground until the ice-rich permafrost table was reached, usually in mid-August, at each of the 24 plots per treatment.

Results

Mean annual maximum thaw depth

Mean annual maximum thaw depth generally varied little between the OTC and control plots (Fig 1). Thaw was deeper at Atqasuk than Barrow and was deeper in dry sites than in wet sites. Thaw was deeper in warmer years (see mean July temperatures in Fig 2). Thaw in this study's wet sites, which are subject to periodic inundation and have thick insulating moss layers, is somewhat shallower than in dry sites, but large relative to thaw depths recorded in other land cover types in the region. At the dry sites the difference between OTC and control plots was generally indistinguishable. At the wet sites the average difference between OTC and control plots was more consistent across years. At the AW site the control plots generally showed deeper average thaw than OTCs, while at the BW site thaw was consistently deeper in the OTC plots compared with control plots. This difference was more pronounced in recent years.

Air and soil temperature

Mean July air temperatures were between 0.3°C and 4.3°C warmer within the OTC plots. The magnitude of this warming varied by site and over time, with the most pronounced warming in later years (Fig 3). The effect of OTCs on soil temperature varied by site and year. The OTCs cooled the soils at the AW site and warmed them at the AD site. At Barrow, OTCs warmed the soils in early years and cooled them in later years. The effect of OTCs on soil temperature diminished with depth.

The change from soil warming to cooling over time at Barrow warranted further examination. Table 2 represents the average difference in temperature between the control and OTC plots over the course of the experiment. Winter temperatures were consistently warmer under the OTC plots and this difference intensified over time. In summer, soil temperatures became increasingly cooler over time in the OTCs.

Table 2. Mean seasonal differences in soil temperature (°C) between OTC and control plots at the BD and BW sites. Differences were calculated by subtracting the mean of the control plots from that of the OTC plots.

Vegetation manipulation

The difference between air temperature and soil temperature at a depth of 10 cm was least in the control plots (Table 3). Regardless of whether or not the OTCs cooled or warmed the soils, the pattern across the three warming treatment types (bare ground, added plant matter, 9 years of warming) was consistent. Within the OTCs the soil temperatures were coolest under the plots receiving additional plant matter. The soils under the OTCs which had been in place for nine years were either warmer or similar in temperature to soil under OTCs where the vegetation was removed. The difference between air (13 cm height) and soil (10 cm depth) temperature within the OTCs was greatest in OTCs where plant matter was added, and this difference was similar to the OTCs which had been in place for 9 years.

Discussion

Previous studies have found that temperature enhancement by the OTCs varied significantly in different plant communities (Marion et al. 1997, Hollister et al.

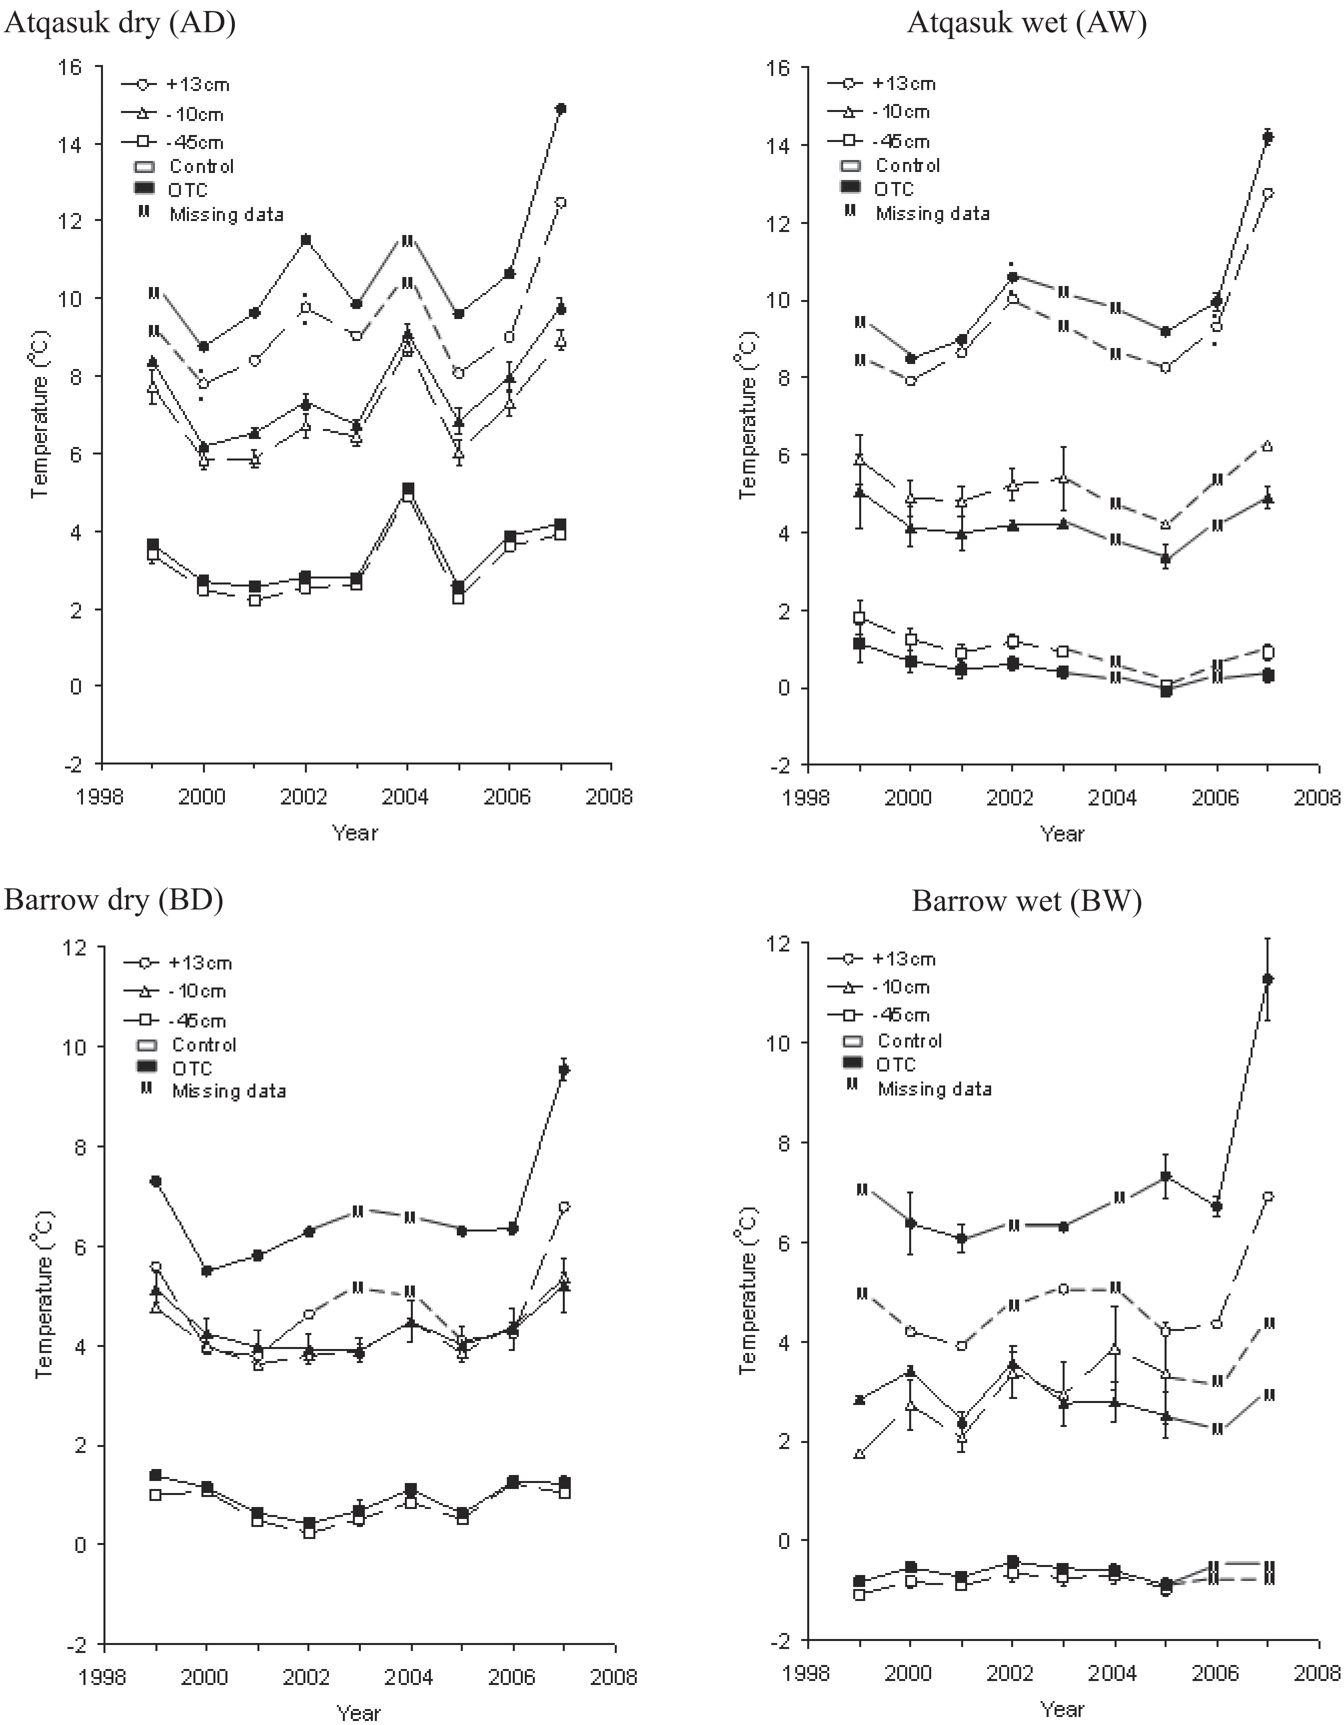

Figure 3. Mean July temperature (°C) of air at +13 cm (circles) and soil at depths of 10 cm (triangles) and 45 cm (squares) in OTC plots (filled symb ols) and control plots (open symbols) at the four study sites. Error bars represent the standard error of the mean (n=2). Missing data are represented by an M; a dot above and below the value to represent missing error bars.

Table 3. The effect of plant removal and addition on mean July canopy and soil temperature within the study plots (°C). Plots included control plots (Control) and OTC plots in place for 9 years (9 years) or in place for one year where the surface vegetation was removed to expose bare ground (Bare) and where the removed vegetation was added (Added) at the four study sites. Measurements were made at canopy height (+13), within 1 cm of the ground surface (0) and at a depth of 10 cm (-10). The difference between the temperature at the plant canopy and at a depth of 10 cm is shown (Diff). Values in parentheses represent the standard error of the mean (n=2).

--- no data due to instrument malfunction

2006). The consistency of results from this study across sites indicates that the sites share a common response to changes in vegetation. At all sites the difference between air temperature and soil temperature measured at a depth of 10 cm was greatest in the OTC plots and greatest in either the OTC plots in place for 9 years or where plant matter was added. It appears, therefore, that vegetation is influencing both soil temperatures beneath the plots and long-term changes in the vegetation layer, such as increased leaf area index (Hollister 2003). Moreover, these significant changes resulting from experimental warming occurred over a period of less than ten years. The most likely explanation for the increase in soil temperature is increased insulation provided by enhanced vegetation growth and plant litter. This result is in agreement with that of the classic Ng and Miller (1977) experiment and modeling exercise, in which increased canopy and litter layers led to a cooling of the soil and a reduction of the active layer. The small size of the plots in this study probably reduced the impact on thaw depth.

These findings indicate that vegetation also plays a role in OTC warming. There was a tendency toward more warming in later years of the experiment, and the OTCs in place for nine years were warmer than the newly installed OTC plots where vegetation was manipulated. Presumably the vegetation minimizes heat loss from the warmed interior of the chamber. Vegetation becomes taller and denser over time, creating warmer conditions that are more conducive to tundra plant growth. Through this process the OTCs retain progressively more heat, leading to greater seasonal average differences between the OTCs and the control plots.

The increase in thaw depth at the BW site in later years of the experiment and the concomitant soil cooling during the summer months warrant further investigation. The two data sets were collected from different plots (temperature from 2 plots per treatment established in 1998 and thaw from 24 plots per treatment established in 1996). The change in temperature diminished with depth and was not significant at the depths near maximum thaw. It is also possible, although unlikely, that minor movements of the sensors due to cryoturbation may have influenced soil temperatures.

Taken together, the long-term warming experiment and short-term vegetation manipulation within the warming experiment demonstrate that vegetation is one of the dominant determinants of air-soil heat exchange at shallow depth at these sites, and that differences in OTC performance at the sites are strongly influenced by vegetation. As the vegetation responds to warming with increased growth, these changes appear to dampen air-soil heat exchange. Not only does this study reaffirm the importance of vegetation in influencing patterns of air-soil heat exchange in tundra regions, it also highlights the value of long-term experimental observations and how these can facilitate our understanding of how climate change may affect tundra ecosystem structure and function.

John Jardine
Arctic Foundations of Canada Inc.
Bill Watt
Arctic Foundations of Canada Inc.

Abstract

Climate change is rapidly warming permafrost in the Arctic, with the result that the traditional sand-slurry piles foundation may not be applicable for new structures with a design lifespan of 50 years or so. One foundation design that may be suitable for the warming trend of permafrost is the thermosyphon foundation design with flat loop evaporator pipes. There is limited published information on the design and performance of this foundation. To address the above points, the performance of several thermosyphon foundations with horizontal evaporator piping at several locations with varied climate conditions, foundation designs, and construction history is presented. Thermosyphon foundations presented herein are all located in Canada in Inuvik, NT, Iqaluit, and Pangnirtung, NU, and Kuujjuaq, QC. Mean annual air and ground temperatures are given for these projects along with design, construction schedule, and ground-temperature changes.

Keywords: flat-looped; foundation; performance; permafrost; thermosyphon.

Introduction

The design and construction of foundations for buildings is a challenge in permafrost with high ice content. The heat from the buildings may warm and thaw the frozen ground resulting in settlement of building; jacking of piles in raised buildings due to the annual freezing of the active layer; and settlement of piles due to creep of high ice-rich soils. There are limited windows for construction during the year, and a construction schedule is influenced by the availability of materials and equipment. Finally, the site and drainage conditions may change due to the construction that may impact the thermal conditions of the site.

The challenges have been increased by climate warming that is rapidly increasing the ground temperature in Arctic regions. The most recent Intergovernmental Panel on Climate Change (IPCC 2007) made the following statements: a) warming of the climate system is unequivocal; b) average Arctic temperatures increased at almost twice the global average rate; and c) temperatures at the top of the permafrost layer have generally increased since the 1980s in the Arctic by up to 3°C. Global air temperature increases since 1975 to 2001 and the future changes predicted by various models are shown in Figure 1. This figure illustrates two points that should be considered in the design of future foundations in permafrost: a) air temperature has increased appreciably since about 1975, and b) this rate of temperature increase will likely continue to about 2100.

Holubec (2007) looked at the mean annual air temperature (MAAT) records at 24 weather stations across the Canadian permafrost regions to obtain MAAT and establish the warming rate at these stations from 1985 on. Data were interpreted by means of linear trend lines to smooth out the MAAT variations from year to year. This provides an estimate of the present mean climate warming rate and allows determining MAAT for a specific year over the next 100 years. Mean annual ground temperatures (MAGT) were estimated for the same locations by assuming that the MAGT was 4.4°C warmer than the MAAT (Smith & Burgess 2000). Results grouped into four general Canadian areas with permafrost are given in Table 1.

Results in Table 1 indicate that permafrost will warm significantly and will start to thaw in most of Canada's mainland permafrost region in less than 50 years, which is the normal design period for new buildings.

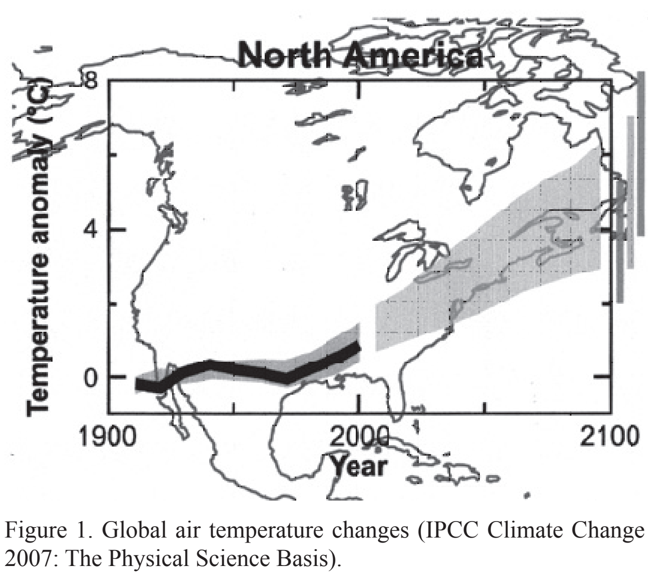

Figure 1. Global air temperature changes (IPCC Climate Change 2007: The Physical Science Basis).

Table 1. Climate conditions across Canadian Arctic in 2006.

Region [a]	MAAT [b] deg C	MAGT [b] deg C	Warming rate [c] deg C/10years
Western Arctic	- 3 to -9	1 to -5	0.7
Central Mainland Arctic	-9.8	-5.4	1.1
Eastern Arctic	-5.8	-1.4	1.7
Arctic Islands	-14.1	-9.7	0.9

a) Results based on average of 3 to 4 climate stations in each Region. b) MAAT & MAGT in 2006. c) Warming rate since 1985

The MAGT's at Inuvik, NT, and Iqaluit, NU, were at about -3.0°C in 2006. These are in general agreement with ground-temperature measurements. The -3°C is the ground temperature at which Johnston (1981) suggests that a passive cooling system should be considered for building foundations. The fact that most of the Canadian mainland permafrost region is in the range of 0 to -5°C and the climate warming rate is about 1°C every decade suggests a cooling system should be considered for building foundations.

Flat Loop Thermosyphon Design

Thermosyphon cooling is a passive thermal system that was first used in Alaska in 1960. Its benefit was clearly demonstrated on the Alaska pipeline, where over 120,000 thermosyphon tubes were installed within pipe piles (Heuer et al. 1985). Thermosyphon is a closed pipe, charged with a gas that is maintained in two phases: liquid and gas.

A thermosyphon continuously transfers heat during winter by evaporation and condensation of a liquid and gas, respectively. Heat transfer occurs when the top of the tube (radiator/condenser) is in an environment colder than the bottom part of the tube (evaporator) located in the ground. A vertical thermosyphon design, normally called thermopile/thermoprobe, expanded into sloped evaporator thermosyphon in 1978; and then in 1994, the flat loop thermosyphon design evolved. The three thermosyphon designs used in building foundations are illustrated in Figure 2.

Brief descriptions of the three designs are:

a) Buildings are supported on thermopiles with a 0.6 m to 1 m air space between the ground and building.

b) Conventional sloping evaporator (CSE) has an evaporator-condenser pipe that slopes beneath the building. The slope allows the condensate to flow to the bottom of the pipe. The building rests on a granular pad, and the evaporator pipes are covered with insulation to retard heat flow into the ground.

c) Flat looped evaporator (FLE) has a looped pipe (evaporator pipe) beneath the building that connects to a larger-diameter riser that functions as the condenser. Evaporator pipes are installed within a granular pad and covered with insulation and granular bedding. The building may be supported directly on the insulation or columns resting on footings on the bedding.

The principle of the flat looped evaporator thermosyphon is illustrated in Figure 3. The FLE design is a relatively recent development (Yarmak & Long 2002). Its performance was tested during the winter of 1993–1994 in Winnipeg, where it was observed to be 1.4 more efficient that the CSE. The FLE started to be installed in 1994 in Alaska and Canada.

The use of the FLE has been much greater in Canada than in Alaska because of different availability of access. The prevalent thermosyphon foundation design in Alaska is the thermopile because of ready access in most locations for large equipment to drill the large holes for these piles. The FLE design is more common in Canada because of the smaller weight of material that needs to be transported to the site and requires only small equipment for installation. Furthermore, the FLE protects a large building footprint at relatively low installation cost.

Since 1994 some 80 FLE systems have been constructed in Canada. Of these, 10 FLE have been placed at the bottom of dams to keep the foundation frozen and 70 FLE under buildings. The FLE system has been used in two configurations: either below slab-on-grade, where the lower building is founded on a gravel/insulation/evaporator pipe system, or the base of the building has a crawl-space that is followed by the gravel/insulation/evaporator pipe system. The majority of FLE have the buildings supported on the slab grade-on design.

The two foundation systems have different requirements for the installation of water and grey water pipes. In the slab-on-grade design, the services are installed in insulated conduits or utilidors below the floor slab. In the crawl-space design; the services are hung from the floor beams. The slab-

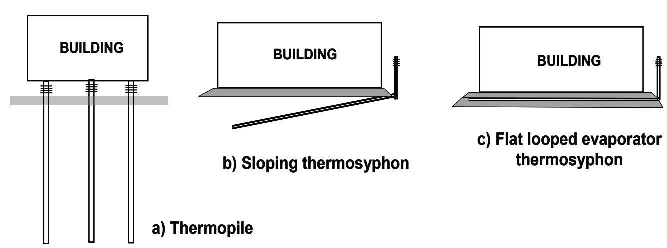

Figure 2. Three thermosyphon designs.

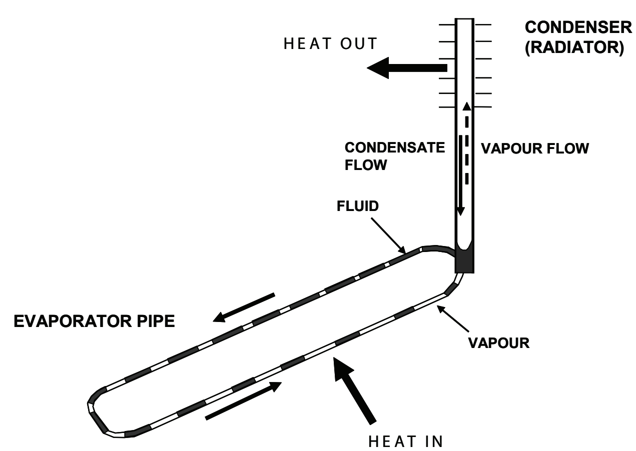

Figure 3. Operation of a flat looped thermosyphon.

on-grade may make repairs or changes to the services more difficult.

The foundation of the flat looped thermosyphon system consists of following basic components: a) 1- to 2-m thick compacted gravel pad; b) evaporator pipes; c) 150 mm bedding below and above the pipes; d) 100 to 200 mm rigid insulation; and e) a vertical radiator. A typical layout of the evaporator pipes and the location of the radiators for a flat looped thermosyphon installation is shown in Figure 4.

Performance

Only limited-performance information is available, because many installations are small buildings constructed on slab-on thermosyphon foundations. Due to the small size of the buildings and the remoteness of the sites, the installations are poorly monitored. Difficulties of the foundations are only noticed if drywalls in the building start to crack or if it is difficult to open or close doors. It appears that the majority of slab-on-grade thermosyphons are working well by the small number of known complaints.

Information on the facilities, their locations, temperatures at time of installation, and type of foundation discussed herein are given in Table 2.

Aurora College

The best performing flat looped thermosyphon foundation, with no problems and having ground-temperature records, is the Aurora College in Inuvik constructed in 2002. This is a slab-on-grade installation with a thick granular pad below the evaporator pipes and good surface drainage control. The natural ground before construction consisted of 0.5 m of granular fill, followed by nearly 2 m of peat and highly ice-rich soil with numerous ice lenses. A reference ground-temperature cable indicates the MAGT to have been about -2.5°C in 2002.

The native ground was excavated to about 3 m and replaced with compacted non-frost susceptible granular fill. Evaporator pipes were installed within a bedding layer and covered with 100 mm rigid insulation. The evaporator pipes were spaced at about 0.8 m. The excavation and granular backfill were completed in May 2002. This was followed by installing the thermosyphon system, charging it with carbon dioxide, and covering the evaporator pipes with insulation and about 1.25 m granular. This was completed in early June. Ground temperature performance from June 2002 to July 2003 is shown by means of ground-temperature profiles in Figure 5.

Figure 4. Typical thermosyphon flat loop, slab on ground installation at Pangnirtung, NU.

Ground-temperature profiles illustrate that the granular foundation started to cool right after it was covered with insulation and about 1.2 m of gravel. The thermosyphons started to cool and freeze the granular fill and natural ground below the evaporator pipes in mid-October and completed the conversion of all pore water to ice early in December. The coldest temperature at 6 m of -4.4°C was reached in May 2003; this warmed to -2.3°C on December 9, 2003. The warmest temperature at the base of the evaporator pipes (depth 0 m), -0.2°C, was reached in mid-September 2003.

One set of ground temperatures measured in September 2007 showed the ground temperature at the evaporator pipes and at 6 m depth to be -0.2°C and -3°C, respectively. The first temperature indicates the maximum ground temperature reached in 2007. However, the second is not representative of the MAGT because data for a whole 12 months is not available.

Inuvik Hospital

This case history has several aspects that are of interest. This is a flat looped thermosyphon foundation with a heated crawl space. The base of the foundation was excavated about 2 m below the ground surface and backfilled with 0.5 m granular fill. The evaporator pipes were installed within 300 mm of bedding and subsequently covered with 200 mm of rigid Styrofoam insulation. The insulation was covered with a membrane liner and 19 mm cement boards to protect the liner. Height from the cement board to the base of the main floor slab is about 1.9 m. The base of the crawl space is about 1 m below the outside ground level. Finally, the excavation between the natural ground and basement wall was backfilled with free draining granular material that was

not covered with a low permeability soil zone to prevent surface water infiltrating the granular fill.

Excavation, granular fill, evaporator pipe, and insulation placement were completed by 19 July 2001. Since the project desired to have the ground below the thermosyphon foundation frozen as early as possible before pouring the footings, a hybrid thermosyphon system was installed. This consisted of cooling coils around the conductor pipes that were cooled by a mechanical refrigeration plant. The cooling plant was activated on 21 August 2001 and switched off permanently on 15 November 2001, when the foundations were completely frozen with a cold reserve. Ground cooling of the foundation by the hybrid system is illustrated in Figure 6. This shows that thaw within the natural ground did not exceed more than about 1 m below the base of the excavation, and the ground was completely frozen by 17 October 2001. The hybrid system was turned off on 15 November 2001, and the passive thermosyphon system started to operate.

The vertical thermistors at the hospital started to be monitored again in mid-September 2002. The changes in ground temperature, at five depths from this date on, are shown in Figure 6.

Graphs presented in Figures 7 and 8 show the warmest and coldest ground temperatures below the evaporator pipes during five years of operations.

Figure 8 illustrates that, for the first two years, the maximum ground temperature 0.15 m below the evaporator pipes was at about -0.3°C, and thereafter it varied between -0.6 and -1.0°C. At a depth of 4.15 m the ground temperature was about -2.5°C for the first two years and then cooled to about -3.5°C.

The minimum ground temperatures varied greatly just below the evaporator pipes, as expected, but steadied at 4.15 m depth after one year at about -7.5°C (Fig. 9).

Two problems developed at Inuvik Hospital. First, the mill that provided the evaporator pipes shipped defective welded A53B pipes that were found to leak slowly at the manufacturer's seam welds. This developed after the evaporator pipes were cooled when the thermosyphons started to operate, and resulted in a loss of refrigerant and some of the thermosyphon loops having to be recharged annually. Since that installation, the installer has used only seamless A104 pipe.

The second problem was caused by surface water penetrating the surface granular zone above the evaporator pipes during the summer. This water froze in the fall when the thermosyphons start to operate and produced localized ice boils between the top of gravel and insulation.

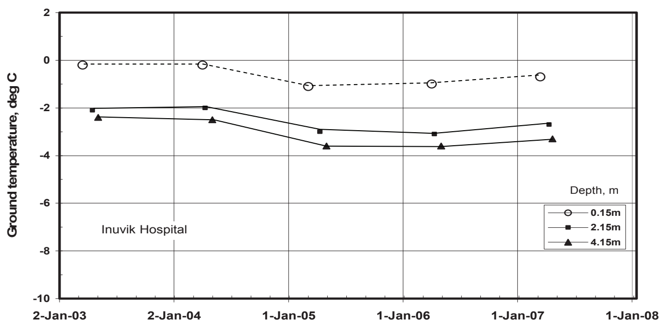

Figure 8. Maximum ground temperatures measured below the evaporator pipes.

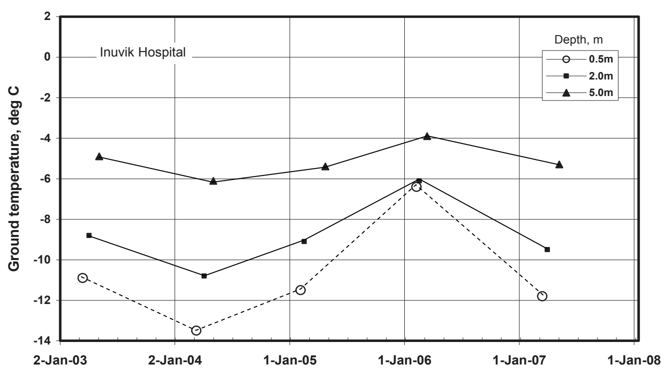

Figure 9. Minimum ground temperatures measured below the evaporator pipes.

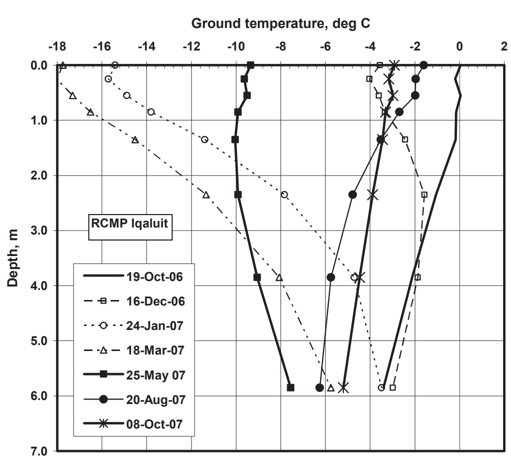

Figure 10. Ground temperature profiles after installation of thermosyphons at RCMP site, Iqaluit, NU.

Other troubled installations

Problems have been observed at three other flat loop thermosyphon installations: 1) In 1994 a FLE foundation with a crawl was constructed under a small Visitor Centre in Inuvik, NT. The central portion of the building started to settle, which is believed to be caused by locating the insulation above the base of the footing and not insulating the concrete columns that conducted heat to the frozen ground. 2) Another above-FLE foundation with crawl space constructed in Rankin Inlet, NU, in 1996 had routed extra heat from a power plant through trenches into the crawl space of the building. It is believed that the heat from the pipes and surface water infiltration through the trenches resulted in settlement of columns. Finally, 3) A Female Young Offender Facility constructed with slab-on-ground FLE foundation in Inuvik, NT, in 2001 exhibited considerable settlement under the eastern portion of the building. It appears that poor foundation cooling in this area was the result of introducing channel bends in the evaporator pipes during construction to accommodate a service piping trench. It is postulated that the four right-angle bends to accommodate the services reduced the efficiency of liquid/gas movement.

Construction scheduling

The normal practice in the construction of buildings on a FLE foundation has been to allow the FLE to operate over the first winter before putting up the structure of the building. The desire to start construction of the building the same year as the thermosyphon was built led to employing mechanical freezing during the summer (hybrid system) at the Inuvik Hospital. Three case histories of thermosyphon construction at Iqaluit, NU (RCMP), Pangnirtung, NU (Health Centre), and Kuujjuaq, QC (Air Terminal) illustrate the time required to develop permafrost with different construction schedules, MAAT, and soil type. Summary of relevant information and ground temperatures attained are given in Table 2.

The RCMP installation demonstrates the benefit in constructing the thermosyphon foundation in early summer. With this schedule, the subgrade froze completely by mid-October (Fig. 10). Since the foundation was left over the winter before adding the building, the absence of a heated slab during the first winter resulted in the coldest foundation at -6.1°C at 5 m below the evaporator pipes.

At Pangnirtung (Health Centre), the foundation with the thermosyphon and insulation was not completed until 24 August 2006. At this site complete freezing was attained in mid-December, and the building was enclosed and started to be heated mid-January 2007. In early October 2007, when thermosyphon cooling began again, the ground at the evaporator pipes was still frozen at -2.0°C, and the ground at 5 m depth was at -4°C.

The Air Terminal at Kuujjuaq differs from the previous two case histories because it has a higher MAGT and a smaller freezing index, and the soil is predominantly silt with higher water content. The thermosyphon installation at this location was completed at the end of August 2006, but was not completely frozen until mid-February 2007. It is estimated the MAGT was -1.2°C at 5 m depth.

Ground temperature regime with longer record of data is available from an earlier installation with sloped evaporator design (Service Building) in Kuujjuaq (Fig. 11). This installation was constructed in 1986, and ground temperatures are available to 1995. It needs to be noted that the MAAT was warmer in 1986, -5.5°C, and about -4.5°C in 1995 and only 100 mm of insulation was used. It is estimated that the MAGT at 5 m depth was about -2.5°C.

Conclusions

1. A majority of the 80 flat loop thermosyphon foundations have demonstrated that this design provides an economical foundation system that will function for some time even with climate warming affecting the permafrost.
2. Problems encountered in four installations were not associated with the flat loop evaporator thermosyphon concept. The problems were due to a) defective pipes provided by the mill; b)inadequate insulation around concrete columns; c)incorporating right angle channel geometry (in section) in the evaporator pipes to accommodate services; and d) allowing surface water into the evaporator granular pad.
3. The air terminal installation in Kuujjuaq shows that frozen ground can be developed, or maintained at MAAT at locations that are not conducive to permafrost. The effectiveness of the flat loop thermosyphon can be increased by increasing insulation thickness, decreasing evaporator spacing, and increasing condenser size.
4. A review of existing FLE installations show a past history of poor granular pad design and construction control, and insufficient attention has been given to surface water control around the building.

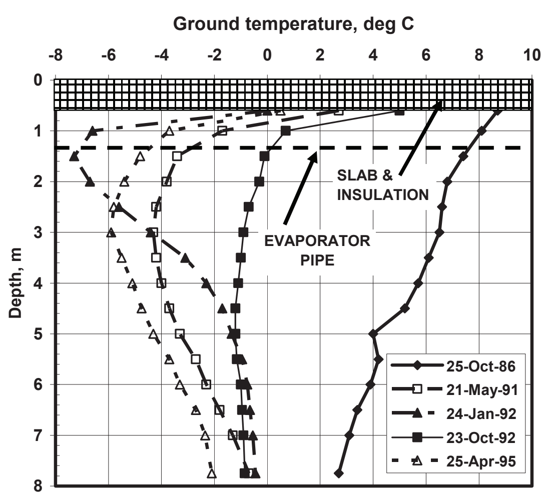

Figure 11. Ground temperature changes at FLE slab-grade at Service Building in Kuujjuaq, BC.

Acknowledgments

The authors would like to thank the Public Works and Services of Northwest Territories in providing information on the projects constructed in Inuvik, and other clients in providing ground-temperature data at their projects.

Abstract

Block failure and retrogressive thaw slump activity are significant modifiers of Arctic costal morphology. This study investigates these erosional processes along ice-rich bluffs of the southern Beaufort Sea coast through a series of analytical models. Block failure potential is linked with different permafrost features like ice wedges and thermo-erosional niches. Failure often occurs along the ice wedge axis when wave erosion undercuts the base of the cliff. Model results indicate that low cliff heights tend to exhibit overturning failure, whereas high cliffs display sliding failure. Headwall retreat of retrogressive thaw slumps are also analyzed using parametric model calculations that incorporate energy balance activity to model melting ground ice. Model findings for block failure and headwall retreat are supported by field observations made in 2007 and previous studies. Using the approaches discussed in this paper, long-term morphologic patterns along Arctic coasts can be estimated using the spatial and rheological nature of permafrost materials and meteorological inputs.

Keywords: arctic coast; block failure; ice wedge; permafrost; retrogressive thaw slump.

Introduction

Coastal erosion in polar environments involves the synergistic interaction of wave-, thermal-, and gravity-induced mechanisms. The theory behind wave-induced erosion processes are reasonably well understood, and given the short open-water season that typically occurs in the Arctic, the magnitude of these effects are thought to be limited. However, the roles of morphologic and climatic coastal erosion processes are not as clearly understood. For example, field evidence indicates that mass wasting processes can occur almost year-round through gravity-driven processes, as large sediment blocks have been observed resting on sea ice as well as within shallow water. Similarly, thermal erosion processes, such as thermokarst, are readily observed when solar radiation raises ice-rich sediment surface temperatures above 0°C in spite of sub-0°C ambient temperatures. Ice-rich bluffs along the Yukon north coast display rates of coastal retreat that cannot be explained by wave action alone. The literature frequently refers to block collapse and retrogressive thaw slump activity as significant coastal erosion processes (Aré 1988, Walker 1988).

In this paper, we examine the potential role of two non-wave related erosional processes: block failure and thermokarst. The mechanics of block failure are studied through analytical models. The safety factor approach to slope-stability analysis is based on a series of widely recognized analytical and numerical solutions (Carson 1971, Chowdhury 1978). In this study, we apply different failure planes and mechanisms for a range of permafrost rheological characteristics, specifically exploring the role of ice wedge and thermo-erosional niche development in block failure. Strength parameters related to ice content and temperatures for coastal bluffs are then used to predict the failure potential for site-specific conditions. Additionally, we analyze the thermal erosion of exposed ground ice in retrogressive thaw slump headwalls through a computational model based on energy balance. Solar radiation and heat flux components are calculated to quantify the ablation of exposed ground ice as well as headwall retreat. The sensitivity of various factors affecting thermal and mechanical erosion of ice-rich coastal cliffs is examined. The complex processes of block failure and retrogressive thaw retreat of frozen cliffs are examined in a series of numerical solutions for a range of input conditions. We also discuss the implications of climate change on block failure and retrogressive thaw slumps and how the findings of this study can be used to predict long-term associated morphologic change under these conditions.

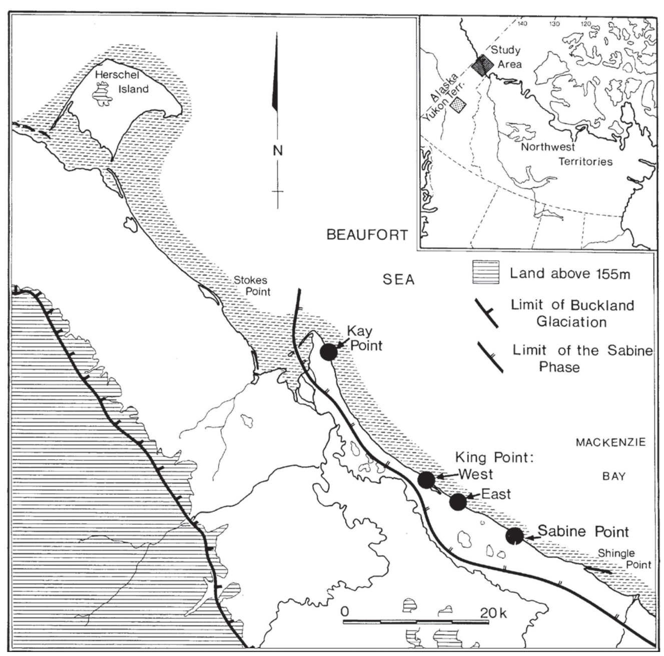

Figure 1. Study area: southern Beaufort Sea Coast.

Study Area

Our study focuses mainly on the southern Beaufort Sea coast (Fig. 1). The Beaufort Sea and its coastal region are the focus of considerable interest for a number of reasons, including human history, land claims, potential oil and gas development, permafrost and ground ice characteristics, and climate change. Extensive segments of the Beaufort Sea coast are characterized by bluffs ranging from 3–30 m in height (Solomon 1995). A previous study near King Point on the Beaufort Sea coast found an apparent spacing of modern ice wedges extending up to 15 m (Harry et al. 1985). This study also reported that most wedges have minimum heights between 4.5 m and 6.0 m. Other studies have described ground ice exposures and thermokarst activity (de Krom & Pollard 1988). Numerous recent block failures and active retrogressive thaw slumps were observed in this area during reconnaissance in 2007.

Block Failure

Model description

Two key features cause block failure along Arctic coasts: 1) the occurrence of horizontal thermo-erosional niches at the base of a bluff, and 2) the presence of ice wedges in backshore permafrost. Block failure is initiated by the development of an underlying niche, while ice wedge geometry determines the block size. The distance between two ice wedges along the coastline determines the length of the block. Figure 2 shows a two-dimensional cross section of a cliff with an ice wedge and horizontal niche. The cliff is characterized by H_c (cliff height), x_n (horizontal depth of the niche), z_n (height of the niche at the cliff face), and x_w (distance of ice wedge from the cliff face).

As a niche is formed at the base of a cliff, the toe of the cliff shifts from its initial position *P* to the new position *O*. According to the Culmann method of slope stability, the failure surface is a plane passing through the toe of the slope (Carson 1971). Following Culmann's assumption, Carson (1971) showed that the potential failure plane is inclined with an angle $\theta = (\alpha/2+\phi/2)$, where α is the slope angle of the cliff face and ϕ is the angle of internal friction of soil materials. In the areas where ice wedges are present, failure usually occurs along the ice wedge (Walker 1988). When an ice wedge and a thermo-erosional niche both are present, there are two possible modes of block failure: sliding and overturning.

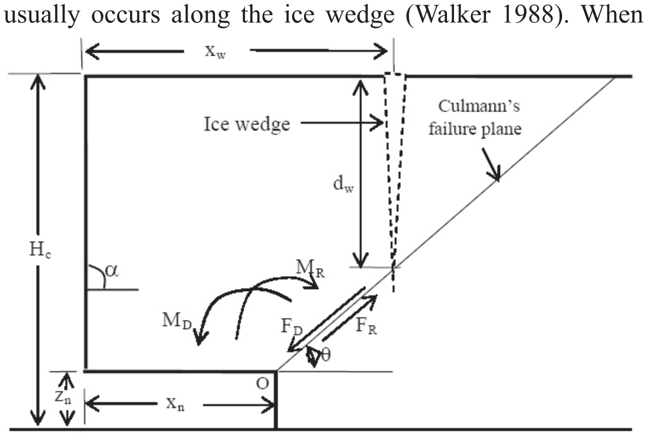

Figure 2. Two-dimensional cross section of a vertical cliff.

Sliding failure occurs when a block of frozen soil slides down the cliff on a relatively planar surface. The sliding mass is assumed to translate as a rigid body down the surface; it does not undergo rotation. When we apply a static balance of forces, the factor of safety against sliding is then defined as the ratio of resisting force to driving force. The driving force consists of the downslope component induced by weight, and the resisting force is the shear strength existant along the failure plane. The latter is comprised of two components: (1) cohesive strength of the soil, and (2) frictional forces derived from the angle of internal friction and the weight component perpendicular to the shear plane. If F_D is the driving force and F_R is the total resisting force, then the factor of safety against sliding is expressed as:

$$F_S=F_R/F_D \tag{1}$$

On the other hand, the cantilever action of the overhanging bluff induces an overturning moment (M_D) at the toe of the bluff. The resisting moments (M_R) are due to the weight of landward portion of the block and to the tensile strength (f_t) of the ice-rich permafrost soil. Overturning failure occurs if the overturning moment exceeds the resisting moment. In this case, the factor of safety against overturning is expressed as:

$$F_O=M_R/M_D \tag{2}$$

Strength of permafrost soils

The long-term strength of perennially frozen soils is of great importance in the evaluation of bluff stability. The strength of a frozen soil depends on its temperature, moisture content, mineral composition, and structure (Tsytovich 1975). Ground ice acts as cement in frozen soil; hence the widely used term "ice bonded." Temperature impacts ground ice physical properties, and therefore, in cases where ice contents are high, it influences soil strength. Tsytovich (1975) reported that the long-term compressive strength of frozen ground strongly depends on negative temperatures and can be expressed as:

$$\sigma_c = a + b(\theta)^n \tag{3}$$

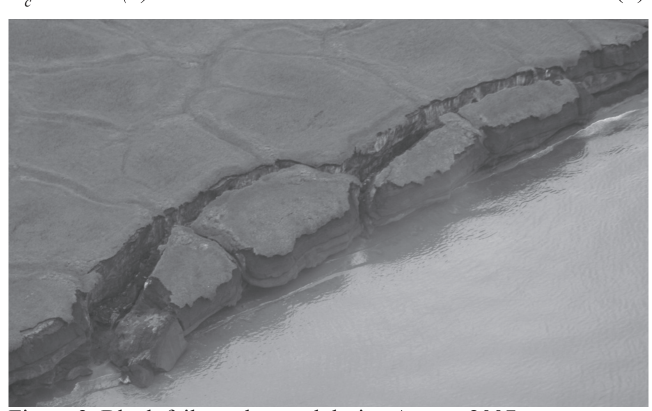

Figure 3. Block failure observed during August 2007.

where, a, b, and n are empirical parameters that depend on frozen soil types and θ is the absolute value of the negative temperature.

Long-term cohesion is expressed as $c = \sigma_c / 3^{0.5}$ (Vyalov 1966). There is limited information on long-term tensile strength of frozen soils, with the majority of available information related to compressive strength. The tensile strength of a frozen soil is substantially lower than its compressive strength (by a factor of 2–6) (Tsytovitch 1975). Based on Vyalov's experiment, Tsytovitch (1975) reported the long-term tensile strength for soils ranging from 30–180 kPa with temperature ranges of -0.2°C to -4.6°C.

Model calculations and discussions

For a given set of rheological conditions, block failures will be governed by the wave-eroded niche depth as well as the depth, location, and orientation of ice wedges. Aerial surveys along the Yukon coast revealed that failure usually occurs within the ice wedge (Fig. 3). Accordingly, the present study includes ice wedges as part of the block failure analysis. In this case, the ice wedge is assumed to have a recent thermal contraction crack and, therefore, no pressure or resisting force along the failure plane within the ice wedge. Thermal expansion pressure at the face of the ice wedge is also considered to be negligible.

Model calculations are performed for different cliff heights, ice wedge locations (distance from the bluff), and niche depths to: (1) obtain critical combinations of input parameters to induce cliff failure and (2) determine associated modes of failure (i.e., overturning vs. sliding). Permafrost soil strengths used in model calculations are based on Tsytovich's (1975) experimental results. A sample calculation using c=100 kPa, f_t=35 kPa, $\phi=20^0$, x_w=4 m indicates that cliff heights up to about 7.5 m exhibit overturning, whereas larger cliffs displayed sliding failure. Calculations using a range of input conditions show that for a given set of soil strength parameters and ice wedge distance, smaller cliffs are subjected to overturning whereas larger cliffs are subjected to sliding. The model is in general agreement with field conditions, as observed block failure in bluffs 3–6 m high were predominantly overturning-type failure. These results are supported by their mechanical nature: in smaller cliffs the sliding force exerted by the weight of soil is less than the total resisting force exerted by the cohesive strength of the soil. Therefore, block failure occurs when the niche extends to a critical distance causing overturning due to cantilever effect of the overhanging mass. The critical niche depth necessary for an overturning failure increases with the cliff height. This is because any increase in niche depth increases overturning moment (M_D) and decreases resisting moment (M_R). This agrees with the findings of Are′ (1988), in which the critical niche depth is calculated from the formula of curvature for an overhanging mass of frozen sediment.

Figure 4 depicts the model calculations for different cliff heights using c=200 kPa, f_t=70 kPa, $\phi=20^0$. It can be seen that, for a given cliff height and soil strengths, the relationship between niche depth and ice wedge distance is linear. It should be noted, however, that when ice wedges are closer to the shoreline, the critical niche depths are close for different cliff heights. In the present discussion, the maximum cliff height for overturning failure is denoted as H_0. Figure 5 shows the variation in H_0 with permafrost soil strength. Calculations are performed for niche dimensions x_n=2 m and z_n=1 m. Results indicate that H_0 increases with cohesive strength, meaning that higher cohesive strength increases the range of cliff heights subjected to overturning. The relationship between H_0 and cohesive strength are linear, meaning that the non-dimensional parameter given by $\gamma H_0/c$ can be considered constant for a given set of rheological properties of cliff materials. Model calculations with cohesive strength ranging from 100 kPa to 400 kPa, ϕ = 0, and an ice wedge distance x_w ranging from 2 m to 10 m show that the values of non-dimensional parameter $\gamma H_0/c$ varies from 0.95 to 1.1.

The calculations discussed above are for cases where the ice wedge depth intersects Culmann's failure plane. Calculations show that overturning can also occur for ice wedges with depths (d_w) less than the depth of Culmann's failure plane (d_{cl}). However in such cases, the ice wedge distance required for failure is less than that previously obtained. Calculations were performed for a cliff height of 10 m using niche dimensions and strength parameters as follows: z_n=1 m, x_n =2 m, c=200 kPa, f_t =70 kPa, and ϕ =20^0. Figure 6 shows variations in critical d_w that produce overturning under a varying x_w and displays that overturning can occur for a d_w less than the depth of Culmann's failure

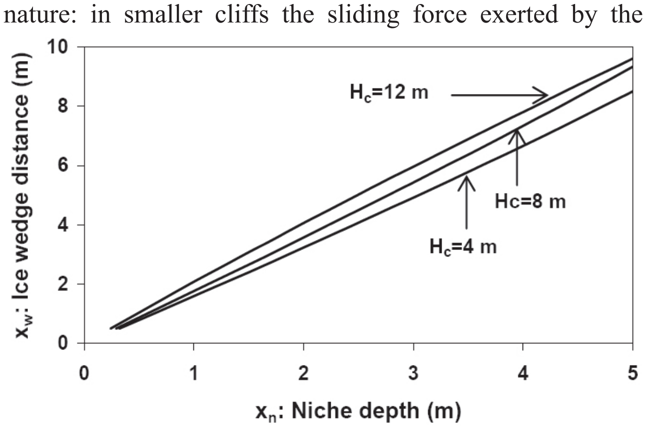

Figure 4. Ice wedge location and niche depth required for failure of cliffs of 4 m, 8 m, and 12 m heights.

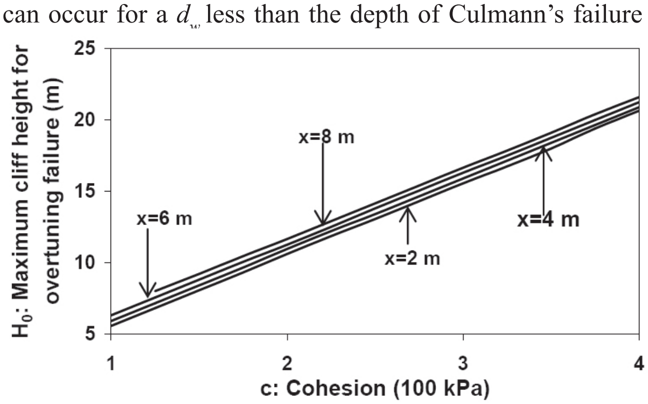

Figure 5. Ice wedge distance required for various cliff heights and material strength.

plane. In such cases, it is found that failure occurs along the plane passing through the toe of the slope and the bottom of the ice wedge and that the critical d_w for overturning increases with x_w.

Retrogressive Thaw Slumps

Model description

Retrogressive thaw slumps are a form of back-wasting slope retreat due to thawing ice-rich permafrost and are frequently observed in thermokarst landscapes. Their morphology consists of (i) a vertical headwall, (ii) a steeply inclined headscarp of ice-rich sediment, and (iii) a lobate mudflow at the base of the slump (de Krom 1989, Lantuit and Pollard 2005). Headwall retreat has previously been linked to thawing degree days (Robinson 2000) and net radiation flux (Lewkowicz, 1986b). Retrogressive thaw slumps have been the focus of several studies involving the field measurement of headwall retreat (e.g., French 1974, French & Egginton 1973, Lamothe & St Onge 1961, McRoberts & Morgenstern 1974), and additional studies have attempted to create empherical models for headwall retreat using energy flux (Lewkowicz 1986b), global radiation and degree-days (Egginton 1976), and thawing degree-hours (Kerfoot 1969). However, most of these cases are based on limited data. The present study formulates a computational model for headwall retreat using energy balance terms.

Headwall retreat can be calculated using the ablation rate of ground ice at the exposed face. The energy available for ground-ice ablation is represented by the following energy balance equation (Lewkowicz 1986a):

$$Q_m = Q_s + Q_l + Q_h + Q_e + Q_g + Q_p + Q_w \tag{4}$$

where, Q_m is energy flux available for ground ice ablation, Q_s is net shortwave radiation, Q_l is net long-wave radiation, Q_h is air convection (sensible heat), Q_e is vapor condensation (latent heat), Q_g is ground heat conduction, Q_p is the heat flux from precipitation, and Q_w represents the heat flux from water flowing down the headwall. Fluxes are measured as energy per time per unit area of the exposed surface (kJ/m^2-sec).

The summation of all sources of energy represents the total amount of energy (Q_m) available to melt the ground ice. The amount of headwall retreat *(R)* through ablation of ground ice can be expressed as:

$$\frac{dR}{dt} = \frac{Q_m}{c_i L B} \tag{5}$$

where, c_i is volumetric ice content in the headwall, L is volumetric latent heat of fusion of ground ice (kJ/m^3), B is thermal quality of the ground ice (e.g., ratio of heat required to melt a unit weight of the ground ice to that of ice at °C). The melting face consists of a mixture of ice, free water, and soil particles. The latent heat for fusion of ground ice is less than that of pure ice. This is because the relative proportion of the ice determines the thermal quality of ground ice. The relationship between ice content and volumetric latent heat reported by Lewkowicz (1986b) shows that latent heat decreases with lower ice contents.

Net shortwave radiation is an important source of ground ice ablation and consequentially, headwall retreat. The amount of energy available from the absorption of shortwave radiation for ground ice ablation is given by:

$$Q_s = (1-\alpha)\, I_i \tag{6}$$

where α is the albedo of ice-rich headwall soils and I_i is the incident solar radiation.

The longwave radiation component (Q_l) consists of the radiation emitted from the headscarp to the atmosphere (resulting in a net energy loss on clear days) and back-radiation reflected by the atmosphere and cloud cover. Longwave radiation (Q_a) from headscarp materials to the atmosphere can be expressed in accordance with the Stefan-Boltzman law:

$$Q_a = \varepsilon\sigma\, T_s^4 \tag{7}$$

where ε is the emissivity of headscarp materials, σ is the Sefan-Boltzman constant (5.735x10-11 kJ/m^{2}sK$^{4)}$, and T_s is the temperature of melting face (°K).

The transmission of back-radiation (Q_b) is a complex process based on experimental data and various assumptions. Snow investigations show that the downward longwave radiation can be adequately expressed by a single air temperature function as: $Q_b = 0.67\sigma\, T_s^4$ for clear skies and $Q_b = \sigma\, T_s^4$ for

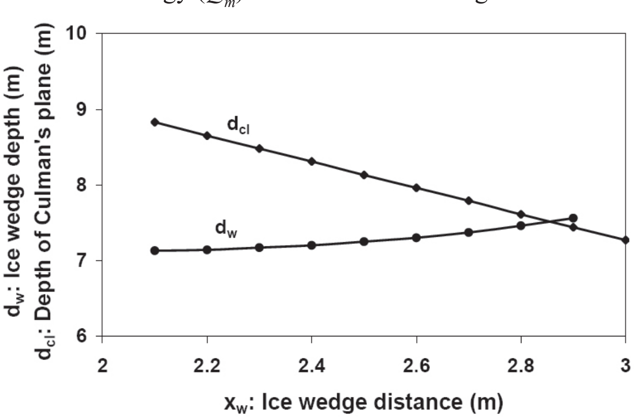

Figure 6. Critical ice wedge depth for failure under varying ice wedge distance.

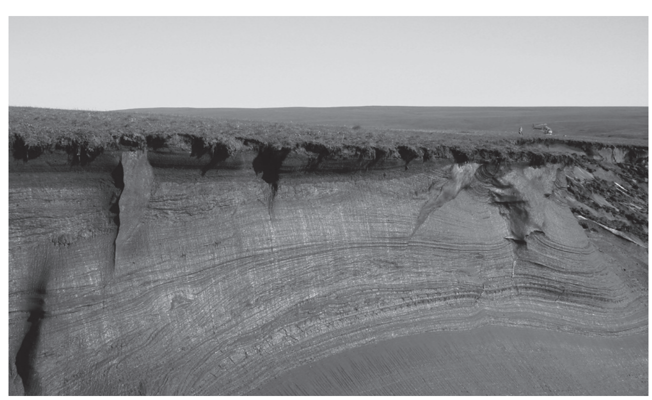

Figure 7. Headwall of an active retrogressive thaw slump on Herschel Island (photo taken on 11 August 2007).

cloud or forest cover (USACE 1998). By combining the findings from incoming and outgoing longwave radiation, the net longwave radiation can be determined using the following equation:

$$Q_l = Q_a - Q_b \tag{8}$$

Turbulent exchange, by convection (Q_h) and condensation (Q_e), varies widely depending on climate and local weather conditions. Following Gray & Prowse (1992), the sensible and latent heat transfer are expressed as:

$$Q_h = D_h u_z (T_a - T_s) \tag{9}$$

$$Qe = D_e u_z (e_a - e_s) \tag{10}$$

where D_h is the bulk transfer coefficient for sensible heat transfer (kJ/m^3 °C), u_z is the wind speed (m/s) measured upslope of the slump headwall at a chosen height, T_a is the air temperature (°C), T_s is the temperature at the melting face (°C), D_e is the bulk transfer coefficient for latent heat transfer (kJ/m^3 Pa), e_a is the vapor pressure of the air surface (Pa), and e_s is the vapor pressure at the melting ice face (Pa).

During periods of retrogressive thaw slump activity, it is reasonable to assume that T_s at melting face is 0°C and that e_s is the saturation vapor pressure at 0°C (6.108 mbar). This allows for the measurement of air temperature and vapor pressure at a single height to apply the bulk transfer method. According to Male & Gray (1981) there is wide range in variation in the bulk transfer coefficients reported by researchers, and these values are typically determined experimentally. However, Lewkowicz (1986a) considered the coefficients to be the same for both sensible and latent heat through the use of a psychrometer constant (mbar/°C), thereby allowing for the application of the bulk transfer method without obtaining field measurements for the coefficients.

Q_g is very small compared to the overall energy budget (USACE 1998). Using the measured ground temperature gradient, ground heat flux can be calculated by solving the one-dimensional, steady state conduction equation:

$$Q_g = -k\,(dT_g/dx) \tag{11}$$

where k is the thermal conductivity of the permafrost soil, dT_g/dx is the temperature gradient, and x is the depth to ground ice.

Q_p is encountered as precipitation falls upon and runs down the ice face(USACE 1998) and can be expressed as:

$$Q_p = C_p \rho_w P\,(T_r - T_s) \tag{12}$$

where C_p is the specific heat of rain (kJ/kg °C), ρ_w is the density of water (kg/m^3), P is the rainfall intensity (mm/unit time), T_r is the rain temperature (°C), and T_s is the temperature of the ice face (°C). The temperature of the rain is assumed to be air temperature or, if available, the wet bulb temperature.

As the temperature of the meltwater flowing down the headwall is close to the melting face temperature (0°C), the conductive heat transfer term Q_w in Eq. (4) is considered to be negligible compare to the overall energy budget.

Model calculation and discussions

Equation 5, supplemented by Equations 6–12, can be solved using a first-order explicit finite difference method in time to calculate the temporal variation of headwall retreat. Model calculations have applied hourly weather data obtained from King Point, Yukon Territory, Canada. Net shortwave radiation is calculated by assuming an albedo of 0.15 for the headscarp based on a regression analysis of field measurements reported by Lewkowicz (1986b). The coefficient for sensible heat transfer component (Q_h) was taken from Lewkowicz (1986b). The energy exchange components Q_e and Q_g are ignored in the present model calculations, as Lewkowicz (1986b) reported that these components are small compare to the total energy flux. Sample calculations are performed for the incoming shortwave radiation ranging from 0 to 400 W/m^2 on the sloping face of a headwall, a wind speed of 20 km/hr, and air temperatures of 2°C and 6°C. Results from model calculations are provided in Figure 8. For a given incoming shortwave radiation, higher temperatures correspond to higher retreat rates, which are due to the melting component of Q_h. Model calculations are on the same order of magnitude reported by other studies in the Arctic (e.g., Lewkowicz 1986a, 1986b).

Headwall retreat calculations were undertaken using data from King Point, Yukon Territory, over a 60-day

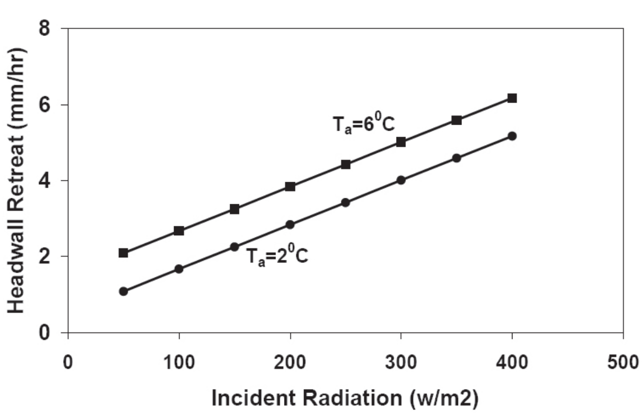

Figure 8. Headwall retreat rates for 2°C and 6°C under different incoming shortwave radiation.

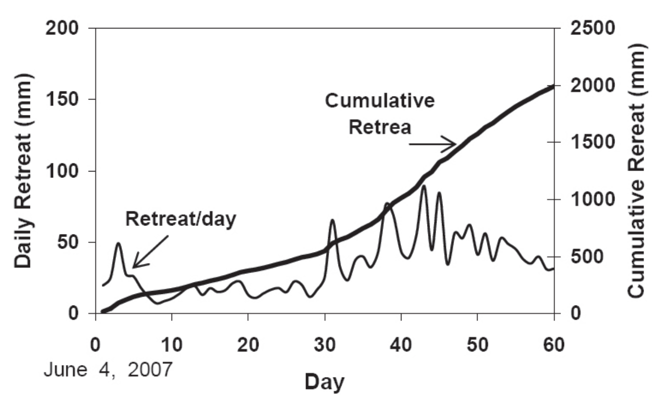

Figure 9. Calculated cumulative retreat using meteorological data at King Point.

period beginning June 4, 2007. Estimated values of daily and cumulative retreat are shown in Figure 9. July retreat is higher than that for June in response to increased solar energy and air temperatures. The calculated values of 34 mm and 90 mm of retreat for average and maximum daily retreat and 2 m of cumulative retreat over a 60-day period is an excellent average approximation of observed retrogressive thaw slump activity in this region.

Concluding Remarks

The present study provides computational models for two important erosion processes common to ice-rich Arctic coastal cliffs: (1) block failure, and (2) headwall retreat of retrogressive thaw slumps. Model calculations (supported by field observations) offer the following conclusions:

a) Block failure typically occurs along Culmann's failure plane, where ice wedges intersect Culman's plane. If ice wedge depth is less than the depth of Culmann's failure plane, failure occurs along the plane passing through the bottom of the wedge and the toe of the overhanging cliff.
b) Low cliffs are subjected to overturning failure, whereas the higher cliffs are subject to sliding failure.
c) In cases where ice wedges intersect the Cullman's failure plane, the maximum cliff height exhibiting overturning failure is dependent on the strength of cliff materials and can be expressed as a constant non-dimensional parameter $\gamma H_0/c$ for a given internal friction angle.
d) Headwall retreat of retrogressive thaw slump is governed by net shortwave radiation. Calculated headwall retreat based on weather data from King Point, Yukon Territories, gives an average value of 34 mm/day during summer 2007.

The block failure model is being enhanced by further quantifying the effects of ice content and ice wedge morphology. Field measurements of headwall retreat and microclimate data are being conducted for final model calibration and validation. Improvement of the thaw model will involve coupling with a slope irradiance model. Further studies relating block failure and headwall retreat are also needed to determine which process is predominant in specific permafrost regions. These models provide insight into morphological processes of Arctic coastlines and suggest potential responses to changing climate conditions by predicting changes in permafrost integrity and retrogressive thaw slump activity.

Abstract

This paper describes and analyzes the exceptionally large rock-ice avalanche of 40 to 60 million m^3 volume that occurred in 2005 from the south face of Mt. Steller (Bering Glacier region, Alaska), which has steep glaciers at the summit. Analysis of seismic signals revealed a series of precursory rock/icefalls and a special sequence interpreted as slip and deformation in glacier ice. Reconstruction of the thermal conditions based on regional climate and radiosonde data yielded mean annual ground surface temperatures of -10 to -15°C for the failure area. Because the slope failure was at depths of meters to decameters we also performed numerical modeling of a 2D temperature profile across the mountain. Results showed that the existence of a hanging glacier in the summit area induces a deep-seated thermal anomaly. We subsequently outline a number of processes that may be effective for slope destabilization with the given thermal conditions.

Keywords: cold permafrost; Mt. Steller, Alaska; rock-ice avalanche; seismic signals; steep glacier; thermal modeling.

Introduction

A large rock-ice avalanche of 40 to 60 million m3 occurred on 14 September 2005 from the southern flank of Mt. Steller in the Bering Glacier-Bagley Ice Field region. The initial failure from a maximum elevation of 3100 m a.s.l. involved significant volumes of both rock and ice from steep glaciers. The avalanche mass travelled for almost 10 km and was deposited on Bering Glacier. As we will show, the failure was from areas in cold permafrost conditions, with the area of failure being thermally disturbed by an overlying steep glacier. Understanding of such large slope failures is important in the context of atmospheric warming and the potentially severe consequences in case of similar events in populous regions.

Increasing temperatures can destabilize frozen rock (Gruber & Haeberli 2007). Recent studies have demonstrated that not only rock surface temperatures but also temperature distribution at depth should be considered for slope stability, and have simulated the effects of projected climate change on the thermal regimes of different mountain topography (Noetzli et al. 2007). In Alaska, atmospheric warming and a related increase of permafrost temperatures have been generally strong in the 20th century. According to borehole observations in low-land areas, permafrost temperatures in the 20th century warmed by 2–4°C by the early 1980s (Lachenbruch & Marshall 1986) and up to 2–3°C during the past two decades (Osterkamp & Romanovsky 1999, Osterkamp 2007). The rise of permafrost temperatures, however, has not been as consistent as the rise of air

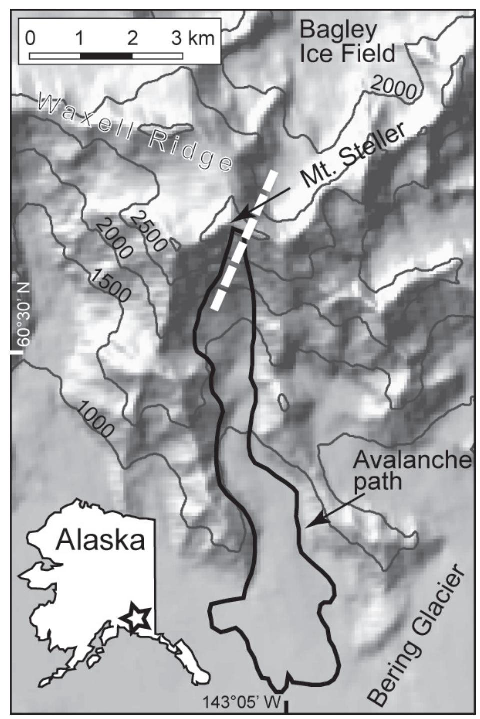

Figure 1. Map showing Mt. Steller and the extent of the 2005 rock-ice avalanche (dashed line indicates the cross section used for thermal modeling, cf. Fig. 5).

temperatures in Alaska, mainly because of the influence of local factors (e.g., snow cover) on the energy balance (Osterkamp 2007). Knowledge on the evolution of permafrost temperatures in Alaskan high-mountain areas is scarce.

Steep glaciers in mountain walls can induce complex thermal anomalies in perennially frozen bedrock. A limited number of studies have shown that even in cold permafrost conditions, overlying glaciers can create temperatures close to phase equilibrium at the ice-bedrock interface (Wegmann et al. 1998, Haeberli et al. 1999). Because on-site access to large high-mountain walls is very limited and often impossible, investigations are typically restricted to remotely based measurements and modeling, although systematic rock temperature measurements exist in the Alps where site access is comparably easy (Gruber et al. 2004).

Seismometers have been used to study rapid mass movements resulting from slope failures (e.g., Weaver et al. 1990, Norris 1994). More recently, seismology has been used as a tool to analyze slope failure processes up to two hours before avalanche initiation (Caplan-Auerbach et al. 2004, Caplan-Auerbach & Huggel 2007), thus revealing new possibilities for the investigation of slope failures.

This study aims at reconstructing the 2005 failure and avalanche at Mt. Steller and the factors that led to this event. Although the site geology is fundamental for the slope failure we will concentrate here on the thermal conditions at the failure site and related transient effects such as atmospheric warming and overlying glaciers. More generally, we want to improve our understanding of large slope failures in steep terrain in cold permafrost and discuss the possible influence of thermal disturbance.

The 2005 Mt. Steller Avalanche

Mt. Steller (3236 m a.s.l., 60°13′N, 143°05′W) is part of the Waxell Ridge, a bedrock massif that separates the Bagley Ice Field from Bering Glacier (Fig. 1). Climatically, Mt. Steller is located close to the divide between the warmer and more humid climate of coastal Alaska and the drier and colder interior of Alaska. Geologically, the Steller S-face consists of tertiary sedimentary rocks that are layered sub-parallel to the surface slope in the failure zone.

The Waxell Ridge is a very remote area with difficult access conditions and almost only visited from the air. The 14 September 2005 rock-ice avalanche from Mt. Steller was identified because its associated seismic signals were recorded at seismometers throughout Alaska and around the world. The Alaska Earthquake Information Center reported that the event had an equivalent local magnitude of 3.8, while analysis of global long period waves yielded a magnitude of 5.2 (G. Ekstrom, personal communication, 2005). Due to the complicated access conditions of Mt. Steller, we based the reconstruction of the rock-ice avalanche on available remotely operating systems such as satellite imagery, airborne observations, and seismic recordings. We used a Landsat ETM+ scene taken a few hours after the avalanche on 14 September 2005 and photographs from a fixed-wing flight the day immediately after the event, repeated in Summer 2006 and 2007. Topographic information was derived from the USGS NED (2 arc sec, ~60 m) digital elevation model (DEM) and available topographic maps. Data from climate stations and radiosonde measurements in the region were used for temperature reconstruction at the Steller site.

Figure 2. Upper section of the avalanche failure zone. The summit hanging glacier failed on a width of ~500 m and an elevation range of ~200 m. The ice thickness is in the range of 20–30 m. Note the liquid water on the exposed rock failure surface, and the large hollow-like cavity at the right margin, possibly indicating the existence of water (photo courtesy of Ruedi Homberger).

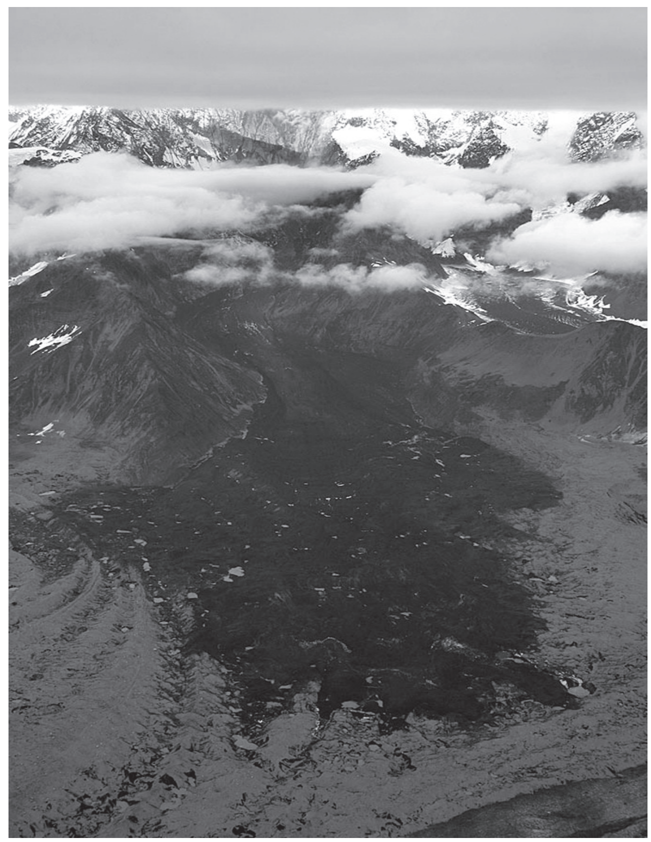

Figure 3. Photo showing the flow path through the glacial valley and the runout area of the rock-ice avalanche on the Bering Glacier For scale, refer to Fig. 1 (photo courtesy of Ruedi Homberger).

The 2005 rock-ice avalanche initiated in the S-face of Mt. Steller that has an average slope of 45° and an elevation drop of 1600 m. At the uppermost section, this face is covered by steep glacier ice which extends over the ridge to the northern side. At the time of the avalanche, the S-face of Mt. Steller was extensively covered by snow, as is typical of mountain walls in this region. The photographs taken the day after the event show that a significant part of the hanging glacier, along with large volumes of bedrock, was involved in the avalanche (Fig. 2). We estimate that 3 to 4.5 million m^3 of glacier ice with ice thickness of 20 to 30 m failed. The failure volume of rock is difficult to assess without precise topographic data. It is evident that almost the entire S-face was affected by the avalanche, but it is not clear which bedrock areas actually failed and which ones were only affected by the passing avalanche. We estimate that bedrock failed between 2500 and 3100 m a.s.l. und crudely estimate the initial rock volume at 10 to 20 million m^3. Additionally, another 2 million m^3 of snow may have been involved in the initial avalanche.

The rock and ice mass from the Mt. Steller avalanche impacted the glacier at the toe of the S-face that extends from ~1700 m a.s.l. towards the south, and eroded several millions of m^3 of glacier ice. The avalanche then traveled on the glacier surface in a laterally confined valley for about 4 km until it reached the relatively flat surface of Bering Glacier where the mass spread and stopped on the debris-covered ice (Fig. 3). The total horizontal run out distance was 9 km, whereas the drop height was 2430 m, with the uppermost failure point at ~3100 m a.s.l. and the lowest run.out point at 670 m a.s.l. The total avalanche volume deposited on Bering Glacier can be reconstructed with an area of 4 km^2 and an average deposit thickness of 10 to 15 m using the undulating topography of the moraine ridges that were filled by the avalanche deposits as a height reference. This yields a total avalanche volume of 40 to 60 million m^3; and thus, the 2005 Mt. Steller avalanche ranges among the largest avalanches observed in recent decades worldwide. These volume estimates furthermore indicate that the initially failed glacier ice made up about 10% of the total avalanche volume, and that probably about 5 to 30 million m^3 of ice, snow, and debris were entrained along the avalanche path.

Seismic Response

Seismic recordings played a particularly important role in the detection and analysis of the 2005 Mt. Steller avalanche. First analyses of seismic signals recorded at several Alaskan stations showed spindle-shaped seismograms typical of mass movements such as rockfall and debris avalanches (Weaver et al. 1990, Norris 1994, Caplan-Auerbach et al. 2004) or snow avalanches (Suriñach et al. 2001). Based on the duration of these signals and the horizontal runout distance, we estimated an avalanche speed of ~100 m/s or possibly even more. It is not completely clear why the avalanche produced such a large seismic signal that was recorded all over the world, but the steep topography with the high S-face and the resulting strong impact at the toe of the face must have contributed to this. The large size of the seismic signal also supports our estimate that a very large mass of >20 million m^3 was involved in the initial failure

Another remarkable aspect of the seismic signal analysis

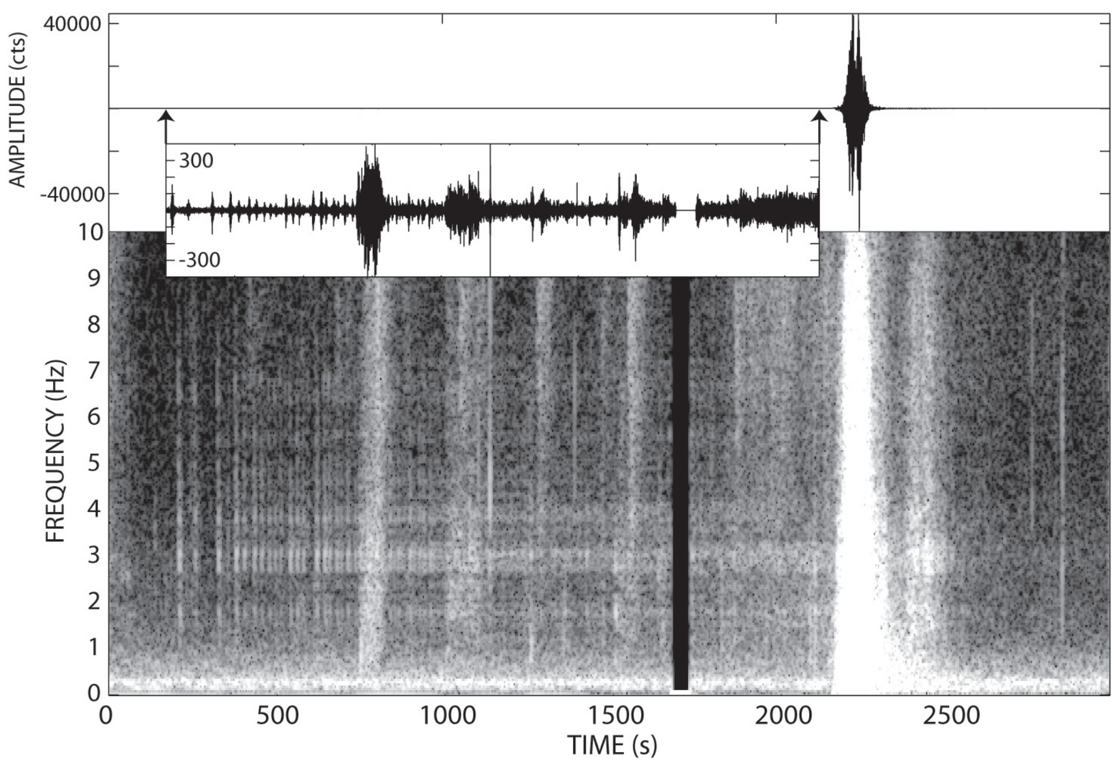

Figure 4. Seismic signal surrounding the 2005 avalanche at Mt. Steller. The top panel shows the time series of groundshaking as recorded at station KHIT, 12 km to the SW of Mt. Steller. The bottom panel is a spectrogram representing signal strength at different frequencies for the time series, with white representing stronger signals. The avalanche is visible at ~2150 seconds into the record. Because the amplitude of the avalanche is so large, a close-up of the precursory time series is shown in the inset. Note the different vertical scales on the two time series. (We acknowledge the Alaska Earthquake Information Center for operating the network and providing the data.)

at Mt. Steller was an unusual precursory seismic sequence occurring up to 30 minutes prior to failure. It should be noted that avalanches initiating in snow or rock have not been observed to exhibit precursory seismicity (Norris 1994, Suriñach et al. 2001, Caplan-Auerbach et al. 2004). Recent studies at Iliamna Volcano (3050 m a.s.l., 60.03°N, 153.09°W) in the Cook Inlet region of Alaska, however, have demonstrated that such precursory signals do occur with avalanches that initiate in ice or at the ice-bedrock interface (Caplan-Auerbach & Huggel 2007). The Mt. Steller precursory seismic signals mimic those at Iliamna in that they exhibit a series of discrete earthquakes which increase in occurrence rate for ~15 minutes before they gradually transform into a continuous ground-shaking (Fig. 4). The 15–20 minute continuous signal eventually culminates in a strong, broadband, spindle-shaped signal believed to represent the actual avalanche. At Iliamna, Caplan-Auerbach & Huggel (2007) interpreted the precursory seismic signals as deformation and slip movement in the ice with slip rates accelerating as failure approaches, and we propose the same mechanism for the Mt. Steller event. The evidence for relating the precursory seismic signals to failure in ice and not in rock supports a model in which the ice of the subsequently failed hanging glacier began to move over 30 minutes prior to failure. This, however, does not necessarily imply that the Mt. Steller avalanche initiated in ice and not in rock. Closer observation of the seismic signal (Fig. 4) shows that a number of smaller avalanches, represented by broadband, spindle-shaped signals, occurred prior to and during the precursory slip events. While the signals of these precursory slip events are well-defined at specific frequencies (i.e., at ~2, 3 and 4 Hz, Fig. 4) the smaller avalanches are identifiable by their broadband spectrum (i.e., all the way up to 10 Hz and more) at ~750, 1000, 1200 and 1500 seconds (Fig. 4). This suggests that the first stages of failure included rock, and that these initial slope failures could have triggered slip along the base of the hanging glacier. Unfortunately, because of the small (<M1) magnitude of the events and sparse nature of the regional seismic network, precise epicentral locations cannot be calculated for the precursory seismicity. However, examination of S-P times at station KHIT suggests a location at a distance consistent with a source at Mt. Steller.

Permafrost Analysis and Failure Interpretation

The purpose of this section is a first estimate of the permafrost conditions at the failure site, including the thermal regime at depth. Our thermal model presented here provides some general and basic insights but may have limitations compared to real conditions at Mt. Steller. We highlight the thermal interaction of permafrost with glacier ice and possible relations to slope stability and failure.

The reconstruction of the thermal ground conditions at the failure site was chiefly based on radiosonde data from Yakutat, located 270 km SE of Mt. Steller, and the closest regional meteorological stations (Cordova, Yakutat, McCarthy, Chitina, Ernestine, and Thompson Pass, 3 to 760 m a.s.l.). The Yakutat radiosonde data yielded a mean annual air temperature (MAAT) of -10.5°C at 3000 m a.s.l. considering the period 1994–2007. However, vertical temperature extrapolation from the closest meteorological stations in the warmer and more humid climate of the Alaskan S-coast using a lapse rate of 0.0065°C m^{-1} derived from radiosonde data resulted in a MAAT of -15.5°C at the 3000 m a.s.l. level. Some, but not all, of this temperature difference may be explained by the fact that the MAAT extrapolated from ground-based climate stations was derived from a 50-year record and, therefore, does not fully reflect the recent warming in Alaska. For subsequent assessment and thermal modeling, we applied the radiosonde-based MAAT value since it may reasonably be assumed that the temperature record of the more homogeneous troposphere is a more accurate approximation of conditions at Mt. Steller than are local ground stations. We set the mean annual ground

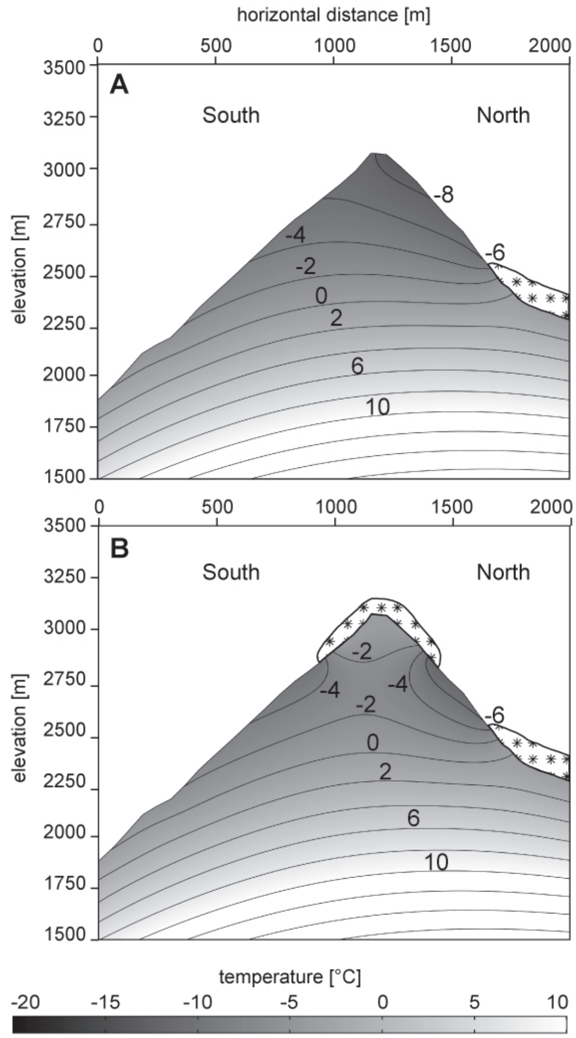

Figure 5. 2D rock temperature distribution in a N-S cross section of Mt. Steller. Distance and elevation a.s.l. are in meters, isotherms in °C. A: Rock temperature without considering overlying glaciers. B: Rock temperature with overlying glaciers (ice depth not in scale). Note the temperature differences at the summit area for A and B.

surface temperature (MAGST) 3°C warmer than MAAT for the S-face and 1°C warmer than MAAT for the N-face of Mt. Steller (Haeberli et al. 2003, Gruber et al. 2004).

Our analysis of thermal conditions at Mt. Steller was concerned with the temperature distribution at the surface and at depth since the failure depth reached meters to decameters depth. Recent studies using a modeling scheme with surface temperature (Gruber et al. 2004) and 3D subsurface heat conduction calculation (Noetzli et al. 2007) have demonstrated the distribution of temperature for idealized 3D topography such as ridges. For Mt. Steller, we calculated a 2D temperature profile along a N-S cross section. Subsurface temperatures were simulated using a steady-state, two-dimensional, finite-element, heat conduction model of 10.5 km width having a base 2000 m below sea level. The upper boundary condition was given by estimated surface temperature (see above), and an inward heat flux of 0.08 W/m^2 was set at the lower boundary. The thermal conductivity for rock was assumed to be homogeneous and isotropic at 2.5 W/m/K, a reasonable average value for sedimentary rock. Noetzli et al. (2007) have shown that realistically small variations of the thermal conductivity do not significantly affect the model result. Transient model runs were not considered because the corresponding boundary conditions for this remote area are poorly known and would introduce additional uncertainty.

We first modeled a temperature profile assuming there was no summit glacier on Mt. Steller (Fig. 5A). Results show steeply inclined isotherms at the summit area with heat flux from S to N, and less inclined isotherms below the summit. Studies in the Alps have demonstrated that steep glaciers in conditions with MAAT of about -5 to -10°C have a cold-based front frozen to the ground but can show much warmer or even phase-equilibrium temperatures at the upper part (Haeberli et al. 1997, 1999). This is due to latent heat dissipation from percolating and refreezing meltwater in the snow and firn layer. For the second model, which includes the summit glacier ice (Fig. 5B), we, therefore, assumed cold ice for the front of the S-face glacier; entirely cold ice conditions for the N-face glacier; and temperate ice for the upper part of the summit ice apron, as well as for the glaciers at lower elevations of the N and S face. Model results show the deep-seated thermal anomaly induced by the glacier ice with bedrock temperatures at the summit region close to phase transition up to several decameters depth (Fig. 5B). Exposed bedrock in the S-face below the hanging glacier is several degrees colder.

Based on our assumptions, the existence of temperate ice and liquid water at the Mt. Steller summit area is possible. Relatively large amounts of liquid water on the bedrock of the formerly glacier-covered failure zone (Fig. 2) photographed a few hours after the avalanche in cloudy weather conditions likely also hint at this; however, this water could also stem from immediate snow/ice melting after the event. Irrespective of the source of liquid water (i.e., from the base of the glacier and/or subsurface rock, or from recent snow/ice melting), it is evidence of quite significant melting conditions at the ~3000 m a.s.l. level at Mt. Steller.

Despite incomplete information, we hypothesize a temperature-related destabilization, with a likely influence of the strong recent warming in Alaska. A MAAT increase of 2–4°C during the past decades could have penetrated several decameters into the bedrock; additionally, the Mt. Steller summit glacier likely experienced a transition to warmer temperatures where infiltration has become more frequent and has warmed large portions of the glacier, possibly to phase equilibrium temperatures. The Yakutat radiosonde data, in fact, is evidence that temperatures above freezing repeatedly persisted at elevations of the Mt. Steller summit in the past few years as late as September. The ~10 days prior to the 2005 failure were characterized by particularly warm temperatures above freezing; and correspondingly enhanced melting could likely have contributed to the slope failure.

A system of well-developed cracks is observable in air photos and could have experienced corresponding effects of hydrostatic pressure variations. However, the 2005 slope failure also involved large parts of bedrock at lower elevation that was not glacier-covered but was in cold permafrost conditions (Fig. 5). It is not clear which mechanisms contributed to the slope failure in this zone, but an effect of the upper warmer part is imaginable. For instance, variations of hydrostatic pressure and effective stress induced by the upper part could cause micro fractures and progressive failure in the lower part (Eberhardt et al. 2004).

Discussion and Conclusions

We have described the 2005 rock-ice avalanche from Mt. Steller in the Bering Glacier region, Alaska, which was one of the world's largest slope failures and avalanches of the past decades. We have focused on the conditions of failure, with a particular eye on the surface and subsurface thermal regime. Seismic signals contributed to an improved understanding of the failure mechanism by providing evidence of precursory rock/ice-falls and indication of deformation and slip of the overlying glacier ice. It is only recently that such processes in glacier ice prior to failure were discovered in seismic signals and more investigation is needed to better constrain the involved mechanisms.

The MAGST reconstruction at the failure zone was mainly based on radiosonde data and yielded temperatures of about -4 to -8°C. Numerical modeling allowed us to estimate the subsurface temperature distribution at Mt. Steller, demonstrating the deep-seated thermal effect of overlying steep glaciers on bed rock temperatures at depth. The radiosonde data should well reflect the recent strong warming in Alaska, and, according to these temperatures, the assumption of polythermal and temperate ice in the S-face and on the summit is reasonable. Nevertheless, there is an uncertainty in the boundary conditions of the thermal model which may range within ~2–3°C.

Our understanding of temperature-driven slope destabilization processes at mountains with permafrost is still very incomplete. So far, based on this study and a number of recent similar slope failures (Haeberli et al. 2003, Huggel et al. 2005, Fischer et al. 2006), we conclude that the existence of steep glaciers in cold permafrost mountains is an important and quickly changing factor of slope stability.

Acknowledgments

Abstract

Recently the traditional view on the geomorphological evolution of periglacial landscapes has been questioned. The geomorphological processes considered most important for landscapes in periglacial regions, in general, are not unique for periglacial environments. On the other hand, there is a suite of geomorphological processes which may be seen as characteristic for periglacial environments. Based on what the author considers characteristic periglacial phenomena and landforms, this paper attempts to identify what might be conceived as the main characteristic periglacial processes. Seasonal or perennial freezing and conspicuous landforms such as extensive talus sheets, polygonal networks, and large-scale patterned ground, dominate descriptions of periglacial regions. Phenomena controlling bedrock disintegration, rockfall, thermal contraction cracking, and sorting of sediments are therefore all seen as the means to identify characteristic periglacial processes. Each of these periglacial processes is shortly described, and the present state of knowledge, or the lack of such, is outlined.

Keywords: climate; geomorphology; modeling; monitoring; periglacial; permafrost.

Introduction

Periglacial regions at high latitude or high altitude experience rapid changes in the ground thermal regime in response to daily and annual as well as long-term climatic variations. Changes in the ground thermal regime and the associated growth or decay of permafrost may destabilize rock slopes or mobilize sediment slopes, possibly leading to major geomorphic changes, accompanied by natural hazards (e.g., Harris et al. 2001, Haeberli and Burn 2002). One practical priority issue of periglacial geomorphology should therefore by to improve understanding of the climatic controls on geomorphic processes, to predict potential hazards. The ultimate scientific aim of periglacial geomorphology, however, remains the formulation of models for cold-climate landscape evolution (French and Thorn 2006).

By tradition, alpine and polar periglacial landscapes are regarded as characterized by efficient frost-driven geomorphological processes. The importance of frost shattering and related processes was equally emphasized. Hence, the geomorphology of periglacial areas was long regarded as controlled primarily by processes driven by freeze–thaw mechanisms.

Originally, the term periglacial was used to describe the climatic and geomorphic conditions of areas peripheral to Pleistocene ice sheets and glaciers. Modern usage refers, however, to a wider range of cold climatic conditions regardless of their proximity to a glacier, either in space or time. In addition, many, but not all, periglacial environments possess permafrost; but they appear all to be dominated by frost action processes (Dylik 1964, French 1976, Washburn 1979, French 2007). In line with this view, the English version of the Multi-Language Glossary of Permafrost and Related Ground-Ice Terms compiled by the IPA's Terminology Working Group (Everdingen 1998), defines the term periglacial as the conditions, processes and landforms associated with cold, nonglacial environments.

Periglacial landscapes

The origin of periglacial landscapes as traditionally defined is recently becoming a theme for renewed debate. The relationship of landscapes to climate is a topic which has simultaneously been regarded as a focus for research in geomorphology and an approach which has fruitlessly occupied the time of geomorphologists over the past several decades. The former view has characterized research by many French and German geomorphologists, whereas the latter has prevailed among Anglo-American researchers. There is little doubt that major differences in climate have a profound effect on landscape development. Disagreement comes with the finer distinctions between degrees of climatic differences evident in past attempts to identify morphoclimatic zones. For instance, if we examine a range of landscapes in periglacial environments, landscape diversity is often more apparent than uniformity. A further problem is the diversity of conditions under which apparently similar landforms can develop. Perhaps the most intractable problem in periglacial geomorphology is the logical temptation of explicit linking of a particular landform with a specific set of climatic conditions. The observation of periglacial phenomena such as, e.g. ice-wedge casts, in climatic environments in which they could not have developed obviously raises the question of climatic change in landform interpretation.

Any modern periglacial landscape should be considered as consisting of a number of landforms currently adjusting according to present climate, and a number of relict features, produced under past climatic conditions. Whether a climatic change is of geomorphic significance depends on its magnitude and duration, and on the properties of the landform considered. The larger or more resistant a landform, the longer, in general, it takes to adjust to a change in climate. In addition, the broad features of landscapes in periglacial environments are also highly influenced by lithological differences.

The validity of the traditionally view on the evolution of a typical periglacial landscape has therefore been questioned in recent times: The importance of geomorphological processes like chemical weathering, rainfall-induced slope processes and river action are emphasized, even though they are not unique for periglacial environments, but occur also in many other climatic settings. For example, Rapp (1960) in his classical study on weathering in northern Sweden demonstrated that solution was more important than mechanical processes. Later Thorn (1992) suggested that frost action may have been overestimated in relation to explaining the geomorphology of periglacial regions. Weathering and transport processes not related to frost may often modify the landforms resulting from frost action, or even preside over landform evolution in many periglacial environments. The action of wind and running water may be two important examples of such ubiquitous processes not limited to cold regions. This development in 2003 lead André to ask the pertinent question: Do periglacial landscapes evolve under periglacial conditions? The significance of this question was emphasized by French and Thorn (2006). On this background we might even begin to wonder what is understood by periglacial processes.

Periglacial processes

The André (2003) paper was published in a special issue of the journal Geomorphology, presenting a selection of papers originally presented at the general session "Glacial and Periglacial Geomorphology" of the Fifth International Conference on Geomorphology held in Tokyo, Japan, in August 2001 (Matsuoka et al. 2003). A study of these papers provide some assistance in identifying what is understood as periglacial processes at the beginning of the 21st century. Broadly the papers could be categorized into four themes: effects of diurnal frost, mountain permafrost, paleo-periglaciation and nonfrost processes in periglacial environments.

This suggests that many periglacial geomorphologists still have their research focus on frost-related processes. Low temperatures as a driving mechanism apparently remain a valid criterion for defining periglacial processes, even though the evolution of landscapes in periglacial environments may be controlled by other azonal processes. Also the steady interest in fossil periglacial features as indicators of past cold environments, points toward this conclusion. The validity of paleoclimatic indicators depends on precise description of, among other things, the climatic control on processes responsible for the landform or sedimentary structure studied. Otherwise, the periglacial feature observed would clearly be of little use as indicator for past cold environments.

So, at the beginning of the 21st century periglacial geomorphologists apparently are defining key periglacial processes as those related to seasonal or perennial frost, a point of view supported by French and Thorn (2006). At the same time, it is recognized that landscapes in periglacial regions are not always dominated by such periglacial processes, but quite often by more omnipresent processes such as wind and running water. On this background it might be considered if the future use of the term periglacial should be limited to describe processes and environments, rather than landscapes?

Having identified the modern implication of periglacial processes, we may proceed towards identifying a number of especially important or characteristic processes. To achieve this goal, we must first consider what is generally seen as characteristic landforms in periglacial environments. Due to space limitations, this will clearly not represent a comprehensive analysis, but will focus on a few landforms and phenomena, by the present author seen as characteristic for landscapes in periglacial environments.

Characteristic periglacial landforms and processes

The perhaps most obvious and impressive landforms in periglacial environments are those associated with steep slopes. In many mountain areas, glacial over-steepening, combined with weathering has led to rock slope instability and the production of large volumes of debris. Outside Holocene permafrost environments, a fundamental distinction is often recognized in valleys partly filled by glacier ice during Stadials of the last ice age. Within the former glacier limits, volumes of talus are limited relative to those at the foot of slopes outside the limits. By implication, the greater volumes of debris reflect the more severe periglacial conditions that prevailed during the Stadial and perhaps also during the deglaciation. Indeed, the impressive size of talus accumulations in periglacial highlands environments has led many researchers to conclude that rockfall is particularly pronounced under cold-climate conditions, due to release of debris from cliffs by frost wedging.

Low-relief periglacial areas are characterized by extensive polygonal networks, patterned ground and different types of frost mounds. All these phenomena are related to temperature induced volume changes of bedrock, sediments, ice, or mixtures of thereof. A highly diversified terminology is attached to the description of the surface expression of such phenomena. For example polygonal networks may appear in the literature under the headings of tundra polygons, frost-fissure polygons, ice-wedge polygons, and sand-wedge polygons, just to mention a few.

These observations suggest that frost-related non-glacial processes leading to rock disintegration, rockfall, rupturing by thermal contraction, and the deformation and sorting of thawed soil may be among what might be seen as characteristic periglacial processes. This assumption will provide the basis for the discussion below.

Characteristic Periglacial Phenomena

Rock disintegration

Evidence suggests that frost action is not the only weathering process leading to rock decay in periglacial environments. Cold-climate weathering is caused by the broader concept of cryogenic weathering, a collective term for a combination of little known physical and chemical processes which cause the in situ breakdown of rock under cold-climate conditions. Pressure release, salt weathering, chemical weathering, biological activity or thermal shocks may all play a role. In fact, chemical weathering (Roberts, 1968, Dixon et al., 2002) and biological processes (André, 2002) are more and more often considered as important actors in cold environments.

Field data on rock temperature and moisture content is essential for improved understanding of rock weathering in periglacial environments and for setting up realistic laboratory experiments. Unfortunately, such data are scarce in literature. In recent years, however, this situation is beginning to change through the publication of such data (e.g., Hall 1997, Hall 2006, Hall et al. 2002, Prick 2003).

This new accessibility of high-quality field data has provided the background for conducting realistic laboratory experiments, investigating the importance of ice segregation for low temperature bedrock breakdown under permafrost conditions (Murton et al. 2001). This experiment demonstrated that ice segregation, frost heave and brecciation in artificial permafrost formed in moist chalk are fundamentally similar to the processes associated with the growth of natural permafrost formed in frost-susceptible sediment. Similarities between the experimentally formed brecciation and naturally brecciated bedrock in areas of contemporary and former permafrost suggest that ice segregation during perennial and seasonal freezing is an important weathering process of frostsusceptible bedrock. By implication, the coarse, angular debris produced by ice segregation in bedrock during cold Quaternary periods was suggested being the sediment source for many of the coarse periglacial slope deposits. It is also very likely that bedrock fracture by ice segregation is significant for rockwall stability in regions of mountain permafrost, and for landform development in such areas in general. On this background Büdel's (1977) original 'Eisrinde' hypothesis absolutely deserves renewed research interest.

Rockfalls

The term rockfall describes the fall of relatively small (< 10 m^3) fragments of rock debris that are released from bedrock cliffs. By tradition, rockfall in periglacial environments has been widely attributed to frost wedging, the widening of cracks and joints by ice during freezing and detachment of debris from cliffs during thaw. Frost wedging is, however, only one of several processes operating on cliff faces (André 2003). Rockfall may also be triggered by stress-release, progressive failure along joints, or build-up of hydrostatic pressure within a rock mass. Indeed, some researchers view the role of freeze-thaw in rockfall as trivial in comparison with intrinsic controls such as stress release, weathering and build-up of joint-water pressures.

The timing of rockfalls remains the main reason for seeing frost wedging as the foremost cause of rockfall in cold environments. Rapp (1960) noted that rockfall at high latitudes is most frequent in spring and autumn, when cliffs was assumed to experience a maximum frequency of freeze-thaw cycles. Rockfall inventories in the Arctic and the Alps (e.g. Luckman, 1976, Coutard and Francou 1989) suggest maximum activity during the spring thaw. In Japan, Matsuoka and Sakai (1999) observed peak rockfall rate 5-15 days after meltout of the cliff face, when seasonal thaw reached an estimated depth of 1 m. Other rockfall inventories, however, emphasize diurnal variations, rather than seasonal trends. This is observed at alpine cliffs with frequent diurnal freeze-thaw cycles penetrating to depths of 50 cm (Coutard and Francou 1988). Rockfalls may also coincide with summer rainstorms, implying that build-up of joint-water pressures is also instrumental in releasing debris. Conversely, Matsuoka and Sakai (1999) in Japan found that intensive rockfall activity is rarely associated with either diurnal freeze-thaw cycles or precipitation events. So it is actually difficult to confirm the hypothesis regarding frost wedging as the main trigger of rockfall in periglacial environments.

Wind action

Due to the general lack of trees, many periglacial regions experience high wind speeds (Seppälä 2004), leading to the formation of different types of deflation surfaces. The vegetation, soil and fine material debris is removed to leave an armoured surface where large clasts are embedded within a matrix of finer sediment. Grains of sand and fine gravel can often be observed in motion during strong winds, blasting vegetation and rock surfaces. Sand dunes or sand sheets may occur downwind of such areas (Ballantyne and Harris 1994, Humlum and Christiansen 1998), but often much of the debris seems not to accumulate as dunes or sheets. Some may become temporarily resident in the snow pack, to thaw out in spring. Some probably finds its way into lakes and rivers on valleys floors. Some may be transported into the sea suspended in the air.

Another characteristic feature related to wind action in periglacial environments is wind-facetted blocks or wind polished bedrock surfaces (Christiansen and Svensson 1998). The wind-eroded surfaces are identified from their smooth and polished surfaces, together with facets and grooves (Christensen 2004). Blowing snow at low temperatures has apparently been the abrading agent for several examples of periglacial bedrock windpolish (Fristrup 1953).

Snowblow

Snowblow by wind is important in most periglacial environments, partly because of the typical absence of high vegetation providing lee at the ground surface, partly because many periglacial regions are found at high latitudes or high altitudes, where wind speed may be high.

The process of snow drifting is important in low-relief periglacial terrain, where the resulting distribution of snow controls heat exchange between atmosphere and the ground surface during the winter, for example on palsas (Seppälä 2004). The thermal importance of the snow cover for permafrost is well demonstrated by the efforts put into determining the n-factor, describing the thermal insulation provided by the snow cover (Smith and Riseborough 2002). In high-relief areas, snow accumulation on steep slopes contributes to the release of avalanches, especially on slopes downwind of extensive mountain plateaus (Humlum et al. 2007).

At low temperatures, the hardness of snow crystals increases, and wind transported snow may act as an efficient abrasive agent in relation to boulders and bedrock (Fristrup 1953). In addition, wind induced accumulations of snow are important as sources of water during the summer, as precipitation generally is low in periglacial environments.

Bagnold (1941) provided much of the groundwork for current steady-state models of sand drift (e.g. Sørensen 1991). The same physical basis has been applied to existing numerical models of snowdrift, such as SnowTran-3D (Liston and Sturm 1998) and the snowdrift index in SNOWPACK (Lehning et al. 2000, 2002a, 2002b). Snow drift prediction models using weather station data have also been developed for meteorological services (e.g., Li and Pomeroy 1997a, 1997b). These models, however, tend to consider snow drift as a probabilistic event and relate conditions to a measurement height, rather than to surface conditions.

Snow avalanches

Snow avalanches represent a periglacial transport process especially important during winter and spring. Although many shallow or midwinter avalanches contain only snow, deeper and late winter avalanches frequently incorporate and transport varying volumes of rock debris. As avalanches tend to follow gulleys, this debris accumulates on valley floors at the mouths of these gulleys in the form of avalanche boulder lobes (Rapp 1960), protalus ramparts (Ballantyne and Harris 1994), or rock glaciers (Humlum et al. 2006).

The meteorological control of snow avalanches represents a research theme in its own right, highly developed especially in Switzerland, Austria, USA and Norway. Several factors affect the likelihood of an avalanche, including weather, temperature, slope steepness, slope aspect, wind direction, terrain, vegetation, and the general snowpack conditions. Different combinations of these factors can create low, moderate or extreme avalanche conditions. Despite the existence of large databases with observations on avalanches, avalanche safety rules still are based mainly on empirical rules of thumb, rather that on strict meteorological-geotechnical analysis.

Another way of investigating the climatic control on avalanches is through analysis of avalanche deposits accumulated during the Holocene (e.g., Blikra and Selvik 1998). Such analyses, however, important as they are, only indicate that avalanches become more frequent during cold periods with frequent snow precipitation, but do not provide the means of detailed insights into meteorological controls on avalanche release. Indeed, some attempts at analysis simply assumes that the presence of what is interpreted as avalanche-derived debris indicate past periods with cold and snowy conditions.

Thermal contraction of frozen ground

Periglacial thermal contraction phenomena such as ice-wedge casts are widespread in periglacial environments. Fossil features in the form of ice-wedge casts are often used to estimate palaeotemperatures, specifically the maximum values of the mean annual air temperature or the mean air temperature of the coldest month (e.g., Washburn 1979, Vandenberghe et al. 1998). The now common use of ice-wedge casts as palaeotemperature indicators arose from an influential study by Péwé (1966a, 1966b) of ice-wedges in Alaska. As later pointed out by Murton and Kolstrup (2003), however, the validity of such attempts at reconstructions still remains uncertain because of limited knowledge of the frequency of thermal contraction cracking under contemporary permafrost environments. In addition, the perhaps complex controls other than meteorological on cracking are still incompletely understood. In fact, snow thickness appears to represent a decisive factor on ice-wedge cracking near the Western Arctic coast of Canada (Mackay 1993). Also the role of surface vegetation still needs to be quantified (Murton and Kolstrup 2003).

Progress in knowledge on thermal contraction cracking requires detailed field observations, supplemented by laboratory and numerical experiments, using real-world meteorological data on climate, landforms and sediments. A numerical modeling experiment on ice-wedge formation was recently presented by Plug and Werner (2001). This attempt at modeling ice-wedge growth turned out to be premature, because of lack of insight in real world conditions (Burn 2004).

Examples of how to expand knowledge on thermal contraction cracking of frozen sediments is given by careful field studies such as, e.g., Mackay (1993) and Christiansen (2005), in great detail describing meteorological and snow conditions related to thermal cracking of frozen ground.

Sediment sorting

Sorting of near-surface sediments in periglacial areas is responsible for the distinct, and often symmetrical geometric shapes known under the general heading patterned ground. The details of the sorting process and the origin of patterned ground has remained elusive for ages, despite much research effort.

Patterned ground is perhaps the most striking feature of the periglacial landscape, and can be found in a variety of forms: Polygons, circles, nets, steps, and stripes. The individual surface forms may range in size from a few centimeters to several meters in diameter. Typically, the type of patterned ground in a given area is related to the amount of larger stones present in local soils and the frequency of freeze-thaw cycles.

Polygons, circles and nets normally occur on level or gently sloping surfaces, while steps and stripes are found on steeper gradients. Both sorted and non-sorted varieties are recognized. The sorted varieties are typically outlined by coarse, stony material, and so are termed “stone circles,” “stone polygons,” “stone nets,” “stone steps,” and “stone stripes.”

The origin of patterned ground involves a complex interaction of several geomorphological processes, including differential frost heaving and mass movement. Recurrent freezing and thawing of water is usually believed to be critical for the development of patterned ground. In permafrost regions and non-permafrost regions affected by seasonal frost, repeated freezing and thawing of soil water transports larger stones toward the surface as smaller soils flow and settle underneath larger stones. At the surface, areas that are rich in larger stones contain less water than highly porous areas of finer grained sediments. These water saturated areas of finer sediments have greater ability to expand and contract as freezing and thawing occur, leading to lateral forces which ultimately pile larger stones into clusters and stripes. Through time, repeated freeze-thaw cycles form the common polygons, circles, and stripes of patterned ground.

There is still much debate as to the detailed mechanisms involved in freeze-thaw sorting, but it is widely agreed that the large scale patterned ground reflects the former existence of permafrost (Ballantyne 1996). Recurrent freezing and thawing of ground is also considered important for other periglacial phenomena such as solifluction and ploughing blocks.

The way ahead for periglacial geomorphology

Periglacial geomorphology is very special. It usually requires some mastery of geology, meteorology and geophysics to plan and carry out efficient investigations of complex geomorphological problems in periglacial environments. On the other hand, especially Quaternary geologists can in a very real sense be seen as applied periglacial (and glacial) geomorphologists. This relation emerges because periglacial (and glacial) geomorphologists combine the historical perspective so dear to geologists with an accentuated awareness and interest of contemporary geomorphological processes. In my opinion, it is exactly this study of geomorphological processes in periglacial environments which provides periglacial geomorphology with integrity, and upon which periglacial geomorphology relies for future scientific credibility.

Geomorphological processes clearly unique to periglacial environments relate to seasonal or perennial freezing, including the growth of segregated ice and associated frost heaving. Many of these processes operate in the near-surface layer subject to seasonal freezing and thaw; the active layer in permafrost regions. Ground seasonally frozen experience a range of special conditions associated with pore-water expulsion and thaw consolidation (French and Thorn 2006). On sediment slopes, this may promote rapid mass failures. On bedrock slopes, disintegration of exposed rock by mechanical frost weathering and several still poorly understood physical and biochemical processes may lead to rock falls. In addition to such characteristic periglacial processes the enhanced effect of wind in periglacial regions clearly deserves further study (Seppälä 2004).

Any study contributing to increased knowledge on geomorphological processes in periglacial environments are by definition important, no matter the specific theme chosen. From a strategic point of view, however, it appears that improved understanding of especially processes related to seasonal or perennial freezing should be seen as having tactical research priority within future periglacial research. Rock weathering in periglacial environments may be considered the mother of many types of sediments, and therefore a key factor for a range of other processes and landforms. Rock weathering in periglacial environments definitely deserves a concerted research effort, along with research on thermal contraction cracking and sediment sorting. These three phenomena together typify landscapes in most periglacial environments.

What is needed within periglacial geomorphology is a detailed monitoring scheme of meteorological parameters and geomorphological processes. Clearly, the use of dataloggers and other automatic equipment will have an important role in this development (Matsuoka 2006).

In this context, the organization in 2004 of a new Working Group (WG) on 'Periglacial Landforms, Processes and Climate' under the International Permafrost Association (IPA) may prove helpful. This WG is aiming at making a database for temporal and spatial variability of periglacial processes with special attention to meteorological controls and the impact of climatic change. To achieve this goal, the WG attempts to establish a global network for monitoring periglacial processes (Matsuoka and Humlum 2005, Matsuoka 2006), highlighting geomorphological processes associated with ground thermal regimes, inside and outside permafrost regions.

The recommended parameters to be measured depend primarily on the purpose of the study and the spatial scale. A cold-climate drainage basin is subjected to a variety of geomorphic processes, including glacial, periglacial, fluvioglacial, nival, gravitational and eolian processes. One research approach may focus on the mechanism of a specific process like rock fall, solifluction or ice-wedge growth, whereas other may aim at evaluating the sediment budget for the whole catchment. Whatever the approach chosen, the search for knowledge on past and present processes influencing landform evolution in periglacial regions is becoming increasingly influenced by more and more refined monitoring protocols, relying upon automatic and sophisticated equipment.

To the present author the common denominator for future periglacial research appears to be a coordinated research scheme embracing mapping, monitoring, experiments, and modeling, with focus on geomorphological processes relating to seasonal or perennial freezing.

Acknowledgments

Most of this paper was written during my sabbatical at University of St. Andrew (Scotland), where space facilities were kindly provided by Professor Colin Ballantyne. Both Professor Hugh French and Professor Norikazu Matsuoka have shared their thoughts on periglacial geomorphology with me during stays at UNIS (Svalbard), and in this way they have influenced the present paper. The responsibility for the actual content, and for any errors and omissions, however, remains fully with me. To everyone, I extend my warmest thanks.

Abstract

The present study aims to examine the interseasonal impacts of water cycle components on subsequent hydrothermal processes in permafrost, focusing on rainfall, snow amounts, and snow start and disappearance timings in the Lena River basin over recent decades. According to climatological analysis, there is a significant correspondence between the interannual variation in snow depth and soil temperature. In addition, both snow cover start and disappearance dates have negative correlations with soil temperature and moisture. These relationships indicate that a wetter climate with earlier snow season tends to produce an earlier start of subsequent growing season, which has been observed in the central Lena River basin in recent years. Based on a one-dimensional land surface model, earlier snow cover start and disappearance dates are correlated with significant increases in evapotranspiration from the boreal forest due to an earlier soil thawing and earlier plant growth and increased supply of soil moisture for plant uptake.

Keywords: active layer; eastern Siberia; evapotranspiration; rainfall in previous year; snow start and disappearance.

Introduction

The Eurasian continent has been a major topic of studies on land-surface-atmosphere interaction and the corresponding impact on not only the adjacent regional climate, such as Asia monsoon (Liu and Yanai 2002) and Arctic climate (Saito et al. 2001, Gong et al. 2007), but global climate change (Bonan et al. 1992, Yasunari et al. 1991). Especially, the variation in water cycle components in cold regions, containing rainfall, snow cover, soil moisture and frozen ground rich with ice, is a distinctive feature of the continental climate systems and has a delayed and durable influence on the overlying atmosphere through the land-surface fluxes of heat and moisture.

In eastern Siberia, which contains vast areas of permafrost, snow melt water directly contributes to the runoff of large rivers (Peterson et al. 2002, Ye et al. 2004) and evapotranspiration via soil moisture and photosynthesis in boreal forest following snow disappearance (Ohta et al. 2001, Sugimoto et al. 2003). These marked variations in water circulation play important roles in climatic feedback by modifying atmospheric anomalies. Thus, the preceding rain and snow conditions are very important for understanding variations in both the basin- and continental-scale water cycle and the climate system of neighboring regions. For instance, several statistical analyses have demonstrated that the timing of snow disappearance and increasing surface temperature in eastern Siberia is one of the possible candidates for long memory of an atmospheric anomaly from winter arctic oscillation and subsequent summer atmospheric circulation over the East Asia (Ogi et al. 2003, Arai & Kimoto 2005). However, few studies have investigated interactions between snow, permafrost, and climate or interannual variations in permafrost related hydrothermal conditions and water and energy cycle processes during the warm season that are possible effects of land memory in eastern Siberia.

The present study, therefore, aims to examine interseasonal impacts of water cycle components on subsequent land-surface processes, mainly focusing on the relationship between permafrost conditions and hydro-climatic components, such as rainfall in pre-winter, snow depth, snow starting timing in early winter and disappearance timing in spring at Yakutsk area in the central Lena River basin, based on observational meteorological data for recent decades. Our analysis is then extended to reveal the durable relationship and processes between these hydrothermal components influenced on the permafrost conditions and interannual variations in surface energy balance, using detailed land-surface energy balance model simulation.

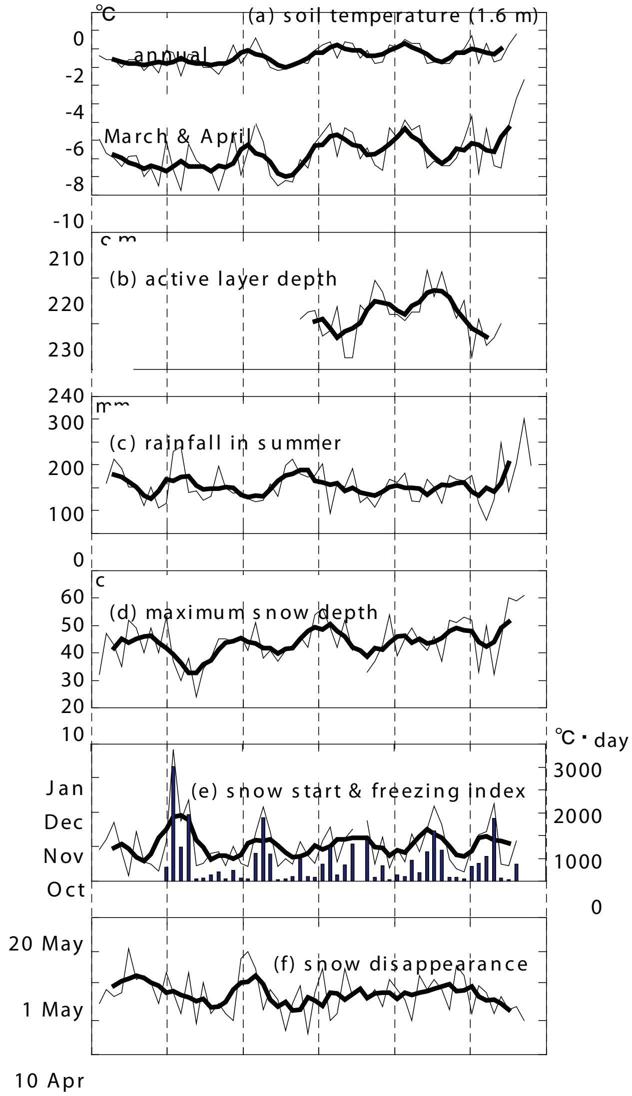

Figure 1. Long-term variations in hydrothermal components; (a) mean annual and minimum (average in March and April) soil temperature at 1.6 m depth at Pokrovsk, (b) active layer depth at Pokrovsk, (c) rainfall amount from July to September at Yakutsk, (d) maximum snow depth at Yakutsk, (e) snow start date with more than 10 cm snow depth (line) and freezing index until the date (bar), and (f) snow disappearance date at Yakutsk from 1950 to 2007. Bold lines denote 5–year running mean.

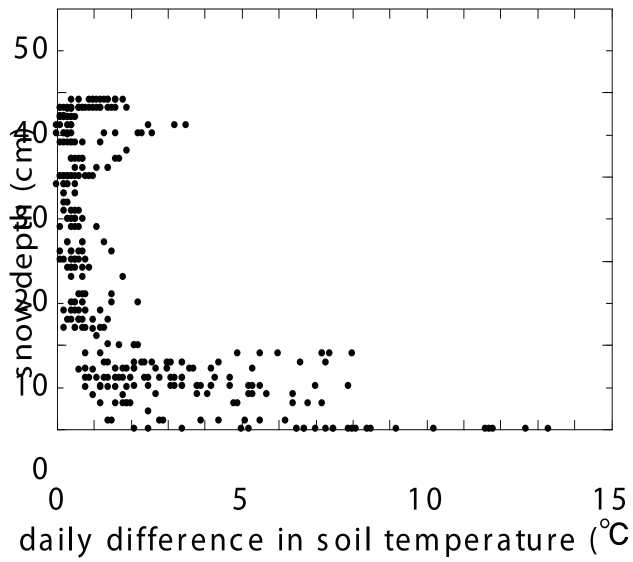

Figure 2. Relationship between daily difference in soil temperature at surface at larch forest site and daily snow depth at Yakutsk from October to December during four winters (2003–2006).

Data and Methods

We used the routine observational data at Yakutsk (62.01°N, 129.43°E) and Pokrovsk (61.48°N, 129.15°E) from a dataset of the Baseline Meteorological Data in Siberia Version 4 (BMDS; Suzuki et al. 2006). The dataset contains daily values of air temperature (°C), precipitation (mm), snow depth (cm) and soil temperature from 40 to 320 cm depth (°C) over a 19-year period (1986–2004). We used soil temperature data at only Pokrovsk since the data at Yakutsk shows strong influences of anthropogenic disturbances. After 2004, daily data was added from a dataset of the NCDC Global Summary of Day up to September 2007. Past data from 1950 to 1985 are added utilizing the Global Summary of Day for daily air temperature, the Global Synoptic Climatology Network of the former USSR (NCDC D9290C) dataset for daily precipitation, the Historical Soviet Daily Snow Depth (HSDSD) dataset for daily snow depth, and Roshydromet station data for monthly soil temperature. Based on the snow depth data, the first date of 0 cm of snow depth in each spring was defined as "snow disappearance date" and the first date of more than 10 cm of snow depth in early winter with lasting snow cover throughout the winter was defined as "snow start date" since this quantity of snow accumulation acts as an effective layer of thermal insulation.

The intensive hydrometeorological observation at larch forest at Spasskaya-pad, Yakutsk, Russia has been ongoing since 1998 by GAME-Siberia project and it continues up to the present. We used several components of the dataset from 1998 to 2007 for the present study. That is, soil temperature in the active layer (0, 0.1, 0.2, 0.4, 0.8, and 1.2 m depth) and volumetric soil moisture content (0.1, 0.2, 0.4, 0.6, and 0.8 m depth).

Before 1998, there is no information on water and energy balance conditions at the larch forest site. Thus, we used estimated surface energy flux calculated by a one-dimensional land surface model (Yamazaki et al. 2004). The model includes three submodels; vegetation, snow cover, and soil. The model divided the canopy into two layers and then represented the fluxes above and within the canopy. The model was applied to the larch forest site at Yakutsk. Daily forcing meteorological quantities of each grid were reconstructed based on the BMDS dataset from 1986 to 2000. Using the daily forcing data, the model simulated hourly water and energy fluxes above and within the forest. The more detailed settings for estimating energy and water flux using the model are documented in Yamazaki et al.

(2007). Yamazaki et al. (2007) demonstrated that the model could reasonably estimate diurnal and seasonal variations in surface energy fluxes at the larch forest.

Results and Discussions

Interannual variations in hydrothermal components

Figure 1 shows interannual variations in hydrothermal components in relation to permafrost conditions at Yakutsk and Pokrovsk sites from 1950 to 2007. Rainfall and snow amounts and variations show hardly any differences between Yakutsk and Pokrovsk.

Soil temperature variation at 1.6m depth indicates decadal fluctuations (Fig. 1a); that is, high temperature peak in 1971, 1981, 1991, and 2000 and low peak in 1966, 1974, 1988, 1994 and 2004. Soil temperatures in March and April at Pokrovsk show annual minimum value contributing to the amplification of the interannual variation in mean annual temperature. The active layer depth calculated by daily soil temperature data at Pokrovsk from 1977 to 2004 (Fig. 1b) has significant positive correlation with mean annual soil temperature ($R = 0.65$, $p < 0.001$). Deeper thawing occurred in early 1980s and early 2000s, corresponding with the warmer soil temperature.

Interannual variation in soil temperature has significant relationship with snow accumulation and its timing rather than rainfall amount in pre-winter (Fig. 1c). Maximum snow depths at Yakutsk (Fig. 1d) range between 15 cm and 50 cm. Basically, years with slow snow depths tend to show a decrease in annual minimum soil temperature ($R = 0.58$, $p < 0.001$). The significant relationship between soil temperature and snow depth indicates that variations in the timing and duration of the seasonal snow cover result in the ground thermal regime during winter (Frauenfeld et al. 2004, Zhang 2005). Snow start date with more than 10 cm of snow depth (Fig. 1e) fluctuates between early October and late January at Yakutsk. As shown in Fig. 2, a decrease in soil temperature is effectively enhanced by the longer duration of shallower snow depth with less than 10 cm during early winter (October to December) at Yakutsk. In fact, a large freezing index until the date with 10 cm of snow depth had significant impacts on the decrease in soil temperature. Namely, years with late timing of snow accumulation have longer and greater freezing intensity so that the soil temperature decreases significantly. It suggests that the thin snow cover has an effective cooling effect on the ground thermal regime when the air temperature is below 0°C until sufficient snow accumulation occurs. Also, soil temperatures tend to sustain cooling anomalies for several years after the large decrease in soil temperatures such as from 1973 to 1976, from 1985 to 1988, from 1994 to 1998, and from 2001 to 2004. During these periods, rainfall in pre-winter as well as snow depth was below average in most of the years. The result implies that durable cooling anomalies likely occurred under dry soil condition.

The snow disappearance date (Fig. 1f) shows relatively short interannual variation between mid-April to early May.

Table 1. Correlation matrix of rainfall, snow timings, soil moisture and soil temperature during 1998 to 2006 at the larch forest site, Spasskaya-pad, Yakutsk.

	Rain autumn	Snow start	Snow disap	Soil moisture	Soil temp
Rain autumn	1.00				
Snow start	−0.18	1.00			
Snow disap	−0.03	0.62	1.00		
Soil moisture	0.87*	−0.80*	−0.35	1.00	
Soil temp	0.38	−0.57	−0.53	0.75*	1.00

(*: $p < 0.05$)

Rain autumn – rainfall amount in pre-winter (July–September); Snow start – snow start date in previous year; Snow disp. – snow disappearance date; Soil moisture – volumetric soil moisture at 0–40cm depth in July and August; Soil temp. – soil temperature at 120 cm depth in July and August.

There is no significant relationship with maximum snow depth ($R = 0.20$, ns). According to Iijima et al. (2007) and Gong et al. (2007), the snow disappearance mainly depends on the atmospheric warming. The snow disappearance dateclosely relate with the date of soil thawing from surface to 80 cm depth at Pokrovsk, although no significant relationship with active layer depth which appears in September. It appears that the snow disappearance timing affects the soil thawing near the surface and also the soil moisture melting which directly affect evapotranspiration from vegetated surface.

Figure 3 shows interannual variations in soil temperature and soil moisture at the larch forest site in Spasskaya-pad near Yakutsk during 1998 through 2007 and variations in snow depth and snow start and disappearance date at Yakutsk. It is found that both soil temperature during wintertime (which indicates intensity of freezing) and soil moisture content at the beginning of warm season show simultaneous interannual variations. That is, there are warmer and wetter years in 2000, 2005, and 2006, while colder and drier years in 1998, 2003, and 2004. Table 1 demonstrates a correlation matrix between rainfall in pre-winter (from July to September), snow start date in previous winter, snow disappearance date, soil temperature and moisture in summer. As described above, it appears that there is a significant correspondence in interannual variation between soil temperature and soil moisture. It implies that thermal condition in active layer is strongly connected with hydro-climatic variations. In addition, rainfall in pre-winter has strong correlation with soil moisture in next summer. It appears that rainfall remains in the active layer through winter and possibly acts as climatic memory of soil moisture. Moreover, both snow start and disappearance timings have negative correlations with soil temperature and moisture. It might be suggested that snow start timing determines intensity of freezing in active layer during early winter, and wet condition during winter also affects soil freezing.

As shown in long-term variation in soil temperature at Pokrovsk, interannual warming and cooling trends are found at the larch forest site. These trends in successive years are basically due to the similar snow and rainfall conditions. These continuous hydro-climatic conditions may maintain

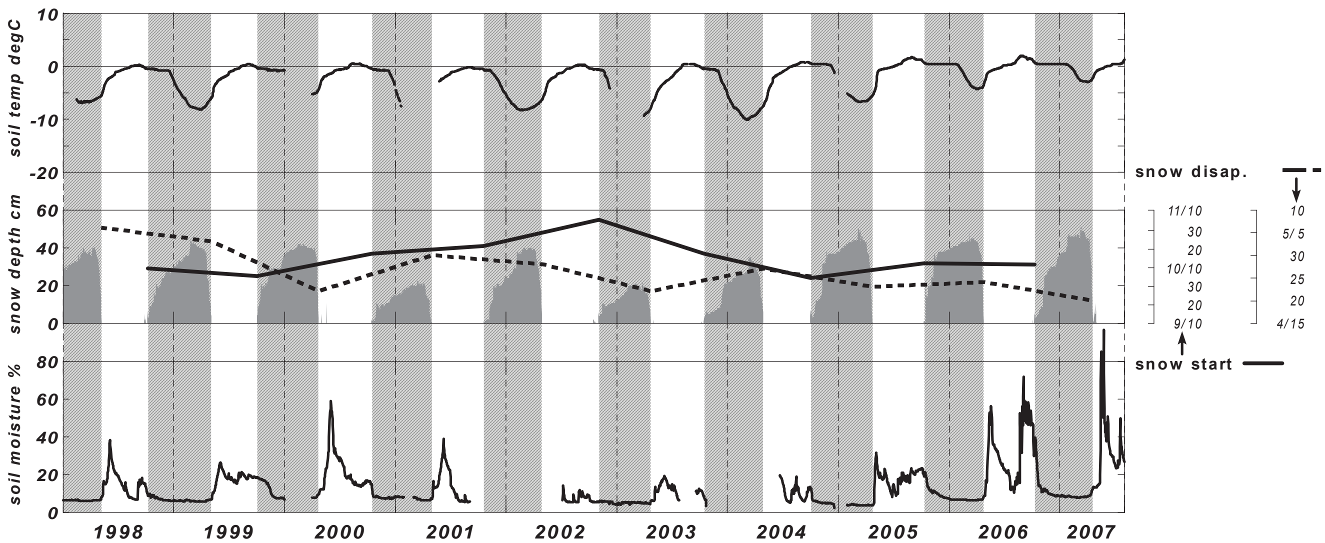

Figure 3. Nine-year (1998–2007) variation in (a) soil temperature, (b) snow depth, and (c) soil moisture. Soil temperature (120 cm depth) and soil moisture (10 cm depth) were observed at larch forest site in Spasskaya-pad, Yakutsk. Snow depth was observed at Yakutsk. Bold and dotted lines denote snow start date and snow disappearance date, respectively. Dark area denotes snow cover period in each winter.

the trend of previous soil temperature anomalies through reemergence in deeper soil layer through soil moisture anomalies (Schaefer et al. 2007).

Snow timing and evapotranspiration in spring

Estimated monthly average of latent heat flux above the larch forest canopy from 1986 to 2000 and its standard deviation are shown in Figure 4. Annual maximum appears in June or July due to the maximum activity of evapotranspiration from the forest. Interannual variation in latent heat flux is less variable in comparison with variation in precipitation. This tendency was recently confirmed by eight-year (from 1998 to 2006) variation in energy flux above the larch forest canopy at the same station based on micro-meteorological observation (Ohta et al. 2006). Though there is a small variation in latent heat flux, the maximum variation appears in May with the largest standard deviation (±6 Wm^{-2}).

Figure 5 shows the relationship between estimated latent heat flux in May normalized by net radiation above the larch forest canopy by the model and both snow starting date in previous winter and snow disappearance date from 1986 to 2000. It appears that both timings have significant negative correlations (snow start date: R = -0.76, p < 0.01, snow disappearance date: R = -0.59, P < 0.05). The relationship with snow disappearance date directly corresponds to the beginning of transpiration since the timing of soil warming after snow disappearance determines foliating of plants at forest floor and trees and also determines timing of soil thawing for supplying plant available soil moisture, which parameterized in the model (Yamazaki et al. 2007). On the other hand, the significant relationship with snow start date in previous winter suggests that the warmer (cooler) anomaly of soil temperature during winter remains until

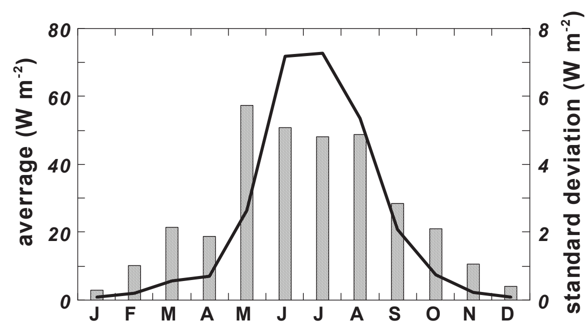

Figure 4. Monthly average and standard deviation of latent heat flux above the canopy at larch forest from 1986 to 2000 simulated by one-dimensional land surface model.

snow disappearance and also cause the earlier (later) timing of soil thawing. Thus, the relationship implies that soil temperature modulated by snow timing strongly influence the evapotranspiration processes in the early growing season.

Figure 6 exhibits the difference of hydrothermal conditions (mainly years with either high or low latent heat fluxes in May) from the difference between the average of the four high years (low years) and the average of the four prior years (same). These values were averaged using each four years (high years: 1990, 1992, 1994, and 2000; low years: 1987, 1989, 1995, and 1998) and the preceding four years in each case. The difference in latent heat flux in May between high and low years exceeds 10 W m^{-2} (Fig. 6a). Snow depth difference is apparent during snow disappearance timing (Fig. 6b). Namely, earlier melting appears in high years. Inversely, snow start timing in early winter shows earlier snow accumulation in high years. In addition, deeper snow depth appears during the winter two years ago. During the previous

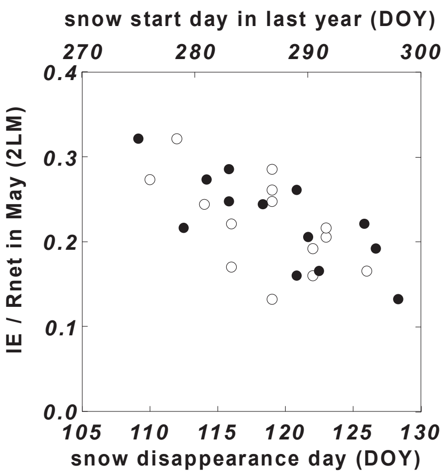

Figure 5. Relationship between snow timings and estimated mean monthly evapotranspiration ratio (latent heat/net radiation). Open and solid circles denote snow start date and snow disappearance date, respectively.

warm season, rainfall in the high years is larger than in low years (Fig. 6c). Due to the large difference in snow depth in the winter two years ago and earlier snow accumulation in previous winter, soil temperature shows large difference during the successive two winters (Fig. 6d). It should be noted that the warmer temperature continuously lasts throughout two years in deeper layer. These durable warming tends to enhance earlier thawing of frozen layer (Fig. 6e). Thus, it might be earlier start of evapotranspiration due to earlier soil moisture supply. Ohta et al. (2006) exhibited that there was a remarkable positive relationship between surface soil moisture and annual amounts of evapotranspiration. They also implied that the effects of snowfall from previous cold seasons and the permafrost conditions affect soil moisture into subsequent growing season and are important to the interannual variations in evapotranspiration.

Conclusions

The present study investigates climatological features of hydrothermal components in the Yakutsk region and its relationship with evapotranspiration during subsequent warming season. The results of the present study are summarized as follows:

1. Long-term variation in soil temperature at Pokrovsk indicates decadal fluctuations and has significant relationship with snow accumulation and its timing. The drier climate with later snow accumulation may produce an anomaly of lower soil temperature and thus shallower active layer.
2. There is a significant correspondence in interannual variation between soil temperature and soil moisture at the larch forest site. In addition, both snow start and disappearance dates have negative correlations with them.
3. Both snow start in previous winter and snow disappearance have significant negative correlation with latent heat flux from the boreal forest in May simulated by a one-dimensional land surface model associated with the start of subsequent plant growing season.

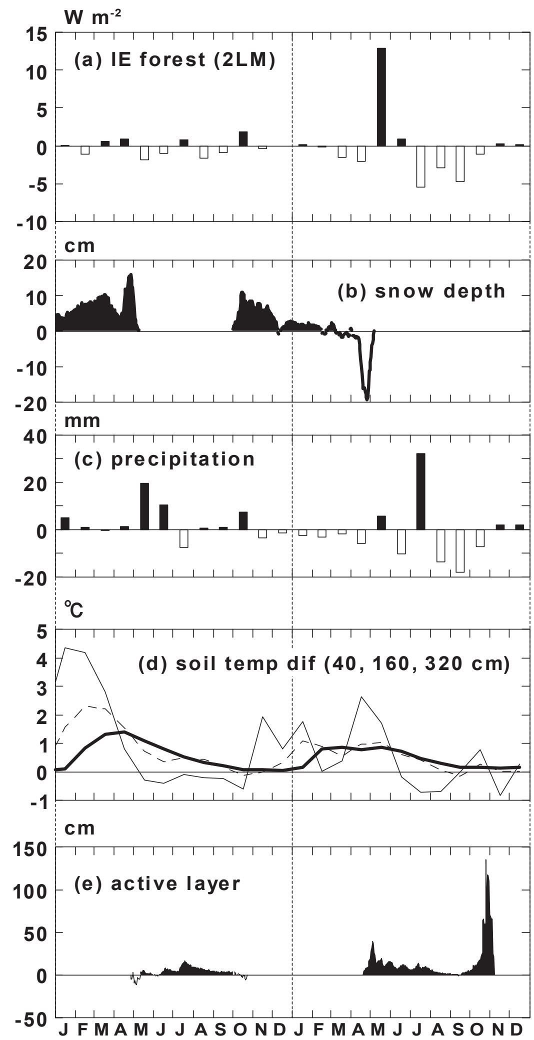

Figure 6. Differences of hydrothermal conditions for the average of the four highest years and the average of the previous for years for high evapotranspiration in May (left panel) and the same for low evapotranspiration in May (right panel); (a) latent heat flux from forest canopy by one-dimensional land surface model, (b) daily snow depth at Yakutsk, (c) monthly rainfall at Yakutsk, (d) monthly soil temperature at 40 cm (thin line), 160 cm (broken line), and 320 cm (bold line) depths at Pokrovsk, and (e) daily thawing depth at Pokrovsk.

Acknowledgments

We extend our appreciation to Prof. B. Ivanov of the Institute for Biological Problems of Cryolithozone for allowing us the opportunity to investigate in Siberia. This work was financially supported by Institute of Observational Research for Global Change, Japan Agency of Marine-Earth Science and Technology.

Topographical Controls on the Distribution and Size of Rock Glaciers in the Central Brooks Range, Alaska

Atsushi Ikeda
Graduate School of Life and Environmental Sciences, University of Tsukuba
Kenji Yoshikawa
Water and Environmental Research Center, University of Alaska Fairbanks

Abstract

Distribution, morphology, internal structure and thermal conditions of rock glaciers were studied in the central Brooks Range, Alaska, an area characterized by continuous permafrost. A positive size correlation was found between the active talus-derived rock glaciers and the source rock walls. The source rock walls of the inactive rock glaciers were limited to a relatively small size. These topographical relationships indicate that direct debris supply from the rock walls at least partly controls the size and activity of these rock glaciers. On six talus-derived rock glaciers, low mean annual ground surface temperatures (-3°C to -7°C) were monitored, and similar low ice content was indicated by DC resistivity measurements. The results approve the interpretation of the topographical analysis based on the assumption that a number of rock glaciers have similar creep property and composition. In contrast, rock glaciers interacting with glacial processes enlarged below the relatively small rock walls.

Keywords: Brooks Range; continuous permafrost; DC resistivity; GIS; rock glacier; rock wall.

Introduction

Distribution, size, and structure of rock glaciers probably reflect the complex input of debris, ground water, and snow which is controlled by local climate and geology. Rock glaciers have been often classified into active and inactive types to discuss the climatic and geological factors that control their long-term movement (e.g., Wahrhaftig & Cox 1959, Calkin et al. 1987, Ikeda & Matsuoka 2002). Active rock glaciers are moving downslope by internal ice deformation. Inactive rock glaciers are stagnant but still contain ice. Barsch (1992) suggested two kinds of inactivity: climatic and dynamic. The melting of ice in a rock glacier accounts for climatic inactivity. Dynamic inactivity results from reducing shear stress within the perennially frozen layer in a rock glacier, which is caused either by a temporal decrease in debris supply or by a downslope decrease in slope gradient. In continuous permafrost areas, where climatic inactivation rarely occurs, the inactivation of rock glaciers has been attributed to the dynamic concept (e.g., Calkin et al. 1987, Solid & Sørbel 1992).

Although size relationships between rock glaciers and their debris source (i.e., rock walls) have indicated quantitative rates of debris production and transportation in mountainous periglacial environments (e.g., Barsch 1977, Barsch & Jakob 1998, Humlum 2000), debris supply has been rarely explored to discuss the size and activity of rock glaciers (cf. Frauenfelder et al. 2003). A topographical analysis by Frauenfelder et al. (2003) indicated that the size of rock glaciers appears to reflect the temperature conditions rather than the size of the debris source. In addition, variable ice content in rock glaciers should be tested further to discuss this matter (Humlum 2000).

In this study the distribution and size of rock glaciers near Atigun Pass in the central Brooks Range, Alaska, were re-examined using recent technologies (see also

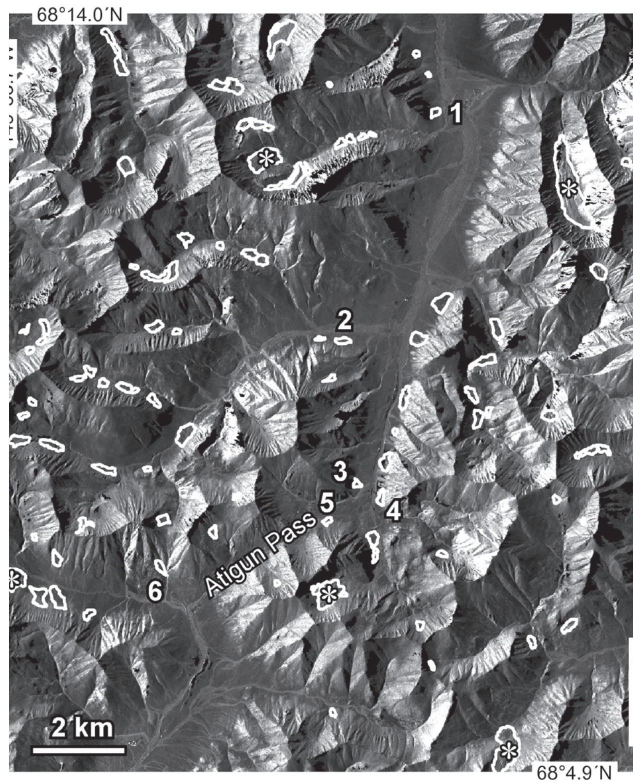

Figure 1. Distribution of rock glaciers (outlined in white) in the Atigun Pass area. An asterisk indicates a rock glacier overflowing from a cirque. The numbered rock glaciers underwent geophysical measurements.

Calkin et al. 1987, for the previous achievement), because the area characterized by simple geology and ubiquitous permafrost appeared suitable for testing 'dynamic' controls from topographical analysis. In addition, temperature conditions and internal structure were studied to assist in the

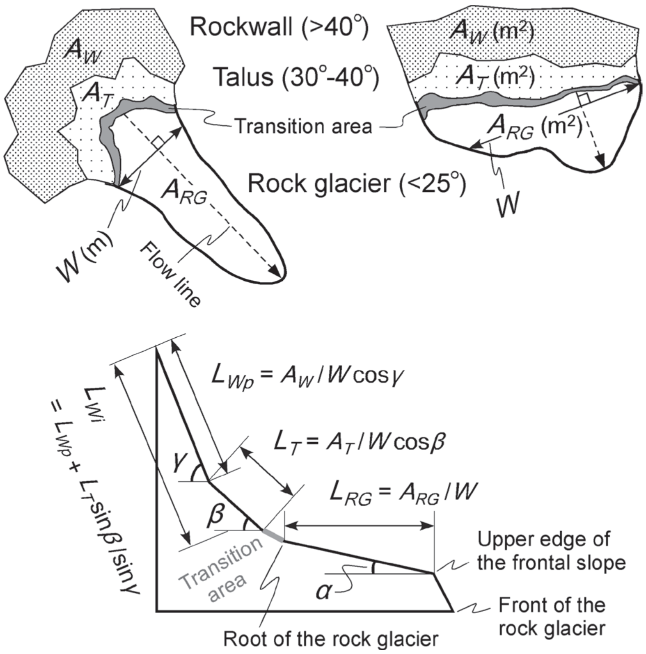

Figure 2. Definition of morphological parameters discussed in the text. Upper figures are plan views and lower figure is a cross section.

interpretation of the topographical analysis.

Atigun Pass lies on the continental divide between the Yukon Basin and Arctic basins (Fig. 1). Permafrost continuously underlies the study area having low mean annual air temperature (MAAT < -7°C) and low precipitation (400–700 mm a^{-1}). Cirque glaciers only remain on the north-facing slopes below the highest peaks ,which reach 2000 m above sea level (a.s.l.), whereas the area was mostly covered with glaciers until the Late Glacial (Hamilton & Porter 1975, Ellis & Calkin 1979). The area consists of sandstone or conglomerate, interbedding shale. The methods of this study are mapping on a digital elevation model (DEM), temperature monitoring on the ground surface and one- and two-dimensional (1D and 2D) geoelectrical resistivity measurements.

Distribution and Morphology

Mapping and measurement of terrain parameters

Using GIS software (ArcGIS ver. 9.2, ESRI Inc., USA), the distribution of rock glaciers was traced on 10 m grid DEM. Topographical parameters assumed to represent climatic and mechanical conditions of rock glaciers (altitude, length, slope angle, area, etc.) were measured for 99 rock glaciers which were clearly identified in 1/63,000 aerial photographs in a selected 13.8 km × 16.5 km area (Fig. 1). The areas of a source rock wall and a talus slope were unambiguously defined by the slope angle: a slope steeper than 40° as a rock wall and a slope between 30° and 40° as a talus slope. A relatively short slope 25°–30° below a talus slope indicated sedimentation by debris flows and avalanches; transportation by permafrost creep can also be responsible for such slope relaxation. Thus, the uppermost point of a slope gentler than 25° was defined as the root of a rock glacier. Besides the 99 rock glaciers, two rock glaciers developed from conspicuous terminal moraines in the selected area. Both of them were excluded from the measurements because they had no direct connection with the cirque walls.

The measured parameters for a rock glacier were: along the central flow line, the altitudes at the upper and lower ends (i.e., root and front), altitude of the upper edge of the frontal slope, horizontal length and aspect of the front (Fig. 2). Horizontal width (W) at the root and horizontal area (A_{RG}) were also measured. The average slope angle of the upper surface (α) was calculated from the horizontal length and the altitudes at the root and edge, and the average length (L_{RG}) from W and A_{RG}. The measured parameters for a source slope were the horizontal areas of the source rock wall (A_W) and the underlying talus slope (A_T), and the average angles of the talus slope (β) and the rock wall (γ). The present size of a source rock wall was represented by the average length of a source rock wall (L_{Wp}), which is A_W normalized by W (see Fig. 2). In addition, the average length of an initial source rock wall after the deglaciation (L_{Wi}) was roughly estimated from the average length of the underlying talus slope (L_T), which probably buried the lower part of the initial rock wall (see Fig. 2 for the calculation of L_{Wi}). Additional data on altitudes and aspect were obtained from 61 rock glaciers around the selected area.

The activity status of rock glaciers (i.e., active or inactive) must be determined by repeated geodetic surveys in the strict sense (Roer & Nyenhuis 2007). In many studies, however, the activity status has been presumed from visual features (e.g., Wahrhaftig & Cox 1959, Calkin et al. 1987, Ikeda & Matsuoka 2002). In this study, rock glaciers having a frontal slope steeper than 35° were classified into the active type and those having a frontal slope gentler than 35° into the inactive type. According to Ikeda & Matsuoka (2002), this classification mostly guarantees the inactive type, although the rock glaciers classified into the active type inevitably include some inactive rock glaciers (see also Roer & Nyenhuis 2007). If a frontal slope mostly steeper than 35° showed partly subsided form (i.e., having a much gentler and thinner part) and a rounded upper edge, the rock glacier was tentatively classified into the active/inactive type. In addition, two rock glaciers were also classified into the active/inactive type, because of the significant disagreement between the steep frontal slopes (c. 10 m high) on the aerial photographs and the gentle angles calculated from the DEM.

Distribution

The rock glaciers in the selected area were classified into 44 active, 40 inactive, and 15 active/inactive rock glaciers. The fronts of the rock glaciers were distributed in all aspects over elevations between 970 m a.s.l. and 1730 m a.s.l. (Fig. 3). The roots of the rock glaciers had a distribution pattern similar to the fronts, ranging between 1015 m a.s.l. and 1835 m a.s.l. The source rock walls mostly faced the same direction as the rock glaciers, whereas the sources of large rock glaciers often faced several directions. The upper limit of the distribution was 100–200 m lower than the major mountain ridges, and on the north-facing slopes it corresponded to

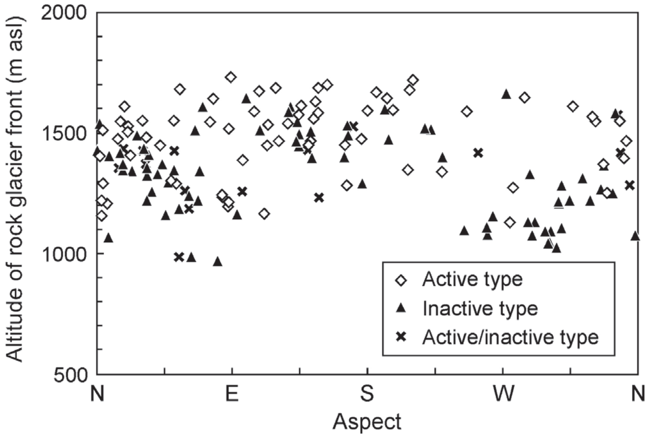

Figure 3. Distribution of the fronts of rock glaciers in the Atigun Pass area.

the present glacial equilibrium line. The lower limit of the distribution corresponded to the piedmont line. The active rock glaciers were distributed at relatively higher altitudes than the inactive rock glaciers, whereas the distributions were largely overlapping except for the west-facing slopes.

Sizes of rock glacier and source rock wall

The topographical parameters were analyzed in terms of the following concepts. The deformation of a rock glacier can be represented by the density, acceleration by gravity, thickness, sine of slope angle, and a creep parameter depending on temperature and structure, using a pseudoplastic flow law for glacier ice (e.g., Wagner 1992). In addition, the long-term (i.e., more than several hundred years) deformation has been assumed to result in a certain length of the rock glacier balancing with debris supply (Olyphant 1983, 1987, Haeberli et al. 1999).

In this study, the L_{RG} values were compared with the L_W (i.e., L_{Wi} or L_{Wp}) values. This was because the size of the rock walls was preliminarily assumed to mainly control the rate of debris supply (determining the thickness of the rock glacier under the balancing condition), although the rate reflected various conditions of the rock wall, such as size, strength, temperature variation, and water content. The assumption was made because parameters other than size were too difficult to evaluate on a large number of rock walls.

The active rock glaciers showed a linear relationship between L_W and L_{RG}, if large rock glaciers overflowing from a cirque were excluded (Fig. 4). In contrast, such a relationship was lacking for inactive rock glaciers. Even larger inactive rock glaciers (L_{RG} > 200 m) had small L_W values. This pattern was more distinct in the L_{Wp}–L_{RG} diagram than that of L_{Wi}–L_{RG}, because the ratios of L_{Wi} to L_{Wp} were, on average, 2:1 for the active type and 3:1 for the inactive type. This indicated the thickening of the talus slopes above the inactive rock glaciers.

The three longest rock glaciers (L_{RG} = 950, 1140 m and 1680 m), all of which overflowed from a cirque, are not within Figure 4a. The longest one was active and had a huge source (L_{Wi} = 2840 m and L_{Wp} = 1940 m); the others were inactive or active/inactive and had relatively small sources (e.g., L_{Wi} = 800 m and 1160 m). Such rock glaciers probably

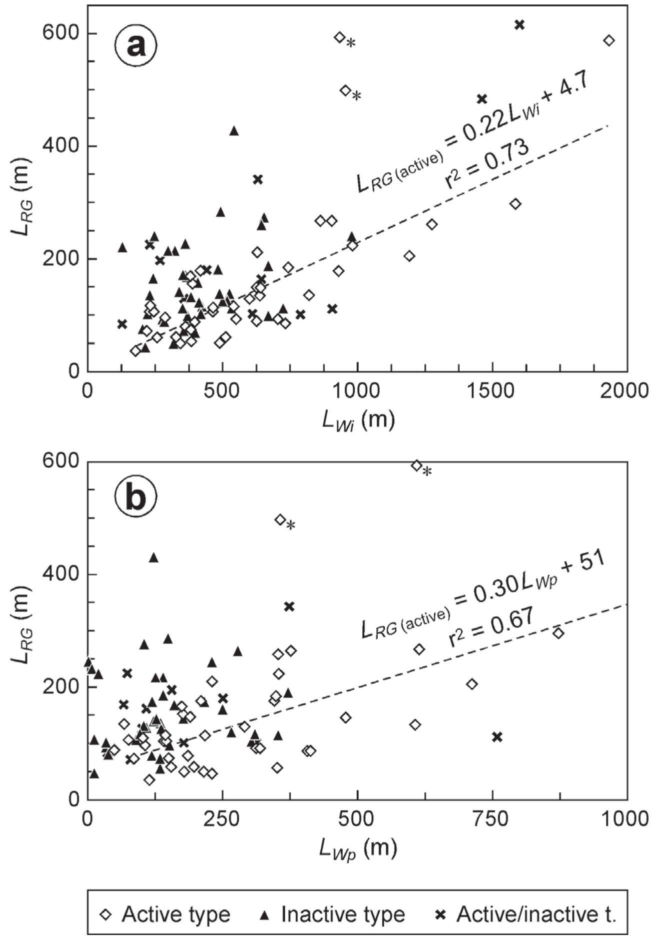

Figure 4. Relationship between average lengths of source rock walls (L_W) and rock glaciers (L_{RG}). Lengths of (a) initial rock walls (L_{Wi}) and (b) present rock walls (L_{Wp}) are examined. See Figure 2 for definition of parameters. *Data of rock glaciers overflowing from a cirque.

included significant amounts of debris that had once deposited as moraines. In addition, glacial ice was often observed at the roots of such large rock glaciers in the active status, which originated from altitudes close to the glacial equilibrium line (Calkin et al. 1987).

The upper surface of the rock glaciers sloped from 2° to 25°. The ranges of α were almost equal between the active type (12° ± 4°) and inactive type (13° ± 4°). The α values of the rock glaciers longer than 400 m also ranged from 8° to 15°. Thus, slope angle appeared to be a minor factor for inactivation and outgrowing.

Temperature and Internal Structure

Ground surface temperature

Ground surface temperatures were monitored on six rock glaciers (A1–6) using miniature data loggers, Thermo Recorder TR-51A (T & D, Japan) (see Fig. 1 for the location). On five rock glaciers (A1–4, A6), a data logger was placed at the surface that was 30–40 m distant from the upper edge of the frontal slope in mid May 2005. A data logger was also placed near the talus foot on A5 rock glacier in late August

Table 1. Mean annual ground surface temperature (MAGST) and DC resistivity stratigraphy of rock glaciers. ρ = calculated resistivity, D = depth of the layer base and AB/2 = half length of the sounding profile (roughly equal to the maximum depth of the sounding). Frontal altitude and aspect for each rock glacier are also displayed.

Site	Altitude	Aspect	MAGST	DC resistivity stratigraphy					
				First layer		Second layer		Third layer	AB/2
	(m a.s.l.)	(degree)	(°C)	ρ (kΩm)	D (m)	ρ (kΩm)	D (m)	ρ (kΩm)	(m)
A1	970	80	−5.1 ± 0.4	8.4–1.6	3.0	25	19	0.22	50
A2	1065	5	−3.3 ± 0.4	0.3	0.7	52	35	20	100
A3	1165	110	−3.6 ± 0.2	1.3	2.7	38			64
A4	1155	265	−6.6 ± 0.3	0.8	1.6	19			80
A5	1345	15	−4.8 ± 0.3	1.1	2.8	41			50
A6	1230	145	−3.9 ± 0.3	0.8	2.2	24	16	13	64

2005. These loggers recorded surface temperatures under a 2–4 cm thick clast at one-hour intervals with a resolution of 0.1°C until the beginning of July 2007. Then, the mean annual ground surface temperature (MAGST) values were determined.

The lack of daily variations in the ground surface temperatures indicated that snow covered the lower part of the rock glaciers from late September to mid May, whereas snow remained near the north-facing talus foot at 1350 m a.s.l. until mid June. The variations in the observed winter temperatures were largely different between the sites. The difference in the temperatures, however, hardly correlated with the elevation of the sites (see Table 1 for the altitudes), which implied irregular distribution of snow cover. As a result, MAGST on the rock glaciers ranged from −3°C to −7°C without correlation with the elevation (Table 1).

DC resistivity

On the six rock glaciers (A1–6), 1D DC resistivity measurements were performed in late July 2005 with the SYSCAL R1 resistivity meter (Iris Instruments, France). All of the rock glaciers were talus-derived and had no contact with glaciers during the Holocene (Ellis & Calkin 1979). The setting of the electrodes followed the Schlumberger array. Modeled resistivity curves fitting with measured values were calculated with WinSev6 software (W_GeoSoft, Switzerland). To compare resistivity stratigraphies, the settings of the inversion analysis were fixed as described in Ikeda (2006). In addition, 2D DC resistivity distributions at a shallow depth (<10 m deep) were estimated by a tomographical method for three rock glaciers (A3–5). The electrode configuration followed the Wenner array. The measurements were carried out with a lightweight resistivity meter, Handy-ARM (OYO, Japan), in early July 2007. Then, we computed the 2D distributions of modeled DC resistivities with RES2DINV software (Geotomo Software, Malaysia), employing the same settings of the inversion analysis as those in Ikeda & Matsuoka (2006).

The 2D resistivity distributions showed low resistivities (1–16 kΩm) within the uppermost layer (<2 m deep), probably corresponding to the active layer. The resistivities near the surface in the 1D profiles, which largely depend on the surface material at the center of the survey profiles, were close to 0.3 kΩm on A2, 1 kΩm on A3–6 and 8 kΩm on A1 (Table 1). Vegetated thin soil on the surface resulted in such low surface resistivities for rock glaciers, because the shale part of the source rock walls produced relatively fine and weathering-susceptible clasts on the rock glaciers. The main components of the debris, however, appeared to be boulders. In fact, the average intermediate-axis diameter of 25 clasts that were measured at intervals of 0.5 or 1 m along a line on a less vegetated part ranged from 25–45 cm for A3–5 rock glaciers (cf. pebbly rock glaciers composed of much smaller debris in Ikeda & Matsuoka 2006).

The resistivities of the layers below 2–3 m deep (i.e., permafrost) were 20–50 kΩm in the 1D profiles (Table 1), whereas those in the 2D distributions increased from 4–16 kΩm at 3 m depth to 30–250 kΩm at 10 m depth. In the case of A4, the exponentially increasing resistivities toward the bottom of the tomogram indicated resistivities higher than 250 kΩm for the permafrost below the measurement limit. The 1D sounding profiles of A3–5 were too short to detect the third layer.

Discussion and Perspectives

Topographical controls through debris supply

Topography of the mountain range roughly restricts the distribution of the rock glaciers. Besides the main divide and piedmont line of the mountain range (i.e., the uppermost and lowermost limits of the distribution), for example, the straight mountain slopes that lack enough concavity to lay rock glaciers strongly restricted the number of westbound rock glaciers above 1300 m a.s.l. (see Fig. 3). In the selected area, the area of the rock walls decreased from 8.8 km^2 on the north-facing slope (0°–45°, 315°–360°) to 3.7 km^2 on the south-facing slope (135°–225°), which may result in fewer rock glaciers on the south-facing slopes through less debris production from the rock walls (see Fig. 3).

The positive correlation between L_{RG} and L_W for the (talus-derived) active rock glaciers (Fig. 4) implies that the amounts of debris supply from the source rock walls control the size of these rock glaciers. This result is contrasted with that of a similar study in the Alps where such a relationship is unclear (cf. Frauenfelder et al. 2003). The correlation in this study partly accounts for the bedrock geology that is much more uniform than the case in the Alps. In fact, such a correlation was found in the Alps for a small number of rock glaciers under a limited geological condition (Ikeda & Matsuoka 2006).

In Figure 4, the L_{RG} values of the extremely long rock glaciers (overflowing from a cirque) are out of the linear trends for the active talus-derived rock glaciers. The lengths that appear not to balance with the relatively small rock walls are primarily attributed to former glacial deposits, which were probably incorporated into these rock glaciers. In addition, if these rock glaciers include glacial ice, the resulting high ice content also contributes to the large size in spite of low debris content. According to the field observation by Calkin et al. (1987), such interaction with glaciers probably occurred on large tongue-shaped rock glaciers in this area.

About two thirds of the data on the inactive rock glaciers (mostly shorter than 200 m) is plotted within the band of the talus-derived active type in the LW–LRG diagrams (Fig. 4). Thus, the difference in the classified activity is difficult to interpret from the size of the source rock walls alone. The LW values of the inactive rock glaciers, however, concentrate in relatively smaller values, which indicates the low potential of the debris supply. The talus thickening above the inactive rock glaciers, which was presumed from the difference in Figures 4a and 4b, is partly because the debris down-transportation by permafrost creep was terminated at the talus foots. This burial of the rock walls with the talus materials decreases the potential of the debris supply from the rock walls. The resulting small input of debris probably prevents the underlying rock glaciers from advancing further, although the initial cause of the inactivation remains unsolved.

As well as the data on the largest rock glaciers that were probably affected by glacial processes, the data on the large inactive and active/inactive rock glaciers (> 150 to 200 m in L_{RG}) in Figure 4 appear not to balance with the size of the source rock walls. This may indicate that the former rate of rock wall erosion per area was higher, or the present source slopes became smaller than the former slopes. Both processes can be responsible for the inactivation of the rock glaciers through decrease in debris supply, although we should exhibit additional data to discuss this matter, avoiding a vicious circle.

Significance of topographical controls in the Brooks Range

The inactivation and restriction of the lower distribution boundary found in Figure 3 cannot reasonably be attributed to the degradation and absence of permafrost in a study area that is classified continuous permafrost, although such phenomena mainly depend on the permafrost distribution and its temporal change in mid-latitude high mountains such as the Alps (e.g., Frauenfelder et al. 2001, Ikeda & Matsuoka 2002).

Additionally, Frauenfelder et al. (2003) found correlation between the length and velocity of active rock glaciers. The latter depended on the MAAT, which was estimated from the locality and altitude for each site, rather than the source area and slope angle. This is mainly because frozen ground softens significantly as the permafrost temperature increases in warm permafrost environments (MAAT > -4°C). In contrast, the dependence of velocity on temperature was insignificant in cold environments (MAAT < -7°C) such as the Brooks Range (Kääb et al. 2007). The MAGST, much lower in the Brooks Range than in the Alps (Fig. 5), also indicates that the creeping depth (mostly within a few tenth meters in depth) of the studied rock glaciers is much lower than the melting point in contrast to the case in the Alps (cf. Arenson et al. 2002). Thus, the difference in a creep parameter between the rock glaciers in the study area is assumed to be much smaller than that in the Alps. This means that in the Brooks Range the effect of debris supply on the size of rock glaciers can be tested using the L_W–L_{RG} diagrams without one major source of noise.

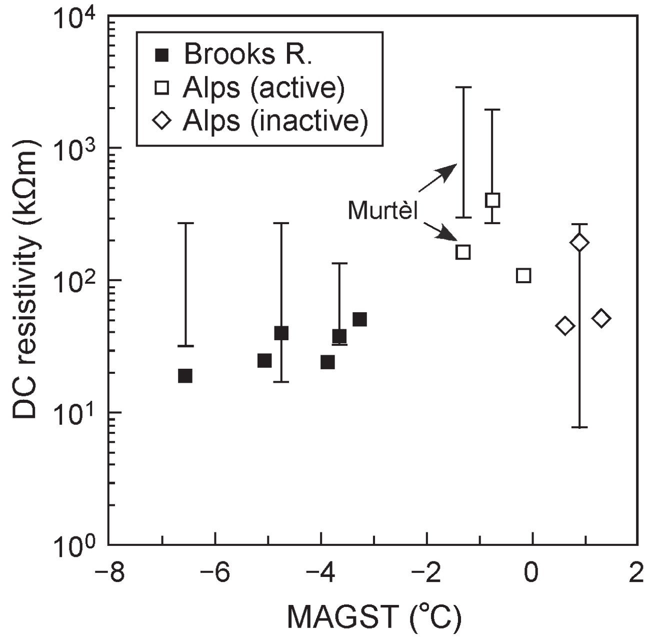

Figure 5. Relationship between MAGST and DC resistivity at 5–9 m depth in the Brooks Range and Swiss Alps. Resistivities from a one-dimensional method are indicated by symbols and ranges of resistivities from a two-dimensional (2D) method by bars. The data in the Alps are from Ikeda (2006) and Ikeda & Matsuoka (2006), except for the 2D data of the Murtèl site from Hauck (2001).

To examine the ice content of the studied talus-derived rock glaciers, the relationship between MAGST and DC resistivity of permafrost (5–9 m deep) of the rock glaciers is displayed with the data of typical talus-derived rock glaciers in the Alps in Figure 5. The DC resistivities from the 1D measurement in the Brooks Range (10–50 kΩm) are lower and less scattered than those in the Alps (50–400 kΩm). The absolute values of the resistivities derived from the 2D measurements are also within the smaller ranges in the study area than in the Alps. These results imply that the ice content in the studied rock glaciers is relatively small for rock glaciers, and the variation in ice content between different rock glaciers is also smaller than that in the Alps (see Haeberli & Vonder Mühll 1996, Hauck & Vonder Mühll 2003, Ikeda 2006, for the interpretation of DC resistivity). Thus, we can interpret the L_W–L_{RG} diagrams assuming that the size of the talus-derived rock glaciers in the study area is roughly proportional to the debris volume in the rock glaciers.

This study shows that the central Brooks Range is a suitable area to investigate topographical controls on rock glaciers. More detailed study will address the long-term rates of rock wall erosion and the advance of talus-derived rock glaciers, and will possibly evaluate the dynamic inactivation and interaction with glacial processes of the rock glaciers quantitatively.

Abstract

The technical properties and general state of permafrost in Greenland is not well documented. A new coordinated investigation has been initiated for ground temperature measurements and permafrost mapping in Greenlandic towns in sporadic, discontinuous, and continuous permafrost zones. We present investigation results from one of the sites, located at Ilulissat in an area of discontinuous saline permafrost. We have established ground temperature measurement stations and conducted a shallow geoelectrical study. Our results show that the sediments in the study area mainly consist of frost susceptible silty clays. The area has permafrost with a maximum active layer thickness between 0.9 m and 1 m. In spite of low permafrost temperatures, a considerable part of the pore water is unfrozen due to high residual salt concentrations. Consequently, the unfrozen water content dominates the geotechnical properties, and the sediments have a limited heat capacity available should the temperature conditions change.

Keywords: ice content; resistivity survey; saline permafrost; temperature measurements.

Introduction

The variability in the thermal state of permafrost in Greenland is presently not very well mapped. A series of well-organized ground temperature stations were operated in a number of West Greenlandic towns from the late 1960s to the early 1980s; however only part of these datasets have ever been published, and no large coordinated investigations have been conducted since. With the NSF ARC-0612533 project, "Recent and future permafrost variability, retreat and degradation in Greenland and Alaska: An integrated approach," a new coordinated investigation has been initiated for ground temperature measurements in Greenlandic towns in sporadic, discontinuous, and continuous permafrost zones. The project conducted in cooperation between Asiaq Greenland Survey, the Danish Meteorological Institute (DMI), University of Alaska Fairbanks (UAF), and Technical University of Denmark (DTU).

Figure 1. Map of Greenland with the location of the field site (Ilulissat) indicated.

This paper concerns one of the locations studied in this project, a field site located close to the airport in the town of Ilulissat, West Greenland (Fig. 1). Here we present the first results from fieldwork conducted in the summer 2007, which included shallow drilling, installation of ground temperature sensors (thermistors), and a shallow geoelectrical survey. Furthermore, we compare these results with investigations conducted from 1978 to 1980 in connection with the construction of the airport.

Site Description

Ilulissat is situated in the inner part of the Disko Bay at approximately 69.2°N and 51.1°W. The climate is arctic with a Mean Annual Air Temperature (MAAT) around -3.3°C (average from 1997 to 2006) with an increasing trend. The long-term variation in MAAT is shown in Figure 2. In the most recent classification by Christiansen & Humlum (2000), Ilulissat is located in the discontinuous permafrost zone.

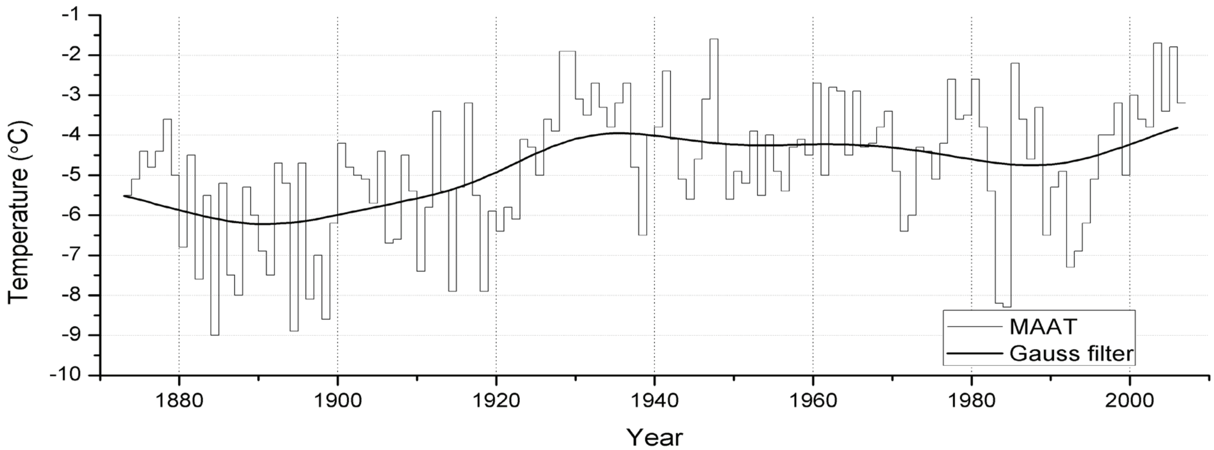

Figure 2. Mean Annual Air Temperature (MAAT) at Ilulissat from 1873 to 2006, as well as a Gauss filter with a filter width of 9 years (Cappelen 2007). These temperatures are measured at a DMI climate station (04216+04221) located in town, not at the airport field site.

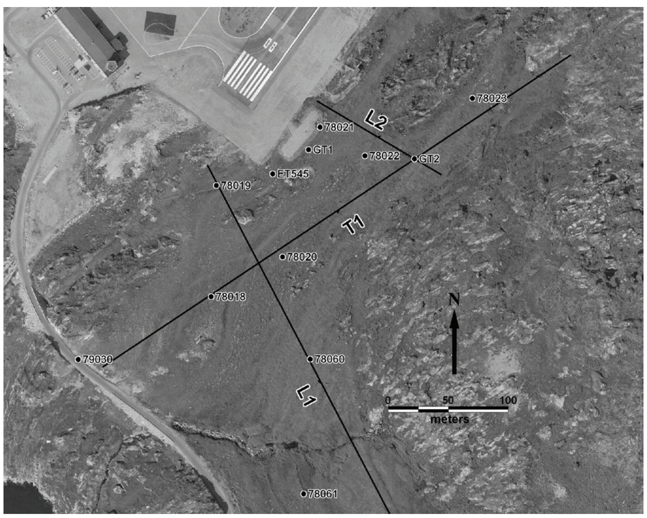

Figure 3. Aerial photo of field site with selected boreholes and survey lines included.

The bedrock in the area consists of Nagsugtoquidian gneisses with amphibolitic bands. It is affected by a series of fault and fracture systems, most importantly a northwest-southeast situated system. The entire area was ice covered during the last glaciation (Weichsel-Wisconsin), and the area was not deglaciated until approximately 9600 years BP (Bennicke & Björck 2002). A series of marine silt and clay rich sediments were later deposited at relatively high sea levels of <50 m. Interaction between eustatic changes and isostatic uplift raised the area above sea level about 5000 years ago (Rasch 2000), exposing the sediments to percolation of precipitation and possibly groundwater flow. This has resulted in depletion of salts in the upper part of the soil profile.

Permafrost was formed relatively early and the sediments have thereby been exposed to the consolidation and fracturing phenomena caused by ice lens formation in fine-grained sediments (Foged 1979).

Previous Investigations

In the period from 1978 to 1980, a series of investigations were undertaken in relation to the construction of the present airport facility. These investigations included drilling of a number of boreholes. Some of these boreholes were equipped with PT100 temperature sensors, which were manually logged at irregular intervals during the survey period. Furthermore samples from the boreholes were analyzed with respect to water content, pore water chemistry, freezing point depression, and consolidation parameters. A geoelectrical study was also conducted, including a number of electrical soundings at the borehole locations. Some of these results were previously published in Foged & Bæk-Madsen (1980), but many have never been published except in internal reports. In this paper, we present data from borehole 78020 as reference data for the new study.

Methodology and Instrumentation

In 2005, ASIAQ installed a ground temperature station (ET545, Fig. 3) next to their climate station at the airport site (climate station operational since 1993 and measures air temperature, humidity, and precipitation). This ground temperature station has PT100 temperature probes at the ground surface as well as depths of 0.25 m, 0.5 m, 1 m, 2 m, 3 m, and 4 m.

In 2007 we installed ground temperature sensors at locations GT1 and GT2 as well as at borehole locations 78020 and 78060 in order to establish information on the spatial variability in the area. All locations are equipped with Tinytag dataloggers with thermistors at 25 cm and 1.6 m depth. The new borehole at 78020, which is 4 m deep, is also equipped with Hobo U12 loggers with thermistors at the surface, 0.25 m, 0.5 m, 0.75 m, 1 m, 2 m, 3 m, and 4 m depths.

Our geophysical survey consisted of three Continuous Vertical Electrical Sounding (CVES) profiles conducted with Wenner and Wenner-Schlumberger configurations using an ABEM SAS4000 terrameter with the Lund Imaging system. This system consists of 61 electrodes on four cables with unit spacing on the two central cables and double spacing on the two outer cables. We used a unit electrode spacing of 5 m on profiles L1 and T1, and 1.5 m spacing on L2. We

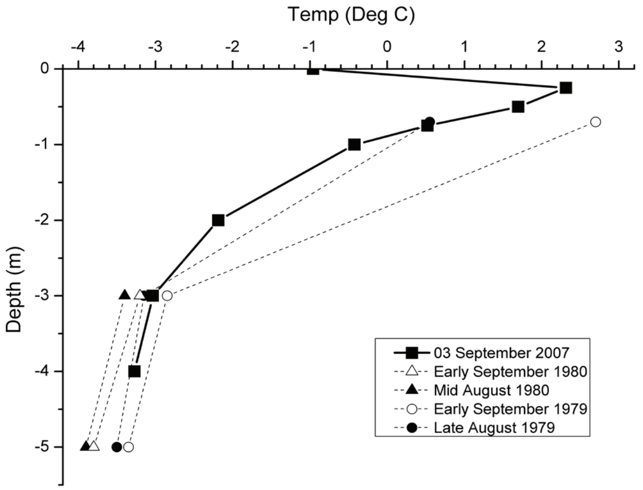

Figure 4. Ground temperature measurements from 1979–1980 (dashed lines) and 2007 (solid line).

have also made Vertical Electrical Soundings (VES) of the Schlumberger type at borehole locations 78018, 78020, and 78060, as well as at the intersection of L2 and T1, using the ABEM SAS4000 terrameter in standard setup. The CVES profiles have been inverted using Res2Dinv from Geotomo Software, and VES soundings using SELMA (Christensen & Auken 1992).

Results

Our continuous measurements of ground temperatures show that the present day maximum Active Layer Thickness (ALT) at the airport field site occurs in the beginning of September. At station ET545 the ALT was 1.0 m in 2006 and estimated to be 0.9 m in 2005 (the estimate is based on late August temperatures at surface and 1 m depth, as the sensors at 25 cm and 50 cm were not yet installed). Figure 4 shows a plot of the temperature measurements from the new installation at the old borehole 78020 location from September 3, 2007. This dataset indicates an ALT of 0.9 m in 2007. The same figure shows a plot of the temperature measurements from late August and early September of 1979 and 1980. In 1979 the ALT is estimated to have been between 1.0 m and 1.2 m. The estimate is based on temperatures at 0.7 m, 3 m, and 5 m depth. In 1980, the upper temperature probe had ceased functioning. The temperatures from the deeper probes were slightly lower than those observed in 2007, indicating a smaller ALT. We conclude that the ALT today is the same or slightly shallower than that observed in 1979 and 1980.

Olesen (2003) established and operated a ground temperature station (OBO) in Ilulissat from 1968 to 1982. It was equipped with 21 PT100 sensors at depths down to 15 m. In the upper 2 m, sensors were spaced at 0.25 m intervals. The sensors in the upper 1 m were only operational from 1969 to 1972. During this period, the average ALT was 1.1 m. This OBO site is located in town, some 3 km from the airport site. The airport site is slightly warmer than the DMI town station (0.4°C average 1997–2006). This shows that there may be significant local variations in air temperature.

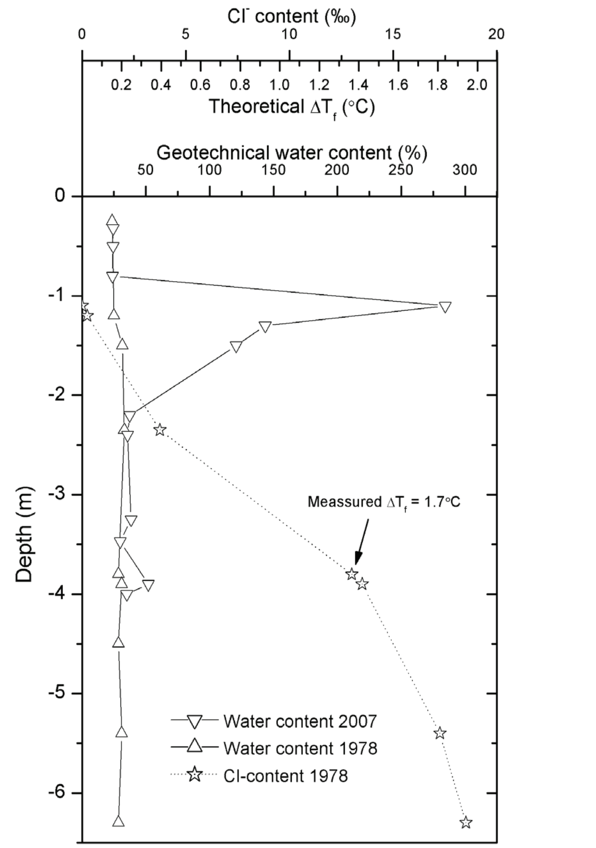

Figure 5. Water contents and Chloride (Cl^-) concentration from borehole location 78020, based on analysis from 1978 and 2007. The figure also shows the theoretical freezing point depression (ΔT_f) based on a pure NaCl solution of the same chloride concentration. Actual measured values of ΔTf are somewhat larger than the theoretical value.

The present ALT is apparently smaller than that observed in early 1970s at the OBO site. However, the difference may be related to a difference in air temperature . The old OBO station no longer exists, and the original location is crossed by a paved road. However, in order to obtain comparative measurements we have installed a new station as close as possible to the old OBO station.

Borehole 78020 was drilled July 26 1978, and is typical for the area. It showed a 6.9 m thick sequence of marine silty to very silty clay deposits, over gneiss bedrock. At the time of drilling, the active layer was 0.4 m thick, and the permafrost was very ice rich down to a dept of 4 m. Figure 5 shows the original water contents measured on samples collected from the borehole, as well as water contents from samples collected at the new drilling in 2007. Typical water contents lie between 23% and 35% and correlates well between the two datasets. However, from 1 m to 2 m depth, the new measurements show much larger water content when compared to the original measurements made in 1978. This is not necessarily due to temporal changes, but more to the fact that during the drilling in 1978, there was no focus on the importance of establishing the actual ice content. The collection of samples was organized to minimize the volume

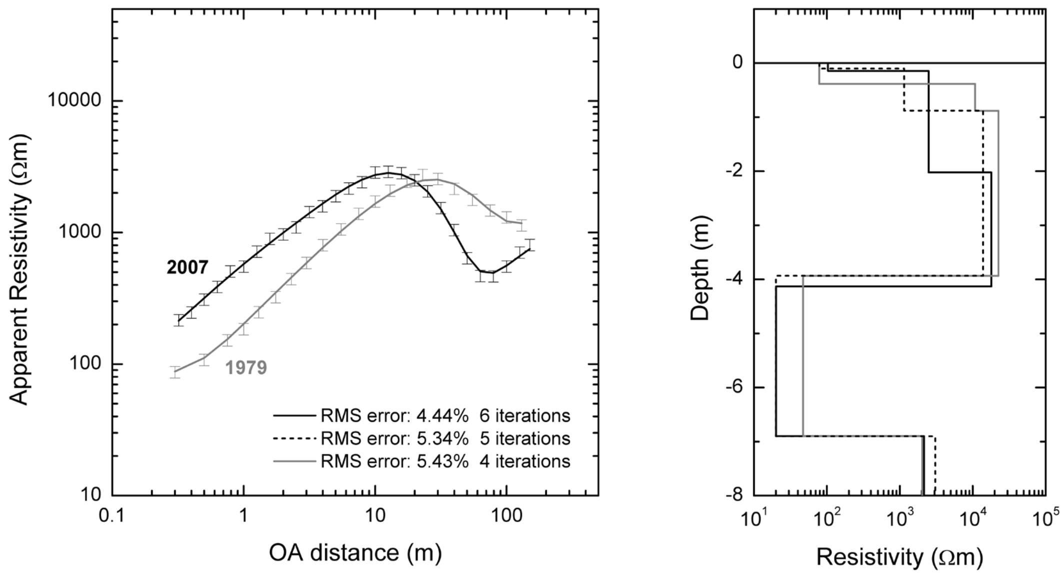

Figure 6. Inversion results from vertical electrical soundings at borehole location 78020, measurements from 1979 (grey lines) and 2007 (black lines). Five layer resistivity models are necessary in order to fit the datasets properly. However, the models are very poorly defined, and for the 2007 dataset two different models fitting the data equally well are indicated (black solid and dashed lines).

of ice lenses in the samples; however, the notes did record the occurrence of an ice rich zone.

Below the 4 m depth, ice was no longer observed in the samples, although temperatures are known to be subzero. The cause is the residual salt content in the marine clay deposits. Figure 5 also shows the variation of the pore water chloride content with depth in the borehole. It is seen to increase drastically from 3.75‰ at a depth of 2.35 m to 18.5‰, almost seawater concentration, at a depth of 6.3 m. These chloride concentrations have been used to calculate the theoretical freezing point depressions (ΔT_f) based on a pure NaCl solution of the same chloride concentration (see separate scale in Fig. 5), using the formula (adapted from Atkins 1994):

$$\Delta T_f = K \cdot c \cdot (1+\alpha) \quad ,$$

where K is the cryoscopic factor (1.86 $K \cdot kg \cdot mol^{-1}$ for water), c is the chloride concentration in mol/L, and α is the dissociation factor (assumed unity). The observed maximum concentration corresponds to a theoretical freezing point depression of 1.94°C. The actual measured values are somewhat lower however, due to a combination of other salts in the pore water solution, the electrochemical properties of the clay particles, and capillary tension in the pores.

The result of the freezing point depression below approximately 4 m depth is that the sediments are unfrozen as observed during drilling in 1978 and that unfrozen water content dominates the technical properties.

One of the effects of the unfrozen state is that the resistivity of the clay deposits is very low. This is observable on the Vertical Electrical Soundings (VES) collected at borehole 78020 location in 2007 and 1979 (Fig. 6). The two VES were collected June 6, 2007 and August 3, 1979. The different active layer thicknesses account for most of the difference observed in the apparent resistivity curves. The inverted resistivity models are also shown in Figure 6, and consist of five layers. Layer 1 is the unfrozen active layer, layers 2 and 3 are frozen sediments of varying but high resistivity, layer 4 is the technically unfrozen layer with low resistivity, and layer 5 is the bedrock. The models are highly undetermined when inverted with no constraints. The inversion of the 1979 data (solid grey line in Fig. 6) was strongly constrained at the depth of the bedrock interface, and loosely constrained within the depth of the active layer and the zone of frozen sediment. The 2007 dataset (solid black line) was first inverted with constraints on the depth to bedrock as well as the bedrock resistivity. In both datasets the apparent resistivity data could only be properly fitted, when the frozen zone was split into a shallow part with lower resistivity (layer 2), and a deeper part with higher resistivity (layer 3). Although poorly determined the depth to layer 3 corresponds well with the ALT in the 1979 data inversion, approximately 0.9 m, so that layer 2 corresponds to the frozen part of the active layer. For the 2007 data, the depth to layer 3 is much greater, and thus a similar interpretation is not possible. However, by constraining thicknesses of the layers, as well as the unfrozen active layer and bedrock resistivities, to fit the values obtained in the inversion of the 1979 data, it was possible to fit the 2007 dataset equally well (black dashed line, indistinguishable in apparent resistivity plot, see Fig. 6). Therefore, the VES results support the hypothesis that no significant changes have occurred in the permafrost conditions of the area over the period of study.

The inverted T1 CVES profile shown in Figure 7 (Fig. 3 shows the location of profile T1) shows the resistivity structure of the area. The upper part of the profile is highly resistive, with resistivities of more than 20 kΩm. Below is a conductive layer with resistivities between 50 Ωm and 600 Ωm. The lower part of the profile corresponds to bedrock at medium to high resistivity. Bedrock is outcropping immediately to the

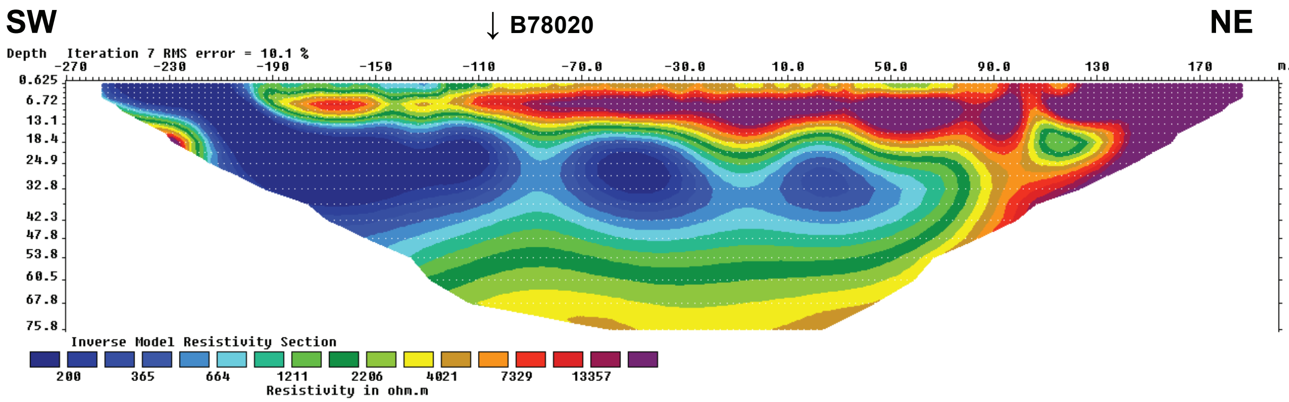

Figure 7. CVES profile (profile T1 in Fig. 3) with an electrode spacing of 5m using ABEM SAS4000 and LUND Imaging System. The profile clearly shows a low resistive layer corresponding to the technically unfrozen layer observed in soundings and boreholes. However the interpreted depths are invalid, due to macro anisotropy caused by ice lenses, and related equivalency problems.

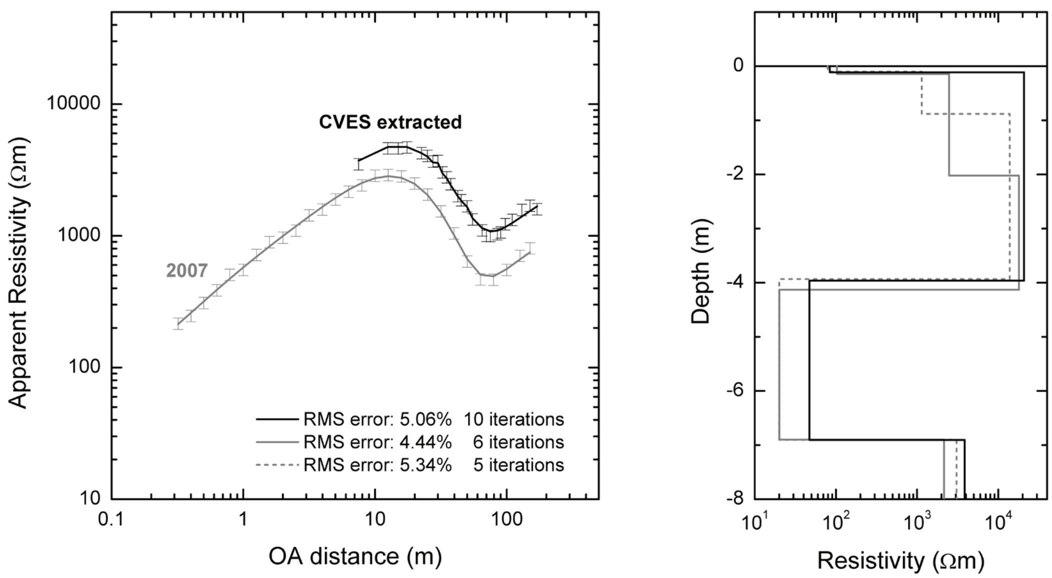

Figure 8. A dataset has been extracted from the CVES profile and inverted as a 1D sounding using a general array inversion scheme. The data could be fitted with essentially the same model as the normal Schlumberger sounding. Only a four layer model was used in this case, as the data density in the top of the profile is not large enough to support an extra layer. The reason for the offset between the Schlumberger sounding curve and the extracted data is the larger potential electrode distance used in the Wenner-Schlumberger configuration in the CVES profile.

southwest and northeast of the profile.

The general resistivity structure of the profile corresponds well with the collected VES. Nevertheless, the depths observed in the inverted resistivity model are much larger than the actual values. The bedrock interface for example is located at a depth of more than 35 m. No efforts to constrain the model resulted in a reasonable fit to the dataset. Similar problems have been observed previously in ice-rich permafrost areas in Greenland (Ingeman-Nielsen 2005, 2006), and are probably caused by pseudo anisotropy due to the presence of massive ice lenses. High ice content in the form of near horizontal ice lenses in the upper 2 meters of the permafrost gives rise to equivalency problems when the measurement system is geometrically large compared to the individual layers. In fact, a thin layered sequence with large resistivity contrasts is electrically equivalent to and indistinguishable from a thicker and isotropic sequence.

Combined with the normal equivalency problem of sandwiching a thin conductive layer between two thicker and resistive layers, this geoelectrical setting proves very difficult to resolve, as indicated by the wrong depths in the CVES inversion and the highly undetermined parameters in the VES inversions.

In order to substantiate this interpretation, we have extracted a subset from the CVES dataset, consisting of all measurements with a center point at the B78020 location plus or minus 10 m, and inverted this dataset using a 1D general array inversion scheme. As presented in Figure 8, it was possible to fit this dataset using essentially the same model as for the 2007 VES. In this case we used a four layer model, as the data density in the upper part of the profile is not large enough to support the extra layer. The only constraints on the inversion were a strong fix on the depth to the bedrock and very loose constraints on the resistivities of the conductive layer and the bedrock. All other parameters we left unconstrained.

This shows that it is indeed possible to construct a geoelectrical model that fits all the collected datasets. Furthermore it indicates that in this type of setting, a 1D laterally constrained inversion scheme could be superior to the more generally applied 2D blocky inversion scheme.

Conclusions

In order to determine permafrost properties in Ilulissat, we have established a number of ground temperature measurement stations and conducted a shallow geoelectrical study. Our results show that the sediments in the study area mainly consist of very frost susceptible, silty clays of marine origin. The area has permafrost with a maximum active layer thickness (ALT) between 0.9 m and 1 m. The ALT today is similar to that observed in 1979 and 1980, although ALT may have been smaller in the cold period during the early 1990s. Permafrost temperatures as low as -3°C to -4°C have been registered, but still a considerable part of the pore water is unfrozen at depths below 4 m, due to high residual salt concentrations and clay surface electrochemical properties. As a result, the unfrozen water content dominates the geotechnical properties. The unfrozen layer was observed directly while drilling in 1978 and in 2007 with vertical electrical soundings and CVES profiles as a low resistive layer. Consequently, these sediments have only a limited heat capacity available should the temperature conditions change.

Climate Change and Arctic Infrastructure

Arne Instanes

Oleg Anisimov
State Hydrological Institute, St. Petersburg, Russia

Abstract

Several authors report that impacts of climate change on infrastructure in the Arctic are already evident. Damage to infrastructure and engineering structures in permafrost regions are often linked to observed increase in air temperature over the last 10 to 20 years. However, these reports do not show in detail how the change in air temperature may affect the active layer thickness and permafrost temperature at specific sites and for specific structures in the Arctic. This paper presents the results of a study of the impact of climate change on Arctic infrastructure based on historical meteorological records. The temperature data are used together with a numerical model to evaluate the possible warming of permafrost at depth, and theoretical impacts on pile foundation capacity at specific sites in the Arctic. Results from permafrost model forced by several GCM-based climatic projections are used to construct the predictive map indicating threats to infrastructure due to potential weakening of the frozen ground.

Keywords: climate change; engineering; foundations; geotechnical; permafrost; warming.

Introduction

For several decades, air temperatures in the Arctic have warmed at approximately twice the global rate (McBean et al. 2005). Zonal-mean temperature north of 60°N has increased up to 2°C since the late 1960s. Contemporary warming in the Arctic is strongest (~ 1°C/decade) in winter and spring, and smallest in autumn. Such changes lead to warming, thawing, and degradation of permafrost. Observational data are limited, and are not available throughout the entire Arctic. Borehole measurements indicate that permafrost temperatures have increased markedly during the last 50 years, (Romanovsky et al. 2002), with rapid warming in Alaska (Hinzman et al. 2005), Canada (Beilman et al. 2001), Europe (Harris et al. 2003), and Siberia (Pavlov & Moskalenko 2002).

In the context of the future climate change one of the key concerns associated with the thawing of permafrost is the detrimental impact on the infrastructure built upon it. Several authors report that such impacts are already evident (Khrustalev 2001, Romanovsky & Osterkamp 2001, Zernova 2003, Gribchatov 2004, Vasilieva 2004). Instanes et al. (2005) and Instanes (2003) conclude that human interaction and engineering construction very often lead to extensive thawing of both continuous and discontinuous permafrost even if climatic conditions remain unchanged. The intergovernmental panel on climate change (Anisimov & Vaughan 2007) also points out that the effect of heated buildings on underlying ice-rich permafrost has been known for a very long time, and may be mistaken for an impact of climate change.

In this paper we used historical air temperature records from three different cities to investigate the change in pile foundation bearing capacity during the last 100 years. We upscaled the results of this historical analysis and constructed the map of potential threats to infrastructure using the hazard index that takes into account regionality of projected climatic and permafrost changes.

Pile Design

Design ground temperature

The strength and deformation characteristics of frozen soils are temperature dependent. It is, therefore, necessary to determine the thickness of the active layer (maximum thaw depth) and the maximum ground temperature along the embedded pile length (Andersland & Ladanyi 2004). These two parameters are incorporated into the site-specific design of foundations in permafrost regions. Conventional engineering design is based on the analysis of historical variations of climatic and permafrost data and accounts for the frequency of extreme events, such as abnormally high temperatures resulting in deeper seasonal thawing of permafrost. Each foundation is designed with construction-specific safety factors that depend on the probability of such extremes.

Adfreeze bonds

The adfreeze bond strength between the pile surface and surrounding frozen permafrost soil is temperature and time dependent. For a specific pile foundation design, this parameter should be determined from geotechnical field and laboratory investigations. For the purpose of this study, a simplified relationship is used, as shown in Figure 1.

Data in Figure 1 may be used to evaluate the effect of changing climatic conditions on the bearing capacity of piles and thus to predict the potentially detrimental impacts of warming and thawing permafrost on the structures built upon it.

Air Temperature Records

The climatic data used in the present analysis were mean monthly air temperatures from three different locations in the Arctic: (1) Fairbanks, Alaska (N64°15′, W147°37′);

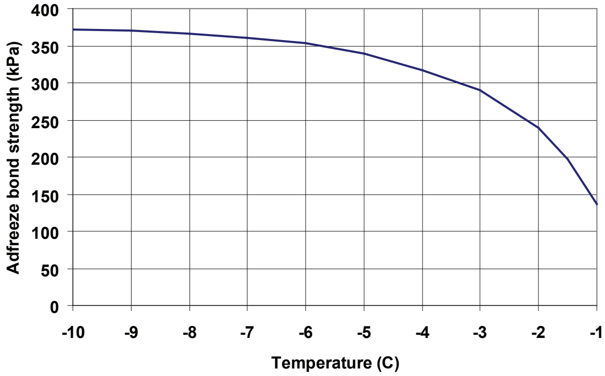

Figure 1. Adfreeze bond strength used in the analysis.

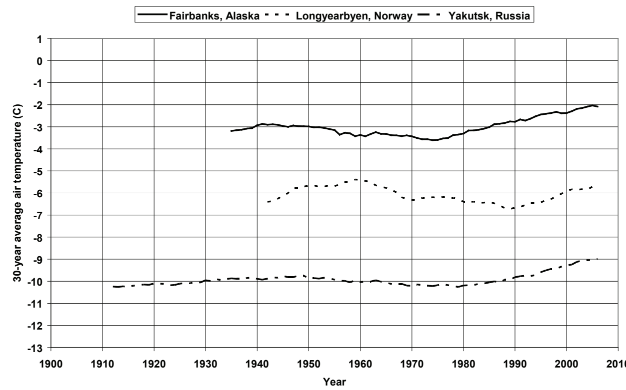

Figure 2. Mean annual air temperatures for Fairbanks, Alaska; Longyearbyen, Norway; and Yakutsk, Russia, smoothed with 30-years running filter.

(2) Longyearbyen, Norway (N78°25′, E15°47′); and (3) Yakutsk, Russia (N62°02′, E129°45′). The sites were chosen based on:

- station time series approximately 100 years or more,
- location near population concentrations and major infrastructure,
- locations representing different climatic and environmental conditions in the Arctic.

All three stations show some indication of increased air temperatures during the last 20 to 30 years. Yakutsk has the longest time series starting in 1829, while the time series for Fairbanks and Longyearbyen start in 1904 and 1912, respectively.

Figure 2 shows mean annual air temperatures for Yakutsk, Longyearbyen, and Fairbanks, smoothed with 30-years running filter. In the last three to four decades temperatures increased by almost 2ºC in Yakutsk, and by 1ºC in Fairbanks (see Fig. 2).

In Longyearbyen there was the decrease of the annual mean air temperature from the maximum of –5.2ºC in 1960 to the minimum of –6.8ºC in 1990 followed by rapid increase by ca. 1ºC since then. Based on Figure 2, the temperatures in the 1960s were still higher than now. However, Longyearbyen had a mean annual air temperature in 2006 that was the warmest on record (-1.6ºC).

Mean monthly air temperatures were used in the thermal model to calculate the changes in the ground temperature at different depth and to evaluate the effect on the bearing capacity of piles.

Permafrost Models and Results

Two permafrost models of different complexity were used in this study. The first is the TEMP/W, version 7.03 (Geo-Slope 2007) software that can model the thermal changes in the ground due to changing temperature or heat flux boundary conditions. This simple model is often used in practical engineering applications and gives good results at point locations given that the model is validated by observational data. More sophisticated model that was used for constructing predictive hazard map for Russian permafrost region is detailed in the next section. The TEMP/W model accounts for the effects of the temperature dependent thermal conductivity, volumetric latent heat of fusion, and soil unfrozen water content. In this study we used a simplified homogenous soil profile consisting of silty sand with the following parameters:

- dry density (γ_d): 16.7 kN/m^3 (ρ_d=1700 kg/m^3),
- water content (w): 20%,
- degree of saturation (S_r): 100%
- porosity (n): 37.1%,
- volumetric heat capacity frozen (c_{vu}): 2300 kJ/(m^{3}K),
- volumetric heat capacity unfrozen (c_{vu}): 3150 kJ/(m^{3}K).

Thermal conductivity and heat capacity was adjusted to changing ground temperature and unfrozen water content using simplified empirical relationships.

The soil profile was modeled using isoparametric 8-nodes quadrilateral finite elements. Mean monthly air temperatures were applied to the surface boundary of the finite element mesh. The initial ground temperature at the start of the analyses (1904 for Fairbanks, 1912 for Longyearbyen, and 1900 for Yakutsk) was set approximately equal to the mean annual air temperature in Figure 2.

It should be noted that n-factors of 1.0 was used in the analysis presented in this paper. Andersland & Ladanyi (2004) suggest that n-factors between 1.2 and 2.0 would be appropriate for sand and gravel surfaces during thawing.

The ultimate goal of the calculations was to evaluate the probability for the ground temperature to exceed the threshold beyond which the pile becomes unstable and is incapable of bearing the load of construction above it. Figure 3 presents the maximum ground temperatures along the embedded pile length for selected years in Fairbanks, Longyearbyen, and Yakutsk, respectively. Maximum ground temperatures for each decade are presented in Tables 1, 2, and 3. It can be observed from the figures and tables that all three locations have the highest ground temperatures after year 2000.

Computed and measured ground temperatures are in good agreement in Longyearbyen. For Fairbanks and Yakutsk the computed values seem to be lower than observed ground temperatures. This is probably due to the effect of the n-factor used in the analysis (see above). The thermal model

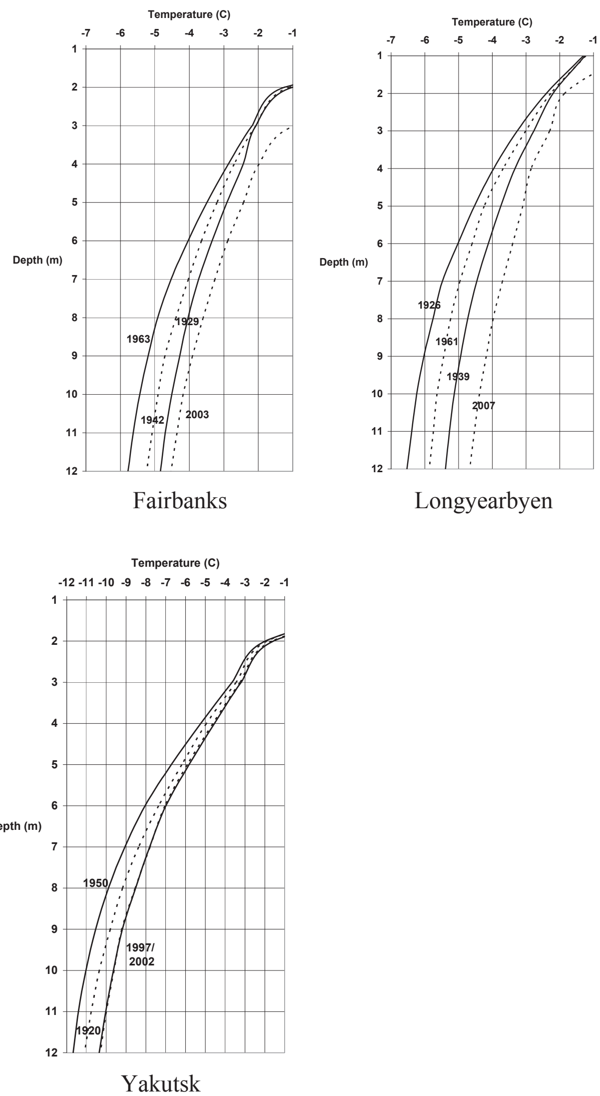

Figure 3. Maximum ground temperature along the embedded pile length, Fairbanks 1929, 1942, 1963, and 2003 (a); Longyearbyen 1926, 1939, 1961, and 2007 (b);and Yakutsk 1920, 1950, and 1997/2002 (c).

should, therefore, be tuned with actual ground temperature observations. However, the main purpose of the study was to look at the relative effect of variations in air temperature over the last 100 years for an idealized soil profile, and the results show that this goal has been achieved.

Pile Capacity

Based on the maximum ground temperatures presented in Tables 1, 2, and 3 and the adfreeze bond strength presented in Figure 1, theoretical pile capacities for a 200 mm diameter pile for the three locations are presented in Figure 4. As follows from the figure, for Fairbanks the theoretical pile capacity has been reduced by 6.5% from the maximum capacity of 627 kN in 1963 to 587 kN in 2003. In Longyearbyen the pile capacity has been reduced by 12.5% from the maximum capacity of 717 kN in 1977 (and 1926) to 636 kN in 2007.

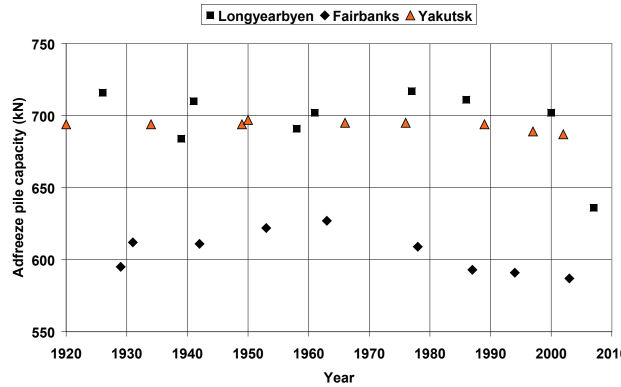

Figure 4. Theoretical adfreeze pile capacity for a 200 mm pile.

In Yakutsk, the theoretical pile capacity has remained almost unchanged, with only slight reduction by 1.5% in the period 1950–2002. This is because ground temperatures in Yakutsk are low (<-6ºC below 5 meters depth, see Table 3), while the adfreeze bond strength does not change much for temperatures below -5 to -6ºC (see Fig. 1). Pile capacities in Longyearbyen are higher than in Yakutsk because the active layer thickness here is much smaller due to the relatively cold summers in Spitsbergen compared to central Yakutia. It implies that the embedded length of the pile that has a temperature below -1ºC (also called the effective pile length) is bigger in Longyearbyen (approximately 11 m) than in Fairbanks and Yakutsk (approximately 10 m).

Hazard Map

Nelson et al. (2001) suggested the hazard index for predictive large-scale mapping of potential risks to infrastructure due to warming and thawing of permafrost. The more recent study by Anisimov & Lavrov (2004) uses modified hazard index, I_G, that is given by the following equation:

$$I_G = \Delta Z_{al} V_{ice} K_s \tag{1}$$

Here ΔZ_{al} is the projected change in the depth of seasonal thawing, expressed in relative units with respect to modern norm; V_{ice} is the volumetric ground ice content, and K_s is the coefficient that characterizes soil salinity.

Changes in the depth of seasonal thawing have been calculated using an equilibrium permafrost model forced by several climatic scenarios. The baseline algorithm developed by V. Kudryavtcev (1974) was modified to account for the presence of the organic layer and for the effects of the changing thermal conductivity of the snow cover. The mathematical formalism has been detailed in several preceding publications (i.e., Anisimov et al. 2007; Sazonova & Romanovsky 2003). All calculations were made in the nodes of 0.5° lat/long grid spanning the northern Eurasian permafrost region.

The model was forced by the contemporary and projected for the future climatic data. We used gridded monthly norms

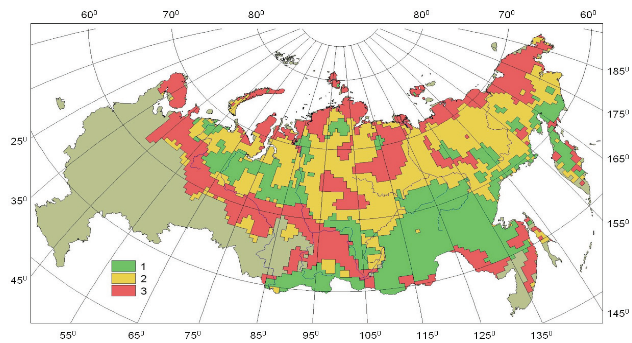

Figure 5. Predictive map of potential threats to infrastructure for 2050. Red, yellow, and green colors designate regions with high, moderate, and low susceptibility of buildings and engineered structures to the ongoing climatic and permafrost changes.

of air temperature and precipitation with 0.5° lat/long resolution as baseline data characterizing modern climate (New et al. 1999). Set of five scenarios of climate change for the 11-year long time periods centered on 2030, 2050, and 2080 has been constructed by superimposing predicted by CGCM2, CSM_1.4, ECHAM4/OPYC3, GFDL-R30_c and HadCM3 GCMs changes of climatic parameters on baseline data. These GCMs were selected as a result of the survey made in the course of the ACIA (Arctic Climate Impact Assessment) because they account for many key processes in the Arctic and provide reasonable fit to the observed climatic trends (Symon 2005). All climate models were forced by the B2 emission scenario. The climatic scenarios are fully documented in the ACIA report (2005) and are available on the web sites of the data distribution center of the Intergovernmental Panel on Climate Change (IPCC; http://ipcc-ddc.cru.uea.ac.uk/ and http://igloo.atmos.uiuc.edu/IPCC/).

Soil thermal properties were calculated using parameterizations that take into account soil type, soil moisture and ground ice content. We calculated winter-average snow depth at each node using monthly precipitation data. The density, thermal conductivity, and heat capacity of snow were prescribed at 300 kg m^{-3}, 0.23 W m^{-1} K^{-1} and 2090 J kg^{-1} K^{-1}, respectively. Vegetation types with prescribed thermal properties and soil type were obtained from the digital global ecosystems database (1992). The model was validated by the data from Circumpolar Active Layer Monitoring program (Brown et al. 2000) and used to calculate permafrost parameters under modern and projected for the future climatic conditions. Results of such calculations differ in detail depending on climatic scenario. Predictive map of hazard index in Figure 7 was constructed using the "median" climatic projection of GFDL model for 2050.

Summary and Conclusions

Historical air temperature records indicate warming during the last few decades in three selected locations representing different climatic and environmental conditions in Spitsbergen, in central Yakutia, and in Alaska. The results from this study suggest that piled foundations have not suffered sufficient loss in bearing capacity to become unstable due to the observed increase in air temperatures. However, the loss in capacity of piles in Longyearbyen from 702 kN to 636 kN in the period 2000–2007 is the early warning of the potentially detrimental impacts of changing climate.

One of the apparent features of the climate change impacts in permafrost regions is strong regionality. Susceptibility of permafrost to climatic changes and associated risks to infrastructure depend on the combinations of local soil, topographic, hydrological, vegetation, and snow conditions. In this paper the large-scale pattern of the future impacts was studied using the hazard index. Although such index provides highly generalized information about the potential impacts on the infrastructure, it may serve as effective tool for resource and land use planning, environmental risk management, and civil engineering in permafrost regions.

Areas of greatest hazard potential in Figure 5 include the Arctic coastline and parts of Siberia in which substantial development has occurred in recent decades. Particular concerns are associated with Yamal peninsula that falls into the highest risk zone, because of the ongoing expansion of the oil and gas extracting and transportation industry into this region. Although temperatures here are relatively low, frozen ground is already very unstable, largely because of its high salinity, and thus even small warming may cause extensive thawing of permafrost and ground settlement with serious impacts on the inrastructure.

Foundation Design Using a Heat Pump Cooling System

Bjarne Instanes
Instanes Svalbard AS, N-9171 Longyearbyen, Norway

Arne Instanes
Instanes Svalbard AS, N-9171 Longyearbyen, Norway

Abstract

On several locations in Svalbard, Norway, it is advantageous to design buildings with on-grade foundations over ice-rich permafrost soils. These types of foundations require insulation material underneath the concrete floor slab and a cooling system underneath the insulation to prevent thawing of the underlying ice-rich permafrost. This type of foundation design may also be beneficial to mitigate the effect of possible future climate warming on the structure. The heat pump cooling system presented in this paper is designed to decrease the temperature of the permafrost foundations soils to a design value. The heat extracted from the ground is used for heating of the building above. The foundation system has been installed at several locations in Longyearbyen and Sveagruva in Svalbard over the last 20 years. From our point of view the foundation design presents an attractive alternative to pile foundations both from an economical and a technical point of view. The paper describes in detail the foundation design using heat pumps, including case studies and cost comparison with conventional pile foundations of the frozen ground.

Keywords: engineering; foundations; geotechnical; permafrost; warming.

Introduction

Foundation design in Svalbard was traditionally based on pile foundations or shallow foundations. These foundation techniques require a ventilated air space of 0.5–1.0 m between the insulated floor and the ground surface. Pipelines for water supply and sewage were insulated and heated and attached outside under the insulated floor of the building. In this manner the heat flow from the building was restricted from entering the ice-rich permafrost soils.

The new technique described in this paper has several advantages compared to conventional piles or shallow foundations.

Climatic Conditions in Svalbard

The Svalbard archipelago is situated 74°N–81°N and 10°E–35°E. The land area is approximately 62,000 km^2 (Fig. 1). Svalbard has an exceptionally mild climate compared to North America and Russia at the same latitude, mainly due to the warming effect of the Gulf Stream and low pressures transporting heat northwards. Longyearbyen is located at 78°N, 11°E on Spitsbergen in the Svalbard Archipelago. Longyearbyen is the main settlement in Svalbard and has today approximately 2000 citizens. The main activities are coal mining, education, research and tourism.

Figure 2 shows the mean annual air temperature at the Longyearbyen/Svalbard Airport during the period 1912–2006. Monitoring of air temperature at the Svalbard airport commenced in 1975. Data earlier than 1975 is from air temperature monitoring in Longyearbyen. Figures 3 and 4 present the air freezing index and thawing index for Longyearbyen. It can be observed from the figures that there is a trend of increasing mean annual air temperatures during the last 20 to 30 years. In the same period the air freezing index is decreasing (indicating warmer winters) and the air thawing index is increasing (indicating warmer summers). However, Figures 2, 3, and 4 also show that the area has previously experienced warm periods, especially 1920 to the 1940s and 1950s.

It can also be observed from the figures that 2006 and 2007 have been extremely warm years, and this advocates a foundation design that can mitigate the effects of possible climate warming.

Conventional Foundation Design in Svalbard

Foundation design in Svalbard was traditionally based on pile foundations or shallow foundations. These foundation

techniques require a ventilated air space of 0.5–1.0 m between the insulated floor and the ground surface. Pipelines for water supply and sewage were insulated and heated and attached to under the insulated floor of the building. In this manner the heat flow from the building was restricted from entering the ice-rich permafrost soils.

In the 1980s the main author, in collaboration with a contractor and the local mining company, developed new equipment for predrilling boreholes for pile installation. The new drill rig was capable of drilling 300 mm diameter holes to a depth of 12 m beneath the surface. This meant that installation and grouting of prefabricated concrete, steel, or wooden piles became the preferred foundation technique in Svalbard.

However, this meant as mentioned above, that the building had to be elevated above the ground which is, in our opinion, not ideal from an esthetical, practical, or economical point of view.

Heat Pump Cooling System

Based on experience from the development of a district heating system utilizing heat pumps in Bergen Harbour, Norway, the idea of using heat pumps in permafrost areas was born. A heat pump will lower the ground temperature, and the heat extracted from the ground can be used in the heating of the interior of the building. In 1986 the first building using the new technique was constructed in Sveagruva, Svalbard (N77°53′, E16°41′) (Instanes 1988). The storage building had an area of 900 m^2. Because of the high foundation loads, pile foundations were not a good solution for this project. The building was therefore placed directly on the ground using heat pumps to artificially lower the ground temperature (Fig. 5).

The following procedure was used for clearing the site and installing the heat pump system (Fig. 6):

- The site was drained and leveled in order to lead surface water away from the building.
- A mimimum 0.5 m thick layer of sand, gravel fill was placed on the natural terrain and compacted.
- Forty mm PVC cooling pipes were placed on the sand, gravel layer in a 100 mm thick reinforced concrete slab.
- The cooling fluid circulated in the pipes is a mixture of glycol and water.
- Two hundred mm thick Styrofoam insulation was placed on top of the concrete slab.
- A plastic film was placed on top of the insulation in order to stop vapour diffusion.
- A 700 mm layer of fine sand was placed between the insulation and the floor of the building (gravel size can also be used in this layer). The thickness of this layer is governed by the necessary slope of drainage pipes.
- The concrete slab on top of the sand layer was reinforced and had a thickness of 150 mm. It was designed for large mobile loads from cranes and vehicles inside the building.

In addition to the first use in Sveagruva described above, the foundation system has been installed for three buildings in Longyearbyen: *Næringsbygget* (1989 and 1992), *Svalbardbutikken* (1990) and more recently in the ISS-building (20052006)(Fig. 7).

The technique is especially useful when the foundation loads are high and in areas with difficult foundation soils such as marine, saline, ice-rich, silts and clays, frequently found in Longyearbyen and Sveagruva (Instanes & Instanes 1998).

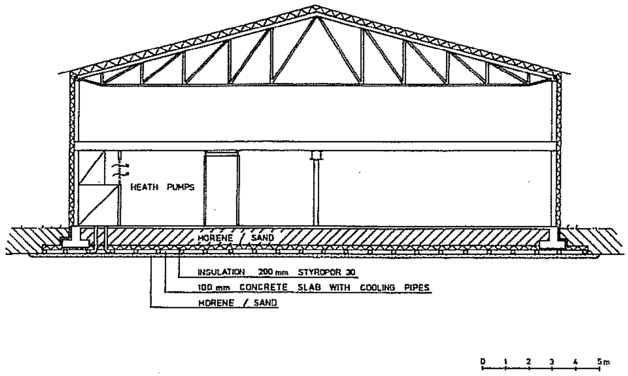

Figure 5. Cross-section of the storage building in Sveagruva.

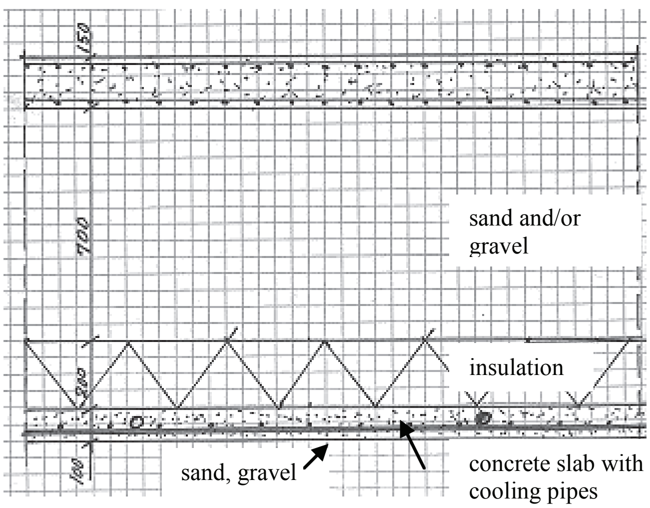

Figure 6. Detail of the foundation system.

ISS-Building, Longyearbyen

The ISS-building is a laundry that was constructed in 2004–2005. The site lies close to the Advetfjord and is thermally affected by the sea. The foundation soils consist of saline (3%–4%), ice-rich, silty clay. The permafrost temperature at 10 m depth is approximately -3°C to -4°C. The design criterion for the foundations was maximum settlement of 5 cm in 20 years. The foundation principle for this building is similar to what has been described in the previous section.

Figure 8 shows the layout of the cooling pipes for the ISS-building.

The total area covered by the cooling pipes is 600 m^2 (15 m x 40 m) and the total length of the pipes was 760 m. The maximum horizontal distance between parallel pipes was 0.75 m. Two parallel systems were installed, one primary main system and one secondary backup system

Pile foundations were considered for this building, but due to the difficult soil conditions, relatively warm permafrost, and the warm interior of the building (up to +40°C), it was not considered a technically safe solution during possible climate warming. The heat pump cooling system was therefore selected.

Figure 7. Overview of Longyearbyen. *Næringsbygget* and *Svalbardbutikken* are located in the center of the photo, ISS-building in the lower right corner.

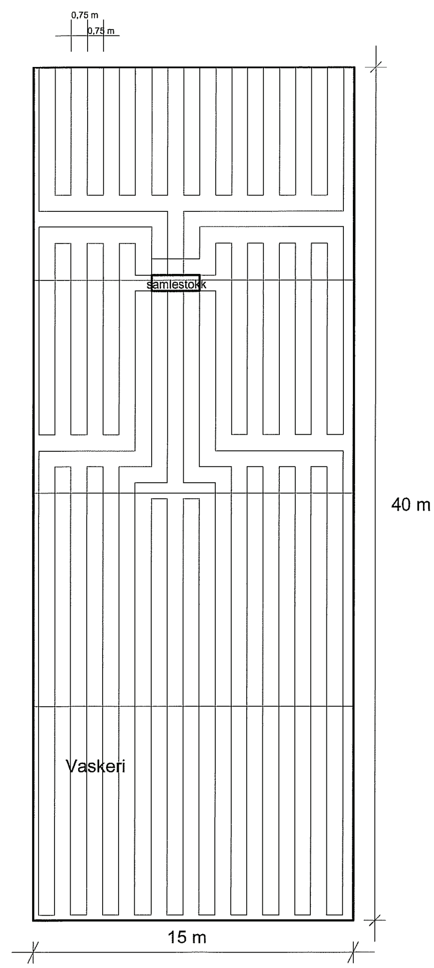

Figure 8. Layout of the cooling pipes at the ISS-buildings.

Thermal Considerations and Costs

The thermal design of the foundation system was based on the principle that the subsurface soils were to be cooled down to -5°C. To estimate the time needed to cool down the surface layers after construction, the thermal model TEMP/W, version 7.03 (Geo-Slope 2007) was used. TEMP/W is a finite element software that can model the thermal changes in the ground due to changing temperature or heat flux boundary conditions. It also accounts for the effects of the temperature dependent thermal conductivity, volumetric latent heat of fusion, and soil unfrozen water content.

Based on the thermal calculations and present climate warming, it was decided to let the cooling system run continuously with an internal fluid temperature varying between -5°C and -10°C.

The additional cost associated with the heat pump cooling system compared to conventional pile foundations was estimated to NOK1000 per m^2 (approximately USD180 per m^2).

Advantages Using a Heat Pump Cooling System

A foundation system in permafrost regions using a heat pump system is advantageous due to a number of reasons:

- The foundation design can be used in marginal zones with discontinuous permafrost or saline soils.
- The energy consumption is limited. The heat loss through the floor is regained by the heat pumps.
- The building can be constructed with the floor directly on the ground and the air space between the floor and the ground is avoided.
- The heat loss from the building because of wind blowing under the building is eliminated.
- The water supply and sewage pipes can be buried in the sand/gravel layer, making the access to the building and the entrance to the building easier.
- It becomes possible to have a warm "ground floor" in the building.
- Heating using hot water pipes can be installed in the floor; additional insulation may then be needed beneath the floor surface.
- For large buildings such as storage buildings and industrial facilities, it becomes costly to have floor structure spanning between piles or pillars. Using an embankment fill, the loads can be transferred directly to the embankment.
- Possible climate change and permafrost temperature increase can be mitigated.

Abstract

In 2002 a new permafrost monitoring program was initiated in Finnmark, northern Norway. A series of miniature temperature dataloggers were installed for continuous monitoring of ground surface and air temperatures. Results suggest that permafrost is widespread in Finnmark. However, the great areas of birch and pine forest in Finnmark appear to correspond to areas without permafrost, due to the forest acting as a snow fence and causing snow to accumulate. Above the timberline, snow depth seems to be the most critical factor for the formation of permafrost.

Keywords: mean ground surface temperatures; Northern Norway; permafrost distribution.

Introduction

Permafrost is widespread in the higher mountains of Norway. Extensive studies in southern Norway show that the lower regional altitudinal limit of mountain permafrost is strongly correlated to the mean annual air temperature (MAAT) and decreases eastwards with increasing continentally (e.g., Etzelmüller et al. 2003). However, there are, to date, few quantitative studies of the distribution of permafrost in northern Norway.

In 2002, a new permafrost monitoring program was initiated in Finnmark, which is the northernmost county of mainland Norway (Fig. 1). A series of miniature temperature dataloggers (MTDs) were installed for monitoring ground surface and air temperatures. Continuous ground surface monitoring was performed at five main sites in a transect starting at Varangerhalvøya in the extreme northeast of Norway, continuing southwest to the interior of Finnmarksvidda, and then northeastwards to the Gaissane.

The main aim of this study is to determine mean ground surface temperatures (MGST) at representative sites in Finnmark in order to provide an initial indication of the presence or absence of permafrost. The results are related to climate data, mainly air temperature and snow cover. In addition, a land-cover classification of the whole county is made that gives a first qualitative picture of the relationship between climate, vegetation and permafrost distribution in Finnmark. A review of the literature of permafrost occurrence in northern Scandinavia is presented, together with new results from 5 years of temperature monitoring.

Literature Review

Permafrost in northern Scandinavia

Until the 1980s, permafrost research in Northern Scandinavia was mainly concentrated on palsas, and a number of studies (cf. references in Åhman 1977) were undertaken following the pioneer work of Fries and Bergström (1910).

However, in the beginning of the 20th Century, field observations and theoretical considerations by Reusch (1901) suggested that permafrost was present in the mountains of Scandinavia. In the following decades few reports on permafrost occurrence in northern Scandinavia were published. A review of Scandinavian permafrost investigations up to 1950s is provided by Ekman (1957). During the drilling of a well at 1220 m a.s.l. in northern Sweden, permafrost was encountered at 70 m depth in bedrock (Ekman 1957). Frozen ground was also encountered during construction work in northern Finland and Sweden (e.g., Ekman 1957, Åhman 1977), but it is often difficult to decide whether these findings are perennially or only seasonally frozen ground (King & Seppälä 1988).

Since the beginning of the 1960s, research on permafrost outside the palsa mires has increased, with most reports on geomorphological indicators (Jeckel 1988).

In the 1980s, studies using geophysical methods encountered extensive permafrost at 50–100 m depth in bedrock in mountain areas of northern Sweden (e.g., King 1982) and Finland (King & Seppälä 1987). On a mountain in northern Sweden, Jeckel (1988) reported a mean ground temperature (MGT) at 2.3 m depth to be -0.8°C at 880 m a.s.l. In a 100 m deep borehole at Tarfalaryggen (1550 m a.s.l.) in northern Sweden, it has subsequently been shown that MGT is approximately -3 ºC and permafrost thickness is estimated to exceed 300 m (Isaksen et al. 2001). In northern Finland, Bottom Temperature of Snow (BTS) measurements suggested a lower limit of permafrost at 600-650 m a.s.l. on north-facing slopes (Jeckel 1988). In Finnmark, quantitative studies on permafrost distribution are limited and are

B) Classified land-cover map of Finnmark county based on Landsat TM/ETM+ satellite images (see text for details).

mostly restricted to palsa mires (e.g., Sollid & Sørbel 1998, Hofgaard 2007). In some settlements, however, permafrost degradation has caused problems during construction work (e.g., Lien 1991).

Study Sites

Three of the sites (D, G, and H), were chosen to optimize comparability and to ensure that the thermal properties were not excessively complex (Fig. 1). These were located at exposed locations, in the main ridge-crest or plateau areas, where snow accumulation is low. The last two sites are located in open (F) and dense (E) mountain birch forest.

The inner part of Finnmark (Finnmarksvidda, site E) is a plain having strong continentally and has the lowest MAAT when reduced to sea level in Norway. Typically, in this area, MAAT is -2.5°C to -4°C, with mean summer temperatures of 8°C to 10°C and mean winter temperatures of -15°C to -20°C. In winter, mean maximum snow depth is 25–75 cm. Towards the N (Site H) and NW (Site D), continentality decreases, with more mountains and more complex climate settings. Towards the NE, at Varangerhalvøya (Site G), mountain plateaus dominate, and the area is in the Arctic climate zone.

Methods

Land-cover classification

In this study, a land-cover map of Finnmark county (Fig. 1B) is developed (in 200 x 200 m resolution), reflecting degrees of density in the vegetation cover. The land-cover map is a subsection of the vegetation map produced for the entire country of Norway. In this map, a total number of 45 Landsat TM/ETM+ images were processed during six operational stages: (1) spectral classification, (2) spectral similarity analysis, (3) generation of classified image mosaics, (4) ancillary data analysis, (5) contextual correction, and (6) standardization of the final map products (Johansen & Karlsen 2005). Analysis performed on the spectral-only data is often denoted as the pre-classification stage of the process, whereas the post-classification process involves analysis and subsequent contextual corrections of the pre-classified image using ancillary data. In the final standardization part of the process, the defined classification units are related and described according to classification schemes well-established in the Norwegian botanical literature (Fremstad 1997). From the overall vegetation map of Norway, different thematic maps can be extracted.

Continuous temperature measurements

Nine (out of 20 in total) UTL-1 (Geotest, Switzerland) MTDs were used to determine the mean ground surface temperatures (MGST). They were buried at the surface (c. 0.05 m depth) and installed in Autumn 2002 and 2003. In addition, one logger was used to monitor the air temperature at G-1. At the other sites, air temperatures were obtained by interpolation from nearby weather stations (Table 1). The thermistors in the MTDs are of the type TMC-1T, with accuracy better than the 0.27°C given by

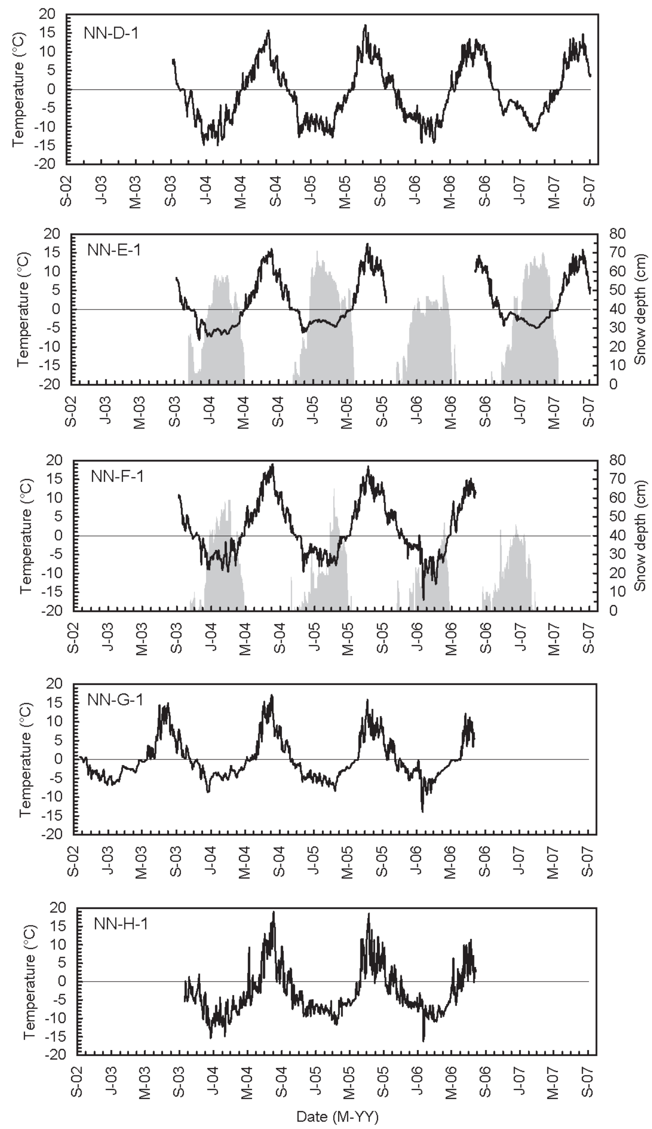

Figure 2. Daily ground surface temperatures obtained at the 5 main locations in Finnmark during 2002–2007. For E-1 and F-1, observed snow depth (grey bars) from nearby official stations are shown.

the manufacturer (Hoelzle et al. 1999). The MTDs were programmed to record the ground surface temperature every 6 hours (2 hours in Gaissane). In addition, the MTDs gave important information concerning damping of short-term air temperature fluctuations through the snow (reflecting the development and thickness of snow cover), the time when melting occurred at the bottom of the snowpack, and when snow disappeared.

Climate data from official weather stations were used to normalize the data sets in respect to the normal standard period 1961–1990, in order to establish the long-term MGST. The method is described by Ødegård et al. (2008). From the MTDs, monthly mean of ground surface temperatures were calculated and analyzed with the best nearby correlated air temperature from an official meteorological station having long-time series (e.g., 30-year period or more). A high correlation suggests low influence of snow and latent heat effects, which give a strong coupling between the air

Table 1. Key temperatures observed at monitoring sites. MGST = Mean ground surface temperature for observation period, maximum and minimum of 12-months running mean of MGST during observation period. MAT = Mean air temperature observed (Obs) and interpolated from nearest station (Int). MAT-anomaly: Air temperature deviation for observation period from nearest station. Air temperature at G-1 is for the period Sep03–Jun06. For interpolation of air temperature at G: 2,3,4, a gradient 0.53°C/100 m was used from G-1 (Laaksonen 1976). For the other interpolated values, the same gradient was used from nearest official weather station. H-1 and H-2 were from Farbrot et al. (2008). Type = Land type class (cf. Fig. 1B).

and ground surface temperatures. Monthly air temperature anomalies (in respect to the 1961–1990 average) can then be used to correct the monthly observed ground surface temperature during the observation period (see Table 1).

Results

Vegetation types in Finnmark

The land cover map of Finnmark portrays the density of the vegetation cover at different levels. The coniferous pine forests are mainly located to the southern, continental parts of the county, constituting the largest areas along the main rivers in the area. In addition, the Pasvik area, south of Varangerhalvøya, is characterized by well-developed pine forests. The mountain birch forest, occupying large areas on Finnmarksvidda, is characterized by an open forest layer with heather and lichen species dominating the ground layer. The more dense and fertile birch forests are located mainly in the coastal regions. The differentiation in the mountain belt generally reflects the low-, the mid-, and the high-alpine belt of the region. Heather communities, with a closed vegetation cover, characterize the low-alpine belt. In the mid-alpine belt, the vegetation cover is more scattered due to harsher climate conditions. The high-alpine belt has bare rocks, boulder fields, and gravel ridges. Few vascular species are adapted to the climate conditions found here. This belt is characterized by mosses and lichen species.

Mean ground surface temperature (MGST)

Mean ground temperatures from 3–5 years of continuous monitoring (Fig. 2 and Table 1) show that:

a) the highest MGST were found in the forested areas (G-1 and E-1);
b) the lowest MGST were observed at the two highest sites (H-1) Gaissane and (D-1) Biedjovággi were bare rock and boulder fields dominate;
c) 12-month running means of MGST show large variation within the observation period at all sites. The difference between the highest and lowest 12-month MGST are between 0.6°C and 1.6°C; and
d) the mean air temperature (MAT) is generally 1–2.5°C lower than MGST. The largest difference is found at the two forested sites (2.8°C), while at the most exposed locations (H) the difference is only 0–0.4°C.

Correlation between ground surface temperature and air temperatures at G-1 is shown in Fig. 3. The results indicate a strong correlation. In general, the site is exposed to strong winds, leading to only a thin snow cover in late winter, probably not more than 0.3–0.5 m.

Data from official weather stations close to the monitoring sites show that the MAT during the observation period was 1.4–1.9°C above the 1961–1990 normal. By normalizing the observed MGT-values (Ødegård et al. 2008), data suggest that mean annual ground surface temperature (MAGST) is below 0°C at six sites. Only the two sites located in forest (E and F) and the lowermost site at Varangerhalvøya (G-4) have positive MAGST.

Discussion

In Norway, the Nordic mountain birch limit is close to the 8°C tetratherm (mean air temperature for June–September) (Wielgolaski 2005). However, the tetratherm limits decrease in relatively continental areas with high day temperatures during summer. This means that continental sites generally have a higher forest limit than more maritime sites even though the MAAT is equal (Meier et al. 2005, Wielgolaski 2005). Forest (mainly birch) is present in the interior of Finnmark where MAAT is far below 0°C (Fig. 1). The timberline is located at about 500 m a.s.l. on Finnmarksvidda (Meier et al. 2005).

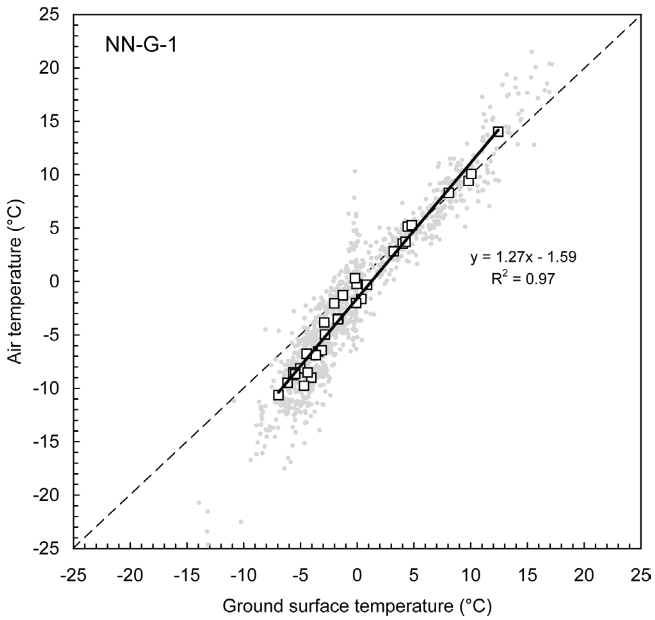

Figure 3. Mean daily (grey small dots) and monthly (open squares) ground surface temperature versus mean daily and monthly air temperature (2 m) during the period of record at G-1 Basečearru (Varangerhalvøya). Linear least squares regression coefficients and coefficient of determination (R^2) for the monthly values are shown.

Two sites, E-1 and F-1, are significantly warmer than the other study sites. The reason is the influence of the forest, which collects snow and therefore has a quite different energy-balance compared to wind-swept locations. Although cooler in summer due to radiation interception and higher evaporation (e.g., Rouse 1984), the near-surface ground temperatures in the forest are considerably warmer in winter than the other locations (Table 1). Hence, the forest in Finnmark largely prevents permafrost formation, making the forest line altitude very important in defining the permafrost limits. Although Scandinavian treelines are expected to advance in response to climate warming, there are indications of recessive treelines in northern Norway in contrast to southern Norway (Dalen & Hofgaard 2005). Above timberline, snow depth appears to be the most critical factor for the formation of permafrost (cf. King & Seppälä 1988). Results from Farbrot et al. (2008) and this study (Table 1) suggest that MGST above timberline in Finnmark can differ by 1–2°C due to variations in snow thickness. This is somewhat lower than values reported from southern Norway (e.g., Hauck et al. 2004, Ødegård et al. 2008).

King (1984) suggests that mountain permafrost in Scandinavia may be divided into continuous, discontinuous and sporadic. Their lower limits correspond to MAAT of -6°C and -1.5°C and sporadic permafrost may occur even in areas with positive MAATs. The transition between these belts is gradual. The temperature values for the lower limits are valid for the central Scandinavian mountain areas with moderately continental climate. The climate of Finnmark shows strong continentality, with generally thin snow cover. The results obtained from the MTDs and Farbrot et al. (2008) suggest that the proposed limits suggested by King (1984) can be adjusted in this region by lowering the limit of discontinuous permafrost to a MAAT of -1°C (Fig. 1). In areas colder than -3°C, permafrost seems to be widespread above timberline.

Conclusions

Miniature temperature dataloggers recording ground surface temperatures have been shown to provide data suitable for mapping the spatial variation in mean annual ground surface temperatures in Finnmark, and thus the possible presence or absence of permafrost at the sites. Results suggest that:

- Permafrost is widespread in Finnmark. The lower limit of discontinuous permafrost outside the palsa mires corresponds to mean annual air temperatures (MAAT) of approximately -1°C,
- Permafrost is probably present in the interior part of Varangerhalvøya. This is probably the northernmost permafrost area in north-western Europe (outside Russia) and can be regarded as polar permafrost
- Birch and pine forest in Finnmark appears to correspond with areas without permafrost. Trees cause snow to accumulate and insulate against strong ground cooling. Below the timberline and beside the palsa mires, formation of permafrost is possible at local exposed sites where snow does not accumulate, or cleared areas (in villages, on roads etc),
- Snow depth seems to be the most critical factor for the formation of permafrost above the timberline. However, variations in mean annual ground surface temperatures due to variations in snow depth seem to be lower in Finnmark (cf. Table 1) than in southern Norway, probably due to generally lower precipitation. Permafrost is apparently widespread in Finnmark in areas above timberline having MAAT lower than -3°C,
- Air temperatures for the previous 3–5 years have been 1.5–2.0°C warmer than the 1961–1990 average. In Finnmark permafrost is "warm" as it is only a few degrees below 0°C, which makes it very vulnerable to warming (cf. Isaksen et al. 2007), and
- The present monitoring program in Finnmark is being continued and will be included within the Norwegian funded IPY-project *Permafrost Observatory Project: A Contribution to the Thermal State of Permafrost in Norway and Svalbard*, (Christiansen et al. 2007). The relation between MGST and snow and vegetation should be further investigated, and similar measurements should be made at other sites to see if these findings can be generalized to larger areas.

Acknowledgments

This study is part of a Norwegian network project, *Permafrost og ustabile fjellsider,* supported by the Geological Survey of Norway, Norwegian Meteorological Institute and the University of Oslo. In addition, part of the study was financed by the Norwegian Research Council (project no.

157837/V30). C. Harris smoothed the English, and two anonymous reviewers gave important improvements to the manuscript. The contributions of all persons and institutions mentioned are gratefully acknowledged by the authors.

Abstract

Mongolian *Larch* forests are situated at the southern boundary of the Eurasian Taiga that vulnerably coexists with the permafrost. This paper describes hydro-meteorological situations at the permafrost underlying forested areas and also in the immediately adjacent permafrost-free pasture slopes, and evaluates the vulnerable and reciprocal features of permafrost and forest. Records spanning nearly two years showed considerably reduced net radiation onto the ground surface, lower air and soil temperatures, and wetter soils at the forest site. The analysis showed small imbalances of energy balance components between atmospheric and active layer heat fluxes estimated independently, if the effects of organic matter and porosity are considered for the soil thermal parameters. This indicates the importance of considering thermal properties of the forest soil in the preservation of permafrost when the forest shading, which greatly reduces incoming solar radiation, is well known.

Keywords: active layer; energy budget; forest; pasture; southern boundary of Eurasian permafrost.

Introduction

In northern Mongolia, the distribution of permafrost is mosaic-like, yielding ecological contrast even over small geographic areas. *Larch* forests dominate on the north-facing permafrost slopes, while pastures dominate the south-facing slopes. Ongoing degradation of permafrost due to recent climatic warming (Sharkhuu 2003) is expected to lead to reduced forested area and to influence the regional hydro-ecological system.

Since 2002, the Institute of Observational Research for Global Change, of the Japan Agency of the Marine-Earth Science and Technology (JAMSTEC) has continuously made hydro-meteorological observations at sites in northern Mongolia, with the aim of understanding the water cycle on the basin-scale and predicting future changes. The distribution and vulnerability of permafrost are the major focuses of this project, because changes in these parameters would significantly alter river runoff regimes and soil wetness, resulting in the degradation of ecosystem services of this region. This paper describes hydro-meteorological situations at the permafrost underlying forested areas and also in the immediately adjacent permafrost-free pasture slopes, and evaluates the vulnerable and reciprocal features of permafrost and forest.

Regional Settings and Observations

The observation sites used in this study are located on the northern forested (NF site) and southern pasture (SP site) slopes east of Ulaanbaatar (Fig. 1a). The nearest meteorological station, approximately 2 km away from these sites, had a mean annual air temperature of -3.5°C from 1992 to 2000. Mean annual total precipitation at Ulaanbaatar, where most of the precipitation occurs from June to August, was only 300 mm.

Analyzing cores obtained by drilling investigation, Ishikawa et al. (2005) found ice-rich permafrost and nearly

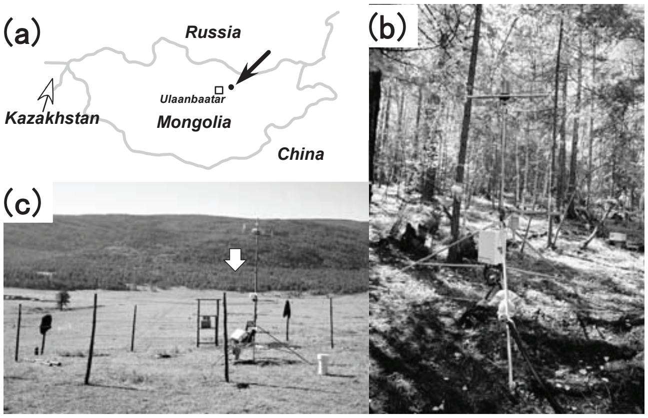

Figure 1. (a) Location of the observational site. Views of the setting of AWS (automatic weather monitoring system) on the (b) NF site and (c) SP site. The arrow in (c) indicates the location of the NF site.

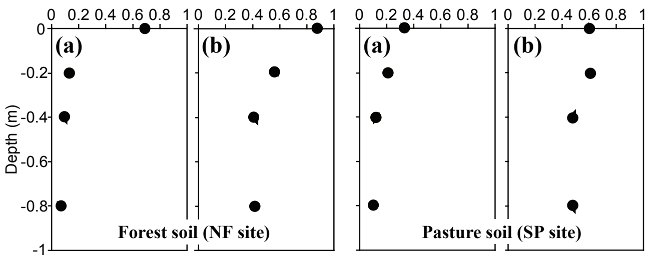

Figure 2. Soil properties at the NF and SP slope sites, based on laboratory analyses. (a) Organic ratio of soil particles (m^3/m^3), (b) porosity (m^3/m^3).

saturated active layer with a thickness of 2.4 m beneath the NF site, while cores showed the SP site to be permafrost-free, highly unsaturated, seasonally frozen ground beneath this site.

In summer 2003, an automatic weather monitoring system (AWS) with a capacity to measure four radiation components, air temperature, relative humidity, wind speed at two heights and surface soil heat flux, soil temperatures at depths of 0, 0.2, 0.4, 0.8, 1.2, 2.4, and 3.2 m, and moistures at 0, 0.2, 0.4, 0.8, and 1.2 m was installed at both sites (Figs. 1b, 1c). Soils at both sites comprised mainly sand cobbles covered with an organic-rich layer of several centimeters. We sampled undisturbed upper-layer soils and analyzed porosity, density, and organic contents in the laboratory (Fig. 2).

Analysis

Neglecting heat supplied by rainfall, the surface energy balance equation during the snow-free period is

$$Q_n = Q_h + Q_e + Q_g \tag{1}$$

where Q_n is net radiation calculated simply by adding the four radiation components; sensible heat flux, Q_h, latent heat flux, Q_e, and the ground heat flux from heat pile, Q_g. The turbulent fluxes Q_h and Q_e were estimated by the Bowen ratio method. The Bowen ratio, B, is expressed after approximating fluxes using gradients in the following manner:

$$B = Q_h / Q_e = C_a \Delta T / (L^{lv} \Delta q), \tag{2}$$

where C_a is the specific heat of air, L^{lv} is the latent heat for vaporization, and ΔT and Δq are the vertical gradients of air temperature and specific humidity, respectively. Combining equations (1) and (2), the latent heat flux is

$$Q_e = \rho_w (Q_n - Q_g)/(1+B), \tag{3}$$

where ρ_w is the density of water. Q_n was estimated from measurements of the four radiation components. We used surface soil heat flux sensor data as Q_g, relative humidity and air temperatures taken at two (for NF site) and three (SP site) heights, removing spurious data from original 10-minute-interval datasets as indicated by Ohmura (1982).

The conductive (sensible) soil heat flux was calculated using Fourier's law of heat transport,

$$j_h^i = -k_h^i \frac{\partial T}{\partial z} \tag{4}$$

where k_h is bulk thermal conductivity, T is temperature, and z is depth for the i-th soil layer from the surface downward. The non-conductive heat component, r_h, is expressed in terms of heat production in W/m^3, and is estimated by considering the one-dimensional energy conservation as formulated by:

$$r_h^i = \frac{\partial}{\partial t}[c_h^i T] + \frac{\partial}{\partial z} j_h^i \ , \tag{5}$$

where c_h is bulk heat capacity and t is time. Total thermal energy stored in the soil layer, $Q_{g\text{-}c}$, is the summation of conductive and non-conductive heats of each layer as

$$Q_{g-C} = \sum_i (j_h^i + r_h^i d^i), \tag{6}$$

where d^i is thickness of the i-th layer. The mid-depth of the i-th layer was set to be at the i-th depth measurement from the surface. Neglecting energy flux in the deepest soil layer, we calculated energy flux components in the upper three layers, having thicknesses of 0.3, 0.3 and 0.4 m from the surface. The finite element formulation used to solve equation (6) is described in Ishikawa et al. (2006).

Calculation of $Q_{g\text{-}C}$ requires data on the bulk thermal conductivity (k_h) and bulk heat capacity (c_h) of each soil layer. The spatio-temporal variations of the above variables are known to be largely dependent on the ratio between soil particle, water, and ice. Two models with different numbers of parameters were evaluated. The first model used conventional parameterization, which does not include the effects of thermal parameters of air occupying porosity and organic matter (Farouki 1981):

$$k_h^i = k_m^{1-n} k_s^{\theta_s} k_w^{\theta_w}\ , \tag{7}$$

$$c_h^i = (1-n)\rho_m c_m + \theta_s \rho_s c_s + \theta_w \rho_w c_w \tag{8}$$

In a second model, we modified equations (7) and (8) in order to consider mineral, water, ice, organic contents, and thermal parameters of air as,

$$k_h^{i'} = k_a^{n-\theta_s-\theta_w} k_o^{\theta_o} k_m^{1-n-\theta_o} k_s^{\theta_s} k_w^{\theta_w}, \tag{9}$$

$$c_h^{i'} = (1-n-\theta_o)\rho_m c_m + \theta_s \rho_s c_s + \theta_w \rho_w c_w + \theta_o \rho_o c_o, \tag{10}$$

where θ is volumetric fraction, n is porosity, ρ is density, k is thermal conductivity, c is specific heat (for subscripts, as follows: m, mineral; o, organic matter; s, ice; w, water). The ρ, c, and k for the mineral, organic matter, ice, and water components of soil modeled in equations (7) ~ (10) were set as $\{\rho_m, \rho_s, \rho_w, \rho_o\} = \{1.55, 0.92, 1.0, 1.3\} \times 10^3$ kg/m^3, $\{c_m, c_s, c_w, c_o\} = \{0.733, 2.11, 4.22, 1.93\} \times 10^3$ J/kg/K, and $\{k_m, k_s, k_w, k_o\} = \{0.54, 2.2, 0.57, 0.026\}$ W/m/K. We used laboratory soil analysis data for the volumetric fraction of organic matter and porosity (Fig. 2).

Results

Due to forest shading, the summer net radiation at the NF site was greatly reduced, corresponding to 26% of that at the SP site (Figs. 3, 4). This was more pronounced in the winter period. We found nearly zero downward shortwave radiation due to further reductions by topographic relief at this site. Mean T_a during the first December, January, and February was -19.4°C at the NF site and -18.1°C at the SP site.

The forest canopy intercepted rainfalls on the forest floor; the NF site received 87.5% and 97.4% of rainfall of that of the SP site during the summers 2003 and 2004, respectively. The interception loss of snow was not obvious; rather, snow depth (SD) at the SP site remained less than for the forest, possibly due to redistribution by wind.

Permafrost condition was found to occur at below 280

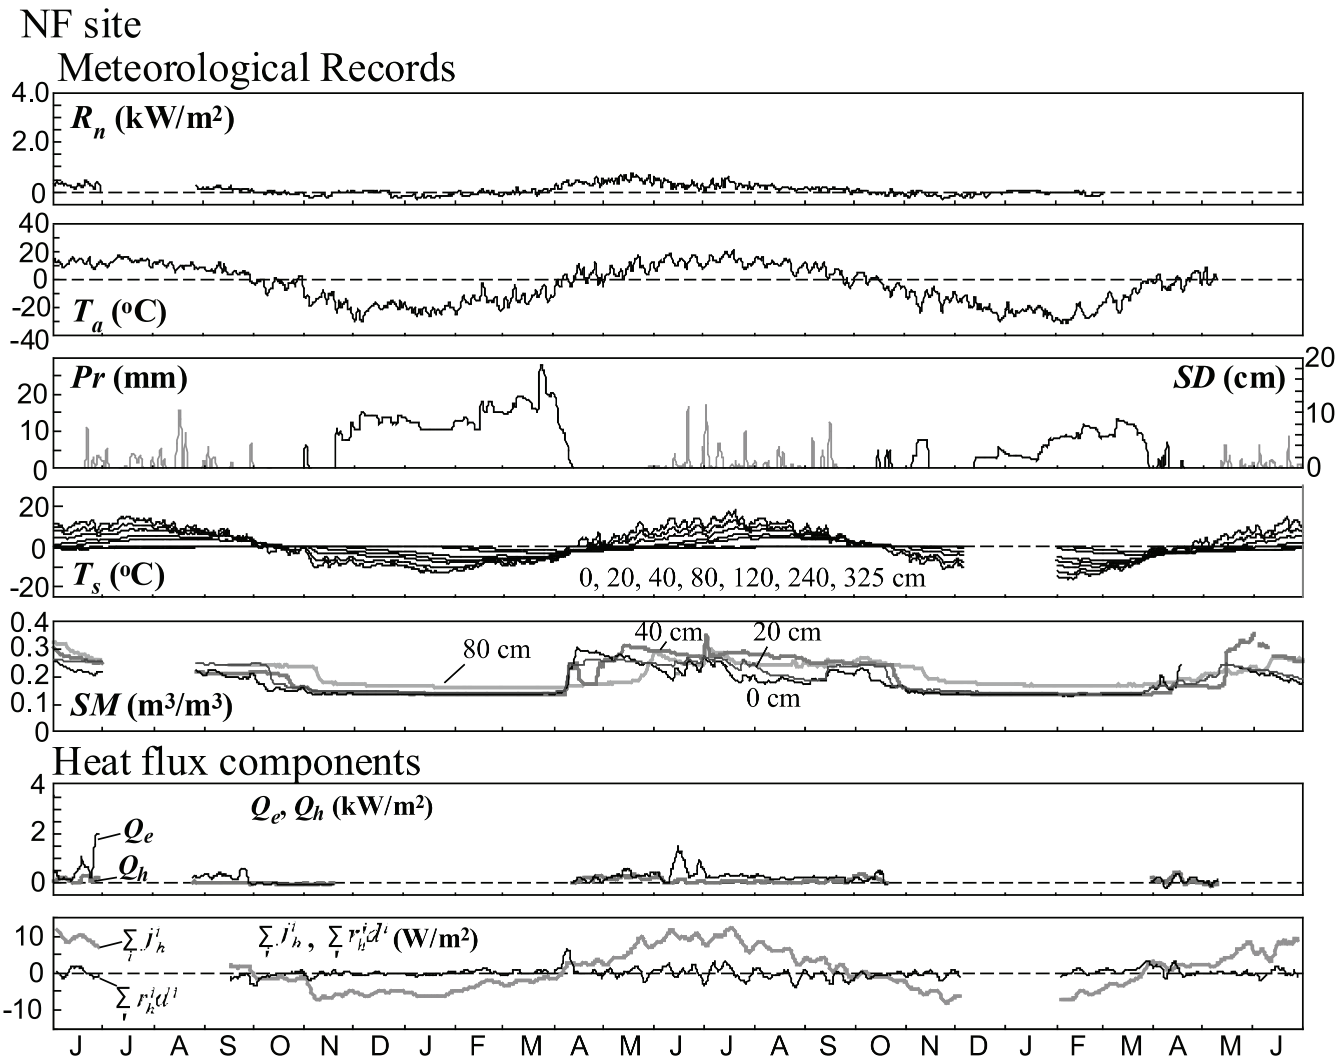

Figure 3. Data and estimated heat flux components at the NF site. See Figure 1b for a picture of the site. Data are missing for some periods due to instrument failure. R_n: net radiation, T_a: air temperature, P_r: rainfall, SD: snow depth, T_s: soil temperatures, SM: soil moistures. For soil moisture, we showed only the upper four depths that were used for calculating soil heat flux components. Q_e: atmospheric latent heat flux, Q_h: atmospheric sensible heat flux, Σj_h^i: total soil conductive heat flux, $\Sigma r_h^i d^i$: non-conductive heat fluxes transferred into the upper three soil layers (0.3, 0.3 and 0.4m in thickness, respectively, extending down from the surface). Five-day running mean values are plotted for each of the heat flux components. For Q_e and Q_h, only results obtained during snow-free period are shown. Calculations of Σj_h^i and $\Sigma r_h^i d$ by equations (9) and (10) are plotted.

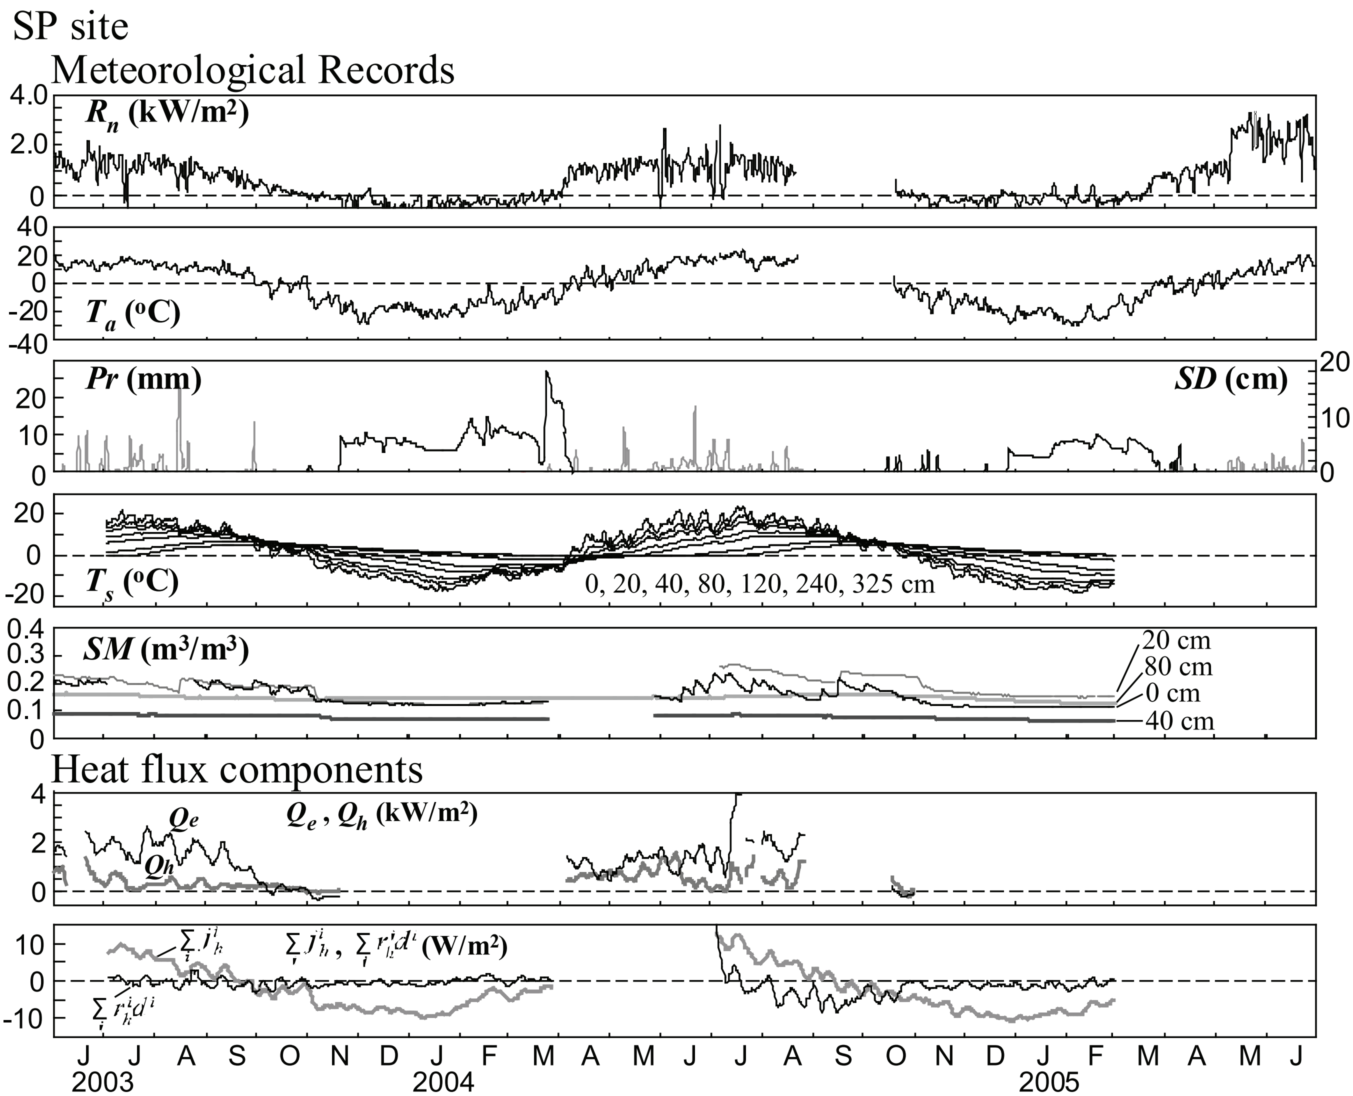

Figure 4. Data records and estimated heat flux components at the southern pasture slope (SP) sites. See Figure 1c for the environments. Same caption as Figure 3.

cm at the NF site, where soil moisture becomes greater for the deeper soils. This is probably due to the impermeability of the underlying permafrost. Contrastingly with the permafrost-free SP site, wet soils were restricted near the surface soil layers. At this site, the regions with significant short-term fluctuation in soil moisture contents are restricted to the shallowest depths (0 and 20 cm), even during the rainy season. Greater net radiation would modulate immediate evaporative soil water loss, as indicated in the greater sensible heat flux at the SP site.

The wet soils at the NF site are probably maintained by lesser atmospheric latent heat (Figs. 3, 4). The ratio of summer evaporation at the FP and SP sites was 0.22; this estimation was approximated with eventual lysimetric measurements. Q_e remained at levels similar to Q_h until the end of May when water for evaporation was mostly derived from snowmelt infiltration and seasonal thawing of the active layer.

Thereafter, Q_h decreased, possibly due to reduced downward shortwave radiation due to the growing forest canopy. Concurrent Q_e, on the other hand, remained higher than Q_h, largely due to water supply from rainfall. The seasonal development of atmospheric heat flux components mentioned here was generally similar to that at the SP site, which experienced greater evaporation from snowmelts, with higher moisture in the seasonal soil thaw and rainfalls.

The origin of soil latent heat is very complicated (e.g., Kane et al. 2001). Consumption of soil latent heat, $r_h < 0$, possibly arises from evaporation and thawing processes, whereas release, $r_h > 0$, arises from condensation and freezing. Furthermore, r_h reflects the heat transfer accompanied by liquid (water, vapor) movements. Identification and quantification of these processes are required for further comparisons between the energy equivalent of water phase changes and changes in soil moisture contents (e.g., Roth & Boike, 2001).

In our study, more negative r_h for JAS 2004 at the SP site than that at the NF site indicates a larger evaporative water loss at the SP site, as suggested by atmospheric heat fluxes (Figs. 3, 4). At the NF site, the most obvious latent heat releases occurred during the snow disappearance period of April 2004, when the temperature over the active layer

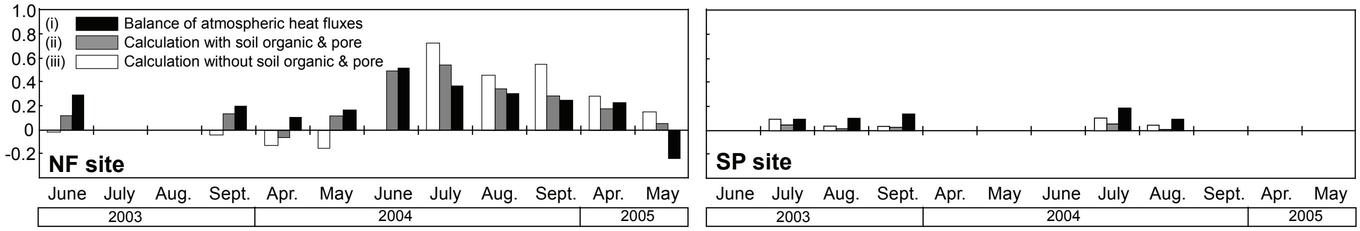

Figure 5. Total soil heat flux transferred into the soil layers (Q_{g-c} up to depth of 1.0m) as expressed in decimal fractions to the net radiation for the northern forested (NF) and southern pasture (SP) sites during the snow-free period (June to September).

increased due to considerable subfreezing to nearly the thawing point in a short period. Similarly, the active layer was warmed in the second snow disappearance period, but this warming was less obvious. Both warming events were probably triggered by pipe-like snowmelt infiltration, which is controlled by snow cover thickness and thus by soil moisture of the near surface soil layer (Beven & Germann 1982, Ishikawa et al. 2006).

Discussion

Figure 5 demonstrates the relative importance of the heat flux components transferred into the upper three soil layers (up to depth of 1.0 m), comparing three calculations: (i) from the balance of atmospheric heat balance components, (ii) without soil organic matter and pores occupied by air (using equations 7 and 8), and (iii) with these parameters (equations 9 and 10). For the NF site, the ratio of soil energy storage to net radiation throughout the period was 22.0%. This value agreed well with that from calculation (iii) (22.1%), but differed with that from calculation (iii) (26.5%). These values approximate the observations at other permafrost sites (e.g., Rouse 1984, Boike et al. 1998, Iwahana et al. 2005, Ishikawa et al. 2006).

For the SP site, the ratio of soil energy storage to net radiation was considerably smaller than that at the NF site, indicating soil heat storage to be a minor contributor. The average value through the period from calculations (i), (ii) and (iii) was 11.5, 5.7 and 2.9%, respectively. We postulate that larger energy difference encountered by calculations (i) and (iii) at the NF site reflect unrealistic parameterization of the soil thermal properties (i.e., thermal conductivity and heat capacity). On the other hand, the difference was not obvious at the SP site where the conventional soil parameterizations without organic and pore effects are probably still accurate.

These findings indicate that energy interaction at the forest site greatly depends on the surface organic-rich layers that prevent the active layer from undergoing further warming during the summer period. Furthermore, this shows the importance of thermal properties of forest soils for preservation and development of the permafrost underlying this slope with well-known forest shading that greatly reduces incoming solar radiation to the ground surface. The pore- and organic-rich forest soil would be fed by fallen leaves and branches from *Larch* trees during autumn. Degrading such soils would accelerate permafrost degradation, even though the forests still shade the ground surface.

Acknowledgments

Local residents and members of the Institute of Hydrology and Meteorology near the observational sites kindly assisted with year-round maintenance of the meteorological instruments. This work was financially supported by the Institute of Observational Research for Global Change, Japan Agency of Marine-Earth Science and Technology.

Developing a Digital Hydrogeological Map of Central Yakutia (The Lena-Aldan Watershed)

L.D. Ivanova
Melnikov Permafrost Institute, SB RAS, Yakutsk, Russia
N.M. Nikitina
Melnikov Permafrost Institute, SB RAS, Yakutsk, Russia

Abstract

A digital hydrogeological map of Central Yakutia is being developed in *ArcView* GIS at scale of 1:1,000,000. This project was initiated in 2005 by the Groundwater Laboratory of Permafrost Institute. To implement the project, a *Microsoft Access* database was created containing information obtained from hydrogeological drill holes and on talik water and subpermafrost water in central Yakutia. The digital map model contains the following main themes: *Hydrogeological Zoning*, *Local Talik Aquifers of the Permeable Zone*, *Subpermafrost Aquifers of the Poorly Permeable Zone*, *Local Talik Aquifers Talik-to-Area Rate, Drill Holes, Possible Use of Groundwater for Drinking Purposes, Water in Intrapermafrost and Open Taliks* and others.

Keywords: aquitard; groundwater; permafrost; subpermafrost; talik; zoning.

Introduction

The Lena-Aldan watershed is situated in the southeastern part of the Yakutian artesian basin, a first-order hydrogeological unit (Tolstikhin 1970). The average thickness of permafrost is 300–400 m, and maximal is 600–800 m. This area contains suprapermafrost and intrapermafrost water in the permeable zone and subpermafrost waters in the poorly permeable zone. Suprapermafrost water of lake and river taliks occurs virtually under all lakes and rivers that are common to abundant in the Lena-Aldan watershed. They yield little water, generally of poor quality. Under the largest lakes and rivers of Lena and Amga, open taliks occur that are hydraulically connected with subpermafrost water. Taliks beneath the Lena River present a stable water supply resource and the water is used for drinking. Intrapermafrost water is found in the fourth fluvial terrace of the Lena River in sand deposits along the surface of the contact with carbonate bedrock. It has good quality and is used for drinking. Subpermafrost water of the Lena-Aldan watershed is sterile, because the permafrost protects it from human contamination. Nevertheless, quality and quantity of water depend on complex litho-tectonic, cryohydrogeologic and hydrodynamic factors. In some cases, subpermafrost water can contain high concentrations of natural occurring chemical elements, which limits its use for drinking.

Classification and analysis of voluminous and diverse data is required in support of groundwater quality management and both municipal and industrial water supply use in Central Yakutia. This task is accomplished by developing a digital groundwater map. The digital hydrogeological map of Central Yakutia, at a scale of 1:1,000,000, is visualized in ArcView GIS for users, and is accessible for editing and updating. Compilation and modeling of geological, hydrogeological and geocryological information have been made by standard methods (Vasiliev et al. 1999, Torgovkin & Fedorov 1999) using the Microsoft Access program and the ArcInfo and ArcView GIS technologies. This map is the first digital groundwater map being developed for a permafrost region.

Methods of Thematic Mapping

During the first phase of the project, a talik and subpermafrost water database was created in *Microsoft Access* compatible with *ArcView* GIS mapping software. The database contains information for more than 200 drill holes. The holes are scattered unevenly over the map area. Most of them are concentrated in major river valleys and lake basins, while the fewest are near watershed divides. The database consists of electronic tables which contain the drill hole identification number and geographic coordinates, hydrogeological unit, lithostratigraphic column, permafrost characteristics, aquifer parameters, and groundwater hydrochemistry.

The next stage was to digitize the Central Yakutia sheet of the Geological Map of Yakutia, 1:500,000 scale (Grinenko et al. 2000) and adjust it to a mapping scale of 1:1,000,000 with generalization of stratigraphic units. The digitized geological contours were used as a raster background for vectorization of thematic layers with consideration of permafrost conditions. Then, statistical processing of data, and analysis and interpretation of general geographical information (descriptive, qualitative and quantitative characteristics, and identification of parameters) were made. This allowed us to integrate the informational resources to the geospatial model and compile the hydrogeological stratification schemes to develop a digital model of the hydrogeological map.

To construct thematic layers of the map, paper maps were first drawn using common mapping methods. Where only sparse data were available, correlation and extrapolation techniques were used (Zarutskaya & Krasilnikova 1988). Then, the layers were scanned and digitized. Numerous and diverse thematic data are referenced in a common spatial coordinate system in the Gauss-Kruger projection (129 central meridian).

Content of the Digital Map

The digital map consists of two components. The Basic component includes several layers: frame, grid, inhabited places, roads and hydrographic features. The Thematic Maps component will have the following layers: *Geological Map, Hydrogeological Zoning, Local Talik Aquifers of the Permeable Zone, Subpermafrost Aquifers of the Poorly Permeable Zone, Local Talik Aquifers Talik-to-Area Rate, Chemistry of Local Talik Aquifers of the Permeable Zone, Chemistry of Subpermafrost Aquifers of the Poorly Permeable Zone, Water in Intrapermafrost and Open Taliks, Drill Holes, Permafrost Thickness Isolines, Possible Use of Local Talik Aquifers of the Permeable Zone*, *Possible Use of Subpermafrost Aquifers of the Poorly Permeable Zone*.

Hydrogeological Zoning layer; the limits of hydrogeological structures of second order correspond to the *Hydrogeological Zoning Map of Russian Federation* scaled 1:2,500,000. In the Lena-Aldan and Lena-Vilyui artesian basins of second order, third and fourth orders of hydrogeological structural units have been identified (Fig. 1 and Table 1), based on our earlier studies (Shepelev et al. 1984, Ivanova & Nikitina 2000).

Local Talik Aquifers of the Permeable Zone layer; aquifers in Cenozoic, Mesozoic, and Paleozoic rocks are mapped in accordance with litho-stratigraphic principle. The aquifer's color in the map corresponds to the stratigraphic subunit color. In case if aquifer is presented by two stratigraphic subunits, two colors are used (Fig. 2)

Subpermafrost Aquifers of the Poorly Permeable Zone layer: maps the first subpermafrost aquifer. The map demonstrates subpermafrost groundwater units in Mesozoic, Paleozoic and Proterozoic formations and the aquitard of Archean metamorphic rock. The color of the aquifer or aquifer unit corresponds to the stratigraphic subunit color.

Local Talik Aquifers' Talik-to-Area Rate layer: the cross-hatching shows the talik-to-area rate value, which is calculated as a percentage ratio of total talik area in a given geomorphological unit to its area, and ranges between 0.5 and 4.0%.

Chemistry of Local Talik Aquifers of the Permeable Zone and *Chemistry of Subpermafrost Aquifers of the Poorly Permeable Zone* layers: background speckle shows the combination of dissolved solids concentration (TDS)

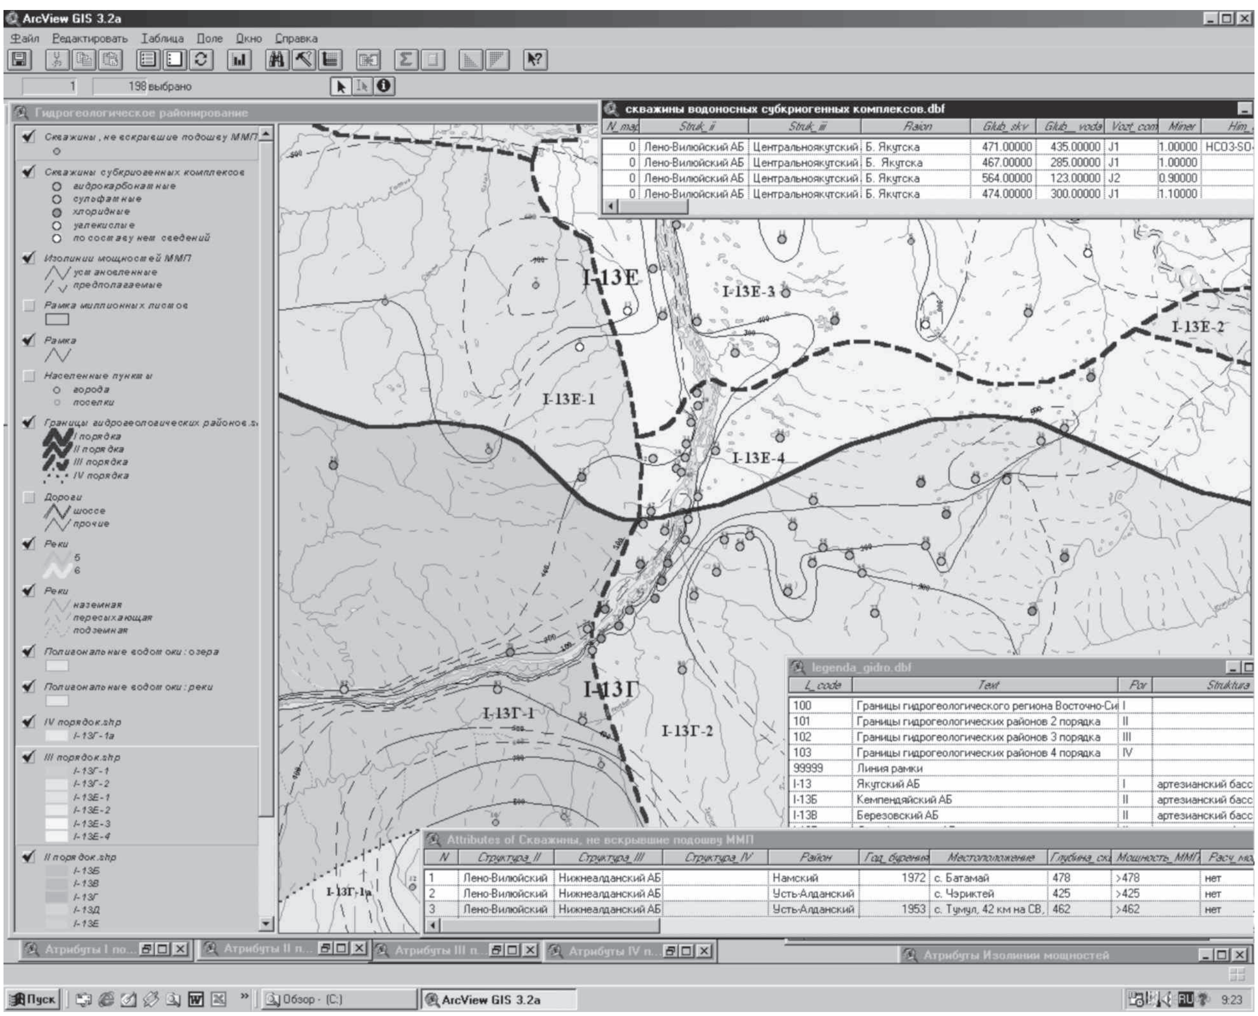

Figure 1. A fragment of *Hydrogeological Zoning* thematic layer combined with *Permafrost Thickness Isolines.*

Table 1. Third- and fourth-order hydrogeological units.

Hydrogeological Unit		Stratigraphic age	Thickness of frozen aquitard, m	Groundwater flow type	Groundwater quality
Lena-Vilyui artesian basin I-13E (I order)	Vilyui artesian basin I-13E-1 (III order)	K	400-600	Tabular-pore and tabular in terrigenous sediments and poorly lithified rocks	Fresh
	Pre-Verkhoyansk artesian basin I-13E-2 (III order)	K_1-J_1	350-450	Tabular and tabular-fissured in terrigenous poorly lithified and fissured rocks	Fresh
	Lower Aldan artesian basin I-13E-3 (III order)	N-K	350-500	Tabular-pore in terrigenous sediments	Fresh
	Central Yakutian artesian basin I-13E-4 (III order)	J, T, Є, A	200-500	Fissure and fissure-vein in terrigeneous in fissured rocks and fissure and fissure-karst in terrigenous-carbonate rocks	Fresh and slightly saline
Lena-Aldan artesian basin I-13Г (I order)	Middle Lena aretesian basin I-13Г-1 (III order)	J, $Є_{1-2}$	310-490	Fissure-tabular and fissure in terrigeneous fissured rocks and fissure-karst in karsted and saline rocks	Fresh and slightly saline
	Buotama-Amga cryogeological basin I-13Г-1a (IV order)	A	600-880	Lithologic aquitard of metamorphic rocks	–
	Lena-Amga artesian basin I-13Г-2 (III order)	J, $Є_{1-2}$	200-500	Fissure-tabular, fissure and fissure-karst in terrigeneous fissured and karsted carbonate rocks	Fresh and slightly saline

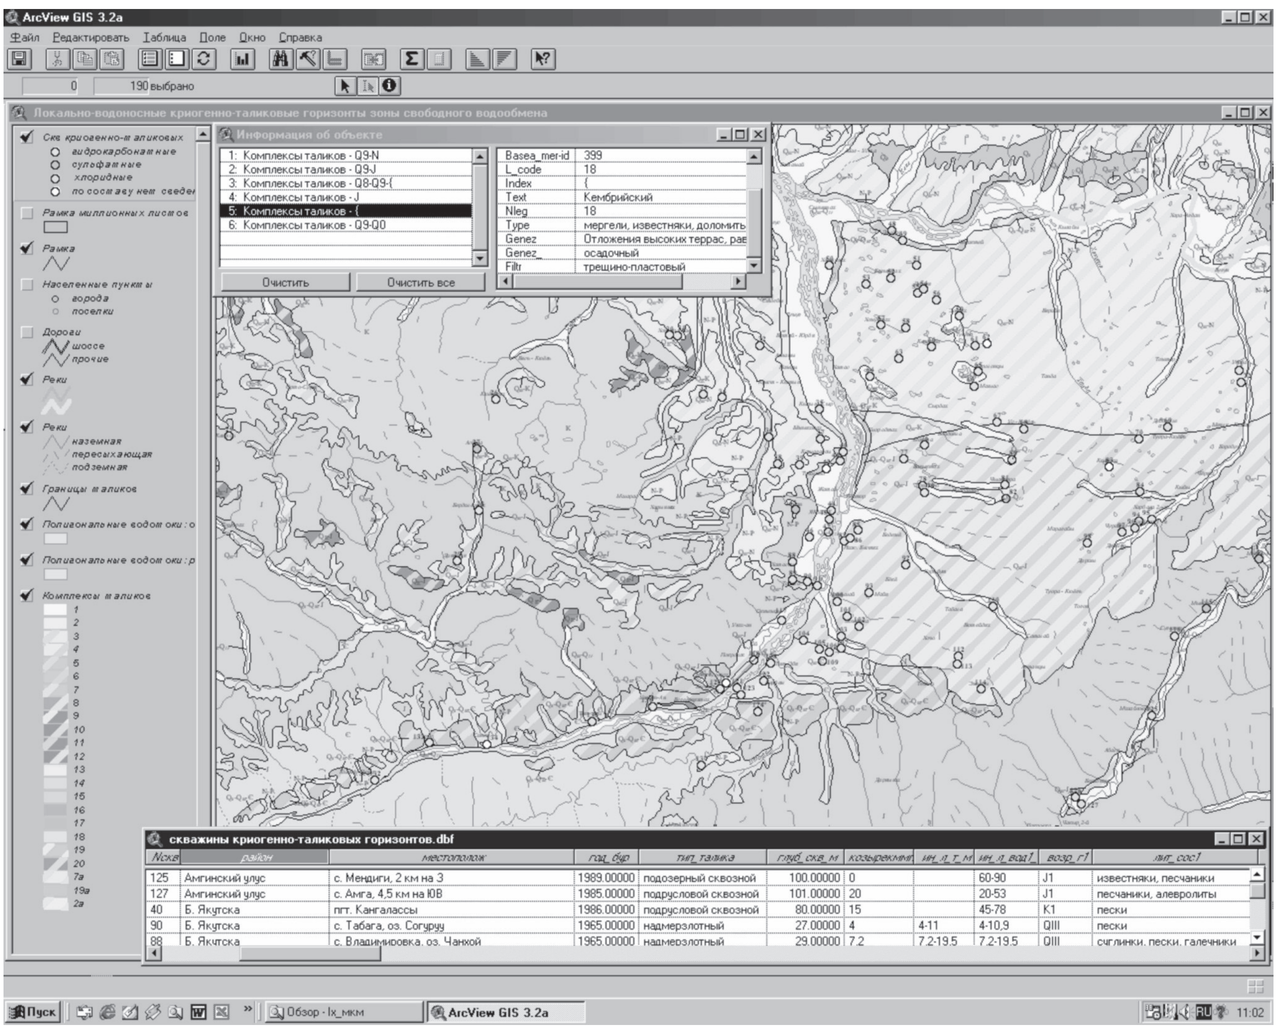

Figure 2. A fragment of *Local Talik Aquifers of the Permeable Zone* thematic layer combined with *Drill Holes* theme.

and anionic composition of underground water in the following gradation (g/dm^3): nearly pure freshwater (up to 0.5), freshwater (0.5–1.0), slightly saline water (1.0–3.0), moderately saline water (3.0–10.0), and very saline water (10.0–50.0).

Water in Intrapermafrost and Open Taliks layer: not-to-scale symbols show intrapermafrost, river and lake open taliks, springs, icings and glades. In *Drill Holes* layer, different symbols show (a) borings through closed talik, open talik and subpermafrost aquifers; and (b) holes that failed to reach the base of permafrost.

Permafrost Depth Isolines layer: shows the depth to the base of permafrost at 100 m intervals. Isolines were constructed based on analysis of measurement data and the well-known method of geographic interpolation.

Possible Use of Local Talik Aquifers of the Permeable Zone and *Possible Use of Subpermafrost Aquifers of the Poorly Permeable Zone* layers: delineate the areas where groundwater quality meets drinking water standards.

Each layer contains an attribute table, which is formed automatically and contains a standard data set. These tables are linked to thematic data in the Microsoft Access database. It is possible to connect attribute tables between the layers, to join the layers, and to add table and raster drawing images to the layer layout.

Conclusions

The digital hydrogeological map will become a more effective tool for accomplishing hydrogeological tasks brought about by groundwater exploration and use in permafrost regions. The map will allow users to change scales without quality loss, abandon the overwhelming integrated maps in favor of interrelated thematic layers in versions that meet their specific purposes, and easily access the data via attribute tables. Information can be stored and added in electronic format and is accessible for analysis and modeling. The digital hydrogeological map will be useful for those involved in water supply, monitoring, conservation, and contamination abatement.

Sensitivity of Permafrost Landscapes to Anthropogenic Impacts in the Northern Verkhoyansk Area, Subarctic Yakutia

Rozaliya N. Ivanova
Melnikov Permafrost Institute SB RAS

Abstract

Three sensitivity levels to human impacts such as deforestation and agricultural practices have been distinguished for permafrost landscapes in the northern Verkhoyansk area situated within the Northern Taiga subzone. Sensitivity of permafrost landscapes is estimated based on cryoindicators such as volumetric ice content, active layer thickness, depth to wedge ice, and thaw subsidence. An essential criterion of permafrost landscape sensitivity is the ground ice: its form, depth, amount, and pattern of distribution in the ground. Sensitivity of landscapes in the northern Verkhoyansk area is the integral characteristic of its geoecological condition.

Keywords: anthropogenic impacts; cryoindicators; geoecological condition; permafrost landscape; sensitivity.

Introduction

The northern Verkhoyansk is a vast northern area that has received little study in terms of permafrost ecology. It is the world's coldest region "called the "cold pole of Eurasia." It has the whole variety of landscapes, ranging from lowland bogs to high mountains, both natural and anthropogenic.

To understand the microclimatic and thermal conditions, as well as the ecological state of natural and anthropogenic permafrost landscapes in the central part of the Yana River valley, monitoring observations on four sites were conducted by the Permafrost Institute during the period of 1989 to 1992. The study area was located in the vicinity of Batagai, at 67°31′N latitude, 134°41′E longitude, 130 m elevation a.s.l. (Ivanova 2003).

Permafrost landscape is defined as a homogeneous natural complex which functions under the influence of cryogenesis, with unique combinations of permafrost characteristics (Fedorov 1991). Permafrost landscape sensitivity is referred to as the degree of its reaction to anthropogenic impacts (Grave 1980).

The geoecological state of permafrost landscapes is deteriorated by disruption of the ground surface, as well as by formation of numerous polygonal structures, thermokarst depressions, cracking of the ground and heaving of peat soils due to anthropogenic factors (frequent fires, damage to the surface vegetation and soil by off-road movement of vehicles, agricultural practices, etc.).

Forest clearing and surface cover disturbances cause strong changes in ice-rich soils. Among the effects are three- to four-fold increase in seasonal thaw depth, melting of wedge ice and development of thaw depressions up to 0.8 m in depth.

Results and Discussion

Three sensitivity levels have been distinguished for permafrost landscapes in the northern Verkhoyansk area situated within the Northern Taiga subzone, based on permafrost landscapes classifications according to terrain sensitivity to anthropogenic impacts and environmental changes (Grave & Melnikov 1989, Fedorov 1991, 1996, Zotova & Tumel 1996, Gavriliev et al. 2001) (Table 1).

The low sensitivity landscapes have low volumetric ice contents (less than 20%). Ice wedges occur below 2.0 m from the ground surface. The thickness of the active layer is 1.0 m or more. The development of adverse cryogenic processes is not expected.

The landscapes of moderate sensitivity have volumetric ice contents of 20% to 40%. The active layer is less than 1.0 m in thickness, surface subsidence is 0.2 to 0.5 m and the top of ice wedges occurs below 1.0 m depth.

The highly sensitive landscapes are characterized by volumetric ice contents of over 40%. Adverse soil and cryogenic processes are present, such as thermokarst depressions 0.5 to 0.8 m in depth, soil disruption and erosion. Ice wedges occur within 1.0 m from the ground surface. The active layer thickness does not exceed 0.5 m.

Moderate sensitive landscapes prevail in the Kumakh site with natural, undisturbed conditions (12 km southwest of Batagai, situated in the intermontane saddle in the Yansk Upland). The site is covered by very wet and swamp meadows and bogs with such growth as *Carex*, *Eriophorum* and *Calamagrostis*. Highly sensitive landscapes occupy some part of the site and include meadows and grass-moss bogs (Fig. 1, Table 2).

Table 1. Cryoindicators for sensitivity estimation of Northern Verkhoyansk permafrost landscapes (the Northern Taiga subzone).

Condition of permafrost landscapes	Volumetric ice content, %	Thickness of active layer, m	Depth to wedge ice, m	Surface subsidence, m
Low sensitive	<20	>1.0	>2.0	<0.2
Moderate sensitive	20-40	0.5-1.0	1.0-2.0	0.2-0.5
Highly sensitive	>40	<0.5	<1.0	>0.5

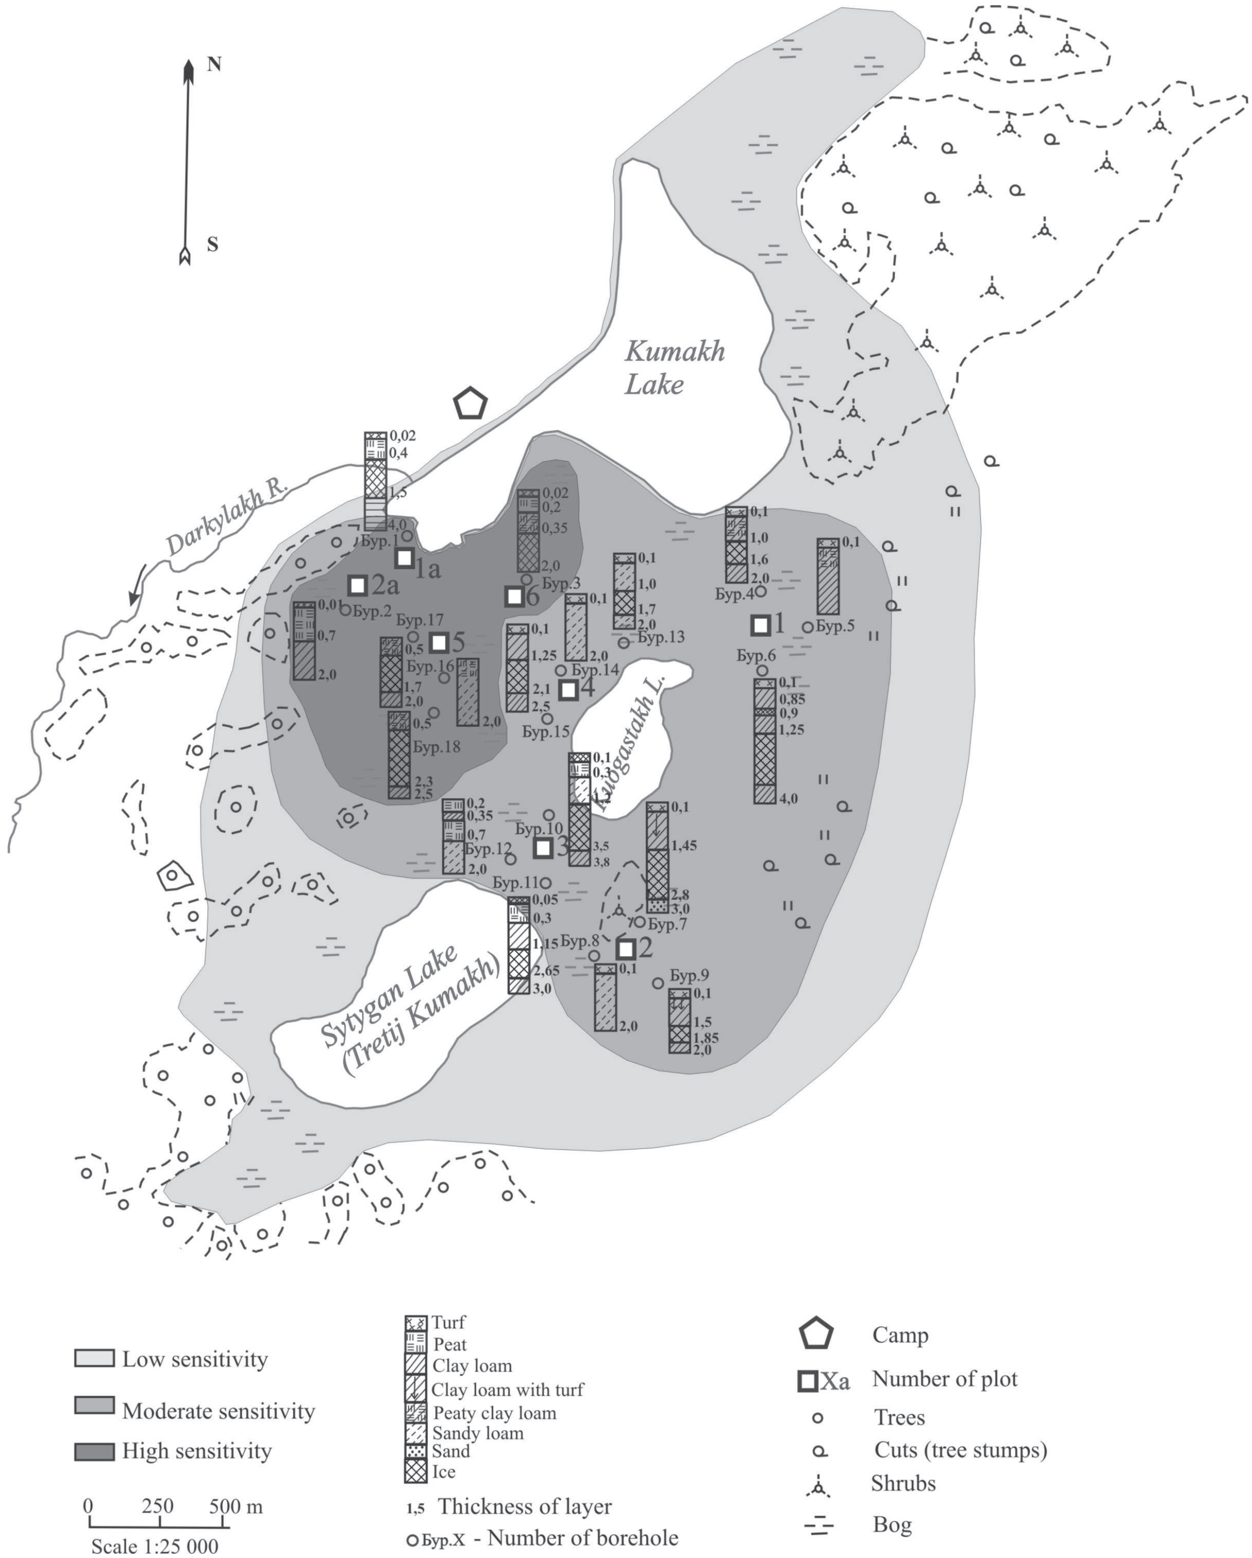

Figure 1. A sensitivity map of meadow landscapes at Kumakh site.

Table 2. Estimation of permafrost landscape sensitivity in Kumakh site.

Plot	Landscape	Volumetric ice content, %	Thickness of active layer, m	Depth to wedge ice, m	Surface subsidence, m	Condition of permafrost landscapes
1	*Carex-Calamagrostis* very wet meadow	>40	0.55	0.85-1.0	0.45	Moderate sensitive
2	*Calamagrostis-Carex* meadow	30	0.65	1.45-1.5	0.35	
3	Waterlogged bog with grass vegetation	>40	0.6	1.15-1.2	0.3	
4	*Carex-Eriophorum* swamp meadow	>40	1.15	1.0-1.25	0.5	
5	Grass-moss bog with low-centered polygons	50-80	0.56	0.5	0.5-0.6	Highly sensitive
6	*Carex-Calamagrostis* swamp meadow	>40	0.55	0.35	0.5-0.7	
1a	*Carex-Calamagrostis* meadow	20-40	0.45	0.4	0.4-0.6	
2a	*Calamagrostis-Carex* flood meadow	20-40	0.46	2.5	0.3-0.6	

The lack of agricultural lands in the Yana River valley causes the clearing of north-taiga forests. We observed agricultural landscapes in the Batymakh and Yuttyakh sites, which are situated on the first terrace of the Yana River. Forest clearing and soil cover disturbance result in intense changes in the soils with high ice content. In the Batymakh site the top 5-10 cm of humus soil was partially removed together with tree roots. Thus the permafrost soils lost 30%-50% of humus reserves that considerably reduced the soil fertility. Ground cover disturbance caused a 3-4 times increase of seasonal thaw depth, from 0.3 to 0.9-1.2 m. Ice content of frozen sandy loams in the site varies from 40% to 60% by volume. The central part of the site is underlain by ice wedges. Here thaw depressions developed up to 0.5 m in depth and 5 m in width. Thus, we can conclude that the top of ice wedges thawed. According to geocryological conditions and sensitivity to anthropogenic impacts, the landscapes in this site are also subdivided to low sensitive, moderate sensitive and highly sensitive categories (Ivanova 2005).

Landscape sensitivity in northern Verkhoyansk area is the integral characteristic of its geoecological condition. The estimation of the sensitivity of permafrost landscape is based mainly on thaw subsidence which directly depends on volumetric ice content of the active layer.

Subsidence is caused by activization of cryogenic phenomena and processes, such as frost cracking in the active layer (width of cracks varies from 0.5 to 6 cm and its depth often penetrates the top of perennially frozen ground); fissured polygons (depth of fissures extends up to 0.5 m); small polygons (depth of cracks extends up to 0.6 m); ice segregation (especially the formation of wedge ice in the top part of permafrost); low-centered polygons and subsidence troughs; block polygons (normally from tens of centimeters to 4-6 m; and occasionally 8-12 m in diameter).

Conclusion

Present-day climatic variations and anthropogenic impacts (tree removal, surface disturbance, ploughing, etc.) add to the effect of cryogenesis on the adverse processes that disturb and modify the landscapes, as well as on the reduction of ecological and economic values of the landscapes in northern Verkhoyansk.

Terrain zoning according to permafrost landscape sensitivity is essential for geoecological monitoring at a local level. It can provide useful contributions to cryoecological databases, as well as help develop environmental protection standards for subarctic regions.

Abstract

We commenced micrometeorological measurements in the Daisetsu Mountains, Hokkaido, Japan, including the monitoring of thermal and hydrological conditions in the ground down to 5 m depth, in July 2005. The temperature conditions at the site were as cold as those within a continuous permafrost zone. Persistent, driving westerly winds prevent snow from accumulating on the mountain permafrost site. The depth of the permafrost base was deeper than 5 m. Relative humidity was high, with large amounts of summertime precipitation (~ 700–1000 mm). It is likely that the soil water condition in the active layer is kept high or nearly saturated during the thawing season due to frequent rainfall and the existence of permafrost. The observed and future long-term data are expected to be used to model the ground thermal and hydrological processes and thereby lead to a better understanding of the relation between permafrost and vegetation ecology.

Keywords: active layer; Japan; micrometeorology; mountain permafrost.

Introduction

The occurrence of perennially frozen ground in Japan has been studied by numerous researchers, as summarized by Ishikawa et al. (2003), who categorized the distribution of mountain permafrost in Japan into three groups in terms of geographic location. Mountaintop permafrost occurs in certain summit areas where the mean annual temperature is sufficiently low to allow the occurrence of permafrost. Such areas commonly have little snow cover because of strong winds. Mountainside permafrost occurs mainly on slopes or depressions such as deglaciated cirques in the Japanese Alps (e.g., Fukui 2003). Extra-zonal permafrost occurs upon certain block slopes at low altitudes, where the mean annual air temperature is considerably above 0°C (e.g., Sawada et al. 2003). The mountain permafrost in the Daisetsu Mountains of Hokkaido, Japan is categorized as mountaintop permafrost and is considered to be highly sensitive to global warming because air temperature has a direct control on the ground thermal regime of mountaintop permafrost (Ishikawa et al. 2003), and because the site is located near the southern limit of permafrost occurrence in the Northern Hemisphere (Fig. 1).

Mountain permafrost within the Daisetsu Mountains is

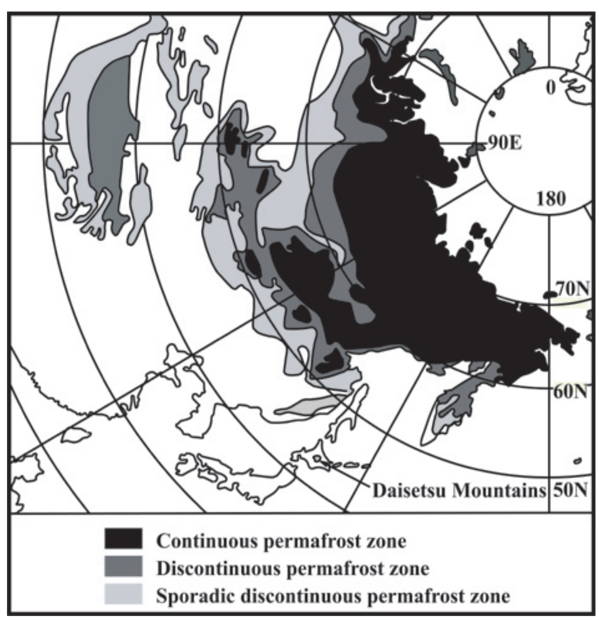

Figure 1. Location of the Daisetsu Mountains. Modified from Harris (1986).

distributed in a complex manner over a large area at altitudes above approximately 1700 m above sea level (a.s.l.). The occurrence of permafrost in this area has been examined by borehole and geophysical testing, as well as the BTS (bottom temperature of snow cover) measurements (e.g., Fukuda & Kinosita 1974, Sone et al. 1988, Ishikawa & Hirakawa 2000). Numerous periglacial features, including patterned ground (e.g., Koaze 1965, Sone & Takahashi 1986, Fukuda & Sone 1992) and palsa bog (e.g., Takahashi & Sone 1988, Sone 2002) have been studied in the Daisetsu Mountains, suggesting the extensive occurrence of perennially frozen ground; however, long-term variations in permafrost temperature have yet to be reported, and the extent of permafrost remains unclear.

Global climate change could alter the physical factors that control the surface energy and water balance, such as air temperature, precipitation, vegetation, radiation, and wind conditions. Such changes could in turn affect the thermal and hydrological regime of the active layer and underlying permafrost. Koizumi & Shinsho (1983) reported a correlation between vegetation distribution and level of ground water table, which is determined by the depth of the permafrost table, in the mountaintop permafrost area of the Daisetsu Mountains. Kudo (1990) noted the importance of soil temperature as a control of vegetation distribution in the southern part of these mountains.

We initiated micrometeorological measurements with the aim of understanding the physical processes controlling the surface energy and water balance in the mountaintop permafrost area of the Daisetsu Mountains. Similar micrometeorological studies have been conducted in many cold regions (Eugster et al. 2000), although the summit areas of mountains have rarely been targeted. The observed data will be used to model the ground thermal and hydrological processes and thereby lead to a better understanding of the relation between permafrost occurrence and vegetation ecology. The data provide fundamental information for process-based modeling of mountain permafrost distribution. Basic meteorological measurements and geophysical surveys of mountain permafrost have been performed in this range over the past 30 years; however, the available information remains insufficient in terms of discussing environmental controls on the occurrence and temporal variation of mountain permafrost.

This paper describes micrometeorological characteristics, including the current thermal and hydrological status of the active layer and upper permafrost, of a site at which a 4 m tower equipped with micrometeorological instruments was installed at a representative point in the area of mountain permafrost in July 2005.

Study Site

The Daisetsu Mountains (43°N, 142°E) are located in central Hokkaido, northern Japan (Fig. 1). The current morphology of the mountains formed during early to middle Quaternary volcanic activity that saw the eruption of andesite lavas. The lava flows formed plateaus at 1700 to 2000 m a.s.l. during early to middle Quaternary, followed by the formation of various volcanic cones. The highest peak in the area is Mt. Asahi (2290 m a.s.l.); the timberline occurs at about 1600 m a.s.l.

An automatic micrometeorological observation system is installed about 400 m northeast of the peak of Mt. Goshiki (Fig. 2) at 2015 m a.s.l. The plateau atop of Mt. Goshiki is relatively flat and is one of the most suitable places in the area for micrometeorological measurements, with a 300–

Figure 2. Summertime view of the study site looking toward the west. The peak in the background is Mt. Hakuun.

400 m fetch in the direction of the prevailing wind. About half of the plateau is covered by patchy vegetation colonies (Fig. 2) of *Diapensia Lapponica* var. *oboata*, *Loiseleuria procumbens, Oxytropis japonica* Maxim. var. *sericea* Koidz, lichens, etc. The heights of the colonies are 20–50 mm. Areas of bare ground reveal volcanic pebble conglomerate (clasts of ~5–20 mm in diameter).

Methods

The data used in this paper were obtained between 2 July 2005 and 14 October 2006. Data losses of several hours were linearly interpolated. Long-term data loss due to instrumental malfunction occurred over periods ranging from several days to months.

Four-component radiation (shortwave incoming radiation Si, shortwave outgoing radiation So, longwave incoming radiation Li, and longwave outgoing radiation Lo) was measured, and net radiation Rn was calculated as $Rn = Si + Li - So - Lo$. Ground heat flux at the soil surface was measured using a heat flux plate installed at a depth of 10 mm. Surface albedo α was calculated every 30 minutes as $\alpha = So/Si$, taking the minimum values from 10:00 to 14:30 (during which time α values were almost constant) to obtain a daily representative midday value. Those values which were thought to be influenced by the accumulation of snow on the upper sensor were removed from the dataset. Air temperature and relative humidity were measured using Pt100 sensors and a capacitance probe, respectively. Rainfall was measured using a tipping bucket rain gauge with a resolution of 0.1 mm. Wind speed and direction were measured using a propeller-type anemometer. These instruments were installed upon a 4 m tripod.

Soil temperature was measured using thermistor probes (104ET; Ishizuka Denshi, Japan) calibrated in an ice-water bath with a precision of 0.02°C and an overall accuracy of less than ± 0.09°C in the temperature range between –20 and 30°C. Measurements were taken at depths of 0.01, 0.05, 0.10, 0.20, 0.30, 0.50, 0.70, 0.90, 1.10, 1.30, 1.50, 1.70, 1.90, 3.00, 4.00, and 5.00 m. Volumetric soil water content was estimated using FDR (Frequency Domain Reflectometry) sensors at depths of 0.10, 0.20, 0.30, 0.40, 0.60, 0.80, 1.00, and 1.20 m.

The model numbers, manufacturer details, heights of measurements, and recording intervals for all meteorological instruments used in this study are summarized in Table 1. Data were recorded using a data logger (CR10X; Campbell Scientific Inc., USA) with a multiplexer (AM16/32; Campbell Scientific Inc., USA). Soil moisture data were measured every 6 hours and recorded; other parameters were measured every 10 seconds, with 30-minute averages being recorded.

Results and Discussion

Air temperature and humidity

Air temperature and relative humidity were measured from July 2005 to October 2006. Figure 3 (upper) shows the seasonal monthly mean, maximum, and minimum air temperature. The mean annual air temperature from October 2005 to September 2006 was -4.6°C. The maximum values of 18.5°C and 17.8°C were observed in August 2005 and August 2006, respectively; the highest daily minimum values of 3.6°C and 6.2°C were observed in the same months, and the minimum air temperature of -27.4°C was recorded in January 2006. The degree of daily variation in air temperature was small in mid-summer and large in winter. For the period from October 2005 to October 2006, the freezing and thawing indexes were 2727 and 1050 degree days, respectively.

Relative humidity was very high. Figure 3 (lower) shows seasonal changes in monthly mean, maximum, and minimum relative humidity. The maximum daily values of relative humidity were 100% on every day of the observation period, meaning that the atmosphere close to the ground was at the dew point especially at night. Daily variations in relative humidity were relatively minor (less than 15%) from mid-November to mid-February, but large (up to 95%) during other periods. The relative humidity fell below 20% only during the daytime on fine days during the snow-free period. Values fluctuated close to the saturation point after every rainfall event.

Largely continuous monitoring of air temperature was undertaken at Hakuun hut (2000 m a.s.l.; ~2 km south of the study site) from 1985 to 1993 (Sone et al. 1988, Tachibana et al. 1991, Nakayama & Sone 1992, Sone & Nakayama 1992, Sone 1994). The mean annual air temperatures in 1985, 1987, and 1988 were -3.8°C, -4.9°C, and -5.2°C, respectively. According to the diagram of Harris (1981), if snow barely covers the ground surface in winter, our study area is characterized as a continuous or discontinuous permafrost zone (Sone 1992). Our temperature measurements also support his conclusion.

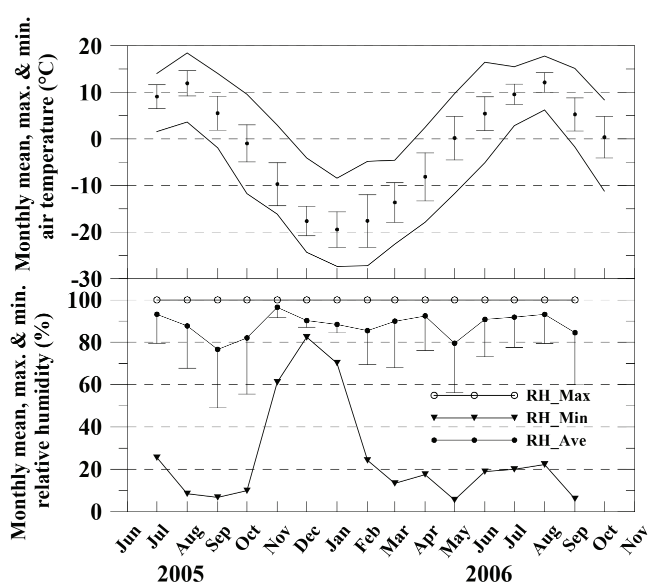

Figure 3. Seasonal changes in monthly mean, maximum, and minimum air temperature (upper) and relative humidity RH (lower). Error bars indicate standard deviations.

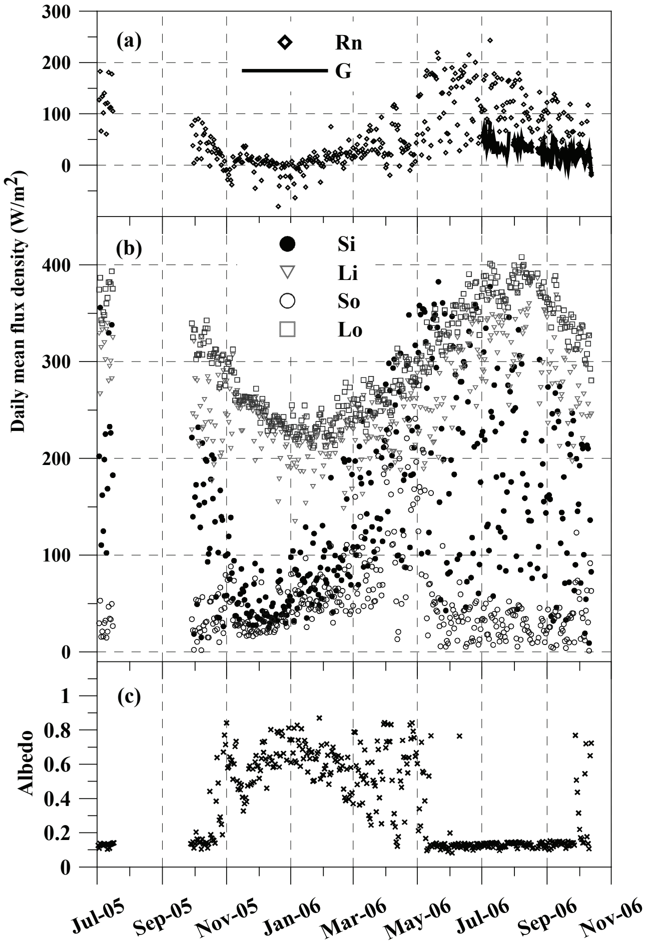

Figure 4. (a) Seasonal changes in daily mean net radiation Rn and daily mean ground heat flux G. (b) Seasonal changes in daily mean values of radiation components (shortwave incoming radiation Si, shortwave outgoing radiation So, longwave incoming radiation Li, and longwave outgoing radiation Lo). (c) Seasonal changes in daily representative albedo (calculated over the period 10:00–14:30).

Radiation environment and ground heat flux

Daily mean Rn values were close to or below 0 W/m^2 in winter and above 200 W/m^2 in early summer (Fig. 4a). These values were strongly dependent on the weather, fluctuating between 50 and 220 W/m^2 during summer. Measurements of ground heat flux were initiated in July 2006. The daily mean value was around 50 W/m^2 during July 2006, decreasing gradually to 0 W/m^2 during the middle of October 2006 (Fig. 4a). The large fluctuations in daily net radiation values were accompanied by similar fluctuations (of 20%–50%) in the ratio of ground heat flux G to Rn (G/Rn). The obtained range in the ratio G/Rn is similar to that reported in some tundra regions, and much higher than that in boreal forests (Eugster et al. 2000).

On fine days from May to July 2006, the maximum values of 30-minute mean Si were about 1100 W/m^2, and Rn was calculated to be about 750 W/m^2 (data not shown). The daily maximum Si and Rn decreased, respectively, to about 200 and 100 W/m^2 on days of bad weather. Si values near the upper envelope were measured on fine days. The recording of Si values lower than those on fine days indicates a large number of days with cloudy or stormy weather (Fig. 4b).

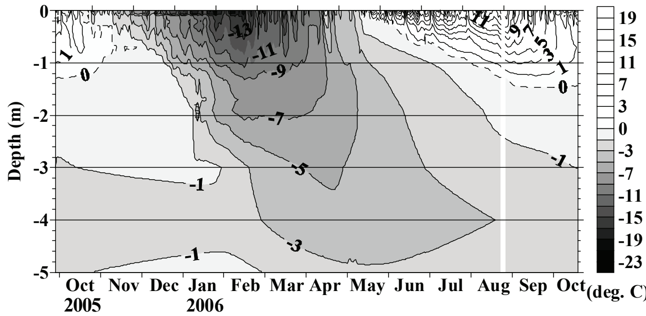

Figure 5. Seasonal variations in the soil temperature profile to a depth of 5 m at the study site from October 2005 to October 2006. Solid isotherms are drawn with increments of 2°C; the dashed line indicates the 0°C isotherm.

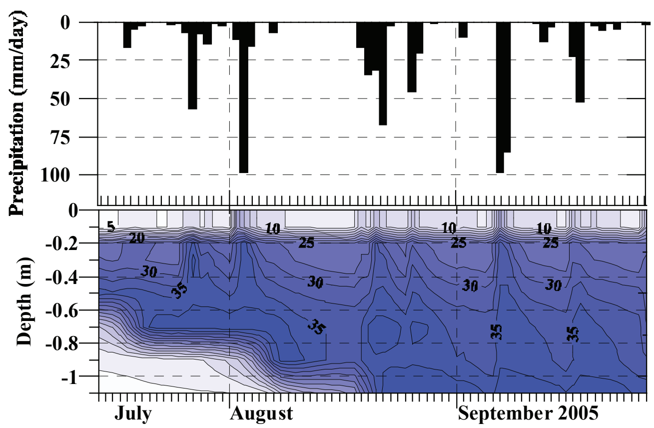

Figure 6. Seasonal changes in daily precipitation (upper) and profile of the volumetric soil water content in the liquid phase (lower; values are given in %).

Albedo values were relatively stable (0.08–0.15) in summer but showed large variations in winter related to snow coverage (Fig. 4c).

Wind direction and speed

Wind data are limited to the period between July and November 2005 because of sensor malfunction during other periods. Two predominant wind directions were recorded: strong westerly winds and relatively weak south-westerly winds. About 30% of the westerly wind velocities (30-minute averages) were in the range of 10–20 m/s, 40% in the range of 5–10 m/s. The equivalent percentages for the south-westerly wind were about 10 and 40%, respectively. The winds during other periods were of lower velocities. Persistent, strong westerly to south-westerly winds were also reported by Sone (unpubl.), who described strong winds from October to April. It has been observed that most of the summit plateaus in the Daisetsu Mountains have little snow cover because of persistent westerly driving winds (Takahashi & Sato 1994).

Ground temperature and water conditions

The ground began to freeze from the surface at the beginning of October 2005 and from the permafrost upward in the middle of the same month (Fig. 5). The entire active layer fell below 0°C in November, reaching -9°C in February. Thawing of the frozen ground commenced in the middle of May 2006. The thaw front developed at an almost constant average rate of 12.2 mm/day until the end of August. A freezeback from the deeper layer was also observed, induced by prolonged cold weather at the end of June.

The active layer thickness was 1.28 m and 1.46 m in 2005 and 2006, respectively, and the depth of the permafrost base was greater than 5 m. The permafrost temperature at a depth of 4 m fluctuated between -1.70°C and -4.84°C during the observation period.

Large amounts of summertime precipitation were recorded at the study site. The 4-month cumulative rainfall amounts from June to September were 813 mm in 2005 and 693 mm in 2006. Sone (unpubl.) measured 4-month rainfall amounts of 929 mm in 1995 and 976 mm in 1996 at a point located about 1 km west of our study site. Soil water content was close to saturated throughout 2005, and variations in soil water showed a strong correlation with rainfall events (Fig. 6). The values of soil moisture presented in this paper were calculated using default calibration curves for sandy soil; however, *in situ* calibration is required for a more accurate discussion of the absolute amount of soil moisture in the active layer.

Although we did not obtain data on evapotranspiration and runoff ET + R at the study site (with regard to discussing the water budget), we roughly estimated ET + R by differentiation of the water balance equation P = dS + ET +R. P and dS are precipitation and change in the amount of soil water storage in a certain period, respectively. The value of dS in the active layer from 15 July to 27 September 2005 was determined from the measured profiles of soil water content (40 mm). The values of P and ET + R in the same period were 770 and 810 mm, respectively. A relatively minor change in soil water storage was observed; almost all of the precipitation water that fell during this period was likely to have been lost to evapotranspiration or discharged laterally. Rapid changes in soil moisture within the deeper active layer indicate the high permeability of the soil (Fig. 6). It is likely that the soil water condition in the active layer at the site was kept high or near-saturated during the thawing season because of frequent rainfall and the existence of permafrost. However, rapid changes in soil moisture throughout the active layer probably reflect the high permeability of the volcanic soil. A degree of lateral runoff may also have occurred, strongly influencing the hydrological regime of the active layer.

Changes in surface conditions

Albedo depends on surface conditions such as snow coverage, soil moisture at the surface, and vegetation phenology. Snowfall began in October 2005 and continued until May of the following year (Fig. 4c). Two snowfall events probably even occurred during June of 2006. Considering that the albedo of fresh snow is 0.75–0.95 (Campbell & Norman 1998), the fact that the measured values were often below 0.7 indicates only partial snow coverage on most days in winter. The large variations in daily mean albedo during winter indicate repeated cycles of snow cover followed by the snow being blown away or sublimated. The observed variations in minimum wintertime albedo values indicate that snow coverage on the ground was highest from the end of December to the beginning of January; most of the accumulated snow had disappeared by the end of February. However, the December–February snow coverage must be confirmed by an alternative method, as the albedo of old snow can be 0.4–0.7 (Campbell & Norman 1998). The summertime albedo showed minor fluctuations (0.08–0.15) relative to those in winter. The summertime day-to-day variations in albedo reflect the moisture conditions of the surface soil: moist soil is darker, with a lower albedo. The albedo values during the snow-free period showed a gradual increase (by about 0.02 on average), together with day-to-day variations. The seasonal change in albedo can likely be attributed to the phenology of surface vegetation. It should be noted that albedo values also depend on the zenith angle and cloud cover (Goodin & Isard 1989); these factors must be considered in further discussions.

Surface temperature

Ground surface temperature was obtained using a directly installed thermistor sensor (Tsurf) at a depth of 10 mm and the Lo values from the radiometer (Trad). Trad is calculated using the Stefan–Boltzmann equation with an emissivity of 0.98. The maximum Tsurf was 33.1°C, recorded in June 2006; the maximum daily range in Tsurf (35.3°C) was observed on the same day. The daily range in Tsurf during mid-summer is about twice that in Ta, and monthly averaged Tsurf is 1.1°C –6.0°C higher than Ta. Trad values agreed well with Ta values for the snow-covered period. Trad in summer showed similarly large daily variations to those for Tsurf, but maximum values of Trad showed an increasing trend during mid-summer. Large differences between Ta and ground surface temperature were found in both winter and summer.

Perspectives

State-of-the-art automatic micrometeorological instruments are able to precisely monitor physical conditions in severe mountaintop areas, where measurements are rarely conducted. We commenced micrometeorological measurements, including the monitoring of thermal and hydrological conditions in the ground down to 5 m depth, with the intention of characterizing the features of the surface energy and hydrological balance at a mountaintop permafrost site in Japan. The information will be used to simulate future changes in the environment.

The newly obtained data support the conclusions proposed in previous studies of wind, rainfall, and air temperature undertaken by other Japanese scientists in areas of mountain permafrost. In addition, we recorded the year-round thermal regime of the active layer and the upper layer of permafrost. We also present, for the first time, continuous and simultaneous measurements of the profile of volumetric water content in the active layer, surface radiation, and air moisture condition at a Japanese mountaintop site. These data will be a base of future long-term monitoring of mountain permafrost and its environment. Additional measurements are required to determine the characteristics of surface energy and hydrological balance at the site.

Abstract

The ongoing site characterization of spilled petroleum hydrocarbon at the abandoned Colomac gold mine site in a discontinuous permafrost region shows variable distribution of accumulated light non-aqueous phase liquid (LNAPL) in the monitoring wells across the site and over time. The site is adjacent to a lake and has between 0 to 4.6 m of overburden soil underlain by fractured greywacke. Different mechanisms, including groundwater fluctuation and thermal regime, have been proposed to account for spatial and temporal variation of the LNAPL at the site. The measured LNAPL showed increased thickness in the winter period. Multiple linear regression was used to correlate the accumulated LNAPL in one of the most yielding monitoring wells with temperature data from a dedicated thermistor-borehole and measured groundwater elevation. The accumulated LNAPL showed significant correlation with both the temperature data and the groundwater water elevation at the site.

Keywords: freeze; LNAPL; migration; mine; permafrost.

Introduction

Discovery of valuable minerals in the Northwest Territory (NWT) in Canada has led to increased mining activities. The adverse environmental impacts of the mining operations during and after closure are a widespread problem, which has received major attention recently. Many of the mining sites used are located in remote areas where a large percentage of the operating cost is due to logistics of moving and maintaining personnel and materials at the site. To offset some of the logistic issues in transporting petroleum fuel as the main energy source to the site and smooth operation of the mine, large volumes of fuel are stored in tanks on site. The designated area of the site where several fuel storage tanks are located is called the *tank farm*. Accidental fuel spillage during transportation or leakage of the fuel tanks in the tank farm area is a looming problem, which is complicated by the presence of permafrost.

To this effect, various studies have been conducted to understand the behavior of spilled fuel in frozen and freezing environment. Permafrost has been shown to be an effective barrier to water flow but not a barrier to the flow of petroleum hydrocarbons (Biggar et al. 1998, McCarthy et al. 2003). Studies conducted with petroleum hydrocarbon (PHC) contaminated soils in freezing conditions showed that the concept of LNAPL exclusion forward of freezing front is applicable (Konrad & Seto 1991, Tumeo & Davidson 1993, Biggar & Neufield 1996, Chuvilin 1999, Barnes et al. 2004). In addition to the concept of LNAPL exclusion, Barnes et al (2004) stipulated physical displacement of the mobile phase PHC from the pore spaces as water expands on freezing. Chuvilin et al (2001a) showed that spreading and transportation of oil in regions of frozen ground is dependent on oil composition, soil temperature, and type of mineral surface.

Literature on migration of spilled fuel within fractured bedrock in a permafrost environment is limited. Iwakun & Biggar (2007) suggested that a lower groundwater table in the winter period may enhance drainage of mobile free phase PHC as light non-aqueous phase liquid (LNAPL) from the overburden soil and fractured bedrock surface at Colomac mine. However, in this study, the measured petroleum LNAPL thickness was correlated with the measured ground temperature to understand the influence of thermal fluctuation on LNAPL migration at the site.

Site Background

Colomac mine was an open-pit gold mine located in a discontinuous permafrost region approximately 220 km northwest of Yellowknife in the Northwest Territories. It operated between 1990 and 1997. When it became uneconomical to operate the mine site, it was closed and abandoned in 1999. It is now the responsibility of the Contaminated Site Office (CSO) of Indian and Northern Affairs Canada (INAC) to remediate the site. The site is underlain by fractured bedrock identified as greywacke, and has between 0 to 4.6 m overburden soil made up of sands and gravel. There are different aspects of the site under remediation but this paper will focus on the tank farm area where fuel spillage occurred.

Between 1990 and 2003, over 24 spills of diesel and gasoline around the tank farm were reported at the site (Fig. 1). Of these spills, two were significant. These include 18,000

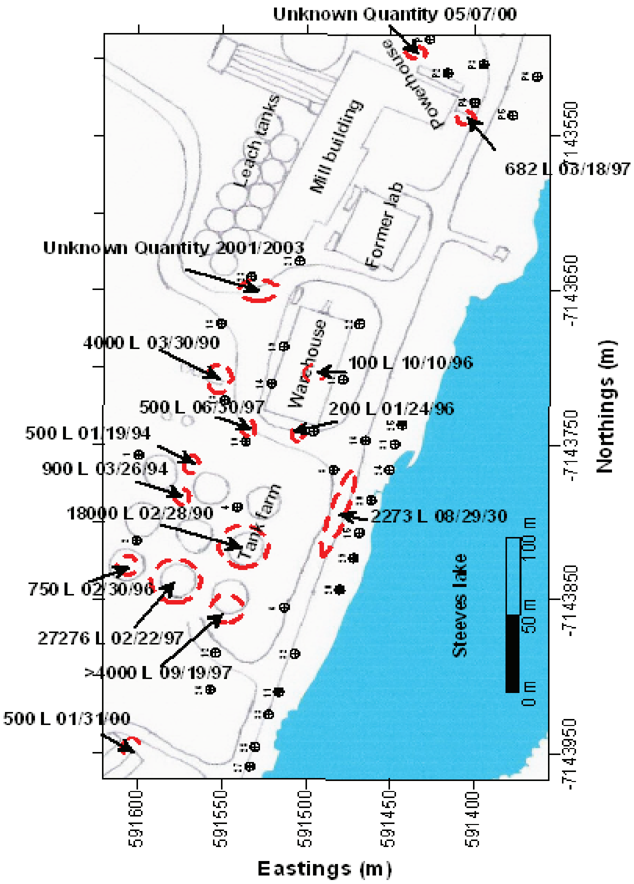

Figure 1. Summary of historical spillage at Colomac mine.

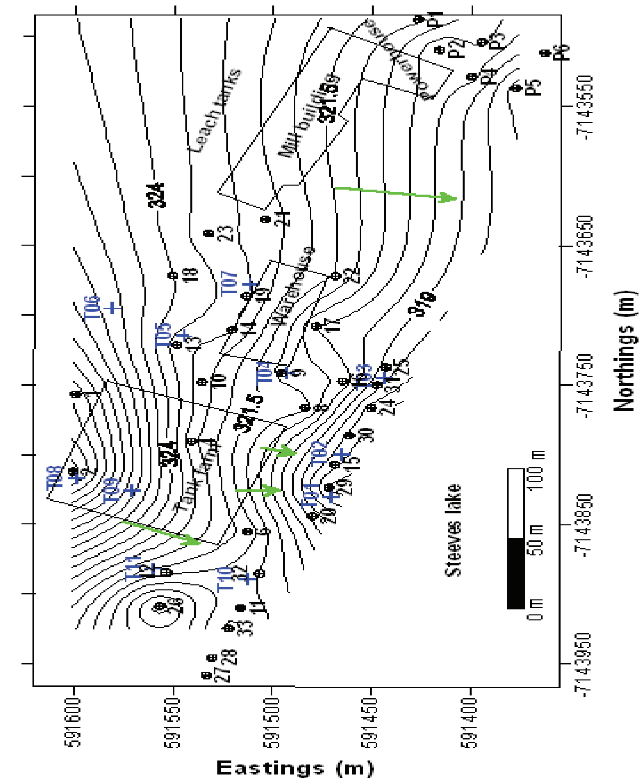

Figure 2. Water table contour for August 2006 showing spatial location of installed monitoring wells and thermistors strings. (Note: thermistor strings are preceeded with T.)

L and 27,276 L in February of 1990 and 1997, respectively, as a result of leakage of one of the fuel storage tanks. After these spills, some measures were taken to curb migration of PHC to Steeves Lake adjacent to the site. These include:

- Installation of 5 m deep interceptor trench lined with corrugated pipe at the west berm of the tank farm in late 1990.
- Placement of skirted boom with absorbent pad along the Shore of Steeves Lake when PHC sheen was observed in late 1990/1991.
- Detailed site characterization and installation of monitoring wells across the site in 2000, shown in Figure 2.
- Replacement of interceptor trench with a frozen soil barrier in 2004 to contain down-gradient migration of mobile phase PHC.
- Removal and biopile treatment of overburden soil at the tank farm area in 2005.

Details of these measures were discussed by Iwakun & Biggar (2007). However, in spite of these measures, petroleum LNAPL is still being observed in some of the monitoring wells across the site. Sheen of PHC at the shore of the lake is also being observed in the summer. Limited effectiveness of these measures shows that knowledge of subsurface behavior of spilled fuel at the site is inadequate. Thus, to improve this understanding, further site investigation was initiated by the University of Alberta Geotechnical Centre and Environment Canada in June 2005.

Site Investigation

Subsurface investigation at this site includes periodic monitoring of depths to petroleum LNAPL, water, and bottom/ice in the wells; thermistor cable installation and thermal profiling; groundwater sampling; hydraulic testing; borehole imaging; rotary coring; and product recovery. These activities have been discussed by Iwakun & Biggar (2007) and Iwakun et al. (2007). However, for completeness of this paper, summaries of pertinent activities and major findings will be given in this paper with particular emphasis on thermistor installation and monitoring of depths to petroleum LNAPL and water.

Depths to product and water

An interface probe was used to measure the depths to petroleum LNAPL, water, and well-bottom. When the measured depth to well-bottom was less than the known depth of the well, ice was inferred at that depth. A summary plot of some of the measurements is shown in Figure 3. The apparent groundwater flow pattern in the summer was inferred from the interpreted isopleths of the groundwater elevation as shown in Figure 2. However, it should be noted that the actual flow pattern may be substantially different from that presented because the fracture networks control the flow direction. In the winter period, apparent flow patterns cannot be inferred because of different thermal distribution at the site as discussed in the subsequent section. Elevated groundwater was noticed in the spring but gradually declined

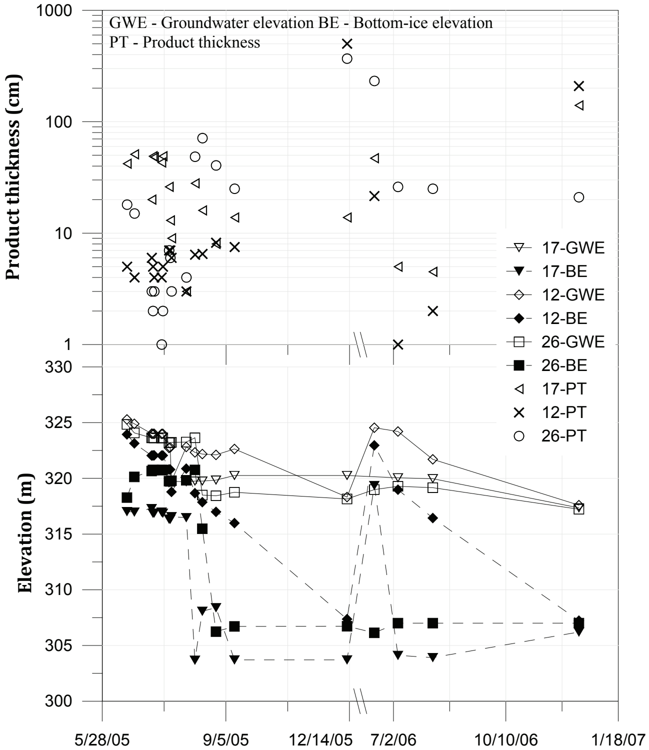

Figure 3. Well-probe data in selected monitoring wells at the site.

as winter approached before freezing.

It was also observed that in early spring, some of the wells were not thawed to well-bottom resulting in an artificial increase in groundwater elevation due to a perched groundwater condition. Thus, at this site, a suprapermafrost water table condition existed from early spring through the summer period. As winter approached, an intrapermafrost water table condition existed across the site except at the warehouse area where the thermal regime was influenced by heat from a generator in the southwest corner of the warehouse building. Due to nearness of the site to the lake, the intrapermafrost water condition may also be influenced by the unfrozen thaw bulb (i.e. talik) adjacent to and beneath the lake.

Ground temperature profiling

To understand the influence of the thermal regime on contaminant distribution, Solinst level loggers, baraloggers, and thermistor strings were initially installed in some of the wells to corroborate the monitored depths to water and bottom-ice at the site between June 2005 to April 2006. Between April and June 2006, new boreholes with dedicated thermistor strings were installed across the site as shown in Figure 2. Each thermistor string consists of eight sensors at specific depths with battery operated datalogger. The boreholes were backfilled with bentonite pellets and water after installation of thermistor string. Sensitivity of the thermistor strings were tested in the laboratory and found to be within ±0.2°C of actual melting point of ice at 0°C.

Summary of other pertinent activities

Some of the wells were hydraulically tested using a packer assembly at discrete intervals in the summer of 2005 and 2006. The results showed higher transmissivity (in the range of 10^{-3} to 10^{-6} m^2/s) within the upper 7 m of the bedrock. At depth, the bedrock has very low transmissivity (in the order of 10^{-9} m^2/s). Rotary bedrock coring at the site corroborates this inference. The fractured upper section of the bedrock appears localized because the transmissivity varied from one well to the other. Borehole imaging using a Well-Vu camera showed what looks like near vertical and horizontal fractures with depth. However, due to drilling method of most of the wells (i.e. percussion hammer drilling), it is difficult to correlate fracture width from post image analysis to that of the hydraulic test. Fissures observed may be due to well-bore scaring during installation. With borehole imaging, zones with marked discoloration were noticed in the upper section of the bedrock but no pooled free phase PHC was observed at the bottom of the wells.

Methodology

From the activities stated above, the observed apparent LNAPL thickness in the monitoring wells (MW) showed that MWs 12, 26, and 17 are the highest yielding wells at the site. Of these, MW 12 and 26 are very close (Fig. 2) but MW 12 is closer to the installed thermistor string. MW 17 is close to the warehouse and its thermal profile may be influenced by the heat generated southwest of the warehouse building. Thus, the measured apparent LNAPL thickness of MW 12 and its thermal profile are used for this study.

The measured thermal profile close to MW 12 and 26 is shown in Figure 4. This thermal profile was used for a simple statistical test with the measured apparent LNAPL thickness using multiple linear regression. Since the measured apparent LNAPL also varies with groundwater elevation as shown in Figure 3, a multiple linear regression test with both temperature and groundwater elevation as independent variables was also undertaken. For this study, the temperature value used for the regression analysis was determined by averaging the temperature value in the upper 7 m of the subsurface. This decision was made because other tests conducted at the site including hydraulic tests, bedrock coring, and borehole imaging, showed that the upper section of the bedrock is highly fractured.

The implication of this is that the apparent petroleum LNAPL in the monitoring wells is assumed to come from the overburden soil and fractured upper section of the bedrock.

Multiple linear regression

This method of analysis was chosen because of perceived dependency of the measured apparent LNAPL in the wells on temperature and groundwater elevation.

Multiple regression demonstrates the consequence of one independent variable with the other independent variable kept constant. The regression coefficients of the variables are calculated using the equation below:

$$\Sigma X_1 Y = b_1 \; \Sigma X_1^2 + b_2 \; \Sigma X_1 X_2$$
$$\Sigma X_2 Y = b_1 \; \Sigma X_1 X_2 + b_2 \; \Sigma X_2^2 \tag{1}$$

where $X_j = x_j - x_m$, $Y_j = y_j - y_m$, and both represent deviation of independent and dependent variables (x, y) respectively; b_j is the regression coefficient of j-th variable. The regression coefficients are used to construct equation to the regression plane given by:

$$\bar{y} = b_0 + b_1 \bar{x}_1 + b_2 \bar{x}_2 \tag{2}$$

where b_0 is a constant. Finding b_1 and b_2 in equation 1 leads to simultaneous equations which can be represented with a matrix of the form AN=B, where N represents a matrix tensor of the unknown regression coefficients and is solved by multiplying the inverse of its coefficient matrix (A) with the known vector (B); i.e., N=A^{-1}B. The tensor of the inverse matrix (i.e., e_{jj} terms) is used in the computation of standard deviation of each regression coefficient (S_{bj}) in combination with the residual variance ($S_{y/x}$), and ultimately used in calculating its level of significance using the t-test. If the calculated t is greater than the tabulated t (from statistical table), then the null hypothesis that the regression coefficient is insignificant is rejected. The relevant equations are shown below:

$$A^{-1} = \begin{bmatrix} e_{11} & e_{12} \\ e_{21} & e_{22} \end{bmatrix} \tag{3}$$

$$e_{11} = \frac{\Sigma x_2^2}{\Sigma x_1^2 \; \Sigma x_2^2 \; - (\Sigma x_1 \; x_2)^2}$$
$$e_{22} = \frac{\Sigma x_1^2}{\Sigma x_1^2 \; \Sigma x_2^2 \; - (\Sigma x_1 \; x_2)^2}$$
$$e_{12} = e_{21} = \frac{\Sigma x_1 \; x_2}{\Sigma x_1^2 \; \Sigma x_2^2 \; - (\Sigma x_1 \; x_2)^2} \tag{4}$$

$$S_{y/x}^2 = \frac{\Sigma Y^2 \; - \; b_1 \, \Sigma Y X_1 - \; b_2 \, \Sigma Y X_2}{n - 3} \tag{5}$$

$$S_{bj} = S_{y/x} \sqrt{e_{jj}} \tag{6}$$

$$t = \frac{b_j}{S_{bj}} \tag{7}$$

An F-test was used to test the level of significance of the multiple regression as a whole using the equation below:

$$F = \frac{b_1 \, \Sigma Y X_1 + \; b_2 \, \Sigma Y X_2}{S_{y/x}^2} \tag{8}$$

The computed F-value is compared with that given in statistical table at a given level of significance. If the computed value is greater than tabulated value, then the null hypothesis that the partial regression coefficients are insignificant is rejected.

Finally, the degrees of association of the variables were tested using multiple correlation coefficients given by the formula below:

$$r^2 = \frac{b_1 \, \Sigma Y X_1 \; + \; b_2 \, \Sigma Y X_2}{Y^2} \tag{9}$$

$$r_{yx_j} = \frac{\Sigma \, x_j \, Y}{\sqrt{x_j^{\,2} + \Sigma \, Y^2}} \tag{10}$$

where r and r_{xyj} are sample and any two variable correlation coefficients, respectively. The computed value is also compared with tabulated value in statistical table to draw inference on the null hypothesis as discussed earlier.

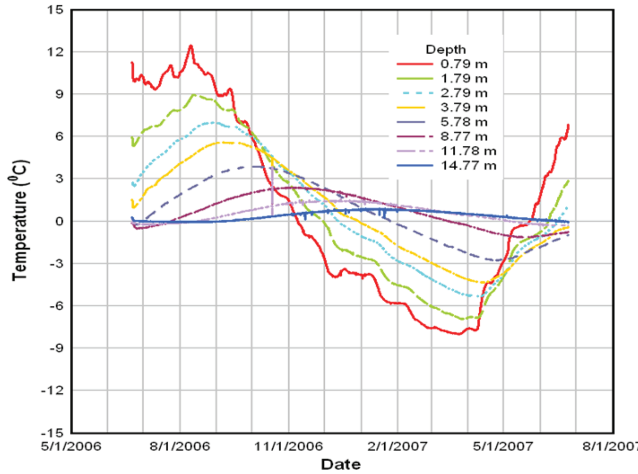

Figure 4. Temperature profile in one of the dedicated thermistor strings "T11" adjacent to MW 12.

Results

The data used for the regression analysis are shown in Table 1. The averaged integral temperature in the upper 7 m was also divided into two, because there is an inflection in the temperature profile between 3 m and 4 m depths from the ground surface due to heat lag effect as shown in Figure 4. The results of the statistical parameters are shown in Table 2. The calculated F-value of the regression equation and the sample multiple-correlation coefficient are greater than the tabulated value for 5% significant level. Thus, the regression equation is statistically significant, and the measured apparent LNAPL thickness correlates well with groundwater elevation and temperature profile at the site within 95% confidence limit as shown in Figure 5.

The partial regression coefficients of the apparent LNAPL (or product) thickness in the well are negative for both groundwater elevation and temperature. This implies that the product thickness increases with decreasing groundwater elevation and decreasing temperature. The absolute partial regressions of product thickness with groundwater elevation and temperature within the upper 3 m of the subsurface

				t-table	2.110

Summary of partial correlation coefficients

Variables	GWE	T 1-7	T 1-3	T 3-7	PT
PT	-0.691	-0.537	-0.769	-0.200	1.000

are 0.691 and 0.769, respectively, and above the tabulated regression value of 0.456 from statistical table at 5% significant level (Table 2). The absolute partial regression of integral temperature from 3 to 7 m depth is 0.2, and below the tabulated r-value. Thus, the product thickness is more sensitive to changes in groundwater elevation and temperature within the upper 3 m of the subsurface than that at depth.

Discussion

Correlation of the product thickness with both the groundwater elevation and temperature profile only depicts association with the variables and does not necessarily imply causation. However, because other tests have been conducted at the site, inference can be drawn on how the decreasing groundwater elevation and temperature contributes to increased product thickness in the monitoring wells. Increased correlation with temperature in the upper 3 m of the subsurface suggests causative active mechanism at that section based on the premise of LNAPL exclusion due to freezing of water in soil matrix (Barnes et al. 2004) and fractures. However, this premise must be further explored experimentally for fissured media under laboratory condition.

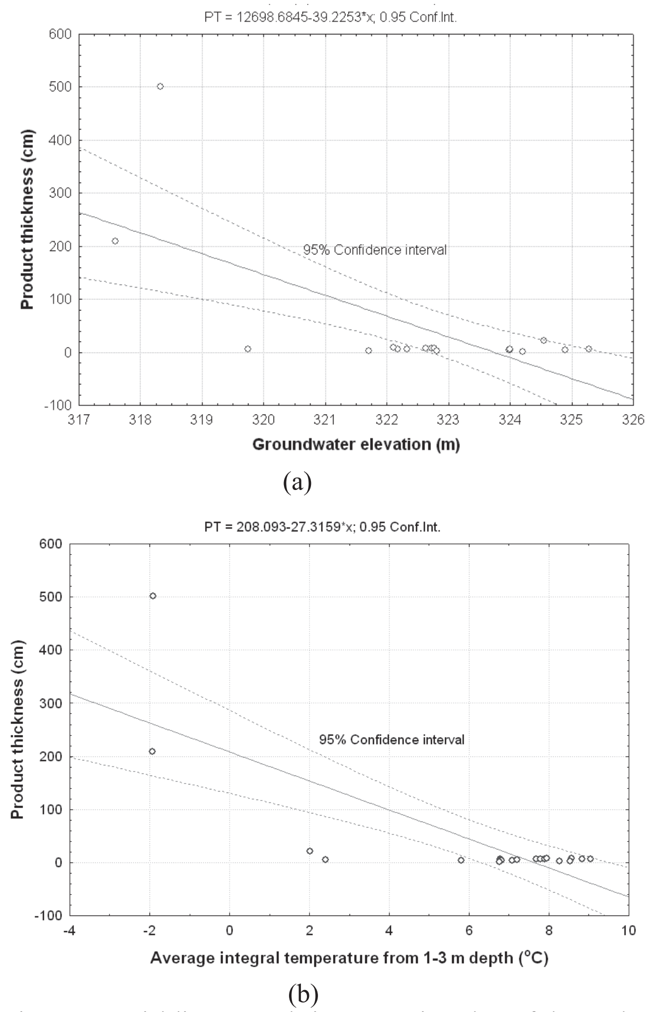

Figure 5. Partial linear correlation regression plots of the product thickness with (a) Groundwater elevation (b) Average integral temperature from 1-3 m depth.

Gravity drainage of mobile residual petroleum LNAPL in the formation due to a decrease in groundwater elevation coupled with LNAPL exclusion forward of the freezing front are hereby proposed as active mechanisms contributing to increased product thickness in the monitoring wells. The associative strength of these mechanisms is downplayed because of continual purging of the accumulated petroleum LNAPL from the monitoring wells. The overburden soil around MW 12 is 2.3 m thick and consists of gravel fill with sand. The well-log showed that multiple fractures exist between the upper 0.7 m of the bedrock surface with strong odor of petroleum hydrocarbon (PHC). Previous site characterization at the site by URS (2002) suggested that LNAPL being observed at the site are the residual LNAPL in the unsaturated zone of the subsurface. Thus, increased correlation of temperature fluctuation in the upper section of the subsurface affirms this.

Lower correlation between the product thickness and averaged integral temperature between 3 and 7 m from the subsurface does not necessarily imply poor influence on the product thickness because other factors such as fracture pattern and network may be masking its association. Though linear regression was used for this analysis, the actual association between the varied parameters may be non-linear. The practical significance of this study is that fluctuation of the groundwater table and freeze thaw cycle may increase recovery of mobile residual petroleum hydrocarbon from the subsurface at this site.

Conclusions

In this study, accumulated mobile LNAPL thickness in the monitoring well is shown to significantly correlate with the groundwater elevation and temperature at Colomac mine site. The petroleum LNAPL thickness increased with decreasing groundwater elevation and temperature. It was hypothesized that gravity drainage of mobile residual petroleum LNAPL at decreased groundwater elevation coupled with LNAPL exclusion are key mechanisms contributing to the observed behavior. The study suggests that product recovery may be enhanced by engineered fluctuation of the groundwater table and thermal regime at the site.

Acknowledgments

This study was sponsored by Program for Energy Research and Development (PERD), Indian and Northern Affairs Canada (INAC) and Environment Canada. Abstract

Since 2002, long-term field research of joint Japan-Mongolian IORGC projects have been concentrated and conducted in Nalaikh and in Terelj near Ulaanbaatar, Mongolia. There are two sites in Terelj (Terelj GL, Terelj FA) and one site in Nalaikh. At these sites we have been measuring the meteorological and permafrost parameters. This paper presents the temperature regime from 2003 to 2007 in boreholes located at these sites. The air temperature trend has increased by 1.9°C in Ulaanbaatar since 1969.

Keywords: active layer; geocryological; near-surface temperature; permafrost; temperature regime.

Introduction

Mongolia is a country of predominated by high and middle height mountains with continental climate, which promote the occurrence and development of permafrost. Permafrost underlies almost two thirds of the country and comprises the Province of Hovsgol, the Hangai, Hentei, and Altai mountains, and surrounding areas. Therefore, there is predominately mountain and arid land permafrost from sporadic to continuous distribution which is spread along the southern fringe of the Siberian permafrost region (Sharkhuu 2001). The permafrost in Mongolia is changing very rapidly under the influence of human activities such as open and close-pit coal mining, forest fires, etc. (Sharkhuu 2004).

This paper presents the temperature regimes between 2003 and 2007 from three observation sites (Terelj FA, Terelj GL, and Nalaikh) located near Ulaanbaatar. Long-term field research of joint Japan-Mongolian IORGC projects has been concentrated and conducted in Nalaikh and in Terelj. Nalaikh is located approximately 40 km to the southeast of Ulaanbaatar and is characterized by sparsely grassed pasture plate area. The elevation is about 1420 m a.s.l. Terelj is located approximately 40 km to the east of Ulaanbaatar and approximately 70 km from Ulaanbaatar by main road. Terelj is characterized by mountainous area with heights of 1550–2195 m a.s.l. In Terelj the south facing slopes are characterized by sparsely grassed grasslands with granite appearing in some places. South facing slopes and adjacent valleys have no permafrost. North facing slopes are covered by boreal forest, beneath which the permafrost occurs.

The objectives of this paper are to review the recent temperature regimes and to compare the air, near-surface, and ground temperature curves at selected sites.

Description of observation sites

According to the geocryological map of Mongolia (scale 1:1,500,000) the study area is located in an insular and sparsely insular permafrost region (Gravis et al. 1971). The insular and sparsely insular permafrost occupies 1%–50% of the total area. There are 18 observation sites in Terelj and 1

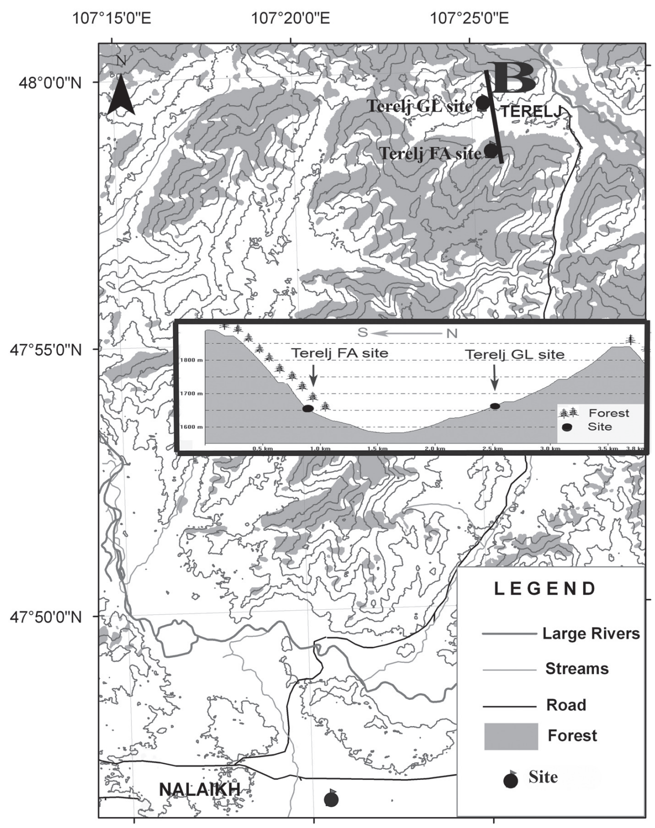

Figure 1. Location of sites. Also the profile along the B line is shown.

site in Nalaikh. In this paper we used the temperature data from 2 sites in Terelj (Terelj GL, Terelj FA) and from the Nalaikh site (Fig. 1).

Terelj FA site lies on a north facing forested slope of 10°–20°. The upper slope is 25°–40°. The elevation is 1656.5 m a.s.l. A 7.5 m deep borehole was drilled at this site in 2002. The ground temperature has been measured in this borehole using the CR-10X datalogger, datamark, and thermorecorder TR52. Terelj GL site lies on a south facing grassland slope of 10°–15°. The upper slope is 20°–35°. The elevation is 1664.4

m a.s.l. A 10 m deep borehole was drilled at this site in 2002. The ground temperature has been measured in this borehole using the datamark and CR-10X datalogger. The Nalaikh site lies on sparsely grassed pasture plate area of the Nalaikh depression. The elevation is 1420 m a.s.l. Boreholes 30.0 m and 7.0 m deep were drilled at this site in 2002. At these sites we also have measured the meteorological parameters at automatic weather stations (AWS).

Used data

In this paper we have used the air temperature and borehole temperature data measured at the Terelj FA and Terelj GL observation sites and at the Nalaikh site. The air temperature has been measured 1 and 2 m above the ground surface at Terelj FA, 1, 2, and 4 m above the ground surface at Terelj GL, and 0.5, 1, 2, and 4 m above the ground surface at Nalaikh. The air temperature data 2 m above the ground surface was used for this paper. Also we have used the temperature data from the 7.0 m deep and 30.0 m deep boreholes at the Nalaikh site, the 7.5 m deep borehole data at Terelj FA, and the 10.0 m deep borehole temperature data at Terelj GL site.

Climate Condition

According to climate change studies during the last 60 years, the mean annual air temperature has increased by 1.56° in Mongolia. Winter temperature has increased by 3.61° and spring, autumn temperature by 1.4°–1.5°. However the summer temperature has decreased by 0.3° (Natsagdorj 2000).

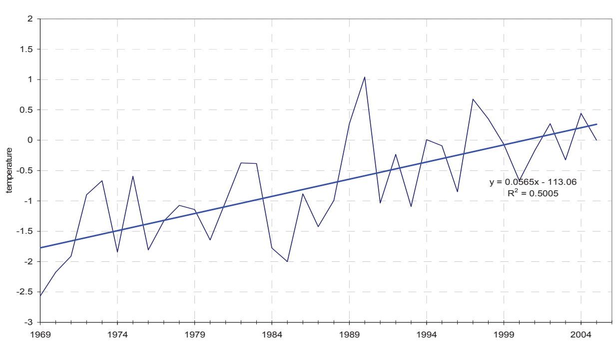

Figure 2. Mean annual air temperature in Ulaanbaatar between 1969 and 2005.

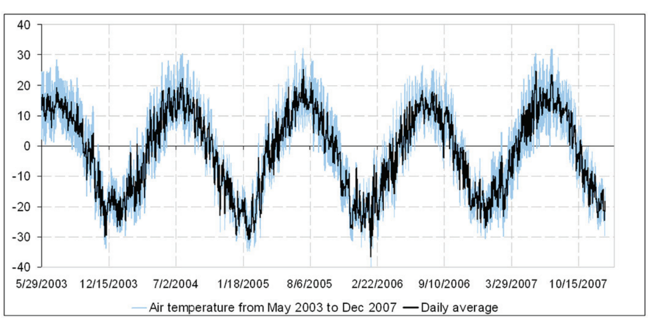

Figure 3. Air temperature at Terelj FA site.

Air temperature trend increased by 1.9° from 1969 to 2005 in Ulaanbaatar (Fig. 2).

Temperature Regimes of Sites

Air temperature

The maximum air temperature has been about +30.0°, and the minimum air temperature about -30.0° for the last 5 years at the Terelj FA site (Fig. 3). The mean annual air temperature was -2.9° for 2003, -2.1° for 2004, -2.97° for 2005, -3.35° for 2006, and -1.69° for 2007.

The maximum air temperature has been about +30.0° and the minimum air temperature is about -30.0° for the last 5 years at the Terelj GL site (Fig. 4). The mean annual air temperature was -1.21° for 2004, -1.36° for 2005, -1.5° for 2006, and +0.63° for 2007.

The maximum air temperature has been about +40.0° and the minimum air temperature is about -35.0° for the last 5 years at the Nalaikh site (Fig. 5). The mean annual air temperature was +0.96° for 2003, +5.82° for 2004, +4.94° for 2005, and +5.41° for 2006.

The air temperature curves are similar for the Terelj sites excepting the mean annual air temperature. But the air temperature curves are significantly different between the Terelj and the Nalaikh sites. The winter air temperature of the Nalaikh site increased rapidly over the last 5 years. At the Nalaikh site over the last 5 years the mean annual air temperature was plus 4.3°, which is disequilibrium with present permafrost in the Nalaikh depression. Mean annual air temperature of the Terelj FA site is minus 2.6° and mean annual air temperature of the Terelj GL site was minus 0.7° for the last 5 years.

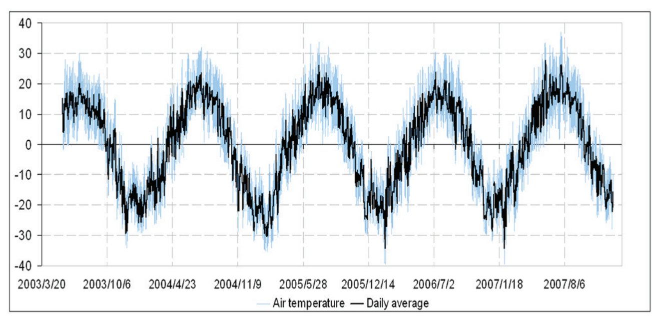

Figure 4. Air temperature at Terelj GL site.

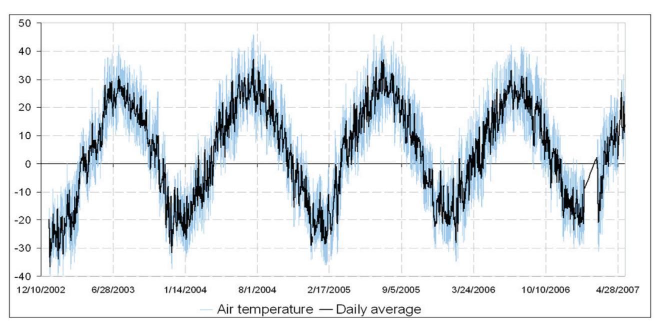

Figure 5. Air temperature at Nalaikh site.

Near-surface temperature

In wintertime the day-night temperature fluctuation is smoother than it is in summertime, because the temperature sensors are under the snow in wintertime (Figs. 6, 7, 8). Therefore, the winter near-surface temperature was higher than the winter air temperature. It means that snow cover has a warming effect at all three sites. So the minimum rate of the winter near-surface temperature was about -22°C at Terelj FA, about -19°C at Terelj GL, and about -26°C at Nalaikh.

In summertime day-night temperature fluctuation is higher than it is in wintertime especially at the Nalaikh site because of sparsely grassed area in Nalaikh. The maximum rate of the summer near-surface temperature was about +38°C at Terelj FA, about +35°C at Terelj GL, and about +60°C at Nalaikh.

Temperature on bottom of seasonally freezing and thawing

At the Terelj FA site the active layer thickness was about 3.8 m for 2004, 3.5 m for 2005, 3.25 m for 2006, and 3.55 m for 2007. The ground temperature ranged from -2.9°C to +0.1°C at a depth of 3.5 m between 2004 and 2007 (Fig. 9).

At the Terelj GL site the seasonal freezing depth was 3.90 m for 2004, 4.0 m for 2005, 4.2 m for 2006, and 3.85 m for 2007. The ground temperature ranged from -0.3°C to +4.9°C at a depth of 4.0 m between 2004 and 2007 (Fig. 10).

At the Nalaikh site the active layer thickness is more than 7.0 m. As shown on Figure 11, at the Nalaikh site the minimum rate of ground temperature was -0.3°C at a depth of 7.0 m between 2003 and 2007. The maximum rate of ground temperature was not possible to determine due to no data in the summertime.

As shown by Figures 9 and 11 above, the active layer thickness is different due to different topography, ground thermal condition, water content, ice content, and surface cover of the sites. The active layer thickness is about 3.5 m at the Terelj FA site. The Terelj FA site is characterized by north facing forested slope 10°–20°. Active layer thickness is about 7.5 m by borehole with a depth of 30.0 m at the Nalaikh site. The Nalaikh site is characterized by sparsely grassed plate area. As shown in Figure 10, the seasonal freezing depth is about 4.0 m at the Terelj GL site. Therefore the thicknesses of active layer and the seasonal freezing depths are different from place to place within a short distance in the mountain area.

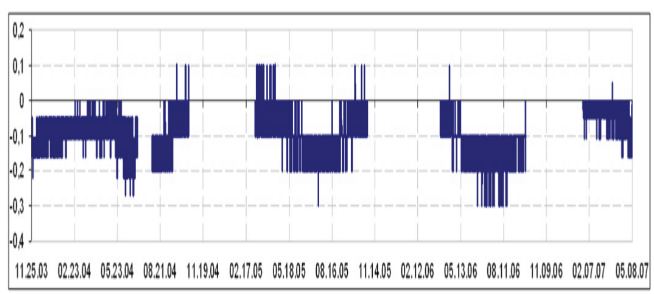

Figure 11. Ground temperature on a depth of 7.0 m at the Nalaikh site.

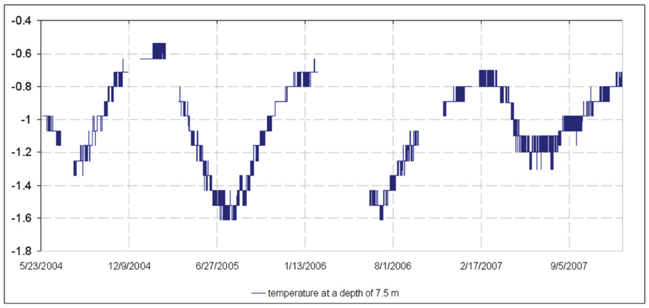

Figure 12. Temperature curve on a depth of 7.5 m from May 2004 to December 2007 at the Terelj FA site.

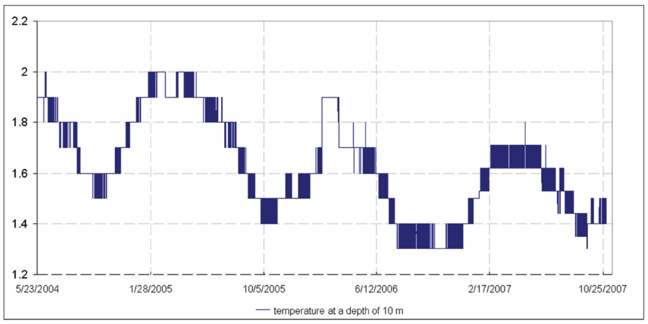

Figure 13. Temperature curve on a depth of 10.0 m from May 2004 to November 2007.

Deep temperature curves at three sites

Figure 12 shows the temperature curve on a depth of 7.5 m at the Terelj FA site. As shown in Figure 12, the depth of yearly temperature penetration is more than 7.5 m at the Terelj FA site. The maximum temperature was -0.55°C and the minimum temperature was -1.6°C between 2004 and 2007. The minimum temperatures were higher in 2004 and in 2007 than they were in 2005 and 2006. The maximum temperatures ranged from -0.55°C to -0.7°C.

Figure 13 shows the temperature curve on a depth of 10.0 m at the Terelj GL site. The depth of yearly temperature penetration is more than 10.0 m. The maximum temperature was +2°C in January of 2005. It had decreased between 2004 and 2007.

The minimum temperature was +1.3°C in September of 2006. It also had decreased between 2004 and 2007. Both temperatures (maximum and minimum) decreased from year to year between 2004 and 2007 because the snow thickness and the duration of snow cover became thicker and shorter in this period of time.

Figure 14 shows the temperature profile of the 30 m deep borehole at the Nalaikh site. The temperature below 5.0 m, is close to 0°. As shown in Figure 14, the active layer thickness was 7.5 m. By this temperature profile there are two layers of permafrost. The first layer is from 7.5 m to 11.4 m; the second layer is from 15.5 m down.

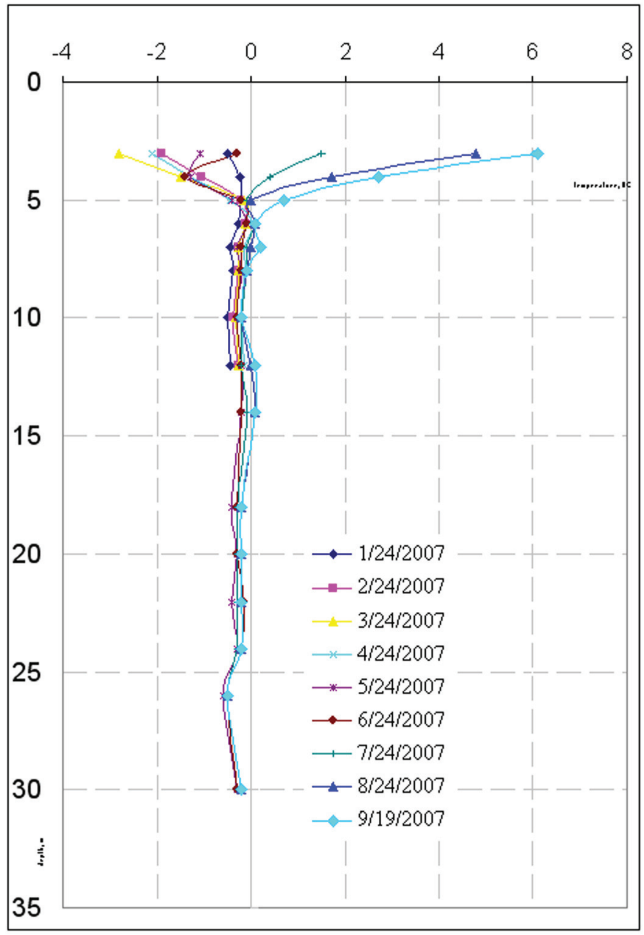

Figure 14. Temperature profile of 30.0 m deep borehole at Nalaikh.

Conclusion

- There are very high amplitudes of air and near-surface temperature at the three sites. Also there are very high day-night fluctuations of air and near-surface temperature. Day-night temperature fluctuation became low in wintertime at the surface, because the sensors lie under the snow cover.
- Near-surface temperature was a little higher than the air temperature in wintertime. So thin snow cover has a warming effect. The snow thickness was about 5–20 cm depending on the topography of the sites.
- The active layer thickness and the seasonal freezing depth are different due to topography, ground thermal conditions, surface cover, water, and ice content. There is a thick active layer at the Nalaikh site.
- Deep temperature is close to 0° at the Nalaikh site. The minimum temperature is -1.6°C on a depth of 7.5 m.
- There are two layers of permafrost at the Nalaikh site.

Recent Changes in Hydrologic Response Observed in Permafrost Regions of Northwest Canada

J. Richard Janowicz
Water Resources Section, Yukon Department of Environment, Whitehorse, Yukon Territory, Canada

Abstract

Air temperature trends have been observed to change over the last several decades in northern North America. Both summer and winter air temperatures have increased in most regions. An assessment was carried out to determine if corresponding trends of hydrologic response are apparent within permafrost regions of North America. Hydrograph characteristics were assessed using the Mann-Kendall trend test. The greatest changes to hydrologic response were observed with winter low flows. The greatest changes in winter streamflow appear to be occurring within the continuous permafrost zone, where flows from the majority of sampled streams have increased. Winter low flow trends in streams within the discontinuous permafrost zone generally exhibit positive trends, but are more variable. Winter streamflow trends within the sporadic permafrost zone are not consistent. Increasing winter streamflow trends have occurred from some mountainous regions of alpine permafrost. Other streams exhibit no discernable change, while some streams exhibit a negative change.

Keywords: continuous; discontinuous; Mann-Kendall; 7-day low flow; sporadic permafrost; trend analysis.

Introduction

The primary control over hydrologic response in northern regions is permafrost distribution, permafrost thickness, and thickness of the active layer (Hinzman et al. 2005). Thick underlying permafrost and a thin active layer produce short pathways to the stream channel, with little or no interaction with subsurface processes. Ice-rich permafrost restricts rain or snowmelt infiltration to subsurface zones, resulting in surface storage in the form of ponds or wetlands. A thicker active layer enhances infiltration and associated groundwater recharge, which in turn would result in greater groundwater contributions to streamflow. Yukon hydrologic response follows this principle, and is closely tied to the underlying permafrost.

Changing climate appears to be resulting in a likewise change in the permafrost distribution of northern regions, including the Yukon Territory. Increasing air temperatures are resulting in permafrost warming and associated thawing, which in turn results in a thicker active layer. Permafrost degradation is expected to be greatest within the discontinuous and sporadic permafrost zones, since these permafrost classes are warmer; and therefore, more susceptible to thawing (Hinzman et al. 2005). Observations within the discontinuous permafrost regions of Alaska disclose the development of extensive areas of thermokrast terrain due to thawing permafrost (Osterkamp & Romanovsky 1999).

Yukon temperature and precipitation trends have been observed to change over the last several decades (Janowicz 2001). Winter and summer temperatures have increased in all regions, with greater winter temperature increases in northern Yukon, and greater summer increases in southwestern Yukon. Winter precipitation has increased slightly in all regions, while summer precipitation is more variable, decreasing in northern Yukon and increasing in southern Yukon. The greatest changes have occurred in western, mountainous regions where both summer and winter temperatures and winter precipitation have increased significantly. These observed trends are in the general order of projections developed by a Canadian Climate Centre global climate model (GCMII), which is based on a 100 percent increase of CO_2 in the atmosphere (Taylor 1997, Intergovernmental Panel on Climate Change 2001).

There have been a number of studies carried out in northern regions of North America on the impact of climate change on hydrologic response (Kite 1993, Burn 1994, Loukas & Quick 1996, 1999, Leith & Whitfield 1998, Whitfield & Taylor 1998, Spence 2002)). Whitfield & Cannon (2000) & Whitfield (2001) assessed climatic and hydrologic variations between two decades (1976–1985; 1986–1995) for stations in British Columbia and Yukon. Hydrologic response was generally found to be characterised by higher year round flows. Mountainous streams were found to have the timing of the freshet advanced, followed by lower summer and fall discharge. Zhang et al. (2001) and Yue et al. (2003) assessed the streamflow records for 243 Canadian hydrometric stations making up the Reference Hydrometric Basin Network, including some Yukon stations, over the period 1967 to 1996. While most of these stations were in southern Canada, they found winter low flows in northern British Columbia and Yukon to have increased significantly. Annual mean and peak flows were observed to have increased in glacerized basins of southern Yukon and northern British Columbia. Burn et al (2004), in the comparison of streamflow of the Liard and Athabasca Rivers in the mountainous, headwater regions of the Mackenzie River basin, found both streams to exhibit increases in winter discharge and some increase in the snowmelt freshet. Dery & Wood (2005) investigated the discharge of 64 arctic or subarctic Canadian rivers from 1964 to 2003. They found a general 10 percent decline in mean annual discharge to the Arctic and North Atlantic Oceans over that period, which is consistent with a decline in annual precipitation in northern Canada over that period. The decline in streamflow was less pronounced in northwestern Canada, where the results were not statistically significant. Their work indicated there were links between annual discharge and Arctic Oscillation, El Nino/South Oscillation (ENSO), and the Pacific Decadal Oscillation (PDO) at interannual to decadal timescales.

There has been only limited work to date on the impact of climate change specific to Yukon hydrology. Janowicz & Ford (1994) used the CCC GCM temperature and precipitation projections, and a correlation approach to assess the impacts of climate change on the water supply to the upper Yukon River. Their analyses indicated that annual inflows to the glacierized upper Yukon River would increase by 39 percent, primarily in summer months, due to increasing temperature and precipitation. Janowicz (2001) carried out an analysis of streamflow to assess the response of the observed temperature and precipitation changes on peak flows, which normally occur as a result of spring snowmelt. The assessment revealed that there has been a dramatic change in mean annual flood (MAF) in some regions of Yukon over the last 20 years, with a progressive decrease in the parameter moving from south to north. The greatest increases in MAF were observed to occur within the sporadic permafrost zone, from predominantly glacierized systems in western Yukon. Smaller increases were noted in southeastern Yukon. These increases correspond to the observed increase in both summer temperatures and winter and summer precipitation. Peak flows from central and eastern Yukon, within the discontinuous permafrost zone, exhibit very little change. Within the continuous permafrost zone, peak flows were observed to decrease progressively moving northward to the Arctic coast.

This paper summarizes the results of a study carried out to assess apparent trends of annual minimum flows in Yukon and adjacent areas of northwestern Canada over the last few decades.

Setting and Methodology

The analyses were carried out using data from the Yukon Territory and the western Northwest Territory west of the 125th parallel of longitude, an area covering approximately 920,000 km^2. This region consists of three permafrost zones: continuous, discontinuous, and sporadic (Fig. 1). Continuous permafrost areas have greater than 90% coverage; discontinuous areas have between 50 and 90% coverage; and sporadic areas have 10 to 50% coverage (Brown et al. 1997). The continuous, discontinuous, and sporadic zones represent 30, 45, and 25 percent of Yukon, respectively (Natural Resources Canada 1995). Hydrometric data from all active and recently discontinued (<5 years) Environment Canada, Water Survey of Canada (WSC), stations on unregulated streams, with at least 25 years of record were used in the analyses. The data were obtained from the WSC website. Because of numerous station discontinuations in

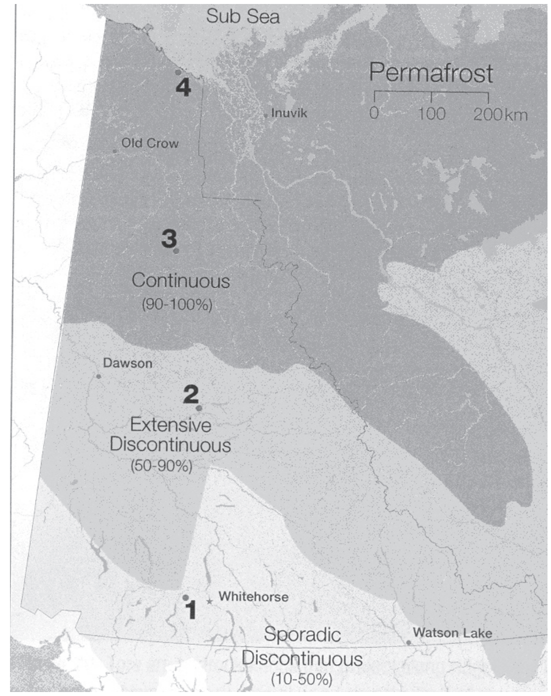

Figure 1. Study area and permafrost zones (from Smith et al. 2004).

the mid-1990s, only 21 stations were available for analyses. These were equally distributed between the three permafrost classes. The 7-day average minimum annual low flow, which normally occurs in late winter or early spring, was assessed in the present study. The 7-day average low flow parameter is a commonly used, minimum flow measure which reduces the variability over a single value.

Trend analysis

The Mann-Kendall trend test was used to assess trends in the 7-day minimum annual low flow parameter. The Mann-Kendall test is a non-parametric test used for the assessment of trends in time series. It is a simple, robust tool which can readily handle missing values. The calculated standard normal variate value (Z) is associated with a specific level of significance. The significance level provides an indication of the strength of the trend. A significance level of 0.001 indicates a very strong trend; 0.01 indicates a strong trend; 0.05 indicates a moderate trend; and 0.1 indicates a weak trend. A level of significance of less than 0.1 indicates there is no discernable trend.

Results and Discussion

Table 1 provides a summary of the trend analyses. Positive trends in winter low flows are generally evident in all Yukon permafrost regions, with the occurrence of this trend inversely related to latitude. Winter baseflows are also generally related to drainage area. In cold regions, the relationship is more pronounced, with smaller drainages having less groundwater inputs to baseflow; therefore, smaller winter flows. While

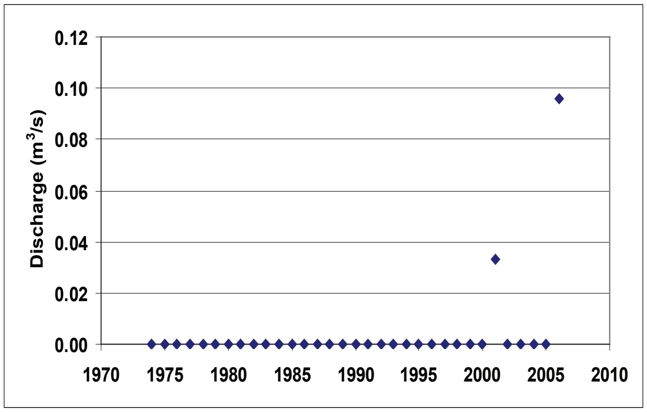

Figure 2. Seven-day average minimum low flow – Rengleng River at Dempster Highway.

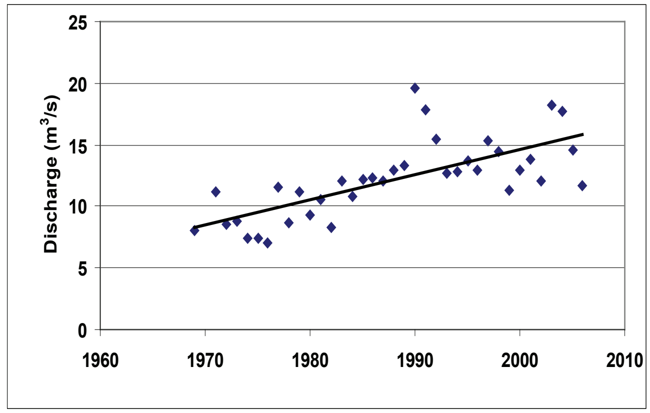

Figure 3. Seven-day average minimum low flow – Arctic Red River at Fort McPherson (r^2=0.49).

summer and winter precipitation have generally increased and decreased, respectively, in permafrost regions, annual precipitation has increased slightly, and there has been a corresponding slight observed increase in annual runoff in continuous and discontinuous permafrost regions. Both precipitation and annual discharge increases are slight, and cannot provide the basis for winter low flow increases. Summer and winter air temperatures have been observed to increase in most regions, and may attribute to the increase in winter low flows. Climate warming produces permafrost degradation, which enhances the interaction between surface and groundwater systems, allowing for greater groundwater contributions to baseflow.

The greatest positive trends in winter low flows appear to have occurred in the continuous permafrost zone, where streams with drainage areas in the order of 5,000 km^2, generally have streamflow throughout the winter. There is an exception for streams along the Arctic coast, where larger streams often experience "zero" winter flows. It is not possible to statistically validate trends from study streams which have had predominately "zero" winter flows in past decades. As with many statistical techniques, the Mann-Kendall test is not able to handle "zero" flows. Figure 2 provides an illustration of low flow trends for a small stream, the Rengleng River (station number 10LC003), with a drainage area of 1310 km^2. Winter low flows in past decades have been nonexistent, while measurable flow during recent winter periods has been observed. The winter flow regime for Caribou Creek (10ND002), with a drainage area of 68.3 km^2, has remained unchanged, with "zero" flows throughout the entire 29 year monitoring period.

Figure 3 provides an illustration of the positive winter low flow trend for the Arctic Red River (10LA002), with a drainage area of 18,600 km^2.

Trends of winter low flow regimes, with increasing flows, are generally exhibited by streams within the discontinuous permafrost zone. Four of the seven assessed streams have statistically significant positive winter low flow trends. Figure 4 illustrates the increasing trend for the Klondike River (09FA003). Even the smallest streams within the discontinuous permafrost zone normally have winter flows, so drainage area is not as strong a factor in influencing winter streamflow, as in the continuous permafrost zone.

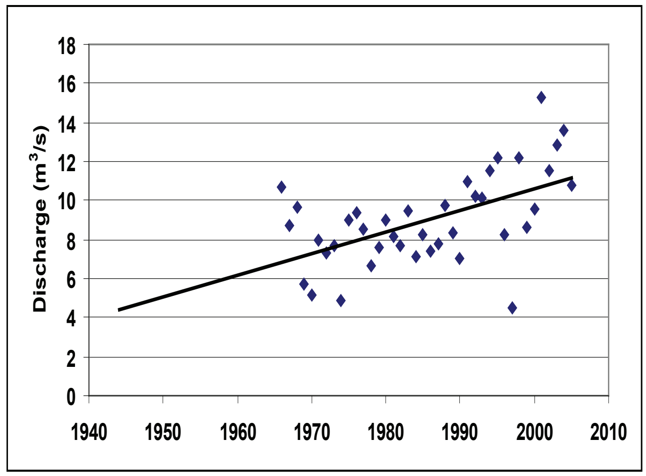

Figure 4. Seven-day average minimum low flow – Klondike River above Bonanza Creek (r^2=0.30).

Trends of increasing winter low flows are not generally strong within the sporadic permafrost zone. Two of the seven represented streams have statistically significant positive trends. Both of these streams are transitional with the discontinuous permafrost zone, and one of these drains a mountainous region with significant alpine permafrost. Other streams exhibit no discernable change, while one stream exhibits a negative change.

Conclusions

An assessment of streamflow response was carried out to determine if there are apparent trends in permafrost regions as a result of observed temperature changes. As permafrost properties change with climate warming, hydrologic response in northern regions would likewise presumably change. Degrading permafrost increases the thickness of the active layer, decreases the overall thickness of the permafrost and, in certain areas, eliminates the presence of

underlying permafrost entirely. These actions place a greater reliance on the interaction between surface and subsurface processes. Annual minimum flows were assessed, which were represented by the mean 7-day low flow. The Mann-Kendall test was used to statistically validate observed trends. Winter low flow trends have experienced significant apparent changes over the last three decades. The greatest changes in winter low flows appear to be occurring within the continuous permafrost zone, where flows from the majority of sampled streams have increased. Winter low flow trends in streams within the discontinuous permafrost zone generally exhibit positive significant trends, but are more variable. Winter streamflow trends within the sporadic permafrost zone are not consistent. Increasing winter streamflow trends have occurred from some mountainous regions of alpine permafrost. Other streams exhibit no discernable change, while one stream exhibits a negative change.

Abstract

In this study, we examine the operational and environmental factors associated with the cap performance of 110 drilling-mud sumps constructed between 1965 and 2005 in the Mackenzie Delta region, Northwest Territories. Thawing of ice-rich cover materials can cause cap subsidence and surface ponding, and may increase the potential for migration of sump contents. To control for the effects of degradation over time, we examined data for the 77 sumps constructed between 1968 and 1977. Significant ponding (>20% of cap area) characterized 65% of the sumps in warm permafrost (>-3.9°C) and alluvial terrain. The largest proportion of sumps with good cap integrity were in cold permafrost (<-7.0°C) on tundra uplands. Many sumps that were operated in summer maintained good cap integrity, and were situated in cold permafrost, further highlighting the importance of site environmental conditions. Variable long-term cap performance suggests that a long-term approach to managing sumps in permafrost terrain is necessary.

Keywords: cap integrity; drilling-mud sumps; Mackenzie Delta region; permafrost.

Introduction

Drilling wastes produced during land-based hydrocarbon exploration in the Canadian arctic and subarctic have been disposed of to in-ground sumps (French 1978a, b) in accordance with Federal legislation. Sumps are excavated into permafrost and are generally situated adjacent to the wellhead. Following the completion of the drilling program, the drilling fluids, cuttings and rig wash are deposited to the sump which is then backfilled to form a cap (Fig. 1). The design intent is to confine the active layer within the cover materials and maintain the saline drilling wastes in the underlying permafrost (French 1980, Dyke 2001).

Operational and environmental factors combine to influence sump performance (French 1985). For example, sumps constructed in cold permafrost are more likely to maintain saline drilling fluids in a frozen state even if climate or vegetation conditions change with time. The potential for sump collapse is enhanced where permafrost is ice-rich because thawing of cover materials or adjacent terrain can lead to surface subsidence and ponding. Accumulation of surface water on or around the sump cap may lead to thermal instability promoting additional subsidence. The capping of unfrozen materials can cause fluids to be squeezed out of the sump. Under contemporary practices, the fluids deposited to the sump in winter are assumed to freeze in situ and the wastes are capped prior to warming air temperatures in spring (Fig. 1). Terrain disturbance adjacent to sumps can lead to surface subsidence and ponding around the cap, but impacts can be minimized by operating on a protective ice pad.

Since 1965, about 150 drilling-mud sumps have been constructed in the Mackenzie Delta region. Sump cap collapse and ponding suggests that permafrost, the primary containment medium, has partially degraded and that the drilling wastes are no longer encapsulated by permafrost (Fig. 2) (Kokelj & GeoNorth 2002).

In this paper we summarize information on the construction practices, environmental conditions and cap integrity for 110 drilling-mud sumps constructed over the past 40 years in the Mackenzie Delta region. Our primary objectives are: 1) To provide a summary of sump cap performance; and 2) to examine the influence of construction practices and environmental conditions on long-term sump cap integrity. This investigation is timely because the proposed Mackenzie Gas Pipeline has stimulated renewed hydrocarbon exploration in the region and sumps remain a waste disposal option in the north.

Figure 2. Drilling-mud sump in the outer Mackenzie Delta. The sump cap has collapsed causing a large pond to form. The arrow indicates submerged willows in the pond. Willows on sump cap in background are approximately 2 m in height.

Study Area

The drilling-mud sumps we examined are located in the Mackenzie Delta and the adjacent uplands in a diverse range of terrain, permafrost and ecological conditions (Fig. 3). Mean annual air temperatures at Inuvik and Tuktoyaktuk are -8.8°C and -10.2°C, respectively (Environment Canada 2007). Mean annual ground temperatures range from -9°C in upland terrain near the Beaufort Sea coast to above 0°C in point bar willow communities of the Delta (Mackay 1974, Smith 1975).

Most of the drilling-mud sumps in alluvial terrain of the Mackenzie Delta are subject to periodic flooding in spring and those in the low-lying northern delta may also be inundated by storm surges in summer (Fig. 3) (Burn 2002). North of treeline, low shrubs grow along point bars, and sedge wetlands occupy the delta plain. Thermal disturbance associated with the numerous lakes and channels, early removal of snow due to spring flooding, and the growth of tall shrubs and associated deep snow on point bars can account for warmer ground temperatures in the Delta than in the adjacent tundra uplands (Mackay 1974, Smith 1975). Ground temperatures at undisturbed sites in the outer delta range from -2 to -3°C (Mackay 1974). Southward the elevated delta plain is vegetated by spruce forests underlain by permafrost between about -2°C and -4°C (Mackay 1974, Kanigan et al. 2008). In the delta, wedge ice and near-surface aggradational ice is associated with spruce forests and sedge wetlands (Kokelj & Burn 2005, Kokelj et al 2007a).

The uplands east of the Mackenzie Delta, including the Tuktoyaktuk Coastlands, are characterized by low arctic shrub tundra (Ritchie 1984). Mean annual ground temperatures are lower than in the delta due to the absence of flooding and thinner snow cover. Ground temperatures decrease northwards with vegetation height and snow cover, so that permafrost on the Tuktoyaktuk Coastlands and on northern Richards Island may be below -8°C (Mackay 1974). The terrain is hummocky and the fine-grained materials are frost susceptible (Kokelj et al. 2007b). Upland sediments

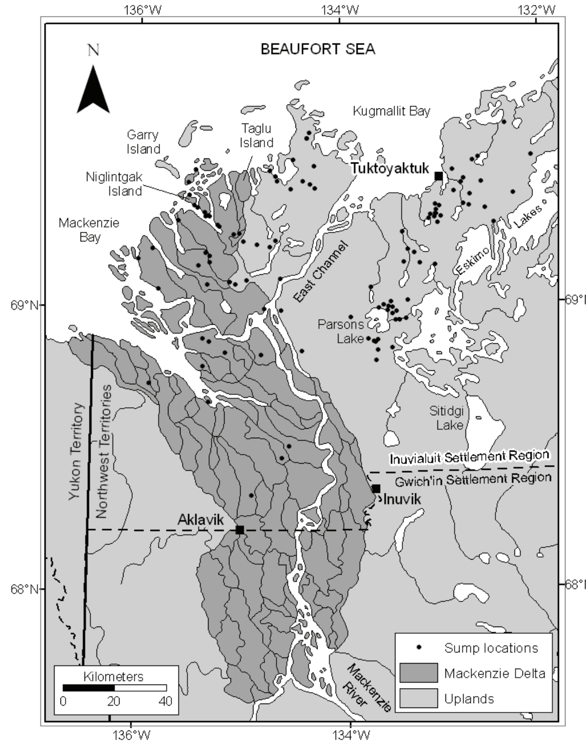

Figure 3. Mackenzie Delta region and drilling-mud sumps examined in this study.

of morainal, glaciofluvial or lacustrine origin contain large volumes of ground ice including massive ice, wedge ice, and near-surface aggradational ice (Mackay 1963, Rampton 1988).

Methods

We examined operational and environmental data for 110 sumps in the Mackenzie Delta region (Fig. 3). Information on the drilling-mud sumps was extracted from an Indian and Northern Affairs Canada (INAC) compilation of sump data and an inventory of sumps in the Inuvialuit Settlement Region (ISR) funded by the Environmental Studies Research Fund (ESRF) and industry (AMEC Earth and Environmental 2005, Komex International & IEG Environmental 2005). The inventory and field methodologies were developed by an ESRF Technical Advisory Group which included government, Inuvialuit and industry representatives. National Energy Board information on site locations and operating dates was used. The sump information collected via these initiatives is publicly available at (http://nwt-tno.inac-ainc.gc.ca/wrd_e.htm).

Permafrost has been utilized as a primary containment medium in northern drilling-mud sumps (French 1980, Dyke 2001). Sump cap collapse and cap ponding strongly suggest that the underlying permafrost is degrading and that the original design intent is not being achieved. Conversely, a sump cap with no ponding suggests frozen ground has been maintained within and around the sump. Field and aerial photograph based estimates of ponding within the sump perimeter was grouped into the three categories of 0% to 5% ponding, 6% to 20% ponding and greater than 20% ponding. We suggest that these categories reflected good, moderate and poor cap integrity, respectively.

The timing of sump closure is of interest because the potential for terrain disturbance is greater during the thaw season and air temperatures at the time of capping influence the thermal state of sump contents. Sump construction and closure dates were not recorded but through consultation with industry and regulators it was determined that commencement and completion dates of drilling provide reasonable estimates for the duration that a sump remained open and the subsequent timing of sump closure. In this study, the "summer operating season" was defined as those months in which the Inuvik monthly climate normals from 1971 to 2000 were above 0°C, which includes May 1 to September 30 (Environment Canada 2007). Sumps were grouped by year of construction into those constructed prior to 1980 (1965-1979), those constructed in the 1980s and recently constructed sumps (1990–2005). The intervals are uneven so the few sumps constructed in the 1960s (5) and 2000s (5) could be grouped into adjacent time intervals.

Mean annual permafrost temperatures may be associated with sump performance since areas of cold permafrost are more likely to maintain sump contents in a frozen state and areas with warm permafrost are more susceptible to thawing after disturbance (Smith & Burgess 2004). Sumps were grouped into three ground temperature classes (-1.0 to -3.9°C, -4.0 to -6.9°C, -7.0 to -9.9°C) based on a generalized map of mean annual ground temperatures (Mackay 1974). Historical ground temperature measurements were also obtained from wellheads adjacent to 14 of the sump sites (Taylor et al. 1998).

Associations between sump-cap ponding and environmental and operational variables were determined using an X^2 test of independence:

$$X^2 = \sum (O - E)^2 / E \qquad (1)$$

where O is the observed frequency in the sample, and E is the expected frequency in the population (Sokal & Rohlf 1995). A test statistic that is larger than the critical value reflects significant differences between the observed and expected frequencies, indicating that there is an association between the two variables.

Results

Table 1a shows that about half of the sumps had minor ponding, while the other half were characterized by moderate to significant ponding. The majority of sumps were constructed and capped between 1965 and 1979 (Table 1b), and the time period for which a sump is open has decreased over the past four decades (Table 1b). All sumps constructed since 1980 were capped within four months of excavation. Only 20% of all sumps were capped in summer and there have been no summer operations since 1986.

1990-2005	7 (n=8)	0	0

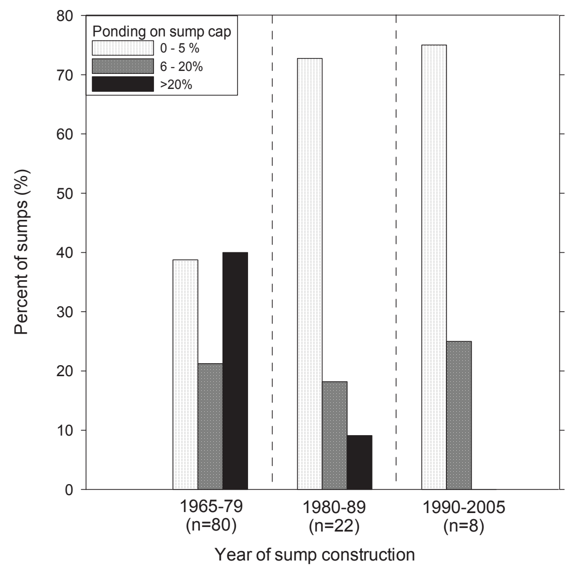

Figure 4. Percentage of sumps affected by minor, moderate and major ponding by period of sump operation. Note that time intervals are uneven.

Sumps constructed since 1990 are characterized by generally good cap integrity in contrast to sumps capped before 1980, most of which have moderate to significant ponding (Fig. 4). There is a statistical association between sump age and cap ponding at the 0.05 level of significance ($X^2_{(4,110)}$ = 13.569; p = 0.009). The good cap conditions of recently constructed sumps may reflect improvements in site selection, construction and closure practices, but may indicate that sump covers degrade with time (Fig. 2).

To investigate the effects of environmental conditions and operating practices on long-term sump integrity and to control for the influence of sump age we reduced the study scope to 77 drilling-mud sumps constructed between 1968 and 1977. Figure 5 shows that the magnitude of cap ponding decreases with ground temperatures. Over 60% of the sumps in warm permafrost (-1.0°C to -3.9°C), coincident with alluvial terrain, were characterized by significant ponding.

Only 30% of the sumps underlain by cold permafrost in upland terrain have significant ponding, and more than half were well intact (Fig. 5). Sump-cap ponding and mean annual ground temperature are associated at the 0.10 level of significance ($X^2_{(4,77)}$ = 8.302; p = 0.08).

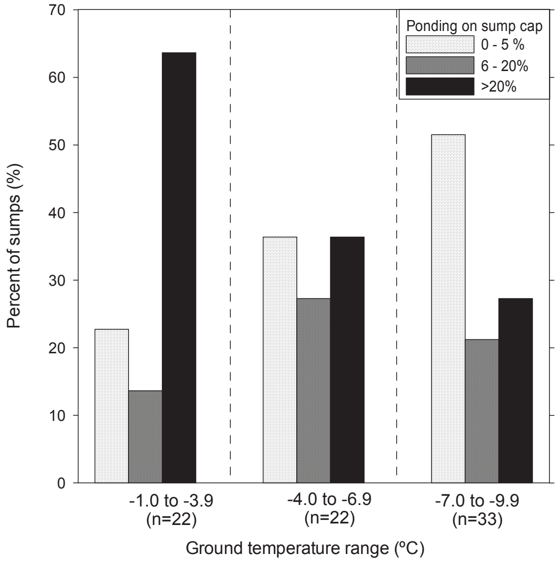

Figure 5. Percentage of sumps affected by minor, moderate and major ponding by mean annual ground temperature class for sumps constructed between 1968 and 1977.

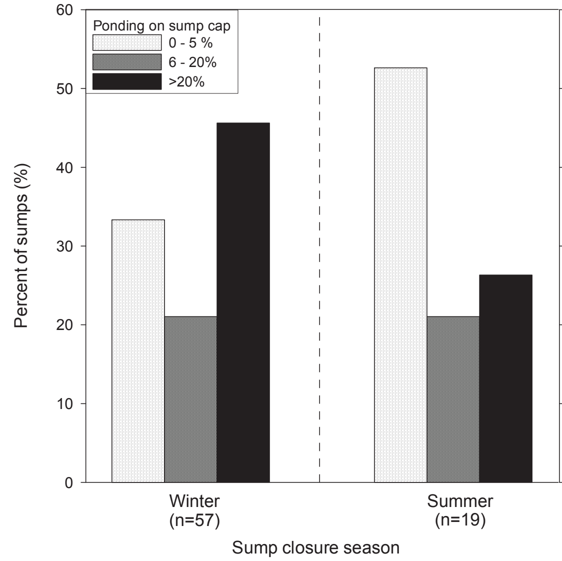

Figure 6. Percentage of sumps affected by minor moderate and major ponding by season of sump closure for sumps constructed between 1968 and 1977.

The sumps constructed from 1968 to 1977 were dichotomized on the basis of the season in which they were closed (summer or winter) (Fig. 6). About 50% of the sumps capped in summer showed minor cap ponding and only 25% were characterized by significant ponding. In contrast, almost half of the sumps capped in winter have significant ponding. Sump-cap ponding is statistically independent of the timing of sump closure ($X^2_{(2,76)} = 2.692$; $p = 0.26$) at the 0.05 level of significance, indicating that the two factors are not associated.

Discussion

Most of the 110 drilling-mud sumps we examined in Mackenzie Delta region were constructed and capped in the 1970s (Table 1). About 40% of these sumps have ponding on or around the sump cap that exceeds 20% of the cap dimensions (Fig. 4). Cap collapse and ponding indicate that the drilling wastes are no longer completely encapsulated by frozen ground and that the primary waste containment medium has been compromised.

The strong association between cap ponding and sump age can partially be explained by improvements to construction and closure practices since the 1970s. These improvements include: a) a reduction in the amount of fluids utilized during drilling and deposited to the sump; b) more efficient drilling operations and reduction to the length of time a sump is open; c) avoidance of summer operations; and d) minimizing disturbance to terrain adjacent to the sump by operating on a protective ice pad. Irrespective of improved practices, there is evidence that sumps deteriorate with time. Submerged willows in many of the sump ponds suggest that collapse occurred subsequent to cap revegetation, possibly after decades of cap stability (Fig. 2). Sumps covers that are presently intact have the potential to subside if permafrost were to thaw as the result of shrub growth and increased snow accumulation, or due to climate warming (Kokelj & GeoNorth 2002).

Cap subsidence and significant ponding was most common on sumps in warm permafrost of the alluvial delta, whereas the zone of coldest permafrost on northern Richards Island and the Tuktoyaktuk Coastlands had the lowest proportion of sumps with significant ponding, and the highest proportion of intact sump caps (Fig. 5). It appears that potential impacts of high ice content permafrost on sump cap integrity in the northern part of the study region was offset by thermal stability associated with cold permafrost (Mackay 1970, Rampton 1988).

The difficulty of maintaining good sump-cap integrity in a warm permafrost environment is indicated by Figure 5 and corroborated by the poor cap conditions observed at many historical drilling-mud sumps in the central Mackenzie Valley where mean annual ground temperatures are above -3°C (C. Baetz - INAC, pers. com.). In our study area, the warmest permafrost coincides with alluvial terrain of the Mackenzie Delta which is also characterized by naturally poor drainage, probably strengthening the observed association between significant cap ponding and warm permafrost.

No significant association was found between the timing of sump closure and sump-cap ponding (Fig. 6). This result was surprising because various complications have been documented in association with summer operations (French 1980, 1985), including a) thawing and loss of frozen backfill; b) degradation of ice-rich permafrost in exposed sump sidewalls; and c) squeezing and seepage of unfrozen fluids up and out of the sump at the time of capping. Closer inspection of the data reveals that most of the summer sumps were located in cold upland terrain. Only four were located in warm permafrost and alluvial terrain and three of these were characterized by significant ponding (Fig. 2). Furthermore, some of the summer sumps may have been contoured or recapped in the years immediately following abandonment. The relatively good condition of several summer constructed sumps in cold permafrost highlights the importance of good site selection.

Regardless of site conditions or construction practices there is a strong association between cap ponding and sump age which suggests that sump conditions can deteriorate over time (Fig. 2). Almost 30% of the sumps constructed during winter in cold permafrost between 1965 and 2005 presently have more than 20% of the cover occupied by ponded water. Many sumps constructed under ideal site and operating conditions have degraded, so it is apparent that other factors may lead to the thawing of a sump over time. For example, well-drained exposed mineral soils that characterize the sump cover favour the growth of tall shrubs which trap snow redistributed by winds (Johnstone & Kokelj 2008). Colonization by tall shrubs can transform a cold snow-free cap surface into one with annual snow accumulation of over 1m thickness causing ground warming and possible thawing of sump contents (Johnstone & Kokelj 2008). Natural sites in the study region characterized by mineral soils and deep snow are often associated with a talik (Gill 1972). It is also possible that rising air temperatures and associated ground warming in the western Arctic has contributed to the degradation of sumps (Osterkamp & Romanovsky 1999, Smith et al. 2005).

Decadal scale sump cap performance in the Mackenzie Delta region strongly suggests that if long-term freezing of drilling wastes in permafrost remains an intended waste disposal option, warm permafrost and alluvial terrain must be avoided. Factors that influence the thermal evolution of drilling-mud sumps such as vegetation succession and climate change cannot be directly controlled by best practices, so the necessity for long-term observation and management of sumps in permafrost terrain should be anticipated. Furthermore, the environmental consequences of sump cap collapse should be better understood so that sump cap degradation can be appropriately managed.

Conclusions

Based on our results and discussion we make the following conclusions:

1. Recent sumps are characterized by good cap integrity, but 40% of sumps constructed prior to 1980 have more than 20% ponding on their surface. The data suggest an improvement of operating and abandonment practices; however this trend may actually reflect the gradual degradation of sump covers over time.

2. For the 77 sumps constructed during the period from 1968 to 1977, poor cap integrity was most prevalent in poorly-drained, alluvial terrain where permafrost temperatures were above -4°C. Sump cap conditions were best at upland sites in cold (<-7.0°C) permafrost. If the objective of a sump is to encapsulate wastes in permafrost, construction in warm permafrost and alluvial environments should be avoided.

3. The season in which a sump was capped was not associated with sump-cap ponding and cap integrity. This is probably because site environmental conditions subsumed the effect of capping season.

4. About one third of the sumps constructed during winter operations in cold permafrost are characterized by significant cap ponding. Factors such as cap revegetation and climate warming may impact long-term sump-cap integrity indicating that a long-term management approach to drilling-mud sumps constructed in permafrost is necessary.

Abstract

Preservation of permafrost is one of the principles adopted in permafrost geotechnical engineering. Using a thermal semiconductor can help toward this purpose. The thermal semiconductivity property of water near 0°, diatomite is used for making a kind of thermal semiconductor after it absorbs water. Experiments on the thermal conductivity difference between frozen and unfrozen diatomite, and on the water retention ability of diatomite, were carried out in a laboratory. The results showed that under the condition of water content equal to 140% (its saturation higher than 70%), thermal conductivity of frozen diatomite is about 1.66 times that of thawed diatomite. However, its water retention ability is inferior. For the purpose of improving the long-term cooling effect of saturated diatomite in field experiment engineering, a 0.1 m thick sand layer was covered on the diatomite protection-slope layer. Four years of data monitoring a 120 m long experimental road arranged at Hongtupo section between K391+000 and K391+120 of 214th National Highway, showed that a diatomite slope-protection layer can delay the degradation of the underlying permafrost and improve the stability of the embankment. In order to improve its performance and reduce future maintenance, it is necessary to pay more attention to the construction season, construction techniques, and local climate.

Keywords: diatomite; permafrost embankment; thermal semiconductor.

Background

Preserving permafrost is one of the most basic principles that are adopted in a cold permafrost area. Prethawing techniques can be an alternative for a small portion or shallow, thin permafrost layer, but excepting such conditions, preservation of the permafrost is frequently used in practice. In order to preserve the permafrost, many researchers and engineers have proposed measures which cool down the permafrost by means of adjusting radiation, convection, or conduction. From the point of adjusting conduction, increasing thermal resistance is often used in a cold permafrost area to raise the permafrost table and prevent the frozen soil below the permafrost table from thawing. For example, EPS and PU are often used because of their low conductivity, but warm permafrost dominates the Qinghai-Tibet Plateau. The above measure is very difficult to ensure the stability of a frozen soil ground-foundation. Active cooling measures are essential for preserving permafrost in this area (Cheng 2005, 2007). Construction material with special thermal conductivity features, with conductivity which is higher at low temperatures than at normal temperatures, can be particularly effective in utilizing "thermal offsets" in the active layer soils.

There is a large difference of thermal conductivity between water (0.6 W/m·K) and ice (2.3 W/m·K). Thus, the water can be regarded as a thermal diode with the critical temperature of 0°C. However, as a construction material, it is unsuitable because of its many known disadvantages in foundation engineering. Light, porous media with strong water absorption ability provide an ideal alternative for utilizing the special property of water. For example, peat soil and urea-formaldehyde have been used as thermal semiconductors in arctic and subarctic permafrost regions (Ersoy 1980, Mchattie 1983, Feklistov & Rusakov 1996). Many field experiments and engineering practices have proven their cooling effects (Ma et al. 2002). However, this method has never been applied in the permafrost region in the Qinghai-Tibet Plateau because of the scarcity of those materials (Ma 2005). Diatomite has high porosity and a great capacity for water absorption. Previous tests have shown that the water content of diatomite can easily reach about 200%.

Strong absorption capacity implies its potential as a thermal semiconductor.

Test on Thermal Conductivity of Diatomite

The testing sample was a kind of coarse-grain diatomite (Fig. 1), produced in Jilin province, China. It has a strong water-absorption capacity and high stability after water saturation. Its bulk density varies from 0.35 to 0.43 g/cm^3; its specific gravity is about 2.1. The bulk density of the testing sample is about 0.4 g/cm^3. Thermal conductivities of the diatomite with different water contents were measured both in the frozen and unfrozen states. Test results are listed in Table 1.

From Table 1, it can be seen that with the increase of water content, the difference in thermal conductivity of diatomite between frozen and thawed states also increases. When the water content reaches 140% (saturation about 70%), the ratio of thermal conductivities between frozen and thawed diatomite is 1.66.

Water Retaining Ability of Diatomite

The thermal conductivity ratio between frozen and unfrozen diatomite is associated with its water content. In the engineering practice, it is necessary for the constructor to know its water retaining ability.

Water retaining ability tests were conducted in the laboratory. Ambient temperature was about 20°. Wind was simulated by fan. Wind direction was parallel to the sample's top surface; wind speed was about 5m/s, which is similar to the field environment. Naked diatomite, diatomite covered by a 2 cm thick sand layer, and a 5 cm thick sponge were monitored. From Figure 2, water loss rate all increased with time under the above three experiment conditions. For naked diatomite, the evaporation rate is faster than the one covered by sand or sponge the first four days. Ten days later, all evaporation rates nearly approximate the same value at 55%. Owing to the availability of sand and its early good effect, sand cover was recommended in the field.

Thermal conductivity (w/m·k)	Frozen	0.26	0.53	0.76	1.08	2.33
	Thawed	0.24	0.35	0.46	0.44	0.78
	ratio	1.08	1.51	1.66	2.47	2.98

Introduction of Experiment Engineering

The field experiment was conducted on a northern slope of Hongtupo Mountains between milestone 391+000 and 391+120 along the National Highway 214 (Figs. 3, 4). It was constructed on the upper part of a gentle permafrost slope. The longitude and latitude of the center of experimental section is 98º58.154′E and N35º14.136′N. This section extended 10° SW. The road surface is asphalt paved. On the left, grass grows well, and vegetation coverage is about 70%; on the right, the earth surface is moist, and the vegetation coverage is about 40%. The roadbed is 2.5 m high on the left and 3.5 m high on the right. Annual rainfall is less than 100 mm, and mean annual air temperature is about -4.5 ºC.

The experiment site is located in permafrost area. The volumetric ice content there is 10%–20%. The natural permafrost table is about 2.4 m; the artificial table is about 8.0 m under the road surface; and the mean annual ground temperature is -0.9ºC. The diatomite experimental section has a total length of 50 m. Diatomite layers 0.4 m thick cover both side slopes.

Construction work can be divided into two parts. At the first stage in November 2003, the dry diatomite was laid on the side slope. In April, 2004, water was sprayed for the

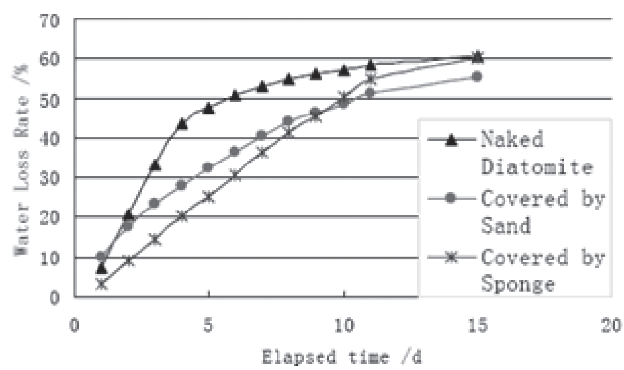

Figure 2. Curves of evaporation ratio changing with time.

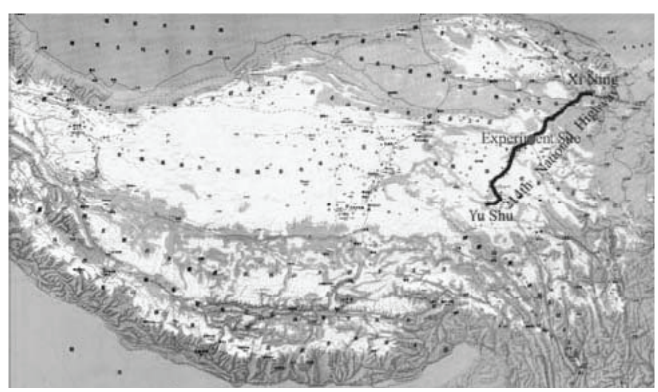

Figure 3. Location of 214th National Highway and the experiment site in the Tibet Plateau.

Figure 4. Experimental section of diatomite protection-slope.

first time. Water content of diatomite reached about 140% at that time. A 0.1 m thick sand soil was put on the diatomite layer to keep the stability of the diatomite cover and reduce evaporation (Fig. 4).

Three monitoring sections were arranged. Two sections (K391+085, K391+100) were the diatomite experiment; another one (K391+050) was a reference. Four monitoring boreholes were drilled for each section. There were located at the east slope-toe, east shoulder, centerline, and left shoulder. Temperature probes were installed in the boreholes at an interval of 50 cm. On both side slopes, 10 temperature probes were installed 50 cm beneath the surface. Monitoring work was conducted between June 2003 and September 2006. Except for a monitoring borehole for measuring natural ground temperatures at K391+085, all monitoring items were identical in the three sections.

Analysis of the Cooling Effect of the Diatomite

Surface temperatures of side slopes

Side slope surface plays a very important role in the thermal balance of a roadbed. High surface temperature is bound to result in the degradation of underlying permafrost. Figure 5 displays the curves of 50 cm deep surface temperature changing with time.

It is evident in Figure 5 that: (1) in a year, slope surface temperatures of reference and diatomite sections behave differently. Compared with the diatomite section, the temperature of the reference section is higher in the summer and lower in the winter. This phenomenon is similar to what happens to the roadbed using EPS or PU. It shows that diatomite can effectively increase the thermal resistance and drop the annual temperature amplitude. Therefore, diatomite can raise the permafrost table and enhance the stability of frozen soil foundation. (2) With time elapsing, the temperature difference between the reference and diatomite sections increased in the summer and declined in the winter. From this point, the diatomite layer served as a thermal insulator and prevented insolation heating from the side slopes into the roadbed in the summer. It served, also, as a thermal conductor and facilitated heat release in the winter.

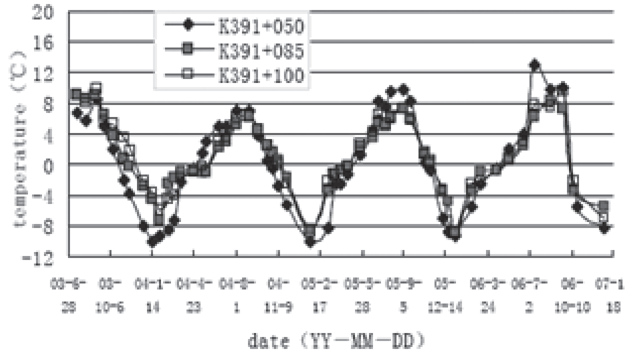

Figure 5. Curves of slope surface temperature changing with the time.

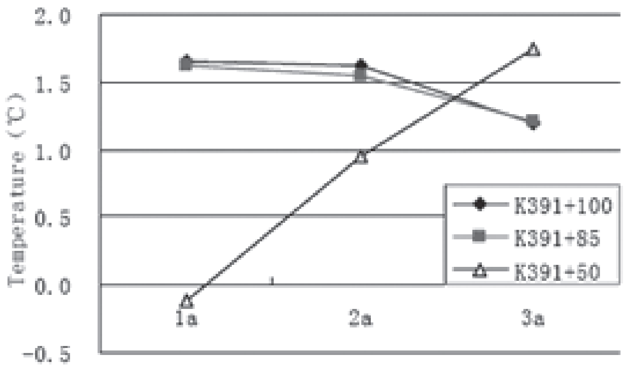

Figure 6. Curves of mean annual temperature of slope surface temperature changing with time.

This phenomenon demonstrates the thermal semiconductor effect of diatomite.

Temperature curves are not adequate proof of the cooling effect of diatomite because the whole year effect is not yet determined. Mean annual temperature is an essential index to affecting the developing trends of the underlying permafrost. In the first two years, the mean annual temperature of the slope surface was lower in the reference section than in the diatomite section, but in the third year, the result was reversed. The mean annual temperature of the diatomite section began to be lower than the reference section (Fig. 6). It can be concluded from the feature of temperature curves that the temperature of diatomite will decline continuously in the next few years, and the temperature difference between the diatomite and the reference section will increase. The cooling effect of the diatomite layer will be confirmed strongly.

The permafrost table

A permafrost table is an often-used index to characterize the cooling effect of engineering measures. It can directly indicate the final effect of diatomite. Figure 7 indicates the permafrost table observed in the boreholes in the reference and diatomite sections.

The permafrost table in a natural state changed little from 2003 to 2004. Therefore, the effect of air temperature changes on the cooling effect of diatomite is minor and can be omitted. The permafrost table dropped abruptly beneath the roadbed in the first year. Although the permafrost table

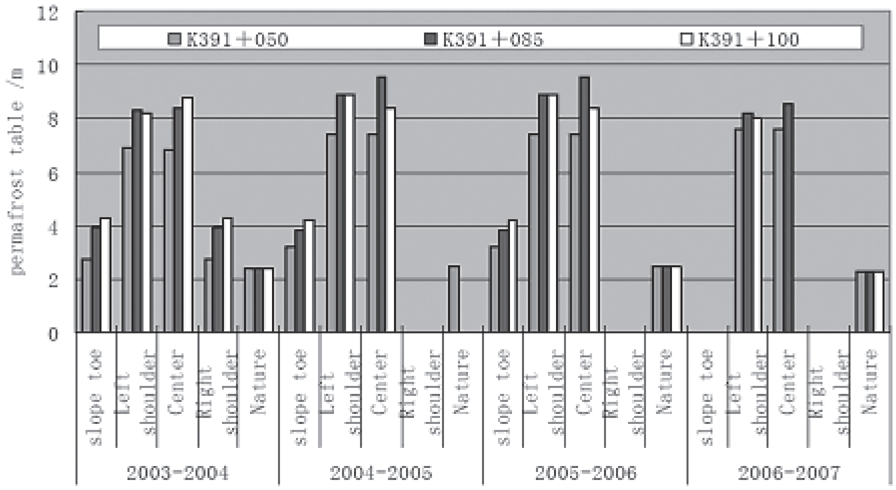

Figure 7. Contrast of the permafrost table between the experiment and comparing section.

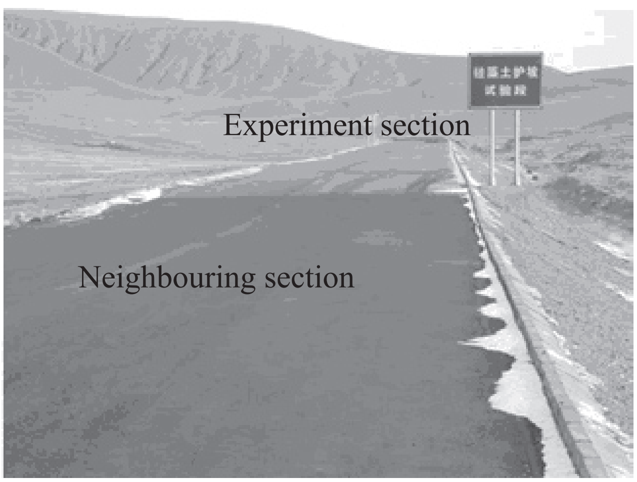

Figure 8. Operational status of experimental section and neighboring section.

in the reference section was higher at the beginning, the trends are more beneficial to the diatomite section than the reference section. In the second and the third year, the permafrost table in the diatomite section fluctuated greatly, but that in the reference section kept lowering. In the fourth year, the permafrost table in the reference section continued to decline, but that in the diatomite section rose. Considering the trend of mean annual surface temperature, the permafrost table will go up continuously over the next several years. The rise of the permafrost table shows that the diatomite layer can act as a good thermal semiconductor when it is saturated with water/ice.

Operational status

As of this year, the experimental section with diatomite has worked for four years. The roadbed kept its stability, and the road surface needed little maintenance. This section kept its good performance. However, in the neighboring section, the asphalt pavement has been repaired one time only two years after construction finished (Fig. 8). Investigation at the end of 2006 showed that waves appeared here.

Problems and Discussions

Although four years of field data prove that the diatomite layer can effectively protect the underlying permafrost, early data are disappointing. It is necessary to analyze the phenomenon in order to avoid future mistakes and to find solutions to problems not previously noticed.

Previous research showed that the construction season plays an important role in the ground temperature under the roadbed and embankment in the initial stage. Its effect can last three or more years (Wen 2006). This is especially true for a roadbed using insulation. In the early spring, ground temperature is relatively low, but topsoils begin to thaw and construction is easier than in the winter. If EPS or PU is added, it can effectively reduce the incoming heat in the coming warm season. On the contrary, if insulation is constructed in the late autumn when ground temperatures are relatively high, it would help prevent heat within the roadway from releasing. In this experiment, diatomite was constructed in the adverse season. Consequently, the permafrost table was deeper and the side slope surface temperature was higher in the diatomite section in the initial several years.

Construction techniques also are important. From November 2003 to April 2004, the diatomite was dry. The dry diatomite is just a thermal insulator and retains the internal heat releasing. Thus, the permafrost table in the diatomite section decreased abruptly in the first year. Furthermore, laboratory test results suggest that the water retaining ability of diatomite is less satisfactory than expected. Due to the lack of maintenance and water-tight measures, the water content changed greatly after April 2004. Investigation in the winter of 2005 and 2006 showed that, although the total water content was more than 100%, the top 3 cm diatomite layer was only about 1%. This layer played a role in insulation during winter. It depressed the semiconductivity performance of diatomite.

Climate also affected the cooling effect of diatomite. The experimental section is located in a cold and arid region. Evaporation potential is far greater than the precipitation.

For diatomite only covered by 10 cm sand, it is impossible to maintain the state of high water content in the diatomite if maintenance is scarce.

Conclusions

Diatomite can be used as a thermal semiconductor. The performance of a diatomite semiconductor improves with the increase of water content. A diatomite semiconductor can delay the degradation of the underlying permafrost and improve the stability of a road embankment; however, because the period of observation was only four years, its long-term effect needs more validation. This experiment demonstrated that it is necessary to pay more attention to construction season, construction techniques, local climate, and maintenance before a thermal semiconductor is utilized to cool down the permafrost embankment.

Abstract

The China-Russia oil pipeline is designed to transport 603,000 barrels of Siberian crude oil per day using a buried pipeline 914 mm in diameter across 1030 km of permafrost and seasonally frozen ground. Construction was scheduled to be between March 2008 and August 2009. The design was significantly challenged by differential frost heaving and thaw settlement. About 500 boreholes to depths of 5 to 20 m were drilled and cored for analyses, and frozen ground conditions were evaluated. Conventional burial construction modes were adopted after detailed surveys and analyses of permafrost conditions along the pipeline route**.** Permafrost forecasts, thermal and strain/stress analyses, measures to mitigate frost hazards, and a design for long-term monitoring and early detection of developing frost hazards were conducted. Mitigative measures using excavation and backfill of non-frost-susceptible soils, insulation, and drainage control were proposed and adopted. A review of the engineering activities and measures undertaken to address these concerns is presented herein.

Keywords: China-Russia oil pipeline; engineering geology; frost heaving; mitigation; permafrost; thaw settlement.

Introduction

A key component of the Siberian-Pacific oil pipeline is a 1030 km-long, 914 mm-diameter spur pipeline to transport 603,000 barrels of oil daily from Skovorodino, Siberia (54.0°N, 123.6°E, 398 m in elevation) to Daqing, China (46.6°N, 125.0°E, 151 m). The spur pipeline will enter Northeastern China near Mo'he (53.5°N, 122.4°E, 350 m) (Fig. 1) and cross 965 km of permafrost and seasonally frozen ground in China.

Potential pipeline routes were hotly debated in the past 12 years. The Mo'he to Daqing route was chosen because it offered the shortest distance through ice-rich permafrost and wetlands reserves, generally more favorable terrain conditions, and easier access to existing transportation corridors. The pipeline, using conventional burial, is designed to transmit unheated crude oil, with an estimated incoming oil-temperature range of -6°C to +10°C at the Mo'he inlet. It traverses 530 km of warm permafrost, of which about 118 km in China is ice-rich. Permafrost features vary greatly over short distances. In the south, it traverses about 500 km of seasonally frozen ground, with maximum frost penetration depths of 1.8 m to 4.0 m. Preliminary and detailed designs were completed by August and December 2007 respectively. Construction is scheduled in 2008–2009.

The design along an unheated pipeline buried in frozen ground required mitigation of frost heaving in the cold season and thaw settlement in the warm season. A series of resultant environmental impacts and geohazards on pipeline foundation stability needed to be economically minimized after the massive pipeline construction and during the operation period. Therefore, proper designs needed to compromise between long- and short-term investments. Since 2004, the permafrost research activities have been focused on the prediction and mitigation of frost heaving and differential thaw settlement of pipeline foundation soils in order to provide technical support for the pipeline design. This paper reviews the overall research activities and engineering measures addressing these concerns.

Study Regions

Topography, geology, and climate

The pipeline route crosses about 965 km of mountains and plains in Northeastern China. In typical soil profiles, peat and humic soils are underlain by clayey sands and sandy clays. The region along the pipeline route is characteristic of a temperate continental monsoon climate with long, dry, cold winters and short, moist, warm summers. Mean annual air temperatures range from 0°C to 1°C in the south to -5°C to -6°C in the north. Annual precipitation ranges from about 400 to 700 mm, 80%–90% of which falls in summer. The vegetation is comprised of cold to temperate mountain needle-leaf forest. Needle and broad-leaf mixed forests and forest steppes gradually appear when moving southwards into the piedmont area. They are eventually replaced by agricultural land at the southern end of the pipeline route.

Permafrost features

Permafrost conditions are characterized by latitudinal and elevational zonation, with local marked variations. The areal extent of permafrost increases northwards from 0% to 65%, and mean annual ground temperatures decrease from 0°C to -2.6°C (Table 1). The observed thickness of permafrost varies from about 1 to 60 m; occasionally permafrost extends to 120 m. Permafrost zones range from isolated patches to widespread discontinuous zones of permafrost. In the northern Da Xing'anling Mountains, tussocks and moss layers are dense, and the thicknesses of surficial deposits are 8–12 m on the shaded slopes of intermontane basins, in wetlands or in lowlands, and on low river terraces. Permafrost

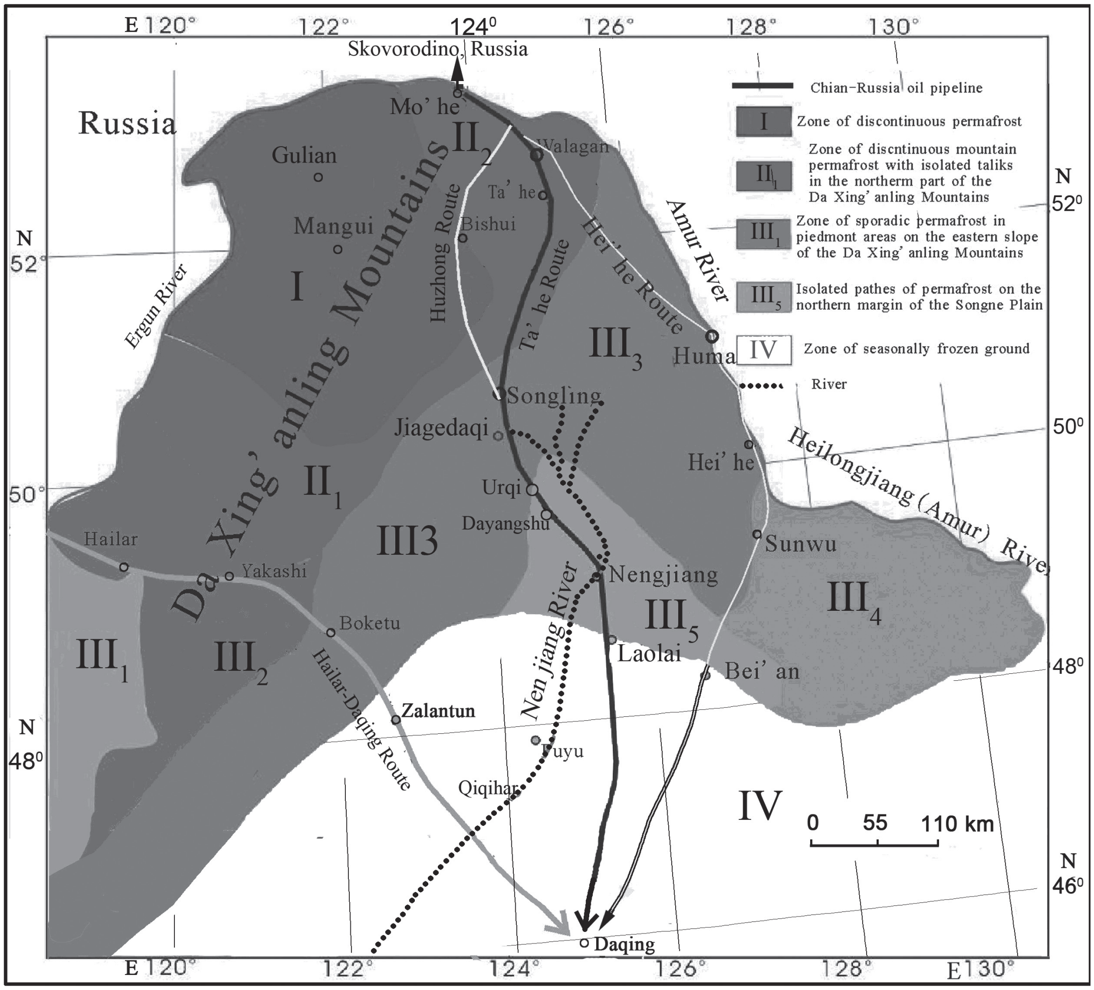

Figure 1. China-Russia oil pipeline routes in Northeastern China (revised from Guo et al. 1981 & Jin et al. 2007a).

can be as thick as about 50 m to 60 m. In contrast, on treeless or sparsely vegetated sunlit slopes with thick surficial deposits, permafrost is either thin or absent. On shaded slopes with dense vegetation, permafrost conditions are intermediate between valley bottom lowlands and sunlit slopes.

Seasonally frozen ground

When moving southwards, the maximum thaw depths in river taliks in increasingly fragmented discontinuous permafrost is 2.5 m to 4.0 m, depending on surface cover, soil moisture conditions, and lithology. Seasonally frozen ground largely replaces permafrost from Da'yangshu southwards (Fig. 1). Topographically, this is the transition between the eastern slopes of the Da Xing'anling Mountains and the northern Nen Jiang River Plain. The lithology consists of silt and/or silty clay. The ground water table is generally shallow, and long, cold winters favor frost heaving when moisture and soil conditions suffice. The maximum depth of frost penetration is 1.8 m to 3.5 m, occasionally to 4.0 m.

Study Methods

Survey and investigation of permafrost

The distribution and thickness of warm, ice-rich permafrost; the types, distribution, genesis and features of hazardous periglacial phenomena and assessment of their potentially adverse impacts on pipeline infrastructures were of particular interest in the surveys and investigations (DOE 2007a). During the feasibility, preliminary, and detailed survey stages, about 500 boreholes with depths of 5 m to 20 m were drilled and cored for analyses.

Assessment and forecast of permafrost conditions

The assessment and forecast of permafrost included evaluation of the present conditions of permafrost along the pipeline route and their possible changes during the next 50 years (DOE 2007b). The assessment was based on 1951 topographic maps, permafrost data obtained during the 1970s, field engineering explorations in 2006–2007, and aerial mapping at 1:2000 along the pipeline route in 2006–2007. The assessment covered soil strata, topography and geomorphology, permafrost features, engineering geology, classification of frost heaving and thaw settlement of foundation soils, overall assessment, and advice on pipeline construction modes (Jin et al. 2007a). The overall assessment considered the genetic types, water/ice contents, and thaw-sensitivity and/or frost-susceptibility of the pipeline foundation soils.

The zonation has three hierarchical levels: zone, subzone, and section of frozen ground engineering geology (Jin et al.

The depth of zero annual amplitude of ground temperature, which generally ranges from 10 to 15 m. Air temperatures were based on meteorological data from 1970 to 2005.

2007a in press). Frozen ground along the pipeline route was first divided into zones of seasonally frozen ground, isolated patches, sporadic, and discontinuous permafrost based on the areal extent of permafrost. The zones of permafrost were divided into thermal stability subzones of very unstable (>-0.5°C), unstable (≥-1°C), and stable (<-1°C) permafrost. The 3rd-tier of permafrost zones was based on the soil moisture content. The overall and by-segment assessment synthesized available information.

Changes of permafrost were projected for Northeastern China during the 21st century using GIS-aided equivalent-latitude models (Wei et al. 2008). Possible changes of permafrost conditions at selected sites along the pipeline route were forecasted using the finite-element method. The prediction considered typical boundary and initial conditions based on the observed present conditions along the pipeline route (Jin et al. 2007a). These conditions included air, ground surface, ground temperature and their seasonality; ice-contents, types of permafrost, and a climate warming scenario of 2.4°C during the next 50 years, and influences of anthropogenic activities represented by removal of vegetation and pipeline operation.

Simulations on pipeline-soil interactions

According to the best estimation, crude oil temperature will vary from -6°C to +10°C at the Mo'he inlet at the start of oil transmission in August 2009. It was assumed that oil temperatures would have seasonal sinusoidal variations for 50 years, and that the top of the pipeline would be buried at a depth of 1.5 m. Thermal analyses focused on temperatures of crude oil in the pipeline and of foundation soils along the pipeline route; and resultant seasonal and long-term freeze-thaw processes around the buried pipe and along the route, both without engineering measures and with some mitigative measures (insulation, backfill of non-frost-susceptible (NFS) soils, and drainage control). Stress/strain analyses included studies on the coupled thermo-mechanical interactions between the pipeline and foundation soils, possible weak segments along the pipeline with and without the mitigative measures, and checks against the design criteria for steel pipeline integrity, safety, and long-term stability.

Mitigation of frost hazards

Engineering measures for mitigation included: 1) stress and strain constraints for pipeline safety; 2) excavation and backfill of NFS-soils at segments with significant frost hazards; 3) drainage and flood controls; 4) insulation; 5) burial depth; 6) transition zones; 7) river and other crossings of linear infrastructures; 8) slope stability; 9) periglacial hazards; and 10) project management in permafrost regions.

Monitoring of pipeline foundation soils

Permafrost temperatures along the pipeline route were measured generally on a weekly basis, using thermistor cables fixed in cased boreholes during the 1970–1980s. During 2007–2008, 12 exploratory boreholes with depths of 15 m to 20 m were chosen for ground temperature measurements using thermistor cables (Jin et al. 2007a).

A program for long-term monitoring of pipeline foundation soils was established to ensure pipeline long-term safety through early detection and proactive mitigations of pipeline foundation soil problems. The monitoring elements included ground temperatures, soil moisture contents, and deformation of the pipeline foundation soils, both in the proximity of the pipeline and under natural conditions, for comparison. There were 20 cross-sections designed and they were to be implemented during and/or after pipeline construction.

Results and Discussions

Assessment and forecasts of permafrost

Permafrost along the pipeline route has been in degradation during the past 40 years due to significant climate warming of about 0.9°C to 2.5°C and increased human activity (Jin et al. 2007b). Frozen ground and engineering geology conditions along the pipeline route were inadequately understood for pipeline design prior to the survey in 2006–2007. Recent surveys indicated that about 118 km of warm, ice-rich permafrost along the route needed particular attention. Generally, these segments are associated with wetlands underlain by thick silts or clays.

The major frozen ground zones included: 1) Mo'he-Walagan zone of discontinuous (65% to 80%) permafrost with isolated taliks; 2) Walagan-Songling zone of discontinuous (35% to 65%) permafrost with extensive taliks; 3) Songling-Jiagedaqi zone of sporadic (10% to 35%) permafrost; 4) Jiagedaqi-Dayangshu zone of patchy (<10%) permafrost; and 5) Dayangshu-Daqing zone of seasonally frozen ground (Fig. 1).

The forecast of permafrost conditions considered permafrost types and cover conditions representative of the pipeline route, the removal of forest vegetation during pipeline construction, and climate warming of about 2.4°C during the pipeline lifespan. It is evident that the permafrost tables will deepen; the rates of temperature increase will slow with operating time, increasing ice contents, and decreasing ground temperatures. However, thaw settlements of pipeline foundations will increase with higher ice contents.

Thermal analyses

Oil temperatures at the incoming Mo'he Pump Station and along the pipeline route will be subject to seasonal and interannual variations due to the heat exchanges along the routes in Siberia and China.

Distribution of oil temperatures along the 965 km route during the pipeline lifespan was a key issue to pipeline-soil interactions and pipeline foundation design due to its control on areal extents and developing trends of seasonal and interannual freeze and thaw cylinders around the operating pipeline. These further control the deformations and stresses on the pipeline, and the mitigative measures required. The simulations results indicated that oil temperatures cool southwards in the warm season, but that they warm southwards during the cold seasons (Sheng et al. 2007, 2008). As a result, the amplitudes of seasonal variations will decrease southwards and reach a quasi-stable state at about Km-870 (Fig. 2). Oil temperatures could slightly increase with elapsing time due to climate warming. However, the average annual oil temperature decreases southwards in the north, then starts to increase from about Km-488. This is because ground temperatures along the pipeline route are low before reaching Km-366, roughly 0°C at Km-366 to Km-431, and above 0°C southwards.

The thaw depth beneath the pipeline in the cold (<1.0°C) permafrost area north of Ta'he generally will be small (1.3 m to 2.3 m), but will increase southwards. In the warm (>1.0°C) permafrost area, the thaw depth will increase sharply. With elapsing time, thaw settlement prevails due to thermal impacts from pipeline operation. Changes of the ice-rich permafrost table will be 0.5 m to 2.0 m. The resultant thaw settlement in the north (Km-0 to Km-317) will be large and will need to be mitigated. In the southern part (Km-317 to Km-630), frost heaving in the wetlands will be a major challenge. The depth of ground freezing beneath the pipeline will decrease from about 0.4 m at Km-317 to 0 m at Km-580. By Km-700 minimum oil temperatures will be greater than 0°C.

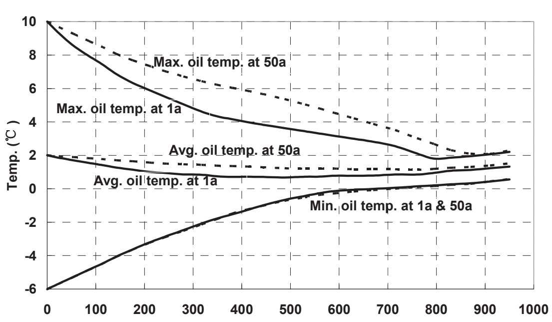

Figure 2. Predicted changes of oil temperatures along the proposed route of un-insulated pipeline.

Two-directional freezing in winter and thawing in summer will occur in soils surrounding the buried pipeline. The thaw cylinder around the pipeline will enlarge with elapsing time but at a decreasing rate with increasing ice contents. The frozen cylinder around the pipeline will diminish with elapsing time, with increasing soil water content, and when moving southwards. Insulation can effectively reduce the development of freeze-thaw cylinders during the early years of operation.

Strain/stress analyses and pipeline safety constraints

Frost heaving and differential thaw settlement will result due to spatiotemporal seasonality of oil and soil temperatures and differences of soils and pipelined oil at certain sections (AGRA Earth & Environmental Limited and Nixon Geotech Limited 1999). However, the pipeline is more tolerant of differential thaw settlement than frost heaving. The largest stress would occur in the center of thaw settlement or in the transition zone between frost heaving and non-frost heaving sections; the largest allowable deformation will increase with section length of frost heaving (Sheng et al. 2007). Therefore, frost mounds pose greater threats to the pipeline. The transition zone between frost heaving and thaw settlement is also hazardous. The length of frost-heaving zones has a significant impact on the pipeline bending moment. Any increase in the length of the transition would mitigate frost heaving on the pipeline.

Numerical analyses were conducted on effective stresses on pipeline under various combinations of oil pressure, pipe-wall thickness, length of transition, frost heaving and differential thaw settlement conditions, to determine the maximum allowable deformations under certain combinations of oil pressures and pipe-wall thicknesses (Sheng et al. 2007, 2008).

The stress/strain criteria for designing pipeline foundations were provided according to the best estimates of potential frost heaving and thaw settlement of soils along the pipeline and analytical results of frost heaving and thaw settlement. A linear transition zone model in which the coefficients of frozen and unfrozen ground were 23.4 and 6 MPa, was used, and the length of the transition zone was 40 m. Pipeline foundation safety with and without mitigative measures and its classification under differential deformation, and under various wall thicknesses, oil pressures, and lengths of transition, were analyzed using numerical models for the pipe-soil interactions (Sheng et al. 2007). Reducing the intensity of longitudinal differential deformations using proper insulation, backfill of NFS soils (bedding), and increasing the wall-thickness of the pipe could effectively mitigate the damage from frost hazards (Jin et al. 2007a, Sheng et al. 2007).

Mitigative measures and construction mode

During route selection, the engineers chose locations with less-frost-susceptible soils, less soil moisture, deeper ground water tables, and sun-lit slopes. Patchy or sporadic permafrost was avoided or crossed in the shortest distance possible. Other considerations included avoidance of solifluction, icings, frost mounds, wetlands and maintenance of slope stability.

During the design phase, insulation was considered for permafrost areas with high ice contents and susceptibility to frost heaving, to minimize the freeze-thaw extent around the pipeline and thermal impacts of heat exchanges with the underlying permafrost. Differential deformations in interfaces of ice contents, soil types, frost-susceptibility, and construction modes required special attention. In sections with shallow, ice-rich permafrost, backfilling with NFS-soils was accomplished. In the section with thick, ice-rich permafrost, a combination of localized backfill of NFS soils, proper insulation, and drainage control were considered. In sections with extensive frost-susceptible soils, drainage control was critical.

During the construction phase, all designs or changes in design were managed strictly according to the opinions of experienced cold regions engineers. The proper construction season for burial of pipeline in permafrost was in late winter and early spring. Careful examinations of excavated soil profiles were important, as surveys were often inadequate in revealing special permafrost conditions. Removal of vegetation adjacent to the pipeline, operation of large equipment, and necessary drainage were controlled.

The burial depth of the pipeline was designed according to the "*Code for Design of Oil Transportation Pipeline Engineering*" (People's Republic of China National Standard 2003), and to accommodate the local conditions such as thickness of frozen ground, geological conditions, transported oil temperatures, and farmland and woodland. The pipeline was conventionally buried in ice-poor and -medium permafrost areas, or areas with shallowly buried bedrock and the total length is 124.9 km. When passing through forests, the top of the pipe was buried deeper than 1.6 m (below the depth that could be impacted by local forest fires) (Zhou et al. 1994). The pipe ditch was 0.2 m deeper than regular areas, and the fine-grained backfill reached a depth of 0.3 m above the pipe top. In areas north of the Jiagedaqi, the pipe top was buried at depths of 2.2–2.4 m because the measured maximum depth of seasonal frost penetration is 2.6 m to 2.8 m in taliks with frost-susceptible soils.

In the seasonally frozen ground areas south of Jiagedaqithe burial depth of pipeline top was set at the depth of 0.4 m above the maximum local depth of seasonal frost penetration from Jiagedaqi to Ne'he, 1.9 m in Yi'an County, 1.8 m in the Lindian and Daqing areas.

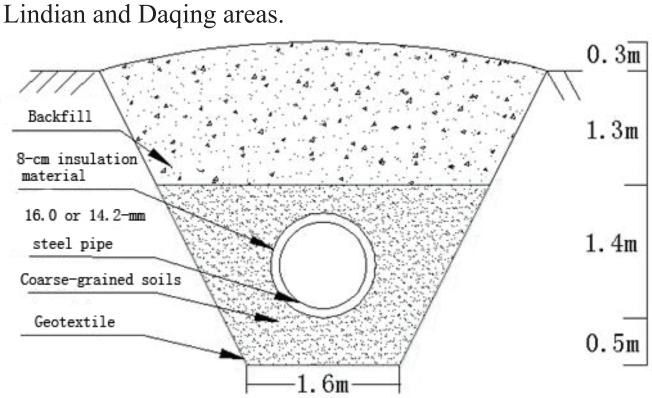

Figure 3. Burial using backfill and insulation for wetlands underlain by thick, high-ice-content permafrost.

The modified burial using coarse-grained (bedding) sand and gravel beneath the pipe was adopted for the ice-saturated and ice-rich permafrost areas. Elevation was not considered because of frequently-occurring forest-fire concerns. The top of the pipe is 1.5 m and the total length of the modified burial is 3.63 km.

In high-ice-content permafrost areas with large active layer thickness, modified burial with insulation and backfill of NFS soils was adopted (Fig. 3) for a total length of 28.3 km. In wetlands underlain by permafrost (total length of 39.2 km), or with frequently-occurring outflow springs (total length of 1.59 km), a similar approach was adopted.

Areas of very ice-rich patchy permafrost, generally less than 3.7 m in thickness, were backfilled with coarse-grained soils (bedding materials). The pipe top was buried 2.0 m. When the thickness of permafrost was large, the pipe top was at 1.8–2.0 m in areas with weakly thaw-sensitive permafrost, or where ice-rich permafrost was partially removed (Tables 2, 3).

Table 2. Results from thermal and strain/stress analyses on backfill and insulation (Sheng et al. 2007).

Mitigative measures	Wall thickness of pipe	Frozen depth beneath pipe	Stress on pipe (MPa)	Thickness (m) of backfill beneath pipe
Backfill, 8-cm Insulation	16.0 mm	0.75 m	315	0.3
	14.2 mm		308	0.5

Table 3. Statistics on mitigative measure for permafrost hazards along the China-Russia oil pipeline..

Type of frozen ground	Mitigative measures	Length (km)
Talik (Seasonally frozen ground)	Pipeline top 0.4 m above the local frost penetration; 0.2 m excess backfill of NFS soils beneath pipe. Pipeline top at 1.6 m in bedrocks	142.86
Ice-poor,-medium permafrost	Conventional burial, pipe top at 1.8 m	209.46
Ice-rich permafrost (non-wetlands areas)	Pipeline top at 1.6 m, 8-cm-thick insulation around the pipe, 0.5 m backfill of coarse soils beneath pipe of 14.2-mm-wall thickness	40.73
	Backfill of NFS soils, 14.2-mm-pipe-wall thickness	21.18
Wetlands with ice-rich permafrost	Pipe top at 1.8 m, 8-cm-thick insulation around pipe, 0.3 m backfill of coarse soils beneath pipe of 16.0-mm-wall-thickness	42.72
Areas with springs		1.59

In ice-rich permafrost areas, the top of the pipeline was buried 1.6 m with backfill of NFS-soils, insulation, and other measures. In wetlands underlain by the ice-rich permafrost or with frequent occurrence of outflow springs (potential icings and frost mounds), frost hazards and pipeline floating due to hydrostatic pressure were mitigated using the modified burial with NFS-soil backfill, insulation, and drainage control. If only partial backfill of NFS-soils was required, its depth was chosen based on local engineering geological conditions. When partial backfill of NFS-soils and insulation was required for protection of permafrost and maintenance of a preset, engineered permafrost table, the depths of backfill of NFS soils and insulation parameters were optimized by thermal and strain/stress analyses (Table 2) (Sheng et al. 2007).

Summary and Conclusions

The China-Russia oil pipeline traverses warm permafrost regions with significant frost hazards in Northeastern China. Significant changes of permafrost were observed or projected along the pipeline route.

Pipeline oil temperatures are expected to generally increase southwards and with time; the effects of climate warming are anticipated to be overshadowed by oil temperature variations; insulation tends to constrain the oil temperature variations and the freeze-thaw cylinder around the pipeline early in the pipeline operation period. Differential thaw settlement is anticipated to have a lesser impact than frost heave on the pipeline.

Conventional burial was chosen for the pipeline in spite of possible significant frost heaving and thaw settlement because of concerns about frequent forest fires, inevitably posing substantial risk to pipeline integrity. Therefore, a system for long-term monitoring and assessment of foundation stability was deemed indispensable for early detection and subsequent proactive mitigation of developing problems.

Abstract

This paper reports permafrost temperatures from three peat mires in subarctic Sweden. There were trends of increasing ground temperatures in the boreholes between 1980 and 2002 of 0.04°C a^{-1} to 0.05°C a^{-1} in the upper 1 m and 0.03°C a^{-1} to 0.04°C a^{-1} in the lower 12–15 m. However, no trend was detected in the middle of the profile. To verify the trends from the mires (with scarce temporal resolution), we use ground temperatures from Abisko Scientific Research Station recorded in an area currently nearby permafrost. Here, ground temperatures have increased on an annual basis and at all seasons apart from the summers, where decreasing temperatures were detected. The changes in ground temperatures could be correlated to increasing air temperature and increasing summer precipitation, but surprisingly not with snow depth. At lower depths the increases may be due to possible increased heating from slightly warmer or more freely flowing ground water.

Keywords: Abisko; ground temperatures; subarctic Sweden.

Introduction

Increases in air temperatures in the Arctic region have been almost twice as high as for the rest of the world during the last decades. This arctic amplification is expected to continue (ACIA 2005). These increases have had and will have profound effects on ground temperatures and, hence, on permafrost distribution (Anisimov et al. 2007). Even though it is widely known that there is a mismatch between air and ground temperatures, as there are other parameters of importance to ground temperatures, increasing air temperature in general increases ground temperatures (e.g., Thorn et al. 1999). For time scales up to a decade, the climatic changes of primary importance for ground temperatures are the changes in air temperatures and snow cover (Osterkamp & Romanovsky 1999). Increasing snow depth increases the insulation of ground from prevailing low winter temperatures and, hence, increases the ground temperatures. In contrast, late snowfall decreases soil temperatures due to the high albedo and the consumption of latent heat during snowmelt (Zhang et al. 2001a). In areas of discontinuous permafrost where air temperatures are close to 0°C, shallow permafrost is especially sensitive to climate warming. In such areas, snow depth and duration are particularly important and, together with air temperature, determine the presence or absence of permafrost.

Increasing ground temperatures have been reported from around the Arctic (e.g., Walsh et al. 2005, Romanovsky et al. 2007, Isaksen et al. 2007, Osterkamp & Romanovsky 1999), but information is underrepresented for the lowland discontinuous permafrost area of northern Fennoscandia. This paper reports permafrost temperatures from three peat mires in subarctic Sweden. Here, important changes in permafrost distribution and active layer depth have been recorded in lowland mires (Akerman & Johansson, submitted). We use the relationships between air temperatures, precipitation, and snow depth to explain the recorded changes in ground temperatures found during the last decades.

Research area

Abisko is located in subarctic Sweden and lies within the zone of discontinuous permafrost (Brown et al. 1998). Mountain permafrost determined mainly by air temperatures is found approximately above 880 m a.s.l. (Jeckel 1988), whereas at lower elevations permafrost is only likely to exist in peat mires (due to the peat's insulating effect) and underneath wind-exposed ridges (due to lack of snow) (Johansson et al. 2006). Ground temperatures have been recorded in peat mires around Abisko (Storflaket and Kursflaket, Table 1), which is located in an area of rain shadow, with a mean annual precipitation of 303 mm a^{-1} (1913–2006) and a mean annual air temperature of -0.6°C (1913–2006). In similar climatic conditions 6 km west of the mires at the Abisko Scientific Research Station, ground temperatures have been recorded in an area currently without permafrost (Abisko AWS, Table 1).

Table 1. The location, depth of measurements and observation periods for the four sites.

Site name	Coordinates (Lat/Long)	Measured at depth (m)	Observation period
Storflaket mire	68º20′51″N 18º57′55″E	0, 0.5, 1, 1.5, 2, 3, 4, 5, 6, 7, 8, 9, 12	1980-1982, 1984-1989, 1994-1997, 2000-2002
Katterjokk mire	68º25′31″N 18º10′29″E	0, 0.5, 1, 1.5, 2, 3, 4, 5	1980-1982, 1984-1989, 1994-1998, 2000-2002
Kursflaket mire	68º21′05″N 18º52′42″E	0, 0.5, 1, 1.5, 2, 3, 4, 5, 6, 7, 8, 9, 12, 15	1980-1982, 1984-1989, 1992, 1994-1997, 2000-2002
Abisko AWS (Automatic Weather Station)	68°21′20″N 18°49′14″E	0.05, 0.2, 0.5, 1	1985 until present

In addition, ground temperatures have been recorded at a mire located 35 km west of Abisko (Katterjokk, Table 1). Due to a very strong climatic gradient that occurs in the area, this site experiences a maritime climate with a mean annual precipitation of 848 mm a^{-1} and a mean annual air temperature of –1.7°C (1960–1990: Alexandersson et al. 1991). The depth of the peat is similar at all mires ~90 cm and is underlain by silt.

Snow depth in winter has increased by 2 cm/decade from 1913 until present in the area, but no statistically significant trend was detected in the start and end date of the snow season (Kohler et al. 2006).

The depth of permafrost ranges from a few meters in the mire located west of Abisko down to 16 m in the other mires close to Abisko (Akerman & Johansson submitted).

Methods

Air temperature monitoring

Air temperatures have been recorded manually at the Abisko Scientific Research Station from 1913 until present (at the outset, every third hour using the same method as used at the Swedish Meteorological and Hydrological Institute, 2 m screen air temperature). In 1984 an automatic weather station was installed and air temperatures have been recorded automatically every 10 minutes since then.

Ground temperature monitoring

At the mires, Copper-Constantan thermocouples were installed in boreholes at depths described in Table 1 and ground temperatures were recorded hourly, the third week of May and September using Campbell loggers.

At Abisko AWS, ground temperatures were recorded using a resistance temperature sensor Pt100 that was connected to an Automatic Weather Station. Data was recorded automatically every 10 minutes.

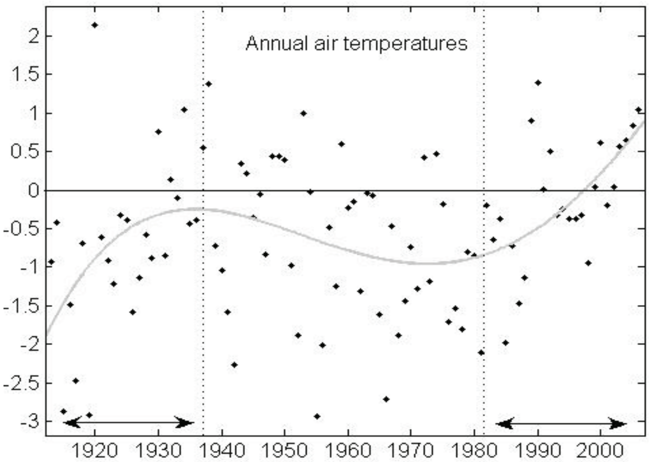

Figure 1. Annual air temperatures and a 4th degree polynomial fit from the Abisko Station, 1913 to 2006. The vertical dotted lines depict the two warming periods for which independent regression analysis was performed.

Data analysis – determining trends and attributing causes of the observed changes

Trends were calculated for the ground temperatures from the three mires and from the Abisko Station by using a robust linear regression, as implemented in the software package MATLAB R2006a. Trends were assumed to be significant for *p* levels ≤0.05. For air temperatures a 4th degree polynomial curve fit was used. To attribute the causes of the observed changes in the ground temperatures, correlation between ground temperatures, air temperatures, snow depth, and precipitation were calculated using multiple regressions (REGRESS) also within the software package MATLAB. All data were normalized and standardized prior to analysis.

Results

Air temperatures from Abisko

The mean annual air temperature at Abisko was -0.6°C between 1913 and 2006. The annual air temperatures at Abisko have during the 20th century experienced an increase in the beginning of the century that lasted until the late 1930s, which was then followed by a slight cooling trend until the mid 1970s and then again followed by an increase that is still ongoing. The regressed mean annual air temperature has been below zero degrees more or less throughout the 20th century, but in the last seven years the regressed annual air temperature has increased above the critical 0°C boundary (Fig. 1). There is an increase in air temperatures during the period of observation of 0.03°C a^{-1} (regression estimate of temperatures). Due to the distinct warming and cooling periods that have occurred throughout the last century, the overall increase in air temperature was not statistically significant (R^2 0.20 *p-value* 0.07). However, when analyzing the two warming periods that correspond roughly with the first 26 years of the record and the last 26 years, statistically significant increases were found (0.09°C a^{-1} for 1913–1938

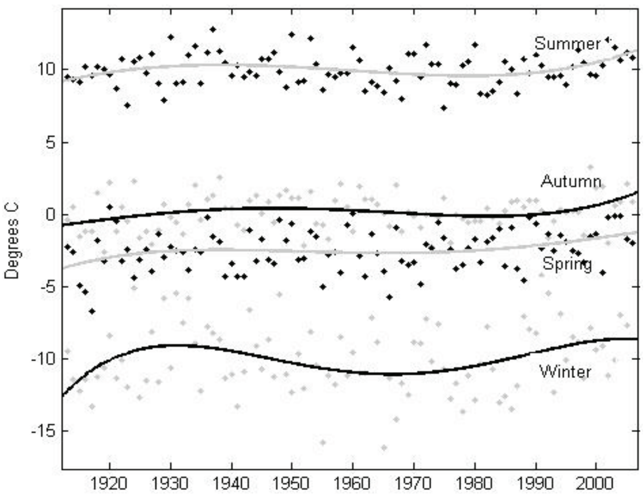

Figure 2. Seasonal air temperatures and a 4th degree polynomial fit from the Abisko Scientific Research Station, 1913–2006.

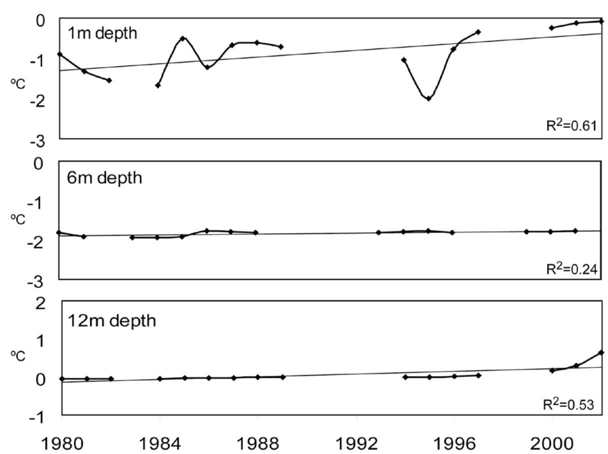

Figure 3. Ground temperatures at 1 m, 6 m, and 12 m depths and linear trends at Storflaket mire measured in September from 1980 to 2002.

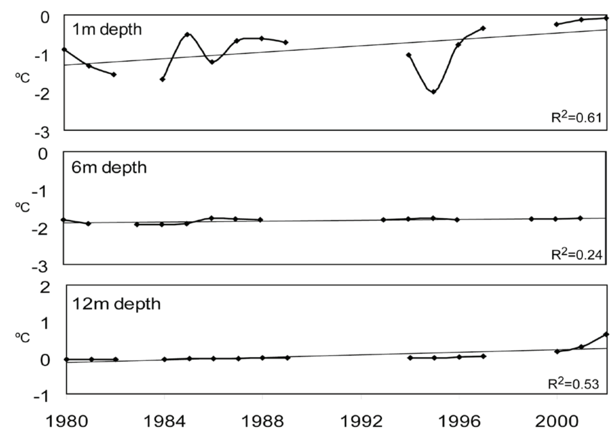

Figure 4. Ground temperatures at 1 m, 6 m, and 15 m depths and linear trends at Kursflaket mire measured in September from 1980 to 2002.

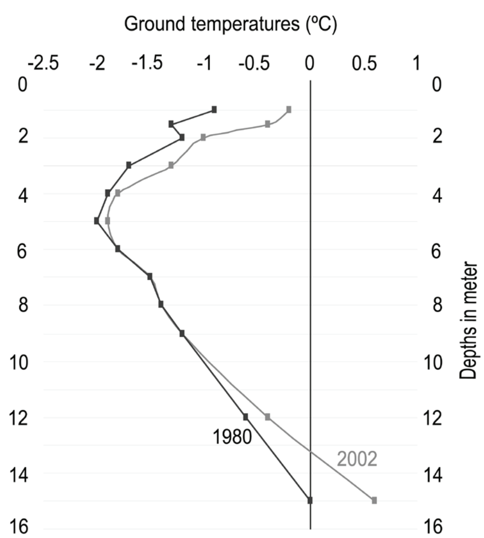

Figure 5. Ground temperatures in September 1980 and 2002 from Kursflaket mire. (Note: There was no subsidence of the ground surface where the temperatures were measured.)

(R^2 0.28 *p-value* 0.005) and 0.10°C a^{-1} for 1981–2006 (R^2 0.43 *p-value* 0.001).

For the whole period of observations there has been an increase in air temperatures in all four seasons that follows the same trend as the annual air temperatures (Fig. 2). The largest increases in temperatures are found in winter (December, January and February) 0.04°C a^{-1} (regression estimates), in autumn (September, October and November) and summer (June, July, and August) an increase of 0.02°C a^{-1} was found. Spring (March, April and May) experienced the lowest increase of 0.01°C a^{-1}. As the seasonal trends follow the annual trends with increases in the beginning of the century, followed by a cooling period and then again a warming period, the trends in increasing air temperatures are not statistically significant for the whole period of observation at all seasons (MAM R^2 0.06 *p-value* 0.02; JJA R^2 0.003 *p-value* 0.6; SON R^2 0.02 *p-value* 0.19; DJF R^2 0.005 *p-value* 0.48). However, over shorter periods of the temperature records, statistically significant trends, like the increases in the beginning and end of the century can be found. In general it is the lower temperatures that have increased.

Ground temperatures from the mires

At Storflaket mire, the ground temperature monitoring has been conducted down to 12 m. There is a statistically significant trend towards warmer September ground temperatures in the upper 1 (0.05°C a^{-1}; R^2 0.61 *p-value* 0.004) and the lower 12 m (0.04°C a^{-1}; R^2 0.53 *p-value* 0.001) depths. In the middle of the borehole no statistically significant trend could be detected (Fig. 3).

In May, statistically significant increasing trends were found at one (0.09°C a^{-1}; R^2 0.38 *p-value* 0.01) and 12 m

Table 2. Regression statistics of ground temperatures between 1985 and 2006 for Abisko AWS including estimates from the regressions of initial and final temperatures and the differences between them.

Time	Depth (cm)	R^2	*p-value*	Regression estimate of temp °C in 1985	Regression estimate of temp °C in 2006	Difference estimated from the regression °C a^{-1}

(0.004°C a^{-1}; R^2 0.89 *p-value* 0) depth, but again not for the depths in between.

At Kursflaket mire, ground temperature monitoring has been conducted down to 15 m. The ground temperatures in September have increased in the upper 1 m (0.04°C a^{-1}; R^2 0.46 *p-value* 0.003) and in the lower part of the borehole at 12 m and 15 m (0.03°C a^{-1}; R^2 0.91 *p-value* 0), while there is no significant trend at depths in between (Figs. 4, 5). In spring no trends were detected at 1 m and 6 m depths. At 15 m there was a statistically significant increasing trend (0.03°C a^{-1}; R^2 0.91 *p-value* 0).

At Katterjokk mire the permafrost is very shallow ranging from 2 m to 5 m; hence, no deeper temperature recordings have been made. The same trend as found in the other two mires was detected, with statistically significant increasing ground temperatures in September in the upper 1 m (0.04°C a^{-1}; R^2 0.53 *p-value* 0.001); but below no significant trend was detected (Fig. 6). In May, statistically significant trends were detected at both 1 m and 5 m depths, and increases of 0.07°C a^{-1} (R^2 0.66 *p-value* 0.0001) and 0.01°C a^{-1} (R^2 0.71 *p-value* 0), respectively, were recorded.

Ground temperatures from the Abisko Scientific Research Station

At the Abisko AWS, the ground temperatures have on an annual basis, increased at all depths (Table 2), but only at 50 cm and 100 cm depth is there a statistically significant trend. In spring, increasing statistically significant trends occur for the same depths, but not in the upper 50 cm. In summer, a decreasing trend in ground temperatures is detected, and down to 50 cm it is statistically significant. In autumn, again we see an increasing trend in ground temperatures, and it is statistically significant for all depths. In winter, there is also an increasing trend that is statistically significant for all depths.

Correlations of air temperatures and ground temperatures, snow depth and precipitation

On an annual basis, we could detect a statistically significant correlation between air temperature and ground temperature at Abisko. The highest correlation is found at the 20 cm depth (R^2 0.66) and the lowest, at the 1 m depth (R^2 0.42). The same pattern is detected for the spring. For summer, no correlation could be found between air temperature and soil temperatures. In autumn, statistically significant correlations could be detected at 5 cm (R^2 0.45) and 20 cm (R^2 0.36) depths, but not at lower depths. In winter, statistically significant correlations between air temperature and ground temperature were found at all depths, 5 cm = R^2 0.64, 20 cm = R^2 0.62, 50 cm = R^2 0.55, and 100 cm = R^2 0.45.

No statistically significant correlations were detected between snow depth and the ground temperature in any of the seasons or on an annual basis at the Abisko AWS.

On an annual basis, a weak statistically significant trend could be detected between precipitation and soil temperature at the 20 cm depth, but not at any other depths. In spring, autumn, and winter no correlations between precipitation and ground temperatures were found, but in summer, a statistically significant trend could be detected at 5 cm and 20 cm depths (R^2 0.30 and R^2 0.23).

Discussion

Mean annual air temperatures at Abisko (Fig. 1) follow the same trend as shown for the Northern Hemisphere (Houghton et al. 2001, IPCC 2007), with a warming period in the beginning of the 20th century continuing until about 1940, followed by slight cooling until the 1970s, and then a second warming period that is still ongoing. Although interannual variation is so large during the last century that the overall increase is not statistically significant, temperature increases are statistically significant in the two warming periods when they are analyzed separately. Similarly, Kohler et al. (2006) did not detect a trend for the whole period (apart from the spring record) but also found statistically significant increases over a shorter time period (1956–2000). The recent increase at the end of the century, mainly due to increases in lower air temperatures, has resulted in a current temperature that is possibly higher than those since at least the Medieval Warm Period (Grudd et al. 2002).

The temporal pattern of mean annual air temperature is repeated in each of the seasons (Fig. 2). For example, Holmgren & Tjus (1996) reported an increase in summer air temperatures from the beginning of the century to about 1940, which was as high as 1.5°C. In addition to the increases in seasonal and mean annual air temperatures, increases in snow depth (Kohler et al. 2006) and active layer depth (Akerman & Johansson Submitted) have occurred in the area.

Increasing ground temperatures could be detected from all four sites, but in the mires, increases in ground temperatures only occurred in the upper and lower parts of the permafrost (Figs. 3, 4). This is accompanied by an increase in active layer depth (Åkerman & Johansson submitted). In the middle, no significant trend was found. Isaksen et al. (2007) also found increases in ground temperatures in mountain permafrost in northern Scandinavia. They detected significant warming down to at least 60 m in depth. Statistically significant correlations were found between the seasonal ground and air temperatures (Isaksen et al. 2007).

We hypothesized that ground temperatures would have been determined by snow depth in addition to air temperatures. This hypothesis was based on studies such as that by Thorn et al. (1999), who worked in a valley close to the Katterjokk mire and concluded that air temperatures could explain as much as 95% of the variance in ground temperatures at shallow depths at some sites. However, at other sites with differing microclimate determined by variation in elevation, aspect, and vegetation cover, air temperatures could only explain as little as 20%. This was suggested to be due to a role of seasonal snow cover (although this was not measured) (Thorn et al. 1999). In addition, Josefsson (1990) found a relationship between ground temperatures and climatic parameters, especially snow cover at four sites near Abisko. Both Thorn et al. (1999) and Josefsson (1991) have interpreted snow cover

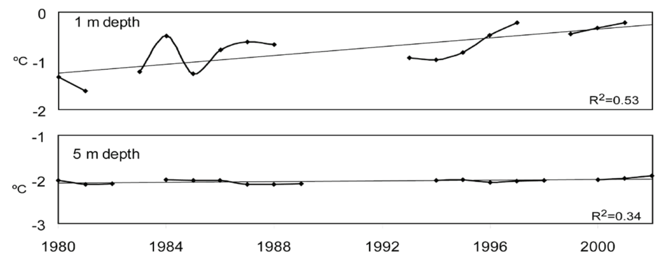

Figure 6. Ground temperatures at 1 and 5 m depth and linear trends at Katterjokk mire measured in September from 1980 to 2002.

as one of the most important parameters that determine ground temperatures in our study area.

We also found correlations between air and ground temperatures. Surprisingly we could not detect any correlation between snow depth and ground temperature even though we used two unique snow datasets from Abisko. Changes in starting and ending dates of snow cover could affect the ground temperatures at Abisko, but no such changes were detected at Abisko (Kohler et al. 2006); hence these cannot explain increases in ground temperatures.

As we found a decrease in summer ground temperatures (Table 2) that could not be correlated to snow depth and air temperature, and the correlations that were found between air temperature and ground temperature explained little of the variance, it can be concluded that other factors also determine the ground temperatures in the Abisko region. The decrease in summer ground temperatures could be caused by a change in vegetation which alters the albedo, shading, and soil moisture. Vegetation has not shifted at the Abisko AWS and, hence, cannot explain the decreasing trend in summer ground temperatures. The decrease in ground temperature was correlated, however, with increases in summer precipitation that have occurred during the last decades. An increase in precipitation increases evaporation which in turn increases the energy consumption resulting in cooler ground temperatures. Similar trends with decreasing summer ground temperatures have been reported from Irkutsk in southcentral Siberia, where they were also attributed to increases in summer precipitation (Zhang et al. 2001b).

The increases in ground temperatures in the lower part of the permafrost might be due to a slight "heat wave" as a result of the warming period at the end of the century. More likely though, there is a possible heating affect from slightly warmer or more freely flowing ground water around and below the frozen bodies of silt and turf. Although, there are no direct measurements of surface and ground water temperatures, temperatures at 12 m and 15 m of just above 0°C indicate that liquid water is flowing at the bottom of the permafrost. However, observations of seasonal variations in ground temperatures at the base of the permafrost are needed to confirm this. If the relatively high temperatures at the base of the permafrost in the mires reflect the movement of liquid water, then the permafrost is even more vulnerable than we first expected because of the influences of warming from above and below.

Permafrost-Related Performance of the Trans Alaska Oil Pipeline

Elden R. Johnson, PE
Alyeska Pipeline Service Co, Fairbanks, AK
Lorena A. Hegdal, PE
Alyeska Pipeline Service Co, Fairbanks, AK

Abstract

The Trans Alaska Oil Pipeline System crosses 1287 km (800 mi) of Alaska, from the Prudhoe Bay oil field on the Beaufort Sea (latitude 71°N) to the marine terminal at the ice-free port of Valdez. Approximately 75% of the route consists of permafrost, transecting the full range of conditions from cold, deep and continuous in the north, discontinuous in the interior, and sporadic to frost-free in the south. The pipeline has operated for over 30 years, transporting nearly 2.5 billion cubic meters (16 billion barrels) of warm crude oil in a harsh, technically problematic, and fragile arctic environment. The lifetime operating reliability of the pipeline has been nearly 99%, with only 12 lifetime spills exceeding the 50-barrel definition. This remarkable performance record attests to the functional, environmental and economic success of the project. This paper describes permafrost-related experiences and engineering lessons learned regarding the performance of the pipeline.

Keywords: crude oil; lessons; permafrost; pipeline; Trans Alaska Pipeline System (TAPS).

Introduction

The Trans Alaska Pipeline System (TAPS) is owned by a consortium of major oil companies and operated by the Alyeska Pipeline Service Co, (Alyeska). The route of TAPS spans the full range of permafrost conditions from continuous and cold, to sporadic and marginal. The 48 inch NPS (nominal pipe size, 122 cm diameter) pipeline has transported up to 334 thousand cubic meters per day (2.1 million barrels per day) at peak throughput and currently operates at about 111 thousand cubic meters per day (700 thousand barrels per day). Oil temperatures have ranged from 63ºC (145ºF) at the northern inlet to 7ºC (45ºF) at the southern outlet. TAPS has now transported nearly 2.5 billion cubic meters (16 billion barrels) of crude oil across the State of Alaska since startup in June of 1977. The safe and effective transportation of these huge quantities of warm crude oil over 1287 kilometers (800 miles), 75% of which contains permafrost, was the primary engineering problem faced by the TAPS designers and operators.

Some permafrost related maintenance problems were recognized shortly after startup (Johnson 1983) including buried pipeline settlement; non-condensable gas blockage of thermo-siphons (heat pipes), and buried insulation system failures. Some of these early issues have been resolved as the immediate effect of initial permafrost thawing has diminished over time. Other time-related issues have been corrected by ongoing maintenance programs.

Designing and building a pipeline across the harsh environment of Alaska has distinguished itself as one of the great engineering achievements of history. Many untried and innovative technical solutions were needed. The design was not perfect, however, and has required consistent monitoring and adjustment over the last 30 years. The remarkable success story of TAPS provides important lessons to those planning similar permafrost sensitive pipeline projects in the future.

Design Challenges

The primary function of the pipeline is to efficiently transport tariff grade crude oil under all environmental and operating conditions experienced over the life of the project. The design life of TAPS was originally stated as 30 years, but as with many infrastructure projects, is now expected to perform well beyond that period (Norton and Miller 2002). In 2004, the federal and state government renewed the grant and lease of pipeline right-of-way for another 30 year period after determining that with proper maintenance the pipeline could safely and efficiently operate for an additional 30 years (Norton et al. 2002).

When oil was first discovered in economic quantities on the North Slope of Alaska in 1968, the pipeline design concept first envisioned consisted of a full length buried pipeline. The pipe itself was purchased assuming a completely buried design. As experts and engineers were engaged, it became clear that warm oil and unstable permafrost were not compatible. The true magnitude of engineering challenge to building a pipeline on permafrost emerged.

The extent and nature of permafrost could not be known until route finding was completed and geotechnical information obtained. Over 5,000 soil borings (1 per 250 m on average) were conducted for characterization and testing of over 15,000 soil samples. Once this information was compiled, frozen and thawed locations could be identified and permafrost found along the route was characterized for engineering purposes as either cold, warm, stable, or unstable.

Permafrost north of the Brooks Range (northern 270 km or 168 miles of the pipeline) was determined to be continuous and cold (Fig. 1). The permafrost temperature on the North Slope is typically about -7ºC near the surface (20ºF) and extends to a depth of nearly 670 meters (2,200 ft). South of the Brooks Range permafrost becomes discontinuous, and then sporadic with varied depth below the active layer.

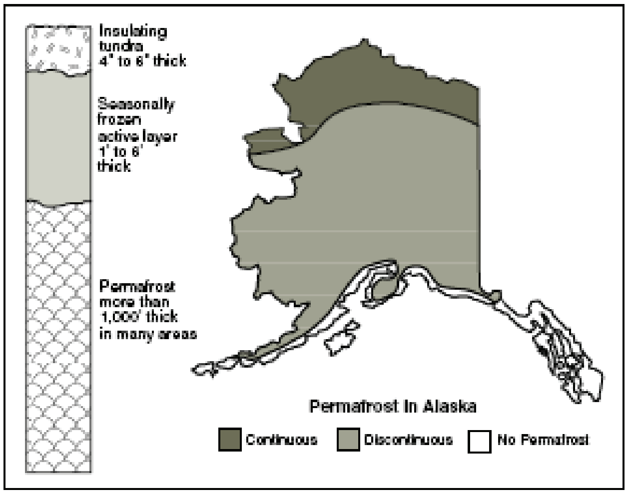

Figure 1. Distribution of permafrost in Alaska.

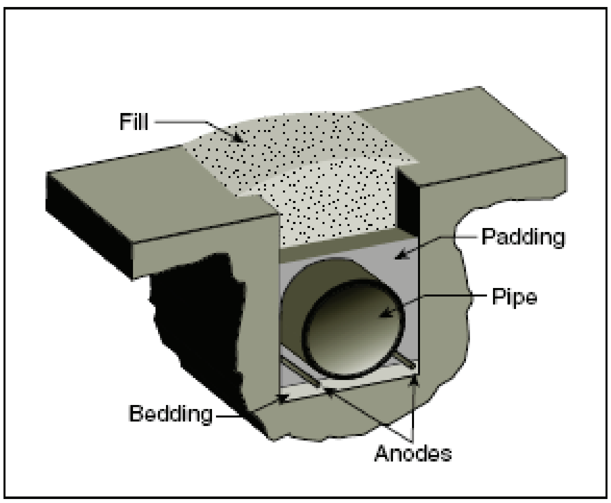

Figure 2. Buried pipeline construction.

Temperatures below the active layer can be near the freezing point and assumed to be -0.3°C (31.5°F) for engineering purposes. Active layer depths vary depending on soil surface material and temperature, from several centimeters to several meters.

Stable permafrost was defined as frozen rock, or clean granular material with no visible ice. Clean granular material was defined as sand or gravel with less than 6% fine material by weight (passing the # 200 sieve). In varied soil profiles, stability was also determined on the basis of a calculated 30-year settlement over the expected depth of thaw of less than 30 centimeters (1 ft).

The key initial design challenge was route finding and mode selection to avoid or minimize the threat to pipeline integrity caused by permafrost. Three basic pipeline design modes were developed and applied depending on permafrost condition (Johnson 1983). These included conventional buried pipelines, above-ground pipeline construction and special insulated buried pipeline construction. Other modes, including bridges and river crossings, special fault crossing, road crossings and animal crossings were employed for unique situations.

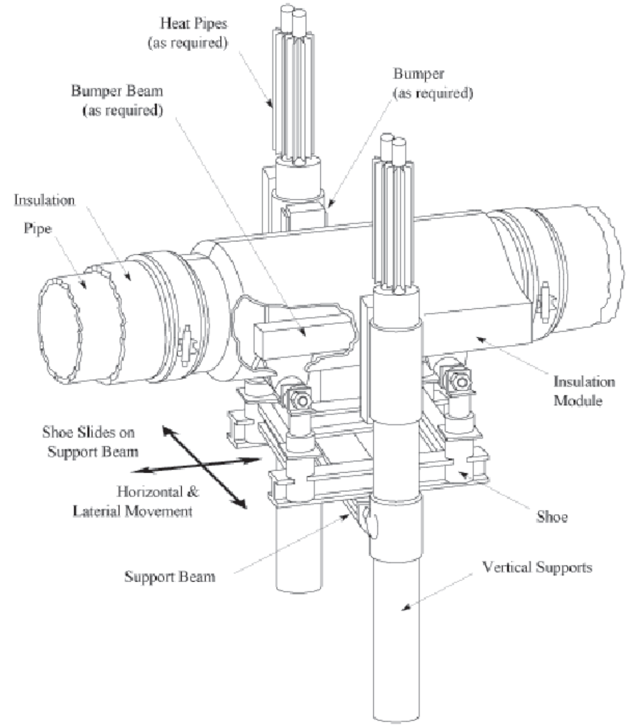

Figure 3. Above-ground pipeline construction.

Buried pipeline construction mode was the preferred mode because it was less costly than others (Fig. 2). The pipeline was buried where thawed or thaw stable ground was encountered. Burial depth averaged 1.5 m (5 ft) and ranged between 1 and 12 m. Buried pipeline required the placement of a cathodic protection system (anodes) to control corrosion. On the North Slope and through mountain passes, the pipeline was often routed along river floodplains because thawed or thaw stable sand and gravel could often be found to allow buried construction. A total of 612 km (380 of 800 miles) or 48% of TAPS was constructed below ground.

The above-ground mode was used where unstable permafrost was encountered. This design avoids permafrost threats by completely bridging over it (Fig. 3). The elegant zigzag configuration (Fig. 4), with thermo-siphon radiators (heat-pipes) often protruding from support pilings visually distinguishes TAPS from all others and makes it one of the most photographed in the world. The zigzag configuration controls the amount of movement associated with thermal expansion, and limited ground movement (static or dynamic). A total of 676 km (420 of 800 miles) or 52% of TAPS was constructed above ground.

Special design constraints dictated the burial of the pipeline at three locations with unstable permafrost which would normally employ an above-ground design. The above-ground mode was thought to interfere with wildlife migration and was not allowed. In this special buried mode, an insulated pipeline was designed with mechanical refrigeration to maintain frozen conditions below the pipe (Fig. 5).

Figure 4. Zigzag configuration of above-ground pipeline.

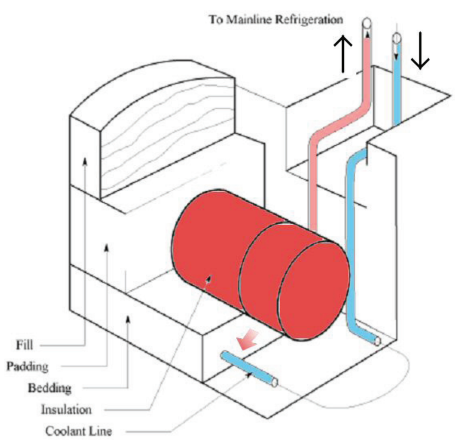

Figure 5. Special buried pipeline construction.

Other environmental conditions and operating hazards

A number of additional environmental conditions besides permafrost had to be considered in the design of TAPS. These included natural hazards such as earthquakes, floods, icings, ground movement, extreme weather, fire, corrosion, and material defects. Human related hazards such as incorrect operation, maintenance error, support system structural damage, vehicle or aircraft impact, third party damage, and deliberate sabotage were also considered.

The design of TAPS considered extreme conditions and events which could be expected within the 30-year project life. Design criteria were used to assure the pipeline could withstand normal operating conditions within safe limits, and withstand extreme contingency conditions without failure.

Operating and Maintenance Experience

Permafrost related operating hazards require ongoing monitoring and maintenance because the nature and magnitude of the threat is constantly changing over time. Alyeska conducts regular monitoring, surveillance, and maintenance activities to inspect the pipeline for changes and to maintain it within specified operating limits. Functional limits are determined for each system component based on principals of Reliability Centered Maintenance (RCM) (Moubray 1997). Monitoring and maintenance strategies are determined based on failure consequence, likelihood, and hazard rate (rate of hazard advance over time such as corrosion or settlement rate).

Monitoring and maintenance strategies are incorporated within written integrity management program procedures. The integrity management plan (IMP) is divided into broad categories for organization and management purposes. The IMP addresses all perceived threats including corrosion, floods, earthquakes, human error, and mechanical breakdown, as well as those related to permafrost. The following integrity management categories are directly or indirectly influenced by permafrost and are described in further detail in the remainder of this paper.

1. Mainline above-ground support systems,
2. Mainline integrity management (curvature, mechanical damage and corrosion),
3. Right of way and facilities civil monitoring,
4. Fuel gas pipeline.

Subject matter experts identified for each program direct scheduled activities, maintain records, assess results and monitor performance. An annual report is prepared to describe previous results, evaluate asset condition, recommend future activities, and recommend improvements in overall program management practice.

Mainline above-ground support system

The above-ground support system is a unique component of TAPS which allows it to bridge over unstable permafrost. Were it not for the presence of permafrost, such a support system would not be needed and TAPS would be similar to most other pipelines. Above-ground portions make up 52% of TAPS.

Key system components include the zigzag configuration, intermediate pipeline supports, anchors, vertical support members, and heat-pipes. The zigzag configuration of the pipeline itself (Fig. 4) is designed to allow controlled pipe movement in response to temperature changes or seismic events. Intermediate supports spaced normally every 18 m (60 ft) provide vertical support. Anchors provide for controlled lateral and longitudinal movement and are spaced typically 550 m (1800 ft) apart.

Intermediate supports consist of two vertical support members (VSM) with support brackets, a cross beam, a sliding shoe assembly and intermediate pipe clamp (Fig. 3). The pipe is allowed to slide laterally and longitudinally through the use of low friction Teflon pads. Anchors consist of four vertical support members with support brackets, anchor platform assembly, and anchor clamp. The anchor assembly is designed to release and absorb energy if differential longitudinal loading exceeds the design level.

The primary function of the above-ground system is to support the pipeline under all operating and contingency loadings. Support system components themselves may fail or sustain limited damage during contingency events as long as the pipeline itself does not fail.

Vertical support members (Fig. 6) are the basic units of vertical and lateral support linking the pipe to the ground. VSM consist of 46 cm diameter (18 inch) pipe piles drilled or driven into the ground to a depth which is determined by soil conditions. VSM depths vary between 5 to 15 m (15 to 50 ft) below ground surface with 11 m (35 feet) being the average.

VSM are designed to resist vertical loads in either up or down direction. A typical 2 m (5–7 ft) active layer is assumed to have no load bearing capacity. Upward frost jacking loads are generated in the active layer and control the minimum embedment depth. Vertical loads are resisted in the region below the active layer, by ad-freeze forces where the ground is frozen, and friction forces where thawed. End-bearing resistance is utilized in some cases. The ad-freeze strength used in design is based on a 30 year estimate of viscous creep in frozen soil and depends on permafrost temperature assumptions (warm or cold). A 30-year creep limit of 8 cm (3 inches) of downward movement was used to determine frozen strength.

A total of 78,000 VSM were used in the construction of the above-ground support system. Of these, approximately 97% rely on maintenance of a frozen soil condition for stability. In warm permafrost, heat pipes are used to maintain a permanently frozen condition. VSM with heat pipes are known as thermal VSM (Fig. 6) and make up about 80% of all VSM used. Heat pipes are closed loop, passive heat exchangers, charged initially with ammonia, and now recharged with CO_2. They are designed to remove heat in the winter when air temperatures are colder than the ground. They super-cool the soil in the load bearing zone compensating for long term heat loss at the ground surface. A single heat pipe is designed to maintain a frozen condition; two heat pipes are installed in each VSM for redundancy. A total of nearly 124,000 heat pipes were used in the construction of the above-ground pipeline support system.

Above-ground support system components are monitored on a frequency which depends on risk and hazard rate. Monitoring consists of observations which may indicate permafrost degradation such as the following;

1. VSM vertical movement determined by elevation survey, load cell testing, or observed out of level cross beam.

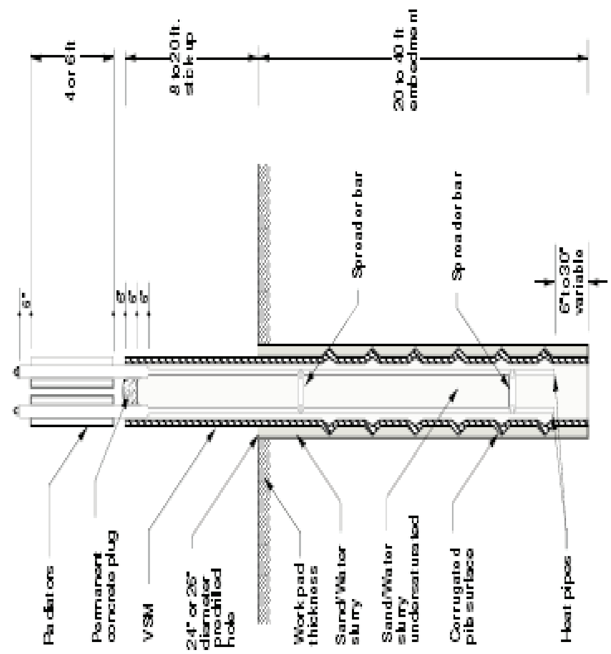

Figure 6. Typical thermal VSM.

2. VSM out of plumb.
3. Heat pipe degradation determined by infrared survey.
4. Tripped anchors, caused by excess lateral load.
5. Intermediate shoes off-center
6. "Floating shoes" not supporting vertical loads.
7. Damaged Teflon sliding base.

Where conditions are observed outside of designated operating limits, maintenance is performed to restore the component to within acceptable parameters. Maintenance may vary from minor adjustments to replacement of system components. A key performance feature of TAPS is its maintainability. Many components are specifically designed for ease of maintenance. The 2007/2008 maintenance year is considered typical of the scale of maintenance activities, consisting of the following;

1. Replace 2 VSM
2. Reposition 4 tripped anchors
3. Load adjust 8 intermediate supports (floating shoes)
4. Repair 9 out-of-location intermediate shoes
5. Replace 1,000 degraded Teflon slide plates
6. Recharge 2,000 degraded heat pipes

Heat pipes have experienced blockage by non-condensable hydrogen gas (a by-product of corrosion). They are monitored by infrared camera able to detect a "cold top" condition indicative of radiator blockage by non condensable gas (Sorensen et al. 2002). Repair of heat pipes is performed by recharging them with CO_2. Repairs are prioritized for southern areas where permafrost is marginal, concentrated blockage zones, slopes sensitive to movement, or locations where VSM movement is observed.

The level of maintenance noted above is considered manageable and provides evidence that permafrost degradation is not a current problem in the operation of above-ground portions of TAPS. Increased maintenance may be anticipated in the future with additional degradation of marginally frozen areas.

Mainline integrity management

While the above-ground pipeline avoids most permafrost related risk by bridging over it, the buried pipeline must adapt to differential settlement of the pipeline caused by permafrost thawing. The buried pipeline design required that foundation soils be either thawed or thaw stable. Thousands of pre-construction boreholes and soil tests were conducted to assure that the pipeline was buried only in suitable locations. Boreholes were closely spaced, averaging 250 m (820 ft) along the length of the line, to help detect random pockets of unstable permafrost.

The long-term (30-year) thaw depth for buried TAPS was estimated to vary from 20 to 37 m (70 to 120 ft) depending on soil type and ice content. Frozen soils were not considered thaw stable if calculated thaw settlement exceeded about 30 cm (1 ft). Geologists logged the pipeline ditch during installation to confirm thaw stability of any frozen soil discovered below pipe depth. The pipeline design had to be radically changed to the above-ground mode on multiple occasions due to the discovery of ice-rich or unstable permafrost.

Some areas of unstable permafrost went undetected in spite of all soil data gathered prior to and during construction. In 1979, after 2 years of operation during the most rapid thaw bulb development, the pipe buckled and leaked at two locations. In each case, short pockets of undetected ice rich permafrost caused approximately 1.3 m (4 ft) of pipe settlement over a span of nearly 122 m (400 ft). The pipe was excavated, encapsulated with a steel sleeve and underpinned using a steel support system to prevent further settlement. One leak location was later cut out and replaced. The other is still operating in a safe and stable condition.

Following these initial leaks, an integrity management program (IMP) was developed to detect, measure and assess other potential settlement locations. The program initially consisted of settlement monitoring rods placed on top of the pipe at suspected locations and extended to the ground surface for survey monitoring. Surveys were used to observe the settlement rate and estimate pipe curvature. Pipe curvature was used as the key performance indicator of potential pipe buckling. The program was also supported by numerous additional soil borings to determine subsurface conditions.

A later enhancement incorporated the use of deformation monitoring, in-line inspection (ILI) pigs (instrumented devices) placed in the pipeline which could detect deformation indicative of incipient buckling. The program was instrumental in detecting a dozen locations requiring repair in the decade between 1980 and 1990.

Later in the 1990s, curvature/deformation in-line inspection tools using inertial guidance systems were developed for use on TAPS. These tools are capable of accurately detecting and measuring high curvature areas (Hart et al. 2002).

Settlement repairs initially involved extensive structural support systems, or excavation and replacement in an above-ground mode. One solution involved the use of chemical grouting, and active ground freezing (Thomas et al. 1982) to restore a frozen condition, and then supplemented with numerous free standing heat pipes to permanently maintain the frozen ground. Another solution where the pipe had settled up to 4.6 m (13 ft), involved abandonment of a short section of buried pipeline and replacement with an 800 m (0.5 mile) section of elevated pipe (Simmons & Ferrell 1986). Less severe settlement locations were corrected by excavating the pipe and returning it to a safe curvature using either mechanical lifting or air bags. A detailed description of pipeline settlement repairs is provided by Ferrell and Thomas (1988). Only about 1.5 km out of 612 km (0.9 miles of 380 miles) or 0.25%) of buried pipe required maintenance as a result of permafrost subsidence.

Now with diminished pipeline throughput, the oil takes longer to reach Valdez and thus experiences greater environmental cooling. The thaw bulb below the pipeline has reached its maximum extent and is no longer growing by an appreciable amount. A concern for future low throughput conditions if oil temperatures drop below freezing, is that frost may penetrate to pipe depth, causing increased wax precipitation and freezing of small amounts of water in the oil. In the extreme case, frost jacking forces could develop if frost penetrates below pipe depth.

The special buried insulated pipeline mode presented a different set of permafrost related issues. An annular, shop fabricated, close-celled polyurethane insulation, encapsulated by a fiber reinforced plastic (FRP) outer jacket was used to insulate unstable permafrost from the heat of the pipe. Brine refrigerant is circulated in 15 cm (6 in) diameter refrigeration piping placed below the mainline pipeline (Fig. 5). Refrigeration plants continuously operate to circulate chilled brine. This design relies on the FRP outer jacket to maintain a waterproof pipe environment. This mode is used on about 6 km (4 miles) of the pipeline.

In some cases the FRP outer shell has not effectively prevented water ingress into the insulation. The insulation has become wet, losing its thermal resistance, and causing increased thermal demand on the mechanical refrigeration plants. Refrigeration plants have had to be overhauled and upgraded. Water ingress has also created pipe corrosion concerns that have required excavation, inspection and replacement of the insulation system. Cathodic protection has been added to control corrosion as part of the repair.

Right of way and facility maintenance

The pipeline work pad used for access during construction and maintenance was constructed on permafrost, roughly in proportion to the construction mode mix (52% above ground, 48% buried). Five of the 10 original pump stations were constructed on unstable permafrost. Several integrity and maintenance related concerns have been identified in conjunction with permafrost along the right of way and at facilities.

A total of 55 sensitive pipeline slopes were identified where soil instability could pose a threat to the pipeline. Many of these slopes depend on frozen ground to assure continued stability. Of the 55 sensitive slopes, 6 were deemed high priority and subject to special slope monitoring activities. Maintenance has been required (Tart & Ferrell 2002), including the replacement of several dozen VSM, drainage enhancements and use of surface insulation and heat pipes to maintain permafrost and control down slope movement.

During design of the pipeline, it was divided into segments based on changes in pipeline risk factors. One concern affecting the design was the potential for soil liquefaction under seismic conditions. The preferred solution for buried pipeline was to place the pipeline at a depth below where liquefaction was predicted to occur. In the above-ground mode, the solution was to either avoid liquefiable soils altogether, or maintain them in a frozen condition.

In November 2002, a 7.9 M earthquake, the largest in the world that year, occurred along the Denali Fault which runs directly under the pipeline (Hall et al. 2003). This large earthquake ruptured the ground 5 m (18 ft) laterally and 1.1 m (3.5 ft) vertically at the fault crossing and produced ground motions slightly in excess of design criteria. The pipeline support system was damaged, but the pipe itself did not leak. The pipeline was shut down for 66 hrs for inspection.

Liquefaction was observed at several locations but all above-ground and buried designs performed within expectations. Following the event, an inertial guidance (curvature/deformation) ILI tool was run to identify areas of hidden damage with none found (Johnson et al. 2003). Also, each of the roughly 1500 original design segments deemed sensitive to liquefaction were reassessed in light of the earthquake experience. One concern was that marginally frozen slopes may have thawed over time, creating increased liquefaction risk. This reassessment is now nearly complete with no unstable areas identified at this time.

The gravel work pad constructed alongside the pipeline for access purposes was designed primarily for short term use during the construction period (Metz 1983). A design objective was to minimize use of hard to obtain gravel materials. In some cases, board stock insulation was used either in the work pad itself or around VSM. The purpose of insulation was to reduce thawing of natural materials to maintain trafficability, while minimizing gravel requirements. It was also used around VSM to minimize active layer depth, decrease jacking loads, and increase lateral load resistance.

Insulation used around VSM has been effective in reducing thaw, but adjacent areas of the uninsulated work pad have settled causing depressions, ponding and limiting access. Maintenance has been required to fill some of the deepest depressions in certain areas.

Pump station facilities were built on permafrost at 5 locations (PS 1, 2, 3, 5, and 6). The remaining pump stations were built on thawed or thaw stable ground. Permafrost pump stations were designed with mechanical refrigeration systems to maintain stability of buildings and piping. Routine survey monitoring is used to determine facility settlement. Settlement of buildings and piping has occurred, in some cases requiring maintenance. Free standing heat pipes have been used to maintain permafrost around buildings.

The most serious challenge for the pump stations has been with the buried annular insulated systems similar to those used on the mainline. Water has penetrated the outer jacket, wetting the insulation and creating corrosion concerns. Nearly all buried insulated facility piping has been excavated and replaced with an "insulated box" system (Johnson 1983). This system uses board stock insulation placed under the pipeline but above the refrigeration piping. Board stock insulation is then placed at the sides of the pipe and the annulus filled with a lean mix concrete grout. Cathodic protection anodes and a CP monitoring system are placed within the grout. Board stock is used to cover the box. This reinsulation system has generally performed well, preventing further thaw settlement and inhibiting corrosion since completion in the early 1980's.

Fuel gas line maintenance

Alyeska operates a 238 km (148 mile) long fuel gas pipeline to provide natural gas fuel for turbines at the four northern pump stations. The line is 10 inch NPS (nominal pipe size, 25.4 cm diameter) for the first 55 km (34 miles) and 8 inch NPS (20.3 cm diameter) for the last 183 km (114 miles). The line was constructed in winter with a snow and ice work pad. It was buried to a depth of 1 meter (36 in) in cold unstable permafrost. Board stock insulation was placed at the estimated active layer depth of 46 cm (18 inches) over the line to help maintain it in a continuously frozen condition at pipe depth.

The gas line is placed adjacent to the Dalton Highway for much of its route. Disturbance of the surface soil during construction combined with dust from the highway has increased surface heat exchange, and caused a deepened active layer in places. Disturbance of drainage paths has caused some erosion and ponding of water over the line. The gas is chilled to -2ºC (28ºF), but chiller upsets have occasionally allowed periods of above freezing gas temperature (0º–20ºC or 32º–68ºF) in the summer.

The overall affect has been a long term deterioration of permafrost in some locations, subsidence of the surface, and thawing to a depth at or below pipe depth in some places. This has resulted in heaving of the line due to thermal expansion, frost jacking during freeze-back and loss of cover over the pipe. However, there has never been a gas line leak from the pipe.

Maintenance activities have consisted of excavation and reburial of the line to repair heaving locations, and/or replacement of fill over the line to restore depth of cover. Maintenance resulting from permafrost degradation has been required on 10%–20% of the line, primarily where it runs next to the Dalton Highway.

Lessons Learned: TAPS and Permafrost

Over 30 years ago the owners of TAPS faced the daunting task of engineering and building a pipeline across the breadth of Alaska under harsh arctic conditions along a route consisting mostly of permafrost. A project of this nature had never before been done. The wisdom of the project was severely questioned at the time, all the way to the President of the United States who authorized it in 1973 only after a tie-breaking vote in Congress. Public expectations were expressed for the highest level of environmental and pipeline safety performance and enforced by strict government agreement and regulation.

The operating history of TAPS now reveals that a warm oil pipeline can be constructed and operated on permafrost. The Trans Alaska Pipeline has been a huge and persistent success over its more than 30 year operating life. It has transported between 10% and 25% of the US domestic crude oil supply, providing a measure of energy security to the people of the United States. It has produced revenues to the State of Alaska to operate the government, generating 80% of the budget, while contributing to a $40 billion Permanent Fund paying annual dividends to Alaska citizens.

Only two pipeline leaks are attributed to permafrost, a 636 cubic meter (4,000 bbl) spill and a 238 cubic meter (1,500 bbl) spill, both occurring in 1979. Careful monitoring and maintenance has been required to mitigate the affects of permafrost hazards. The scale of maintenance attributed to permafrost has been reasonable and manageable, historically estimated to range between 5% and 10% of operating costs. A notable sum, but small compared with the overall benefit generated by the pipeline.

The following lessons regarding TAPS and permafrost are summarized based on the author's experience.

1. The TAPS above-ground design has performed all its functions with relatively minimum maintenance. Its robust and redundant design, built for maintainability, is a beautiful thing in both form and function.
2. The TAPS buried design is more sensitive to permafrost than the above-ground design, requiring comparably more maintenance to address permafrost issues. It is difficult, if not impossible, to find all random pockets of unstable soil using preconstruction boreholes and close construction inspection. Less than 1% of the buried pipeline has required maintenance associated with permafrost subsidence. The advent of inertial instrumented In-Line-Inspection (ILI) tools effectively detects subsidence locations, allowing preventive maintenance to be performed and mitigating subsidence risk.
3. The TAPS special buried, insulated and refrigerated design is maintenance intensive and recommended only as a last resort. Mechanical refrigeration is costly to operate, and buried insulation can not be made reliably waterproof. Wet insulation not only aggravates thaw subsidence, but contributes to corrosion problems which are very difficult to mitigate with cathodic protection. The environmental benefit afforded by this design in facilitating animal migration is questionable.
4. Permafrost related operating hazards require ongoing monitoring and maintenance because the nature and magnitude of the threat is constantly changing over time. An integrity management plan is needed to identify risks, assess condition, and outline permafrost related maintenance options.
5. Any global climate change is not expected to threaten the future operation or integrity of TAPS. Increased maintenance may be expected on above-ground portions, and possibly buried insulated portions especially in marginally frozen southern zones. The above-ground design readily accommodates maintenance and should not experience significantly increased risk. Permafrost risks on buried portions have been largely diminished as thawing has reached its maximum extent.
6. The TAPS fuel gas line provides a small scale view of problems to be anticipated by a larger gas transmission pipeline. More than 10% of the gas line has required permafrost related maintenance attention. The tundra is fragile and is degraded by many construction and operating factors.

Final advice for arctic pipeline engineers is summarized in the words of Dr. Harold Peyton, acclaimed pioneering designer of TAPS: "Engineers must balance the heat flow equation or Mother Nature will do it for them."

The Impact of Light-Colored Pavements on Active Layer Dynamics Revealed by Ground-Penetrating Radar Monitoring

Abstract

Ground-penetrating radar (GPR) has been used to study the variations in the depth of the frost table throughout a complete thaw-freeze season at Kangerlussuaq Airport, western Greenland. In autumn 2000, three test areas were painted white on the parking area of the airport in order to reduce further development of depressions in the asphalt pavement. One of these areas has been used in the GPR investigations to compare the variations of the frost table underneath a normal dark asphalt surface to that below a more reflective surface. Results clearly indicate a correlation between the use of the reflective surface and a reduced depth of the frost table. In late summer, the difference in the depths of the frost table is approximately 0.9 m. The results should promote interest in the development and use of light-colored pavement materials.

Keywords: active layer; ground-penetrating radar; permafrost; reflective surface.

Introduction

The presence of permafrost is an important aspect in civil engineering in arctic regions. Thawing of ice-rich permafrost leads to consolidation of the active layer above. The construction of road and airport embankments changes the thermal regime of the ground, and may lead to permafrost degradation under or adjacent to such structures. This problem is now amplified by the effects of climate warming. Mapping the lateral and vertical extent of permafrost as well as actual ice-content is, therefore, an important part of geotechnical site investigations in arctic regions. Ground-penetrating radar (GPR) has proved to be a useful method for mapping the distribution of permafrost (Annan 2002, Annan & Davis 1976, Pilon et al. 1992); especially the frost table is often observed as a strong reflection in the GPR data (Jørgensen & Andreasen 2007, Ingeman-Nielsen 2005, Arcone et al. 1998). Thus, repeated GPR surveys can reveal yearly variations in thickness of the active layer.

Figure 1. Kangerlussuaq Airport. The investigated area is surrounded by the circle.

This paper is based on repeated GPR investigations from May until October 2007 on the southern parking area at Kangerlussuaq Airport, western Greenland (Fig. 1). The objectives of the measurements were to study variations in the depth of the frost table throughout a complete thaw-freeze season and to compare the differences of the depth underneath a normal dark asphalt and a more reflective surface (a white painted area).

Site Description

Kangerlussuaq Airport is built on a river terrace (altitude 30–50 m) at the head of the 170 km long fjord, Kangerlussuaq (Søndre Strømfjord), located just north of the Polar Circle at 67°00′N and 50°42′W. In the western part of the area the terrace is made up of fine-grained glaciomarine sediments partly covered with fluvial deposits of sand and gravel. In the eastern part fine-grained marine deposits are absent.

The climatic conditions at Kangerlusssuaq are arctic continental, determined by its northern location and its position in a 2-3 km wide valley surrounded by mountains (plateau altitude 400–600 m). To the east the Greenlandic ice sheet, with altitudes up to 3 km, has a dominant influence on precipitation and winds. These conditions result in a dry sub-arctic climate with winter temperatures down to -40°C (-40°F) and summer temperatures up to 20°C (68°F). From 1977–99, the mean annual temperature was -5.7°C and the mean annual precipitation was 151 mm (Danish Meteorological Institute 2007). Since the middle of the 1990s the mean annual temperature in Kangerlussuaq has increased to -4.0°C (Fig. 2). Nevertheless, Kangerlussuaq is still underlain by 100-150 m of continuous permafrost (Tatenhove & Olesen 1994). The entire active layer is frozen during the winter, but in late summer the depth of the frost

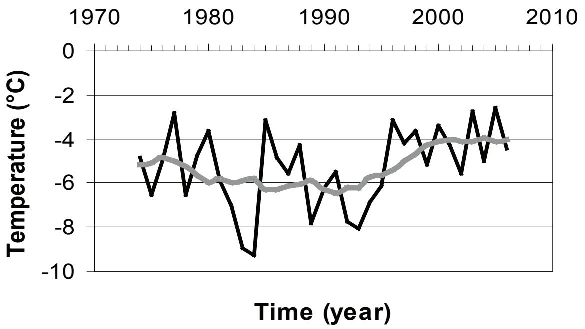

Figure 2. Mean annual air temperature (black) and nine year average temperature (gray) in Kangerlussuaq, 1974-2006 (Danish Meteorological Institute 2007).

table is up to 3.0 m in the open terrain (Ingeman-Nielsen et al. 2007). However, under areas covered with asphalt the depth of the frozen surface is greater, and in some areas this causes melt-water to concentrate under the pavement.

Methodology

In the period from May until October 2007, eight GPR investigations were carried out at the southern parking area of Kangerlussuaq Airport (Fig. 1). In addition, one investigation was carried out in July 2005 and three investigations were carried out in a period from May until August 2006 (Jørgensen & Andreasen 2007, Jørgensen et al. 2007).

GPR systems produce a short pulse of high frequency electromagnetic energy which is transmitted into the ground. The propagation of the signal depends on electrical properties of the ground, which are mainly controlled by the water content of investigated materials. Changes in the dielectric properties will cause a reflection of parts of the transmitted signal, while the rest of the signal will continue to propagate into the ground. Reflection will occur at each successive interface in the ground, until the signal has been damped by losses in the ground. The reflected signal is detected by the GPR receiver, and travel times for individual radar waves can be used to display the results in a radargram, in terms of received amplitude as a function of travel time.

Results from a GPR investigation give insight into the structural changes in the ground but do not directly show the composition or type of the materials investigated. To calibrate the GPR results from Kangerlussuaq Airport, a borehole was drilled and a trench was dug in August 2005.

We applied a GSSI Model SIR-20 with two ground coupled 400 MHz and 900 MHz (GSSI Model 5103 and GSSI Model 3101) antennas. All measurements were conducted along the same profile (Figs. 3A, 3B) with the antennas towed about 3 m behind a car. The GPR profiles were recorded by survey wheel, and traces were collected every 0.05 m (20 traces per meter).

The post-processing included band-pass trace-filtering to reduce electronic and antenna-to-ground coupling noise, spatial filtering to remove coherent background noise, and

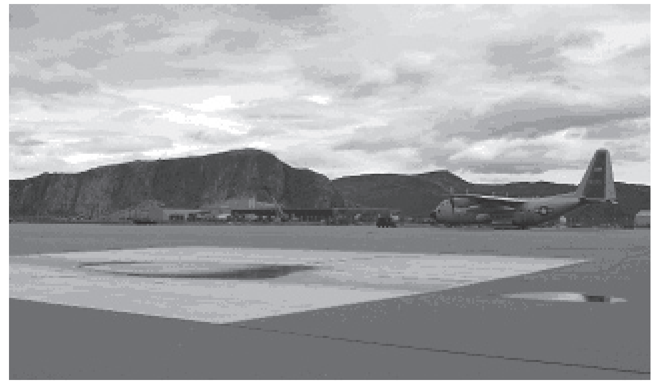

Figure 3A. White painted asphalt surface on the southern parking area of Kangerlussuaq Airport.

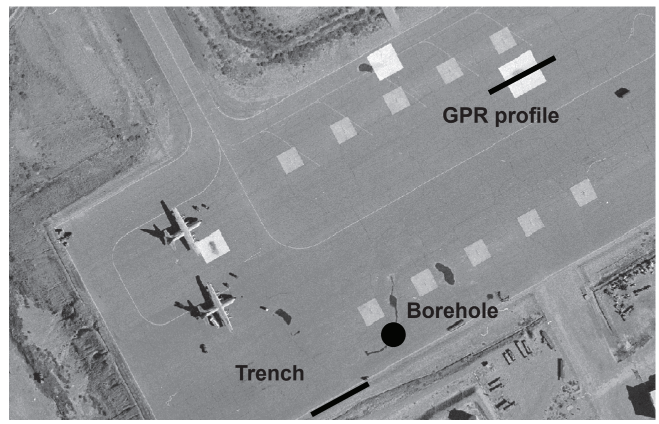

Figure 3B. Placement of GPR measurements across the white painted asphalt surface shown in Figure 3A. The location of the trench and borehole is also shown.

a running average to make a horizontal smoothing of the recorded signal. The processing was carried out using the program ReflexW 3.5 from Sandmeier Scientific Software.

Results

Figure 4 illustrates the difference in the depth of the frost table underneath the normal black asphalt surface and the more reflective surface (white painted area). The variations of the depth of the frost table throughout the thaw-freeze season are illustrated in Figure 5.

According to borehole data from August 2005, top soils were unsaturated and unfrozen until a depth of 3.5 m. The trench revealed a depth of the frost table close to 4.0 m. The velocity of the radar waves in the unfrozen sediments underneath the southern parking area was estimated to be 0.13 m/ns by combining the GPR results with the results from the borehole logs and the trench.

The GPR results (Fig. 5) illustrate the progressive lowering of the frost table. The results also show the effect of the white surface on the depth to the frost table. The fact that the changes in depth to the strong reflection on the radargrams are aligned with the boundaries of the painted area (26 m wide) confirms that this reflection is actually the interface between the frozen and unfrozen ground.

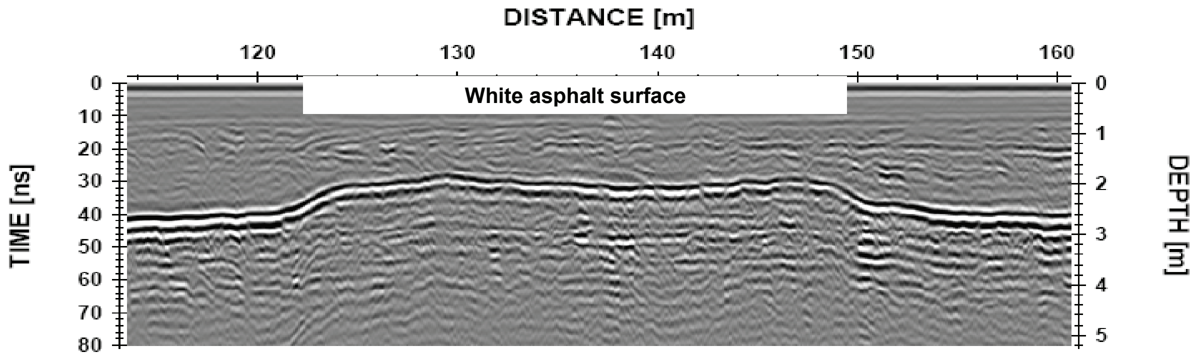

Figure 4. Radargram from July 2007 showing the depth of the frost table. The frost table is seen as a strong reflector in the depth of approximately 2.7 m underneath the normal dark asphalt surface (left and right parts of the radargram) and 2.1 m underneath the white painted area (middle of the radargram).

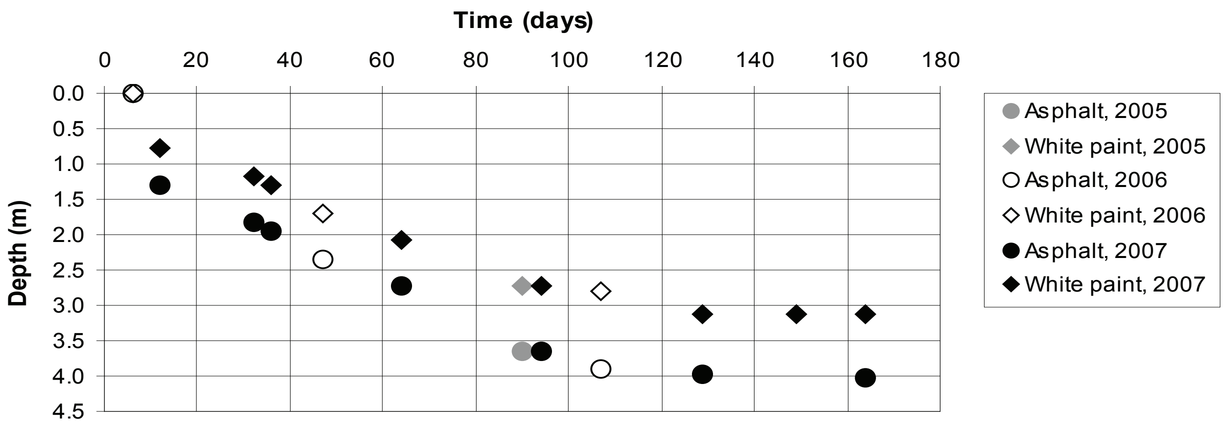

Figure 5. Variations of the depth of the frost table underneath the normal black asphalt surface and the white painted area. The time is shown as number of days from May 1st.

It appears that a stable situation is approached underneath the surfaces between the two measurements carried out in September (Fig. 5). The maximal difference between the depths to the frost table is found as approximately 0.9 m at the end of the thawing period (Fig. 5).

Discussion

We have performed GPR measurements across a reflective surface (white paint) eight times in the period from May until October 2007. The measurements have shown a clear correlation between the use of the reflective surface and a reduced depth to the frost table. At the end of the thawing period the difference in the depths to the frost table is approximately 15 ns.

Based on borehole information, the measured depth of the frost table (procured by the trench excavation) and GPR data collected at the locations of the borehole and the trench in August 2005, the radar wave velocity in the unfrozen sediments was found to be 0.13 m/ns, which corresponds to a permittivity of 5.3. The top soils at the borehole location were unsaturated sorted sand until a depth of 3.5 m with water content in the range of 2%–5% (Jørgensen and Andreasen, 2007). Using a calibration curve empirically determined by Topp et al. (1980) and soil parameters (density 2.70 g/cm^3 and porosity 30%), which is generally used for sandy materials in the area, a permittivity of 5.3 result in a water content of 4.75% for the material. This value lies within the interval of the water content measured in the soil samples from the borehole.

The low water content and well sorted sandy material, which result in a low adherence of the water particles, gives us a situation close to dry conditions and temporal changes in the velocity due to changing pore-water content in the unfrozen sediments were therefore neglected in the present study. An increase in water content will result in an increased permittivity of the material, which will lead to a decreased velocity of the radar waves. A water content of 9.50%, twice the amount of the determined value, would have reduced the maximal difference between the depths to the frost table underneath the two investigated surfaces to approximately 0.2–0.3 m.

Our results have shown that the change in active layer thickness due to the increased reflectivity of surface amounts to approximately 0.9 m in late summer. This constitutes a major difference in the thermal conditions below the reflective surface and the normal dark asphalt surface, and the results should promote interest in the development and use of light-colored pavement materials to reduce settlements under arctic infrastructures caused by the annual thaw-freeze cycle and increasing thickness of the active layer.

Acknowledgments

This research was mainly funded by the Commission for Scientific Research in Greenland (Kalaallit Nunaani ilisimatuutut misissuinernut kommissioni) and partly funded by the Polar Earth Science Program, Office of Polar Programs, National Science Foundation (ARC-0612533).

We would like to thank the Greenlandic Airport Department (Mittarfeqarfiit) for granting us access to the airport area in Kangerlussuaq, and the Municipality of Sisimiut (Sisimiut Kommunianut) for help with accommodation and transportation.

Abstract

Knowledge of the varying surface patterns (landforms), extent, and expansion rate of thermokarst is essential to understanding the response of northern ecosystems to climate change and human impacts. Field studies and airphoto analysis have revealed 22 thermokarst landforms associated with varying heat and mass transfer processes, terrain conditions, and ground ice. These include deep and shallow thermokarst lakes, thaw-lake basins, thaw-lake sinks, thermokarst pits, thermokarst troughs and pits, collapsed pingos, thermokarst shore bogs, thermokarst bogs and fens, thermokarst gullies, thermokarst water tracks, beaded streams, thaw slumps, detachment slides, sink holes and tunnels, glacial thermokarst, collapse-block shores, block landslides, thermokarst conical mounds, irregular mounds, and nonpatterned thawed ground. The extent of permafrost degradation was assessed using airphotos taken across the discontinuous zone, revealing 5% of the area has thermokarst, 62% has permafrost, 21% is unfrozen with no recent permafrost, and 12% remains undetermined. In continuous permafrost of arctic Alaska, thermokarst terrain was evident on 13.5% of the area, and 1.5% was unfrozen under deep non-thermokarst lakes. The rate of degradation based on airphoto analysis at four sites revealed the area affected by thermokarst increased 3.5–8 % over ~50-yr.

Keywords: Alaska; classification; degradation; extent rate; permafrost; thermokarst.

Introduction

Permafrost is an integral component of many northern ecosystems because it supports the ground surface, modifies microtopography, influences soil temperature and moisture, subsurface hydrology, rooting zones, and nutrient cycling (Van Cleve & Viereck 1983, Ford 1987). It is sensitive to climate directly through changes in air temperature, snow cover, or moisture's effects on soil thermal properties, or indirectly from fire frequency or human disturbance with numerous positive and negative feedbacks (Brown and Grave 1979, Osterkamp 1983, Lawson 1986, Esch & Osterkamp 1990, Nelson et al. 2001). Of particular concern for thermokarst, is the warming of permafrost in Alaska by up to 4°C during the last three decades, 2-4°C since the Little Ice Age, and 10°C or more since the end of the Pleistocene (Anisimov & Nelson 1996, Osterkamp 2007). Thawing of ice-rich permafrost can lead to wholesale conversion of ecosystems from terrestrial to aquatic or wetland systems, or conversely cause wetlands to become better-drained (Van Cleve & Viereck 1983, Burn 1998, Osterkamp et al. 2000). In Alaska, 28% of the land has continuous (>90% area), 51% discontinuous, and 8% sporadic/isolated permafrost (Brown et al. 1997).

Where ground ice in fine-grained sediments exceeds the pore space of the soil, thawing of the permafrost can cause the surface to settle or liquefy. The amount of settlement is directly related to the amount and type of ice. These in turn are related to complex interactions of slope position, soil texture, hydrology, and vegetation over time (Shur and Jorgenson 1998). Due to these interactions, the pattern and rate of permafrost degradation can be highly variable. As a result, the nature, extent, and rates of permafrost degradation in Alaska have been poorly quantified.

This paper tries to improve our understanding of thermokarst in Alaska by: (1) classifying and characterizing landforms associated with surface permafrost degradation; (2) estimating the extent of the thermokarst across Alaska, and (3) assessing the rate of degradation in selected areas.

Thermokarst Landforms

Twenty two thermokarst landforms associated with specific processes of permafrost degradation have been identified based on their microtopography and vegetation characteristics (Shur 1977, Jorgenson & Osterkamp 2005, Jorgenson et al. 2007, Shur & Osterkamp 2007). These are discussed below with respect to their distribution, characteristics, processes, and lateral rates of degradation. Terminology is mostly from Everdingen (1998). We focus here on surface changes, yet recognize that permafrost also can degrade from the bottom and that ice-poor permafrost can degrade without creating visible thermokarst.

Thermokarst lakes (alas lakes) are common throughout Alaska (Wallace 1948, Hopkins 1949, Osterkamp et al. 2000, Yoshikawa & Hinzman 2003, Jorgenson et al. 2006) and northern Yukon (Burn & Smith 1990). In Alaska, they are particularly abundant on the Innoko, Koyukuk, and Yukon Flats in central Alaska, on the Seward Peninsula and Yukon-Kuskokwim Delta in western Alaska, the western

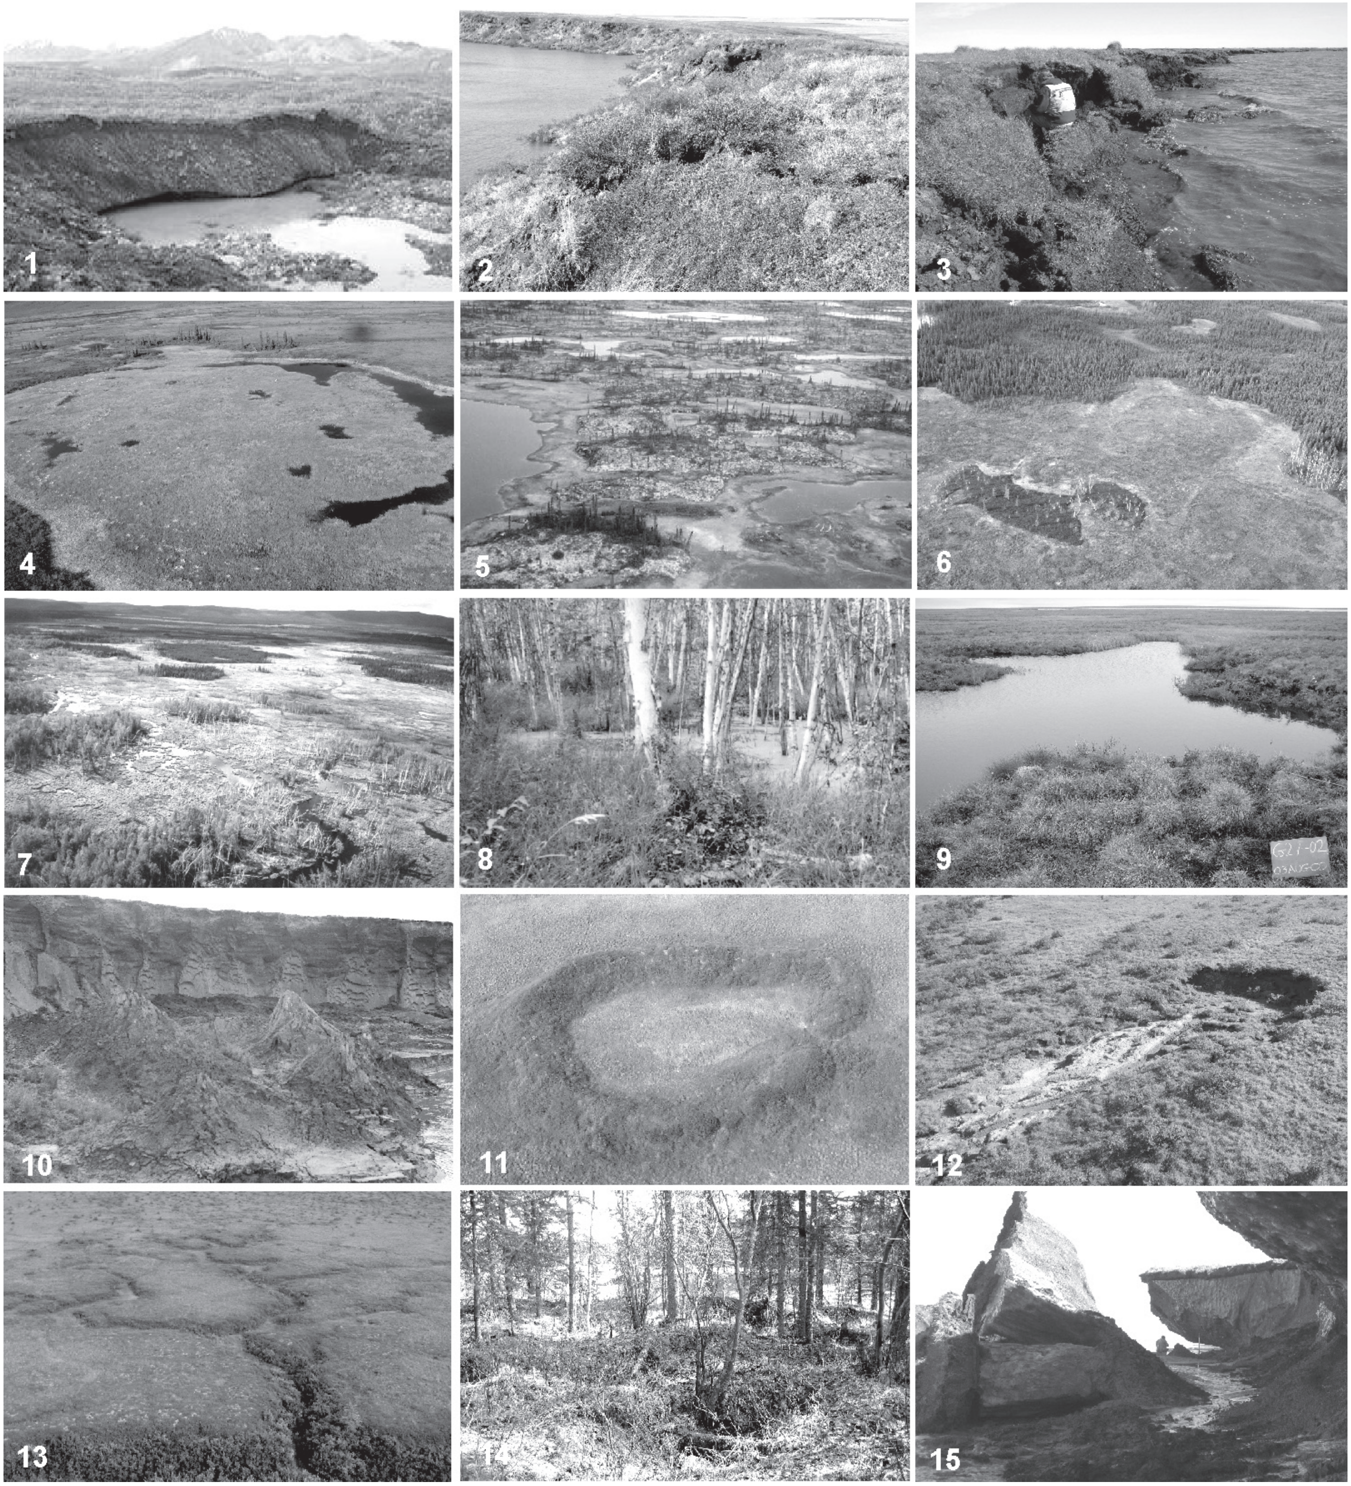

Figure 1. Fifteen thermokarst landforms in Alaska (from left to right on succeeding rows); including: (1) glacial thermokarst on the Muldrow moraine; (2) deep thermokarst lake in yedoma near Cape Espenberg; (3) shallow thermokarst lake near Teshekpuk Lake; (4) thaw-lake basin in Kobuk Valley; (5) thermokarst shore bogs near Innoko River; (6) thermokarst bog in Kobuk Valley; (7) thermokarst fen on Tanana Flats; (8) thermokarst pits on Tanana Flats; (9) polygonal thermokarst trough near Colville Delta; (10) thermokarst conical mounds near Colville River; (11) collapsed pingo near lower Noatak River; (12) thaw slump that started as a detachment slide in Noatak Basin; (13) thermokarst gullies in Kobuk Valley; (14) irregular mounds near Chena River; and (15) collapse blocks undercut by thermo-erosional niche along eroding coast near Cape Halkett.

Beaufort Coastal Plain near Barrow, and the northern Brooks Foothills (Hopkins 1949, Britton 1957, Black 1969, Tedrow 1969, Carter 1988). Permafrost degrades both laterally along the shores, and vertically beneath the water. Rates of lateral degradation range from 0.1 to 2 m/yr depending on ice content, soil texture, and thickness of the surface organic mat, slumping of the banks, and removal of shoreline material by waves. Water depths for shallow thermokarst lakes are typically 1−3 m. Deep thermokarst lakes have water depths >3 m and are classified as a separate thermokarst landform. They typically are found in areas with thick Pleistocene loess deposits, such as at the lower portions of the western Brooks Foothills (Carter 1988) and Seward Peninsula (Hopkins 1949).

Table 1. Thermokarst landforms and processes associated with permafrost degradation.

Landform	Mass Transfer	Heat Source[1]	Hydrologic Regime	Dominant Ice Type	Typical Size	Settlement (m)	Lateral Rate (m/yr)[2]
Deep Thermokarst Lake	Colluvial Waves	Water	Flooded, precip., surface flow	Segregated, ice wedge, other massive ice	1−1000s ha	2–10	0.5−2
Shallow Thermokarst Lake	Waves	Water	Flooded, precip., surface flow	Segregated and wedge ice	1−1000s ha	1–2	0.2−2
Thaw-lake Basin	Colluvial Waves	Water	Drained lake, laterally	Same as above	1−1000s ha	1–10	Banks stabilized
Thaw-lake Sink	None	Water	Drained out bottom	Same as above	1−1000s ha	1–10	Banks stabilized
Thermokarst Pits	None	Still Water	Flooded, precipitation	Ice wedges, thick layered ice	10s of m^2	1–2	na
Thermokarst Troughs and Pits	None	Still Water	Partially flooded, precipitation	Ice wedges	10s of m^2	0.5–2	na
Collapsed Pingo	None	Still Wat., Air	Flooded to drained	Intrusive Ice	ha	3–10	Little after collapse
Thermokarst Bogs	None	Still Water	Saturated by precipitation	Thick layered, Reticulate,	ha	1–2	0.1–0.5
Thermokarst Shore Bogs	None	Still Water	Saturated by precipitation	Thick layered, Reticulate,	ha	1–2	0.1–0.5
Thermokarst Fens	None	Flowing water	Groundwater	Thick layered, Reticulate,	10s of ha	1–2	0.5–1
Thermokarst Water Tracks	None	Flowing Water	Surface flow	Ataxitic, reticulate ice at permafrost surface	100s of m^2	0.2–1	na
Thermokarst Gullies	Fluvial	Flowing Water	Surface flow	Ice wedges	100s of m^2	1–3	na
Beaded Stream	Fluvial	Flowing Water	Surface flow	Ice wedges	ha	1–3	na
Sink Holes and Tunnels	Fluvial	Flowing Water	Groundwater	Ice wedges, cave (tunnel) ice	10s m^2 at surface	Pits 2–5	Little after collapse
Thaw Slumps	Colluvial	Air, Water	Surface flow	Ataxitic, reticulate, ice wedges	100s of m^2	1−5	Highly variable
Detachment Slides	Colluvial	Air	Drained, surface flow	Ataxitic, reticulate,	100s of m^2	0.5–2	Little after slide
Block Landslide	Colluvial	Air	NA	Ice wedges,	100s of m^2	3–10	2−10
Collapse-block Shore	Colluvial Fluvial	Air	Flowing water, waves	Ice wedges	10s of m^2	na	2−10
Conical Thermokarst Mounds	Colluvial	Air	Drained	Ice wedges	10s of m^2	2–5	na
Glacial Thermokarst	Colluvial	Air	Flooded by precipitation	Massive glacial ice	10s of ha	5–30	Highly variable
Irregular Thermokarst Mounds	None	Air	Drained	Lenticular, Reticulate, Ataxitic	m^2	0.2–1	na
Nonpatterned Ground (non-thermokarst)	None	Air	Drained, precipitation	Lenticular, Pore	na	<0.2	na

[1] Direct solar radiation effects not included. Heat is transferred through soil or sediment in most cases; directly to ice in cliff exposures.
[2] Thaw settlement values, and lateral degradation rates are generalized estimates based on limited data.

Thaw-lake basins develop after a thermokarst lake is breached by stream channels and drained (Britton 1957, Jorgenson et al. 2006). A distinct outlet is evident. They are prevalent in the northern boreal forest transition zone and arctic tundra, in contrast to southern thermokarst lakes, which usually paludify with bog vegetation.

Thaw-lake sink is a special type of thaw-lake basin caused by thawing of permafrost below or surrounding a lake, and drainage through subsurface sediments. These lakes may only partially drain and the water level becomes controlled by groundwater (Yoshikawa & Hinzman 2003). They are particularly abundant on abandoned floodplains on the Yukon Flats, where thick, frozen fine-grained overbank deposits overlie alluvial gravels. Once surface deposits thaw and hydrologic connections are made through the underlying gravel, water drains out the bottom.

Thermokarst pits form as small depressions on ice-rich deposits in the discontinuous zone. They often coalesce to form larger bogs and fens. Degradation is primarily vertical from increases in the active layer, and a talik, the unfrozen zone between the seasonally frozen active layer and the permafrost, quickly develops underneath the pits. Thaw settlement typically is 1–3 m and the pits fill with water.

Thermokarst troughs and pits are abundant in northern Alaska (Black 1969, Billings & Peterson 1980, Jorgenson et al. 2006). They form as a result of the degradation of ice wedges, and at an advanced stage, the thawed ice wedges form a polygonal network of water-filled or drained troughs surrounding high-centered polygons. Degradation occurs vertically as the active layer deepens and melts the underlying ice. Settlement generally is 1–2 m, although in areas where water flow through the trough network reinforces the degradation, settlement may reach 3–4 m. During initial stages of ice-wedge degradation, only scattered pits may be evident where they form at ice-wedge intersections. These features are uncommon in boreal regions due to the sporadic occurrence of ice wedges.

Collapsed pingos form by rapid thawing of massive ice in the cores of the pingos. Water is usually impounded in the center of the collapsed pingo and eventually breaches the rim of thawed material. Pingos are common across northern Alaska (Carter & Galloway 1979), but collapsed pingos are rare, except near the lower Noatak River.

Thermokarst bogs are circular depressions that are widespread on flats throughout central Alaska (Drury 1956, Jorgenson et al. 2001). They are associated with ice-rich, fine-grained soils on abandoned floodplains, lowland loess, and sloping retransported deposits. Vegetation is dominated by ombrotrophic Sphagnum and ericaceous shrubs. Bogs slowly degrade laterally at rates of 0.1–0.5 m/yr and thaw settlement typically is 1–3 m (Jorgenson et al. 2001).

Thermokarst shore bogs occur along slowly degrading margins of shallow thermokarst lakes in the boreal forest region (Drury 1956). Shore bogs are considered distinct because the bogs can expand both into the lake and outward toward the collapsing margin. Thus, the lakes may appear to shrink due to paludification even as the adjacent permafrost continues to degrade.

Thermokarst fens occur on flat to gently sloping terrain where groundwater discharges to surface springs, particularly along the northern foot-slopes of the Alaska Range (Racine & Walters 1994, Jorgenson et al. 2001). The fens are associated with degradation of thick-layered ice in silty abandoned floodplains and lowland loess. They form long, linear depressions often associated with birch forests. Vegetation is dominated by minerotrophic herbaceous vegetation (Racine et al. 1998). Degradation is initiated by lateral degradation at rates of 0.5–1 m/yr and thaw settlement typically is 1–3 m and up to 5 m (Jorgenson et al. 2001). Collapse along the margins of the fens forms a distinctive moat with slowly flowing water.

Water tracks are shallow, linear, parallel depressions that form on gently sloping hillsides in areas with continuous permafrost or on toe slopes with retransported deposits in the discontinuous zone. They are formed by the thawing of ice-rich soils near the surface by supra-permafrost groundwater movement. They are not associated with degrading ice wedges.

Thermokarst gullies form when channelized surface-water flow has deepened the active layer and thawed the ice-rich upper permafrost. They are abundant throughout northern and central Alaska. Where water becomes sufficiently channelized on ice-rich soils, gullies 1–5 m deep may develop that include some mechanical soil erosion (Tsuyuzaki et al. 1999). They are typically associated with thawing ice wedges.

Beaded streams are formed by the melting of wedge ice by flowing water in small lowland streams on flat terrain with formation of pools at the intersection of ice-wedges. They are very identifiable features of arctic lowland terrain with distinctive water quality (Oswood et al. 1989).

Sink holes and tunnels (pipes) occur in gently sloping areas where groundwater flow from hillsides encounters ice-rich colluvium and retransported deposits in the valley bottoms (Carey and Woo 2002, Fortier et al. 2007). Groundwater flow can thaw massive ice (Holocene ice wedges or Pleistocene massive ice deposits) at considerable depth. Removal of the ice leads to rapid collapse (days to weeks except in forests where roots can form a supporting structure for years) of the overlying soil and creation of sink holes. The distribution, extent, and mechanism of these features are not well known.

Thaw slumps are caused by the retrogressive thawing of ice-rich permafrost at a steep head-scarp face. Thaw slumps occur throughout northern and central Alaska and northern Canada (Burn & Friele 1989, Brease 1995, Huscroft et al. 2004, Lantuit & Pollard 2005, Kokelj et al. 2005). They occur on gentle to steep slopes. Typically they are initiated by detachment slides. Removal of the active layer exposes permafrost to rapid thawing. After initial degradation, the thawed area often expands laterally upslope along the exposed headwall. While thaw slumps may be limited in extent they can have important consequences on the water quality of downslope lakes and rivers (Kokelj et al. 2005). They are common adjacent to rivers, lakes, and coastlines.

Detachment slides involved the flow or slide of material associated with thawing of the ice-rich intermediate layer, increase in pore pressure in the active layer, and subsequent flow of thawed material (Lewkowicz & Harris 2005). Some slides initially can be limited to the active layer without thawing of ice-rich material at the permafrost surface, in cases where heavy rain has increased the soil moisture content and submerged weight. However, after detachment, thawing of the permafrost ensues. Detachment slides often transform into retrogressive thaw slumps. Slides were numerous in both Alaska and the Yukon after extensive forest fires in 2004 (Lipovsky et al. 2005).

Block landslides are created by the cracking and falling of ice-rich blocks of permafrost from tall, steep faces (Dyke 2000). The fallen or sliding blocks thaw or erode away to maintain a steep cliff face.

Collapse-block shores are associated with shoreline erosion that degrades permafrost soils and is common in northern Alaska along the Beaufort and Chukchi seas (Leffingwell 1919, Reimnitz et al. 1988, Jorgenson & Brown 2005, Mars & Houseknecht 2007). In ice-rich soils, thermo-erosional niches are formed by the thermal and mechanical erosion of ice-rich sediments along riverbanks, lake shores, and coastlines (Leffingwell 1919, Walker & Arnborg 1966). The undercut bluffs often crack off in large blocks. Shoreline retreat often is rapid (m/yr).

Conical thermokarst mounds (baydzherakhs) form from thawing of extremely ice-rich permafrost, where the ice wedges are very old and large (UAS 1959). Soil remaining in the center of polygons thaws and slumps into cone-shape mounds. Mounds often disappear in short time. They are indicative of extremely ice-rich, Pleistocene-age permafrost.

Glacial thermokarst forms highly uneven topography and kettle lakes and is common on ice-cored moraines in the Brooks, Alaska, and Chugach ranges. Numerous kettle lakes of early Holocene age and related to retreat of Wisconsin-era glaciers from their terminal moraines are well known throughout previously glaciated regions. Contemporary kettle lakes form in moraines formed during the Little Ice Age, such as at the terminus of the Muldrow Glacier. Water depths are highly variable, ranging from 5 to 30 m, and the water usually is turbid from slumping banks.

Irregular thermokarst mounds are common throughout lowland forests in central Alaska, although they are often indistinct and easily overlooked. They occur on all types of permafrost terrain where soils are ice-poor or where the active layer thaws sufficiently to equilibrate with changed climatic conditions. Usually, the mounds are 0.2−1 m high and 1−3 m across. Where permafrost persists at depth, the mounds become better drained and the lower-lying hollows become wetter. In warmer areas where permafrost has degraded to deep depths, or been entirely eliminated, all microsites become well-drained.

Nonpatterned thawed ground presumably is common on rocky hillsides, gravelly lowlands (abandoned glacial outwash), or gravelly floodplains, where thawing of ice-poor permafrost results in little to no thaw settlement. Detection is difficult because no surface changes are evident, the rocky soils resist penetration for thaw depth or temperature measurements, and evidence of a previously frozen state is often lacking. Permafrost degradation can still cause large ecological changes because increased subsurface drainage improves soil aeration.

The large variation in landforms associated with surface permafrost degradation is a result of the many complex and interacting factors found across the broad geomorphic environments of Alaska (Jorgenson & Osterkamp 2005, Shur & Osterkamp 2007). These include differing climates and rates of warming, physiography, soil texture, mass and heat transfer processes, hydrology, and ice content and morphology. Fire also has a widespread role because changes to the surface energy balance and soil properties are large and instantaneous (Burn 1998, Hinzman et al. 2001).

Extent

Assessment of the extent of thermokarst features is difficult due to the heterogeneity of ecological responses, diverse spectral characteristics, varying thaw settlement depths, and a wide-range of sizes of thermokarst features, ranging from 1 m^2 to 1000s of ha. To overcome these issues, Jorgenson et al. (2007) used airphoto interpretation and point-sampling on 655 airphotos to determine the abundance of thermokarst features across Alaska (Fig. 2).

Interpretation of 387 airphotos from the discontinuous zone (subarctic climate) revealed that 5% of the area has thermokarst terrain, 62% has permafrost unaffected by thermokarst, and 21% is unfrozen with no recent permafrost (e.g., active floodplains, south-facing slopes). In 11.9% of the area, permafrost status could not be determined (primarily bedrock areas that are thaw-stable). When considering only areas where current or recent permafrost was evident (67%), 7% of permafrost-affected areas have degraded. The most common types of thermokarst included: thermokarst fens (1.8% of total area); thermokarst bogs (1.0%); thermokarst lakes (1.0%); thaw-lake basins (0.3%); glacial thermokarst (0.5%); and thermokarst pits (0.3%) within the subarctic zone.

In the continuous permafrost zone, 13.5% of the terrain showed recent or old (early-mid Holocene) permafrost degradation on 268 airphotos. Common landforms included: thaw-lake basins (7.1 %), deep and shallow thermokarst lakes (1.9 %), thermokarst troughs and pits (2.3 %), thermokarst gullies (1.1%), water tracks (0.7%), and beaded streams (0.4%).

Some commonly described thermokarst features, however, were not encountered by the sampling indicating that overall coverage of the features was negligible. Thaw slumps, detachment slides, and thermokarst gullies were not encountered, although they were evident adjacent to a few sampling points. Conical thermokarst mounds, collapse blocks, and sink holes were not encountered.

While photo-interpretation is effective at identifying distinctive thermokarst features, there are two major types of terrain in which permafrost degradation is particularly

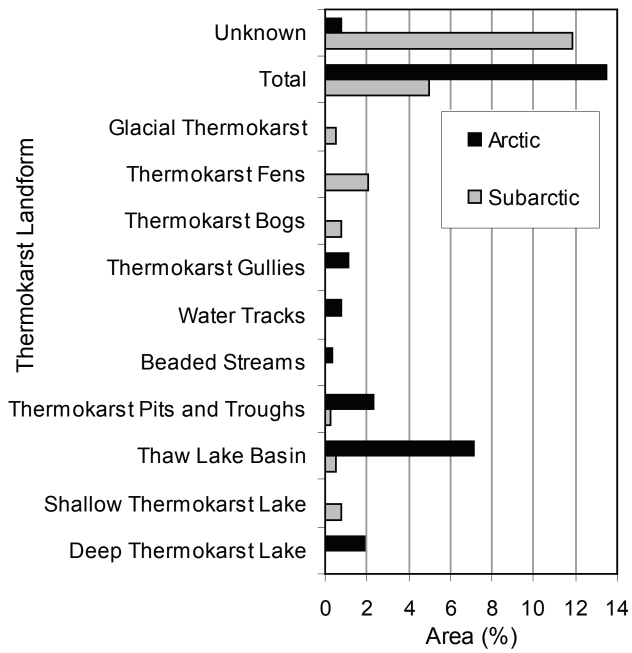

Figure 2. The extent of thermokarst features in arctic and subarctic, Alaska.

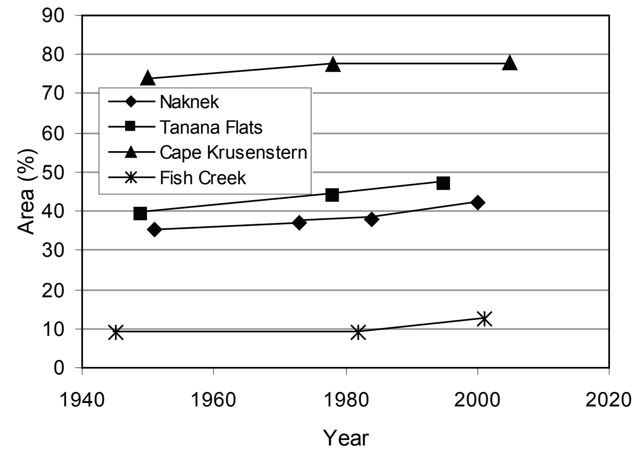

Figure 3. Changes in extent (% area) of thermokarst features from circa 1950 to circa 2000 at four sites in Alaska.

problematic to interpret. First, interpretation of thawing of ice-poor, thaw-stable permafrost is not possible because of the lack of thermokarst. This condition is prevalent in bed-rock controlled upland and alpine terrain in the discontinuous zone. In the discontinuous zone, degradation status of 11.9% of the terrain was unknown because of the lack of surface patterns indicative of thermokarst. Second, determination of thermokarst lakes and thaw-lake basins is problematic because not all lakes and basins in permafrost terrain develop from thawing and collapsing of ice-rich permafrost. In particular, lakes occurring in sand dunes and sheets can occur as simple impoundments in low-lying swales. Ground-ice data from Lawson (1983) and Pullman et al. (2007) show that eolian sand has negligible amounts of excess ice and the terrain is not capable of sufficient thaw settlement for thermokarst-lake formation. In addition, many shallow waterbodies are infilling remnant water in drained-lake basins (Jorgenson and Shur 2007). The photo-interpretation indicated 5.1% of the terrain had lakes, but only 1.9% was classified as thermokarst because a large portion of the Beaufort Coastal Plain is covered by eolian sand and slightly pebbly sand sheets. Areas with lakes interpreted to be thermokarst lakes are limited to extremely ice-rich deposits of limited distribution, such as delta overbank and glaciomarine deposits. The Pleistocene loess deposits in the Brooks Foothills have deep thermokarst lakes, but lakes in this hilly terrain are very limited in extent. Similarly, 7.1% of the basins were classified to be of thermokarst origin, while 7.5% to be of non-thermokarst origin.

Rates

The rate of thermokarst formation has yet to be assessed comprehensively due to the huge area, varying landforms, and lack of sufficient high-resolution imagery. Rates determined for a few areas, however, provide insight into degradation rates over the last half century. Below we provide rates across a climatic gradient from the zone of isolated permafrost, where mean annual air temperatures (MAAT) are 2°C, to the continuous zone, where MAATs are as low as -12°C (Fig. 3).

At Naknek in southwestern Alaska, thermokarst bogs have been developing in glacio-lacustrine deposits that have ice-rich permafrost dominated by layers of thick, clear, horizontal ice. Total area with thermokarst features has increased from 35.5% in 1951 to 42% in 2000 within the 9 km^2 study area. On the Tanana Flats, where thermokarst fens and bogs are abundant on abandoned floodplain deposits, thermokarst terrain has increased from 39% in 1949 to 47% in 1995 (Jorgenson et al. 2001). On the coastal plain near Cape Espenberg, where thermokarst lakes and thermokarst pits and troughs are abundant on eolian silt and thaw-lake deposits, thermokarst terrain has increased from 73.9% in 1950 to 78.1% in 2005. The high percentage of thermokarst terrain was due to the prevalence of old, drained thaw-lake basins. Finally, tundra near Fish Creek, where thermokarst polygonal troughs are common on flat upland terrain and drained lake basins are common on sandy soils in lowland terrain, thermokarst showed little change between 1945 and 1982 (9%), but had expanded to 12.5% in 2001 due to thawing of the top of ice wedges (Jorgenson et al. 2006). Overall, thermokarst terrain increased in percent area by 3.5 to 8%. The Naknek and Fish Creek areas showed more rapid thermokarst from ~1980 to ~2000, compared to the earlier ~1950 to ~1980 period, while Tanana Flats and Cape Espenberg showed more constant rates of increase between the periods.

Conclusions

There is a broad diversity of patterns and processes associated with surface permafrost degradation and its ecological consequences. Twenty-two thermokarst landforms have been identified that vary in relation to climate, geomorphic environments and soil texture, hydrologic regime, ice morphology and content. The extent of thermokarst varies from 5% of the surface area in the discontinuous zone to 13.5% in the continuous zone. The age of thermokarst features remains unknown. Overall, thermokarst terrain increased in percent area by 3.5 to 8% at four sites over a ~50-yr period, and at two of the sites the rate of thermokarst development increased during the last 20-25 yrs relative to the first 20-25 yrs since ~1950. This diversity complicates the analysis and modeling of the response of permafrost to climate change.

Abstract

A recent scientific focus on the thermal regime of openwork blocky deposits has lead to the conclusion that air circulation in the pore spaces and exchange with the atmosphere may be particularly important processes of heat transfer in such materials. This contradicts our data from the coarse openwork active layer of the Larsbreen rock glaciers. Visual observations and temperature data give inconsistent results on air circulation activity at this site, and we conclude that this process seems less important here compared to what is reported from other areas. Other thermal processes at the site, in addition to conduction, include water vapour transport and subsequent sublimation, and meltwater infiltration followed by several refreezing and melting events. More data is needed to understand the complex process pattern in the coarse active layer of these rock glaciers, and further instrumentation is planned as part of the IPY-project 'TSP Norway – Thermal State of Permafrost in Norway and Svalbard.'

Keywords: active layer; coarse debris; heat transfer; non-conductive processes; rock glacier; Svalbard.

Introduction

In openwork blocky debris such as rock glaciers, coarse talus deposits, and block fields, reported mean annual temperatures are often lower than in adjacent finegrained material (Harris & Pedersen 1998, Hanson & Hoelzle 2005). A recent scientific focus has lead to the conclusion that this temperature anomaly is due to air exchange between the blocky debris and the atmosphere and circulation of air within the material (Harris & Pedersen 1998). Circulation could be by free or forced convection (Nield & Bejan 2006). Free convection is driven by temperature-induced density differences of the air and may operate in gravel-sized materials or coarser if the degree of water saturation is less than about 40% (Johansen 1975), while forced convection is driven by pressure gradients as, for example, induced by high wind speeds (Ping et al. 2007). However, the general importance of this process is still largely unknown (cf. Juliussen & Humlum, in press) as many studies consider extreme cases with large pore spaces (Gorbunov et al. 2004) and steep slopes (Delaloye et al. 2003).

In this paper, we identify and discuss thermal processes operating in the coarse openwork active layer of some rock glaciers near the glacier Larsbreen in Svalbard (Fig. 1), based on visual observations from the active layer in Spring 2006 and temperature data from the active layer 2005–06.

Study Site

In Svalbard, low mean annual air temperatures (MAAT) of -5.1 to -7.1°C (1961–1990, ©Norwegian Meteorological Office) result in continuous permafrost except beneath temperate parts of glaciers. The permafrost is typically some tens of meters to 100 m thick in major valley bottoms and close to the sea, but up to 400–500 m thick in the mountains (Humlum et al. 2003).

Rock glaciers are common features in Svalbard (Sollid & Sørbel 1992). At the study site, rock glaciers are creeping out from the talus slope in front of and in a lateral position to the Larsbreen glacier (78°12′N, 15°36′E, 250 m a.s.l.) (Fig. 1). The rock glaciers in front of the glacier were deformed by the glacier advance during the Little Ice Age, but still each individual rock glacier can be traced back to the talus cone from which it is creeping, while the longitudinal furrows separating the rock glaciers are all associated with inter-cone depressions.

In the winter, snow accumulates in the depressions to depths of several meters. The rock glacier fronts, on the other hand, are covered by only a thin and sporadic snow cover. Avalanches are frequent in the study area, and cover the rooting zone of the rock glaciers with snow in the winter. By bringing snow and rock debris to the rock glacier rooting zone, they are probably a driving factor for the rock glacier development at this site (Humlum et al. 2007).

The rock debris in the rock glacier is talus material composed of Tertiary sandstones and shales (Hjelle 1993). Average clast size (b-axis) is 15.0 cm at the surface and 8.5 cm close to the permafrost table, and the clasts are slabby (c:a axial ratio of 0.24 to 0.32 and b:a axial ratio of 0.66 to 0.73, see also Fig. 2). The active layer is openwork, and the pore volume is filled with air in summer and a mix of air

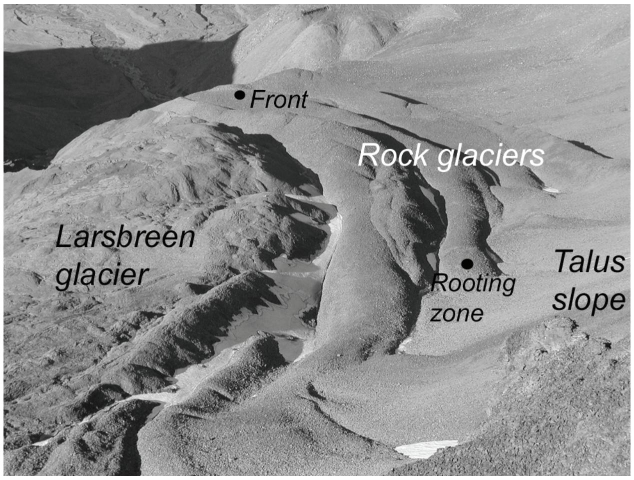

Figure 1. Photo showing the debris-covered front of the Larsbreen glacier, the rock glaciers, and the sites with active layer temperature measurements at the front and at the rooting zone.

and ice in the winter. The active layer is about one meter thick on the rock glaciers, and less than half a meter in the depressions between the rock glaciers.

Methods

Visual observations

The active layer was manually excavated at irregular time intervals during Spring 2006 to visually observe spatial and temporal changes in ice content and the structure of the ice during the melting season.

Temperature measurements

The active layer thermal regime on the rock glacier has been monitored close to the front (at the surface and at depths 0.35 m, 0.70 m, and 0.90 m) since Autumn 1999 and just below the rooting zone (at the surface and at depths 0.30 m, 0.60 m, and 1.15 m) since Summer 2005 (Fig. 1). Air temperature at the site was measured in a 0.15 m high naturally-ventilated stone cairn. Tinytag miniloggers with a precision of ±0.2°C were used both for air and active layer temperature monitoring. Temperature was logged at hourly intervals.

Since active layer temperatures were logged at two sites only, ground surface temperatures below the snow cover were measured manually at irregular time intervals through the winter and Spring 2006 to detect any spatial variability not recorded in the logger series. High spatial variability in winter ground surface temperature may reflect zones with rising and sinking pore air within individual convection cells (e.g., Goering 2002), while low variability would be against a hypothesis of effective, distinct convections cells.

Calculation of Rayleigh numbers

The potential for free air convection in a porous medium can be explored by estimating the Rayleigh number, which determines if heat transfer in a fluid is mainly by convection or conduction (Nield & Bejan 2006). It is given by:

$$Ra = \frac{C\beta gKH\Delta T}{\nu k} \tag{1}$$

where $C, \beta,$ and ν are the volumetric heat capacity, expansion coefficient, and kinematic viscosity of the pore fluid (in this case air); g is gravitational acceleration; K is the intrinsic permeability of the blocky debris layer; H is the thickness of the layer; ΔT is the temperature difference between the top and bottom of the layer (warmer boundary below); and k is the effective thermal conductivity.

Free convection can be expected if the Rayleigh number exceeds a critical value. In the case of closed upper and lower boundaries, such as represented by a continuous snow cover and the permafrost table, respectively, this critical value is $4\pi^2 \approx 40$ (Nield & Bejan 2006). When there is no snow, and the pore volume is open to the atmosphere (open boundary), the critical value is 27 (Serkitjis & Hagentoft 1998).

The Rayleigh number is estimated from the temperatures logged at the front and at the rooting zone. The effective thermal conductivity was estimated with an empirical relationship to porosity n (Johansen 1975):

$$k = 0.039n^{-2.2} \tag{2}$$

A value of 0.3 was used for the porosity. The hydraulic permeability was estimated with the approach of Fair & Hatch (1933), also used by Goering (2002):

$$K = \frac{1}{5}\left[\frac{(1-n)^2}{n^3}\left(\frac{\alpha}{100}\sum\frac{p}{d_m}\right)^2\right]^{-1} \tag{3}$$

where α is a particle shape parameter; p is the percentage of particles held between adjacent size limits; and d_m is the geometric mean size of those limits. These parameters are estimated from clast size measurements. The Rayleigh number estimates are conservative, as a minimum estimate of the hydraulic permeability was used.

Results

Visual observations

Visual observations from the active layer excavations in spring indicated that several types of non-conductive heat transfer processes had operated in the previous winter: infiltration and refreezing of meltwater, and sublimation of water vapour, the latter forming delicate hoar.

Interstitial ice was found in distinct zones, filling the open pore spaces or forming icicles (Fig. 2). Ice accumulations were largest beneath thin snow. Initially, the ice accumulations occurred in distinct zones as extensions of localized meltwater pathways through the snowpack (e.g., Conway & Benedict 1994, Albert et al. 1999). Thus, the ice formed by refreezing of infiltrating surface meltwater reaching the cold active layer. As the melting season progressed, ice accumulations became more widespread. After the snow cover was completely melted, the ice in the active layer started to melt from the surface.

Figure 2. Photos showing icicles and interstitial ice in the pore volume of the active layer. Vertical section of ruler is 17 cm. Photos taken 26.04.2006 (left) and 04.05.2006 (right).

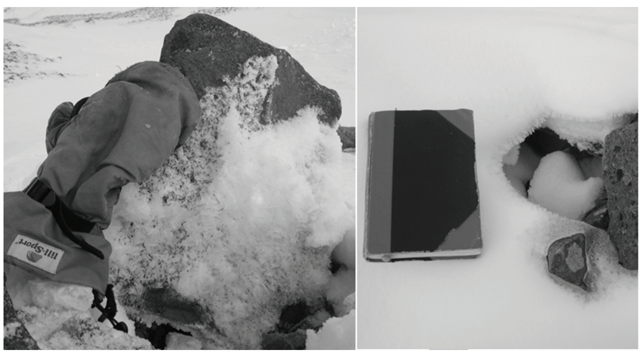

Figure 3. Left panel: Large hoar crystals occupying the pore volume and the base of the tilted block. Glove for scale. Photo taken 24.04.2006. Right panel: Funnel through the snow cover. Note the hoar on the funnel rim. Notebook (width 10cm) for scale. Photo taken 10.05.2006.

Well-developed hoar was found in the upper part of the active layer, in places filling the entire pore volume, and on snow funnel rims (Fig. 3). The hoar crystals were largest and most common near the surface of the rock glaciers where snow was thin or absent and active layer cooling was most effective. Hoar was also superimposed on some of the icicles, but not all, suggesting several episodes, both in the early winter and in the spring, of meltwater infiltration and refreezing. The prevalence of hoar suggests transport of water vapour in the pore volume towards the colder upper part of the active layer and subsequent sublimation.

Funnels through thin snow covers were frequently observed after snowfall (Fig. 3). Funnels indicate exchange of air between the pore volume and the outside (Keller & Gubler 1993).

Active layer temperatures

Average daily temperature in the air (at 15 cm height) and in the active layer at the rock glacier front and at the rooting zone for the period Sept. 2005–June 2006 are given in Figure 4. Active layer freeze-back occurred in the middle of September and was immediate, due to the lack of water in the coarse materials. At the front, negative temperatures prevailed in the active layer until May, and active layer temperatures followed the ambient air temperature throughout the winter. The shift to positive temperatures in May was immediate down to 0.35 m depth, but at 0.70 m depth there was a zero curtain period (stable temperature at 0°C) of about a week. This indicates that the upper 0.35 m was more or less free of ice, while some ice existed deeper in the active layer that required energy to melt before the temperature could switch to positive values.

At the rooting zone, the temperatures followed the air temperature until the onset of December, when the site was covered with avalanche snow. For the rest of the winter, the active layer temperatures followed only the main trends in the air temperature as high-frequency fluctuations were masked by the snow. The temperature curves from both sites show several episodes of sudden temperature increase, indicating meltwater infiltration and refreezing during the winter season, forming the observed ice accumulations (Fig. 2). These episodes occurred in periods of warm weather in the autumn, in January during an unusually warm and wet period, and in the spring melt season. In May and June, a snowmelt and zero curtain period of at least one month delayed active layer warming at the rooting zone. The zero curtain period started more or less at the same time at all depths, reflecting the abrupt nature of the infiltration process. The zero curtain period was significantly longer at 1.15 m depth, reflecting that melting occurs from the surface only and possibly indicating a higher ice content than at shallower depths.

The estimated Rayleigh numbers are also given in Figure 4. Since the Rayleigh number is a function of the active layer temperature gradient, it fluctuated in rhythm with the active layer temperatures through the winter. At the front, the theoretical critical Rayleigh number (open boundary) was frequently exceeded, indicating possible episodes of free convection at this site. The estimated Rayleigh numbers for the period 2000–2005 were of comparable size (not shown).

At the rooting zone, the Rayleigh number fluctuated in rhythm with that at the front and with the ambient air temperature, with the highest values well above the critical value (open boundary), until the site was covered by avalanche snow. Below avalanche snow, the Rayleigh number increased to a maximum just above the critical value (closed boundary) and showed less fluctuation than at the snow-free site. Keeping in mind that the Rayleigh number estimate was conservative, there is a potential for free convection also at this site.

Ground surface temperatures (GST)

The manually measured ground surface temperatures are displayed in Figure 5 as average values for each date with one standard deviation. Between 7 and 22 measurements were made at each visit. Continuous ground surface temperature measurements at two sites within 20–30 m from the rooting zone profile are also given (GST1 and GST2), along with the surface temperatures at the rooting zone and air temperature. The standard deviation of the manual measurements was mostly below 1°C, even when Rayleigh number estimates show a potential for convection. This suggests that there were no highly effective convection cells. Moreover, the temporal evolution of the ground surface temperatures was

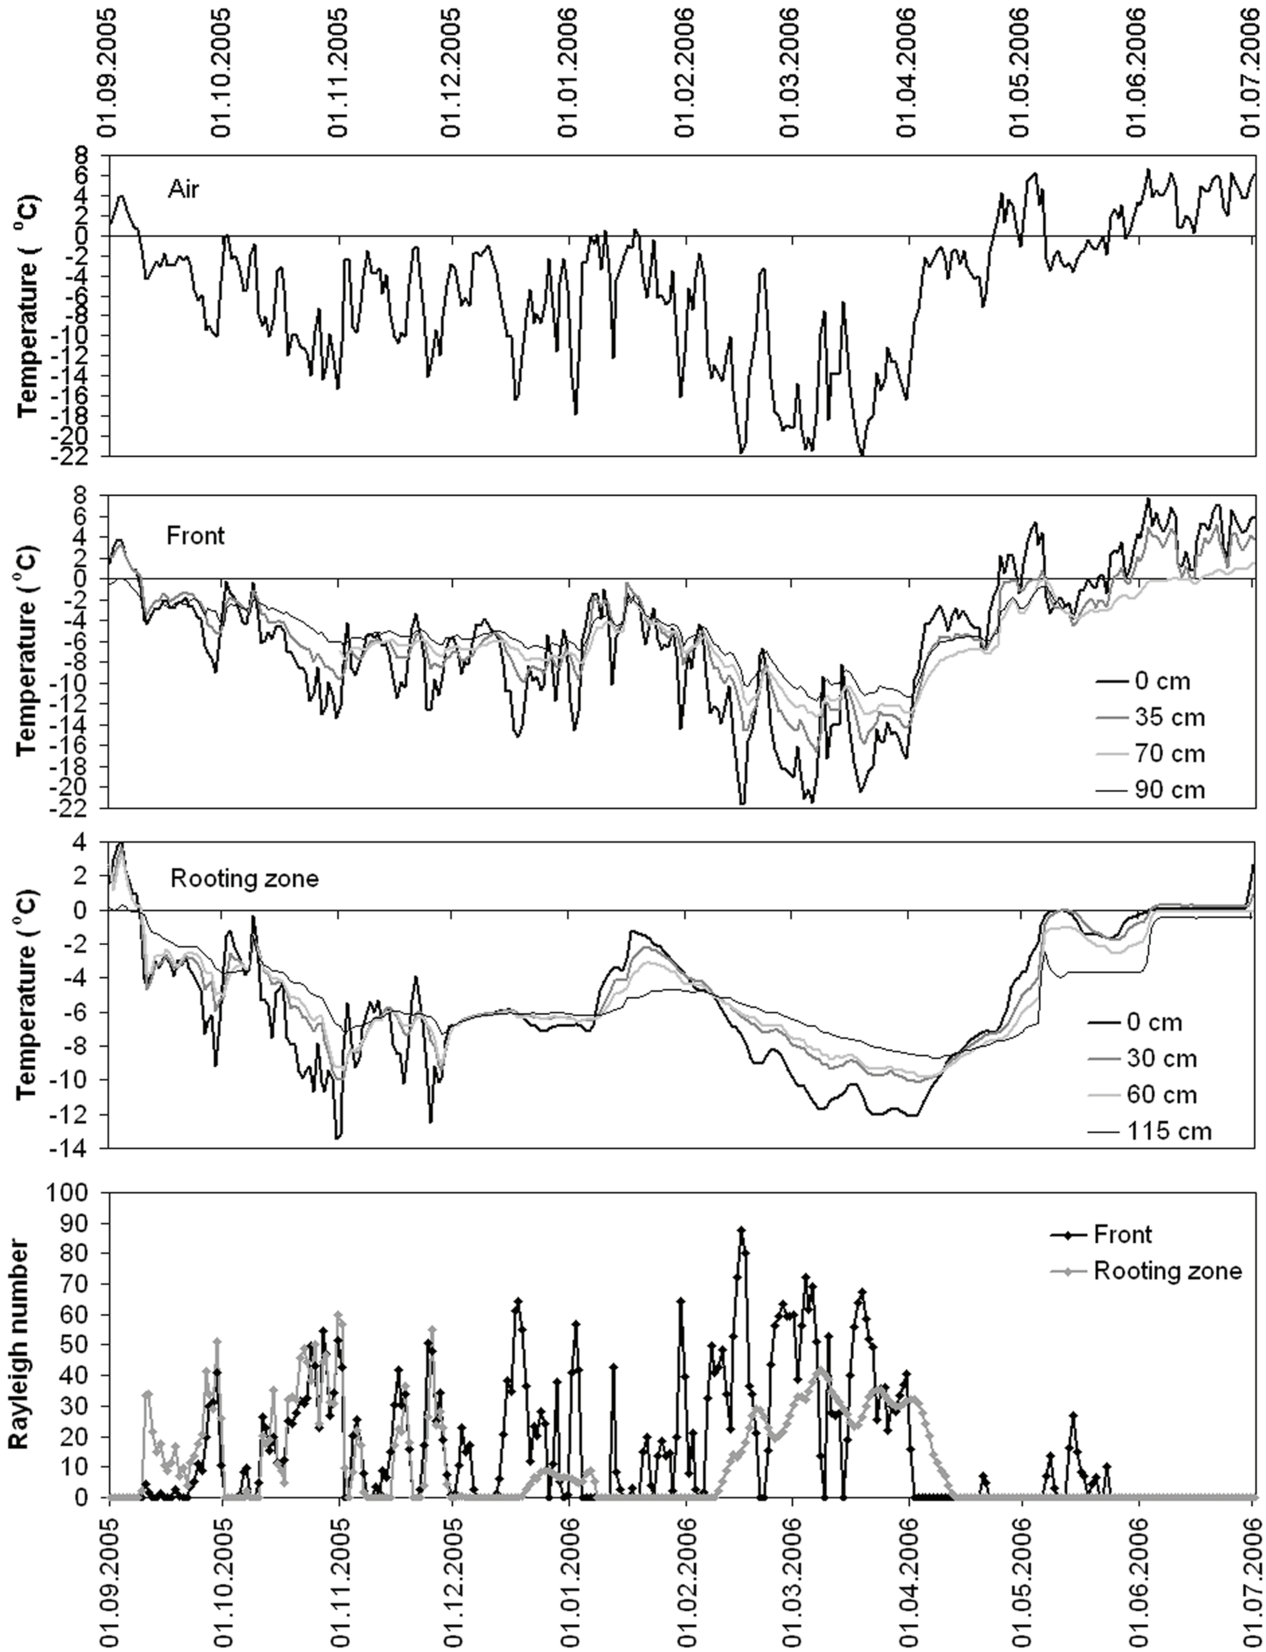

Figure 4. Daily air temperatures (at 15 cm height), active layer temperatures and estimated Rayleigh numbers at the front and at the rooting zone for the period Sept. 2005 – June 2006.

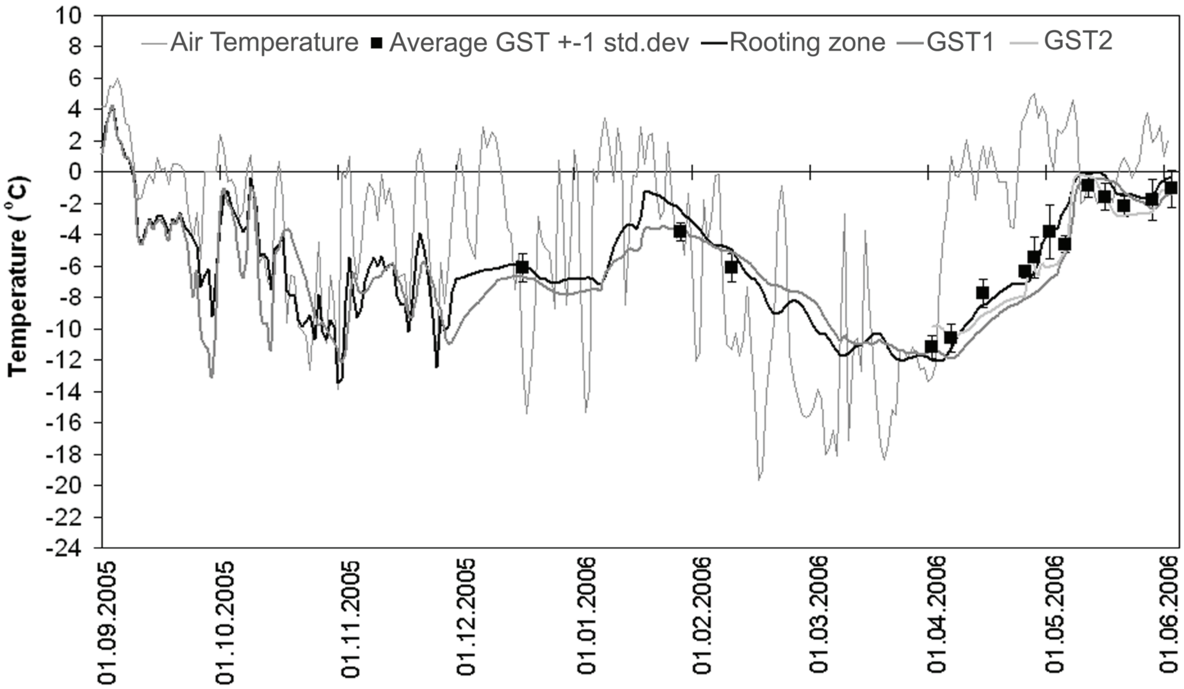

Figure 5. Average GST ± one standard deviation, based on measurement campaigns at irregular time intervals. Continuous ground surface temperatures at two sites with thick snow (GST1 and GST2), surface temperature at the rooting zone and air temperature (official temperatures from Svalbard airport, provided by the Norwegian Meteorological Office) are also given. GST2 starts on April 1.

the result of heat conduction through snow, as shown by snow temperature measurements, rather than by circulation of pore air in the active layer. The highest spatial variability in manually measured ground surface temperatures was due to a differential snowmelt pattern.

Discussion

Considering air convection in the active layer, the Rayleigh number and the spatially distributed GST revealed inconsistent results. While convection should be expected according to the Rayleigh number, both under open and closed boundary situations, no distinct convection cells were identified in the GST data. Funnels indicate that air exchange with the atmosphere is operating where the snow cover is thin (<10 cm). No funnels were found in thick snow covers. A possible explanation for the discrepancy between the Rayleigh number estimate and the GST data could be that the convection process is less efficient than described by e.g., Goering (2002), so that it is not detected in the spatially distributed GST data. Preservation of the delicate hoar supports that. The convection process may, perhaps, rather be viewed as a series of releases of 'heat bubbles' as described by Hanson & Hoelzle (2004), having negligible influence on the thermal regime. Instead, conduction is probably the main thermal process (cf. Gruber & Hoelzle 2008).

The presence of hoar in the upper part of the active layer indicates transport of water vapour and subsequent sublimation. Transport of water vapour may be by diffusion or air convection. Test measurements of relative humidity in the active layer pore volume, show saturated conditions for most of the winter, except for three shorter periods totalling 11–12 days, when the relative humidity decreases to 93–98% in the upper 0.35 m. Some upward vapour diffusion can be expected, at least during these periods, but it is at present not known to which degree this process can explain the amount of hoar in the upper part of the active layer. The drops in relative humidity nicely give the timing of air exchange between the pore volume and the atmosphere.

As the snow melts in spring, meltwater infiltrates the highly permeable active layer. The (initially small amount of) meltwater will first refreeze close to the surface in the active layer due to the cold content of the active layer. The observed icicles and extensions of meltwater pathways through the snow pack (Fig. 2) are formed in this way. As more meltwater is released and the cold content of the active layer decreases, the meltwater may infiltrate deeper into the active layer and eventually reach the base of the active layer, where it refreezes due to the colder permafrost below. Sawada et al. (2003) measured an accumulation of about 0.2 m of ice in only a few days in a block slope in Japan. This ice requires energy to melt and further delays active layer development (cf. Woo & Xia 1996).

Other processes, such as wind-forced convection (Humlum 1997) and heat radiation (Johansen 1975), may also be important for the thermal regime of coarse-grained active layers. Lack of relevant data precluded a discussion of these processes here.

Further studies are planned at the site as part of the IPY-project "TSP Norway—Thermal State of Permafrost in Norway and Svalbard." This involves an attempt to measure relevant energy fluxes (cf. Smith & Burn 1987, Rist & Phillips 2005).

Conclusions

Heat transfer processes in the coarse-grained active layer of the Larsbreen rock glaciers in Svalbard have been discussed based on visual observations of ice in the active layer and temperature data. The following conclusions can be drawn:

- Considering air convection in the active layer, the Rayleigh number and the spatially distributed GST data reveal inconsistent results. Convection of air in the pore volume of blocky debris seems less important here compared to what is reported from other areas. Winter air exchange between the pore volume of the blocky layer and the atmosphere may operate through snow covers thinner than about 10 cm.
- Hoar in the upper part of the active layer indicates transport of water vapour, by diffusion or air convection, and subsequent sublimation.
- Water from snowmelt infiltrates and refreezes in the active layer. Melting of this ice delays active layer development.

Abstract

Water balance computations are a tool for developing a better understanding of hydrologic processes and their interaction for all types of environments. In this case study, water balance computations are carried out for an Arctic watershed characterized by continuous permafrost, lack of trees, low hydraulic gradient, negative mean annual temperature, and a snow cover for eight to nine months. The Putuligayuk River is a north draining river that drains 471 km^2 and empties into the Arctic Ocean. The snowmelt event, in late May or early June, is the major hydrologic runoff event of the year that results in 80% of the snowpack leaving the basin as surface flow. During the summer months, evapotranspiration (ET) exceeds precipitation with 60% of rainfall precipitation leaving the basin as ET and 40% as runoff. Annually, 60% leaves as runoff and 40% as ET.

Keywords: Arctic; evapotranspiration; continuous permafrost; precipitation; runoff; surface storage; water balance.

Introduction

It is abundantly clear that the Arctic is undergoing change from permafrost warming (Lachenbruch & Marshall 1986) to glacier mass wasting (Arendt et al. 2002), to snow cover reduction (Robinson et al. 1993), to reduction in sea ice extent (Maslanik et al. 1999, Vinnikov et al. 1999), to increasing shrub abundance (Sturm et al. 2001), to later freeze-up and earlier break-up (Magnuson et al. 2000), to many other changes (Hinzman et al. 2005). Hinzman et al. (2005) summarizes numerous kinds of evidence of environmental change, what the climatic drivers are and what are the implications. During this environmental change, hydrologist struggle with quantifying various hydrologic fluxes to improve our understanding of the Arctic hydrologic cycle with methods prone to error and considerable year-to-year natural variability. Water balance computation, generally at the small watershed scale, is one tool used to advance our knowledge of Arctic hydrology (Kane & Yang 2004). Unfortunately these studies are of short duration (no trends observed) and only at the small catchment scale (~400 km^2 or smaller).

Both the domestic and industrial demand for water and the impact that climate change is having on the hydrologic cycle in the Arctic warrants that we improve our hydrologic understanding. The number of hydrologic stations in the Arctic is quite low, the longevity of these stations is relatively short (except in Russia), and most stations are located at low elevations along the coasts or major drainages. Since 1999, we have been monitoring the runoff from the Putuligayuk River, including other complementary hydrologic and meteorological data. Reported here is the seasonal water balance for this 471 km^2 low-gradient catchment (Fig. 1) draining into the Arctic Ocean.

Setting

The Putuligayuk River (Fig. 1) is part of a nested watershed study (Kane et al. 2000) on the North Slope of Alaska that drains an area south of the Prudhoe Bay oil field

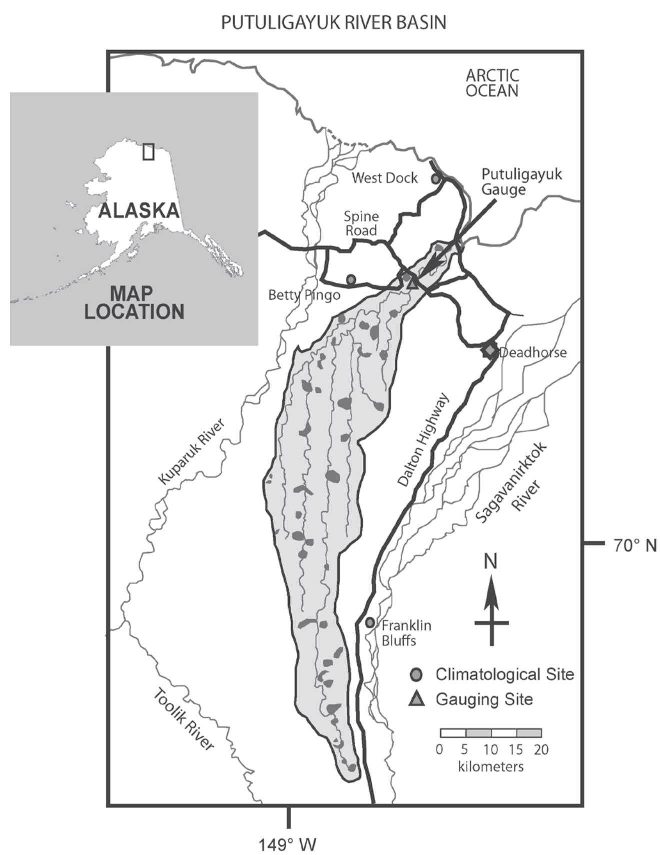

Figure 1. Location map of the north–draining Putuligayuk watershed on the North Slope of Alaska.

before flowing northward through the middle of the field and into the Arctic Ocean. It is a patchwork of lakes, drained lakes, and numerous other permafrost features such as high and low centered polygons, pingos, strangmoor ridges, frost boils, and hummocky terrain. This is an area of continuous permafrost with a maximum measured depth of 600 m, treeless and mostly vegetated with sedges with some shrubs in riparian areas. The elevation at the top of the watershed is 109 m and at the gauging site, 7 m. The active layer is typically around 35 to 55 cm at summer's end (Hinzman et al. 1998) and is composed of surficial organic soils (~20 cm although quite variable) over mineral soils.

Flow ceases in this basin during the winter months with breakup occurring in late May or the first two weeks in June, just prior to the summer solstice. The snowmelt breakup is the biggest runoff event of the year; this is substantiated by the U.S. Geological Survey, which first gauged this stream from 1971 through 1986 (1980 and 1981 missing). Little or no other complementary data were collected during this gauging period. For the past few years, snowfall precipitation has averaged about 40% of the annual precipitation. Redistribution by wind is a major component of the hydrologic cycle of this region. Elevational depressions (drainages, drained lakes, ponds, etc.) are depositional areas for blowing snow, and exposed areas are eroded. Snow damming in the river and smaller drainages (including lake outlets) delays the runoff event by several days; typically the tundra snowcover is almost completely absent before any runoff of significance is measured at the gauge.

During the summer months, evapotranspiration exceeds precipitation. This means that the surface storage of water in the ponds, wetlands and lakes decreases over the summer. Some late summer precipitation may replenish some of this deficit; however, most of the deficit will be made up during the following spring break-up (Bowling et al. 2003). In the summer, as the watershed dries out, the drainage network becomes fragmented. This explains why there is minimal runoff response during the summer months to precipitation, although it comprises 60% of annual precipitation.

Methods

Since 1999, we have been collecting hydrologic and meteorological data on the central coastal plain on the North Slope of Alaska in the near vicinity of the Arctic Ocean. One objective of this data was to perform a water balance determination of a low-gradient watershed that is in an area of continuous permafrost. The three main features of the water balance equation are the input (P), changes in various storage terms (ΔS), and outputs (ET and R); if we ignore storage terms, this equation can be simplified to:

$$P - ET - R \pm \Delta S = \eta \qquad (1)$$

where

P = precipitation, both snowfall and rainfall (possibly condensation)
ET = evapotranspiration (possibly sublimation)
R = discharge throughout the entire period of flow
ΔS = Change in surface storage
η = error term on closure

Summer liquid precipitation gauges exist at three sites (Fig. 1) immediately adjacent the Putuligayuk catchment: at Franklin Bluffs, Betty Pingo and West Dock. In addition there are meteorological measurements at each of these sites that collect 10 m profiles of air temperature, relative humidity and wind speed profiles; incoming and outgoing long- and short-wave and net radiation fluxes, wind direction, soil temperature, barometric pressure, and soil moisture data are also measured. Snow surveys of snow water equivalent (SWE) on the ground are carried out the last week of April. For the Putuligayuk catchment there are several measurements sites (number varied from year to year) where 50 snow depth and 5 density measurements are made at each site to get an estimate of the average SWE for that area.

The Putuligayuk River is gauged on the Prudhoe Bay oilfield where it crosses the Spine Road. A stage-discharge relationship has been developed with the stage being measured continuously during the warm summer season with both a float-type water level recorder and a pressure transducer, both located in a stilling well in the center of the river. During break-up the stage-discharge relationship is not reliable as there is some ice and considerable wind redistributed snow in the channel that slowly erodes as flows increase during the ablation season. Snow damming, both at the outlet of lakes and in the river channel, is an important hydrologic process as it delays the runoff response by several days. Typically, most of the shallow snow cover on the tundra disappears before the runoff has increased significantly (initially there is some local runoff along the roadway). The flow is gauged each day during the breakup once the flow seriously starts to increase. Once the flow starts to significantly increase during ablation, the flow continues to increase and peak even if a cold period sets in (Bowling et al. 2003). Historically, there are several years of stream gauging data as this site was operated from 1970 to 1979 and 1982 to 1986 by the U.S. Geological Survey. From the work by Bowling et al. (2003), it is clear that meltwater from the snowpack is responsible for recharging the copious number of lakes in the catchment and also producing the observed runoff. The flow gradually recedes over the summer with only small peaks in response to summer precipitation.

Studies carried out by researchers associated with the Water and Environmental Research Center at the University of Alaska (Rovansek et al. 1996, Mendez et al. 1998, Bowling et al. 2003) have demonstrated that in this part of the Arctic, it is common for summer evapotranspiration (ET) to exceed precipitation. Therefore a drying of the watershed (shrinkage of wetlands, ponds, and lakes) and fragmentation of the drainage network takes place during the summer. Meteorological data are collected so estimates of ET can be made over the basin as reported on by several groups working in the area (Kane et al. 1990, Rovansek et al. 1996, Mendez et al. 1998). Shutov et al. (2006) also presents methods conveniently adapted for calculating evaporation when detailed information on the hydrology and meteorology is missing.

Here we are going to use the Priestley-Taylor (Priestley & Taylor 1972) method to estimate the catchment ET:

$$-Q_e = \alpha(\Delta/(\Delta + \gamma))\ (Q_{net} + Q_g) \quad (2)$$

where

α = empirical parameter elating actual and equilibrium evaporation
Δ = slope of saturated pressure curve
γ = psychometric constant
Q_{net} = net radiation
Q_g = ground heat flux
Q_e = latent heat flux

The amount of water lost over the catchment from the watershed is equal to:

$$ET = Q_e/(\rho_w * \lambda) \quad (3)$$

where

ET = evapotranspiration
ρ_w = density of water
λ = latent heat of vaporization

The value of α varies with both space and time (Mendez et al. 1998); it was highest for lakes, intermediate for wetlands, and lowest for uplands; for wetlands and uplands it decreases during the summer.

It is very difficult to make field estimates of storage changes in this watershed at the seasonal or annual time scale. The numerous lakes, ponds, and wetlands represent a distributed storage reservoir for both rainfall and snowmelt. The amount of snowmelt water stored in a watershed each spring depends upon the ET and precipitation amounts the previous summer. In this water balance analyses we assume that the difference between the incoming precipitation (both rainfall and snow on the ground at winter's end) and export from the watershed (runoff and ET) represent the change in storage. Or it is assumed that there is no closure error.

Results and Discussion

Table 1 shows the water balance computations for the Putuligayuk catchment for a 9-year period from 1999 to 2007. An examination of the runoff hydrographs for the years gauged (Kane et al. 2000, Bowling et al. 2003) shows a significant runoff response to snowmelt, with very little response to summer precipitation; typical snowmelt and summer hydrographs for 3 years are shown in Figure 2. The hydrograph for 2003 shows a very high peak runoff that corresponds to the maximum SWE measured in the watershed. Also the average of the runoff from snow divided by SWE or the snow runoff ratio (0.78) is much greater than the average rainfall runoff ratio (0.36). This is true for each year also.

Although, the 9-year averages of SWE at winter's end (9.5 cm) and summer rainfall (8.5 cm) are very similar, a majority of the runoff is generated from snowmelt. Of the total precipitation, 60% left the basin as runoff over the 9-year period. This is considerably higher than found in more temperate climates and is partially due to the continuous permafrost in the basin. The global average for runoff has been reported as 36% (Baumgartner & Reichel 1975). However, there was considerable year-to-year variation in annual runoff, from 33% to 79% of annual precipitation. Part of this annual variation can be explained by changes in surface storage, magnitude of SWE and summer rainfall, and the timing of some of these events. If one looks at the data in Table 1, it can be seen that in the summer of 2005, with the second lowest warm season precipitation, the runoff ratio the following year was the second lowest for the 9-year duration. This is due to snowmelt water going back into surface storage after the previous dry summer when ET was equivalent to the summer precipitation. Wet years generally have high runoff ratios and dry years just the opposite; this is due to limited storage. In addition to the amount of precipitation, the timing is important; SWE is more likely to run off while summer precipitation is more likely to result in ET that produces a surface storage deficit. Late summer precipitation when ET is low can also significantly reduce the surface storage deficit that can develop over the summer when ET exceeds precipitation. The likelihood is that the wettest month of the year will be at the end of summer; however in any single year it can be September, July, or even June.

SWE at the end of winter averaged 9.5 cm and varied from a low of 8.2 cm to a high of 11.2 cm. Summer precipitation has averaged 8.5 cm the past 9 years; the range is quite wide as it ranges from 1.5 to 13.7 cm. There were three years when the summer precipitation was very low and produced drought conditions, at least for part of the summer: 6.0 cm in summer 2000, 5.0 cm in summer 2005 and 1.5 cm in summer 2007. The importance of the low summer precipitation is reflected in the amount of water stored in the watershed, both as surface and subsurface stores, and the deflated hydrologic runoff response to snowmelt the next year.

It is not clear why both the snow and rainfall runoff ratios are so low the first summer in 1999. As we were not monitoring the hydrology and meteorology in 1998, we have to rely on limited data from outside the catchment. There is some evidence that 1998 was a dry summer, but that does not explain the low rainfall runoff ratio. One weakness of this study is our inability to quantify the surface storage in the myriad of lakes, ponds, and wetlands that cover this landscape. Bowling et al. (2003) showed that in a 3-year period, 1999 to 2001, 24% to 42% of the snowmelt water went into storage. This water is lost back to atmosphere over the following summer, mainly to ET.

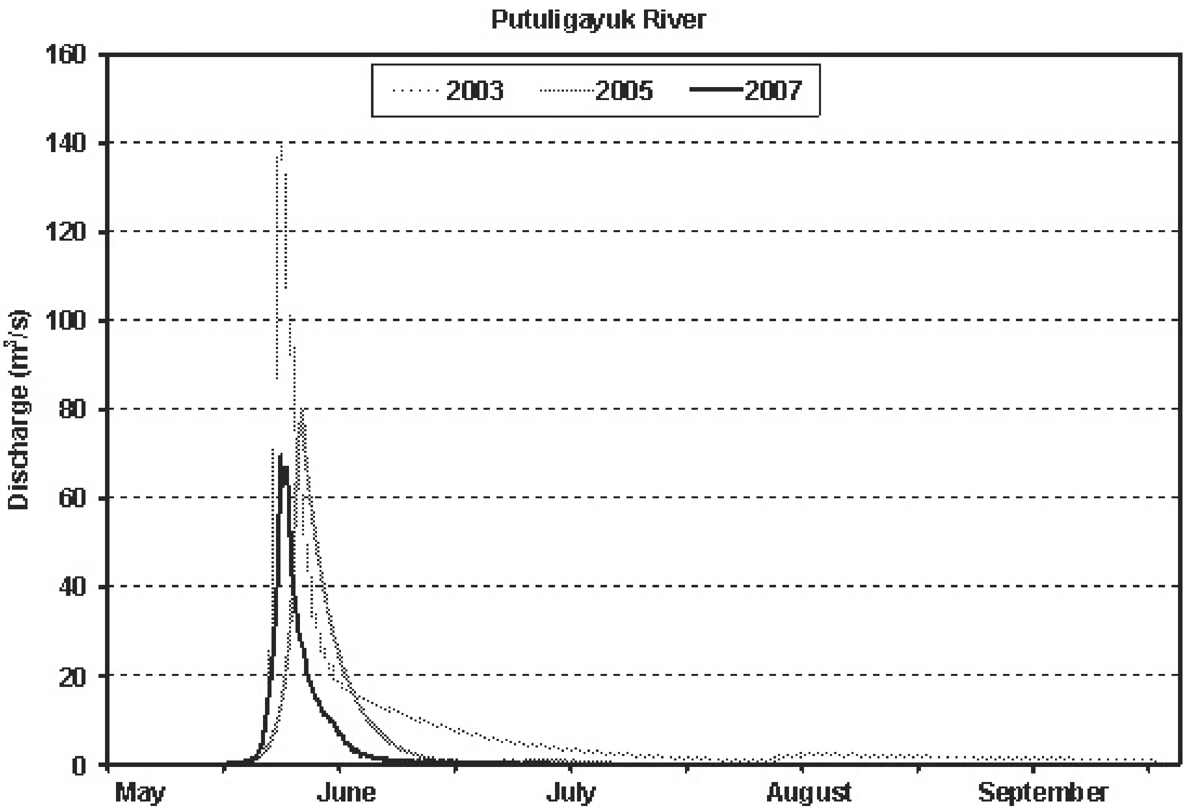

Figure 2. Typical annual hydrographs demonstrating the dominance of snowmelt runoff in the annual hydrologic cycle for the Putuligayuk River catchment.

There have been several water balance determinations for what is referred to as the nested watersheds of the Kuparuk basin (Lily et al. 1998, Kane et al. 2004), although the Putuligayuk catchment is just outside to the east. There are similarities in the water balance of other neighboring watersheds (Imnavait, Upper Kuparuk and Kuparuk) and this watershed; however there are also interesting contrasts. It can be anticipated that snowmelt will be a significant runoff event in these watersheds with average runoff ratios exceeding 0.5 and for individual years near 0.8 (Table 2). One interesting feature of the Putuligayuk catchment is the high average runoff ratio of 0.8 for the snowmelt period. This value is both surprising because this is a low-gradient watershed and it has much more surface storage (lakes, ponds, and wetlands) than the other three watersheds mentioned above.

It is clear that the snowmelt runoff response of the Putuligayuk catchment depends on the timing and amounts of precipitation the previous summer. Typically precipitation increases monthly throughout the summer and any deficits that develop in storage are partially replenished by summer precipitation, particularly at summer's end when ET is minimal. Significant precipitation at the end of summer produces high runoff response the next spring, while summer

Table 2. Summary of runoff ratios for 3 watersheds on the North Slope of Alaska.

Basin	Total Runoff Ratio	Snow Runoff Ratio	Rainfall Runoff Ratio
Putuligayuk River [1] (n = 9 years)	0.60	0.80	0.40
Upper Kuparuk River [2] (n = 7 years	0.62	0.49	0.68
Imnavait Creek [2] (n = 19 years)	0.50	0.66	0.41
Kuparuk River [3] (n = 4 years)	0.58	0.86	0.35

1. This paper 2. Kane et al. (2004) 3. Lilly et al. (1998)

drought conditions will result in a low runoff yield during the following ablation.

The summer runoff response of the Putuligayuk River can only be described as not impressive (Fig. 2). From the end of snowmelt to summer's end, the discharge is generally in recession with only a few very small responses to precipitation. Kane et al. (2003) discussed how permafrost land forms could retard surface runoff, and McNamara et al. (1998) described how the active layer slowly yields water during the summer and results in an extended recession that lasts through freeze-up in the fall. Otherwise the stream would cease flowing during the summer; this is actually a possibility in the summer of 2008 because of the extreme drought conditions of the summer of 2007.

Conclusions

This low-gradient river has a surprisingly high runoff ratio, both annually and during snowmelt. A majority of this runoff leaves the basin during and immediately after snowmelt, but first any surface storage deficit from the previous warm season must be replenished. Summer runoff response is minimal and generally ET exceeds P, which results in drying out of the basin and fragmentation of the drainage network. This is particularly true earlier in the summer when the probability of precipitation is lower than at the end of summer. Drought conditions during a summer result in lower than expected runoff response the following year. Storage is the most significant unknown in this computation; we just do not have adequate tools for getting quantitative estimates of subsurface (active layer) and surface storage. However, it is clear that the amount of surface storage is low in terms of average annual precipitation. Estimates of ET spatially over the watershed could be improved with more data, but the likelihood of this happening is quite low. With the record low summer precipitation in 2007, it is predicted that the snow runoff ratio for 2008 will be quite low unless the SWE is considerably above the 9-year average of 9.5 cm.

Abstract

The CRREL Permafrost Tunnel is a well-known location for studies of Late Pleistocene syngenetic permafrost. Our detailed cryostratigraphic mapping in the winze of the tunnel was based on study of cryogenic structure, ice content of the sediments, and different types of massive ice. The results show that original ice-rich syngenetically frozen silts were partly reworked by thermal erosion, which proceeded mainly along the large ice wedges. Gullies and underground channels, formed at various depths, were filled with ice and sediments, the structure and properties of which differ from the original syngenetic permafrost. In the winze, thin peat layers underlain by distinct ice lenses were observed. These layers mark the former positions of the permafrost table during peat accumulation, which occurred during slower sedimentation periods.

Keywords: Alaska; cryofacial analysis; cryostructure; mapping; syngenetic permafrost; thermal erosion.

Introduction

The well-known CRREL Permafrost Tunnel located near Fairbanks, Alaska, offers exposures of the Late Pleistocene syngenetically frozen silts with large ice wedges. The tunnel, constructed more than 40 years ago, consists of a main horizontal adit, which reaches 110 m in length, and an inclined winze 45 m long.

Ice-rich silts exposed in the tunnel belong to Goldstream Loess Formation of Wisconsinan age and are underlain by the gold-bearing Fox Gravel (Péwé 1975, Long & Péwé, 1996). Silts of eolian origin were partly reworked and retransported by slope and fluvial processes (Péwé 1975, Hamilton et al. 1988).

Similar syngenetic ice-rich permafrost with huge ice wedges was observed in many unglaciated areas of Siberia and Northern America. In Russian literature they are known as "Yedoma" or "Ice Complex" sediments (Katasonov 1978, Popov et al. 1985, Romanovskii 1993). Such permafrost has been studied in the continuous permafrost zone, and its occurrence in central Alaska is a rare phenomenon.

The tunnel, and particularly its adit, has been extensively studied by geologists and recently by permafrost scientists. Sellmann (1967) made general sketches of the exposures and characterized the stratigraphy and main types of ground ice observed in the tunnel. Detailed geological and paleoenvironmental studies of Quaternary sediments in the tunnel were performed by Hamilton et al. (1988).

Shur et al. (2004) identified features related to original syngenetic permafrost and showed the impact of thermo-erosion processes on the structure of the permafrost. Bray et al. (2006) performed mapping of permafrost in the main adit. Both works were focused on identification of differences between original permafrost and later modifications of it. However, in-depth understanding of syngenetic permafrost formation requires more detailed studies of permafrost properties and cryogenic structures. This paper presents detailed cryostratigraphic studies performed in the winze, where the original syngenetic permafrost is preserved better than in the main adit.

The main goals of our study were: (a) to compile a cryostratigraphic map of the winze, (b) to describe cryostructures of the permafrost, (c) to reconstruct events of the permafrost and sedimentary history of the study area, and (d) to estimate the ice content of the sediments.

Methods

The section of the winze 38 m long and from 12 to 18 m below the surface was studied in 2005–2006. The cryostratigraphic mapping used a cryofacial analysis proposed by Katasonov (1978). This analysis is based on the close relationship between cryostructure assemblages and specific terrain units, and reveals the way permafrost was formed. Cryofacial analysis has been especially useful for study of syngenetic permafrost (Katasonov, 1978).

The mapping of one wall and ceiling of the winze was performed in the scale 1:20; several sections were studied

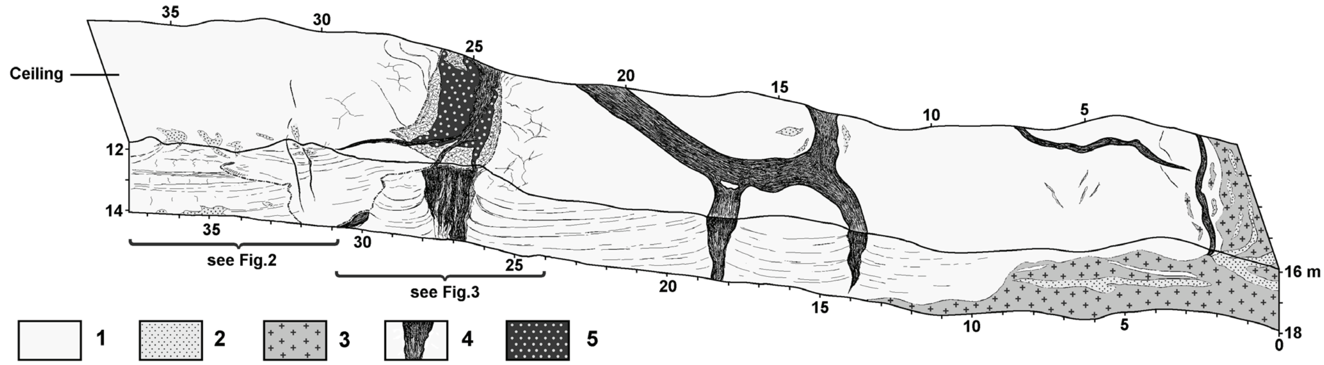

Figure 1. General view of the left wall and the ceiling of the winze. 1–silt; 2–sand; 3–Fox Gravel; 4–ice wedge; 5–thermokarst-cave ice.

greater detail (scale 1:4). Figure 1 shows the general view of the winze; more detailed fragments are shown in Figures 2 to 4. AMS radiocarbon dating (Fig. 2) was performed at the University of Arizona.

Results

The permafrost soils in the winze are mainly silts with sand lenses. The main cryostructure is micro-lenticular (Shur et al. 2004, Bray et al. 2006), which is characterized by occurrence of very small sub-horizontal (sometimes wavy) discontinuous ice lenses. The thickness of uniformly distributed ice lenses (and vertical spacing between them as well) usually does not exceed 0.5 mm.

Several varieties of micro-lenticular cryostructure can be distinguished in the winze (e.g., latent micro-lenticular, micro-braided). Micro-lenticular cryostructure (including all its varieties) is the most typical cryostructure of syngenetic permafrost; usually it occupies not less than 50–60% of the entire thickness of such sections (Kanevskiy 1991, 2003).

In the winze, gravimetric moisture content of the sediments with micro-lenticular cryostructure varies from 100% to 240% (Fig. 4a, Ssection 1). The similar range (80–180%, average 130%) was found in the adit of the tunnel (Bray et al. 2006). Organic content of the sediments varies from 3.3% to 9.5% by weight (Fig. 4a); the greatest values are specific to the organic-rich layers. The radiocarbon dates for these layers vary from 31, 000 to 35,000 y BP (Fig. 2).

Seven thin organic-rich horizons were observed in the upper part of the winze, at a depth of 12–14 m from the ground surface (Fig. 2). At the depth of about 0.4 to 0.6 m below each peat horizon, there are distinct ice (or ice-rich) layers (referred to as *belts* in the Russian literature). Numerous thin cracks partially filled with ice (ice veins) extend downward from the peat layers to a depth of up to 0.5 m. These cracks form polygons up to 0.5 m across.

Numerous sites of former gullies and underground channels were observed at various depths. They had been cut by running water in the silty sediments and afterwards filled with thermokarst-cave ice and soils, the structure and properties of which differ from the original syngenetic permafrost (Shur et al. 2004, Bray et al. 2006, Fortier et al. 2008).

In the winze, the gully filled with sediments was observed at the interval 29–35 m (Figs. 1 to 3). A truncated ice wedge affected by thermal erosion is located under this gully. The sediments filling the gully are mostly ice-poor stratified silts with lenses of sands. They contain numerous inclusions of organic material, which were interpreted as having been reworked by water. The organic content of the sediments in the gully varies from 7.0% to 22.8% and is much higher in comparison with the original permafrost (Fig. 4b).

Cryostructures in the lower part of section 2 (Fig. 4b, 60-165 cm) vary from latent micro-lenticular to porous. The gravimetric moisture content of this part of section 2 varies from 70% to 100% which is smaller than the water content of the original syngenetic permafrost. Such water content is unusual for sediments with very small amount of visible ice. It can be attributed to the higher organic content (Fig. 4b). Sediments with an organic content of 9–12% have a gravimetric moisture content of 70–80%, whereas sediments with organic content of 14–16% have a moisture content of 90–100%.

The cryostructures and ice contents of the upper part of the section 2 (Fig. 4b, 0–60 cm) are similar to those of the original permafrost; the gravimetric moisture contents here vary from 110% to 140%. This indicates change of sedimentation mode and decrease of sedimentation rate at the last stages of gully infilling.

Ice wedges observed in the winze have width of up to 1.8 m; their apexes terminate at the stratigraphic contact between the silts and the underlying alluvial gravels (Fig. 1). The exposure of ice wedges at the ceiling of the winze allows for an estimation of the shape and size of polygons, which reaches 8–12 m.

A horizontal body of thermokarst-cave ice crosscutting the ice wedge is exposed on the ceiling in the upper part of the winze (Fig. 3, section A-B). Its thickness varies from 0.2 to 0.35 m and it is underlain by a silt layer (0.1–0.4 m thick) with a reticulate-chaotic cryostructure (Shur et al. 2004, Fortier et al. 2008). This ice body is aligned with the ice wedge; however, it is wider than the wedge and therefore incised in the permafrost surrounding the ice wedge. The thermokarst-cave ice body is crossed by numerous sub-vertical ice veins, forming a small secondary ice wedge (Fig. 3, section A-B). Similar structures were observed in the adit (Shur et al. 2004, Bray et al. 2006).

Discussion

The study shows the prevalence of ice-rich syngenetically frozen silts with some areas partly reworked by thermal erosion, which proceeded mainly along large ice wedges. The evidences of syngenetic freezing, including undecomposed tiny rootlets and the prevalence of a micro-lenticular cryostructure, were observed directly above the contact between silts and poorly sorted alluvial gravels. The occurrence of micro-lenticular cryostructure varieties is typical for syngenetic permafrost, and is mostly linked to different rates of sedimentation (Kanevskiy 1991, 2003). The great variability of gravimetric moisture content of silts can be associated with the different cryostructures.

We associate the ice layers (belts), located beneath organic-rich horizons (Fig. 2), with the bottom of the active layer at the periods of temporary stabilization of the ground surface which occurred during periods of slower sedimentation favorable to peat accumulation. Approximate positions of the active layer at this time are denoted with arrows in Figure 2. During periods of very slow sedimentation, small polygons were formed due to shallow cracking at the stabilized surface.

There are several lines of evidence to suggest thermal erosion processes were going simultaneously with syngenetic permafrost formation. First, the occurrence of ice veins in the thermokarst-cave ice body suggests that the ice wedge continued to grow after its partial destruction by thermo-erosion and the subsequent formation of the thermokarst-cave ice. Second, the cryogenic structure of the upper part of the "gully" section (Fig. 4b) is identical to the cryogenic structure of the original permafrost.

Conclusions

Mapping in the winze of the CRREL permafrost tunnel shows the prevalence of ice-rich syngenetically frozen silts with micro-lenticular cryostructure. Periods of slow sedimentation were marked by peaty horizons and distinct ice layers, located at a depth of about 0.4 to 0.6 m below every peat horizon. These ice layers show the former positions of the permafrost table during the peat accumulation. Small ice veins extend downward from peaty horizons, forming polygons up to 0.5 m across.

The original syngenetic permafrost was partly reworked by thermal erosion, which proceeded mainly along ice wedges. No clear evidence of thermokarst was observed. Thaw unconformities are connected with the development of gullies and underground channels. These cavities were filled with water and soils, which froze back in situ, and which differ in structure and properties from the original syngenetic permafrost. Thermal erosion processes were going simultaneously with accumulation of syngenetically frozen silts and ice wedge development.

Acknowledgments

We thank the Cold Regions Research and Engineering Laboratory (CRREL) and its Fairbanks office for the opportunity to perform our studies in the tunnel. We are grateful to Margaret Cysewski, Eva Stephani, and Matthew Dillon for their field and laboratory assistance. Abstract

It has been known that a chilled gas pipeline buried in frost susceptible soil can be subjected to frost heave deformation. Frost heave itself has been studied by various researchers, but experimental observations of the mechanical interaction between the gas pipeline and the surrounding frost bulb has been rarely reported. The purpose of this study is to experimentally observe the interactive behavior between a chilled pipe and frost bulb under simplified conditions. The authors carried out an axis-symmetric freezing experiment which promotes formation of a concentric frost bulb. It is obviously difficult to measure the interactive stress, as well as the stress distribution, in the specimen. Therefore, the authors adopted complementary calculations for stress evaluation. Though the specimen is assumed elastic and homogeneous in the calculation, changes in the interactive stress between frost bulb and the pipe are estimated during frost bulb formation based on the observation results and analysis.

Keywords: experiment; frost bulb; mechanical modeling; pipeline; stress.

Introduction

A chilled gas pipeline installed underground may be subjected to frost heave, since a frost bulb forms around the pipe in frost-susceptible soil. This phenomenon has been studied by numerous researchers. Even in recent studies, Razaqpur and Wang (1996) proposed their practical models for frost heave estimation considering water migration based on the Clausius-Clapeyron equation; for example. Mikkola (2001) demonstrates the applicability of a mathematical model in which a physicochemical structure of the soil is described by using remeshing techniques for the Galaerkin method. As an engineering approach, various evaluation methods applying the segregation potential theory have been developed by Nixon (1982, 1987a-b), Konrad (1987), Shen & Ladanyi (1991), and Selvadurai & Shinde (1993). The authors also have been studying engineering estimation based on Takashi's equation, as a practical evaluation method with a beam on an elastic foundation model. Though frost heave behavior of the pipe with growth of a frost bulb has been researched, interactive stress acting between the frost bulb and chilled pipe has been rarely measured directly.

The purpose of this study is to experimentally observe the interactive behavior under a simplified condition and to consider an engineering evaluation method for interactive stress estimation. The axis-symmetric experiment proposed in this paper aims to promote concentric formation of the frost bulb and to measure stresses acting on the pipe with the growth of the frost bulb. Since it has been known that volumetric change in the frost bulb shows anisotropic properties and is affected by the constraining stress acting in the growing direction of ice lens, the pipe and the surrounding specimen were set vertically to exclude the effect of the force of gravity. As a result, the formation of a concentric frost bulb could be expected in the horizontal plane. Considering the difficulty in measuring the interactive stress at the boundary between the frost bulb and the pipe, the authors adopted a mechanical model for reasoning the interactive stress with known boundary conditions at the inner surface of the pipe and at the periphery of the specimen.

This mechanical model was also applied to examine the anisotropic properties in frost heave ratio during freezing. The calculated stresses on the inner surface of the pipe were compared with the observed stresses and the anisotropic properties of frost heave are discussed.

Axis-Symmetric Freezing Experiment

In multi-dimensional freezing of frost-susceptible soil, frost heave ratio is depending on the direction of freezing and the constraining stress. If the pipe is set horizontally and frost bulb forms in vertical plane, concentric formation of frost bulb cannot be expected, because the constraining stresses vary with the location in the vertical plane due to gravity force. In order to consider the interactive behavior between pipe and frost bulb, simplified condition without the effect of gravity force is preferable for both empirical and analytical evaluations. Therefore, the pipe and the cylindrical specimen surrounding the pipe were set vertically to promote concentric frost bulb formation in the horizontal plane to realize a quasi-one-dimensional behavior.

Table 1. Experimental conditions for consolidation.

Material	Kaolin	
Specific gravity of particle	2.64	g/cm^3
Water content Before consolidation	70	%
Water content After consolidation	50	%
Amplitude of load	80	kPa
Time for consolidation	170	hrs

Consolidation phase

First, frost susceptible material, kaolin, is filled in the mold and vertical load is applied from the top of specimen. Water contained in the specimen is drained from the top and the bottom through porous stones. The temperature of the laboratory is kept at +1°C during consolidation, and the temperature of the specimen is expected to be the same at anywhere in the specimen at the beginning of the freezing phase. The experimental conditions are tabulated in Table 1.

Freezing phase

After the consolidation, the outer mold is removed. The specimen keeps its position with constraint by a rubber membrane covering the outer surface of the specimen. Then, cold antifreeze starts to run through the pipe to promote the formation of the frost bulb. In the freezing phase, the top plate of the specimen is replaced with a thick acrylic plate to prevent vertical growth of a frost heave and to observe the formation of a horizontal frost bulb. The temperature of cold antifreeze is controlled to gradually decrease to keep the freezing rate in radial direction of 1 mm/hr based on the heat transfer analysis in advance. The final temperature of cold antifreeze was set at -10°C. Photo 1 shows the experimental apparatus during the consolidation phase and the freezing phase.

Measurement and observation

On the inner surface of the pipe, four sets of strain gauges for circumferential and vertical directions were set at the middle height of the specimen. The temperature distribution within the specimen was measured by four thermo-meters to confirm the growth of the frost bulb.

The change in peripheral length of the specimen was recorded by a wire gauge and was used for estimating the constraining stress at the outer boundary based on the spring coefficient of rubber membrane. In addition, frost bulb formation can be observed through the acrylic top plate.

If one wants to directly observe the interactive stress between the outer surface of the pipe and the inner surface of the specimen, installing a pressure gauge at the boundary may be a solution. However, the contact condition for adfreeze strength is affected by the gauge. In this paper, the authors adopt a mechanical model for reasoning interactive stresses using known boundary conditions at the inner surface of the pipe and the periphery of the specimen. This mechanical model will be introduced in the following section.

Experimental result

Pictures of the specimen during the freezing phase and after the experiment are shown in Photo 2. The size of the

(a) Consolidation phase

(b) After the freezing

Photo 2. Observed frost bulb: Picture (a) was taken during the freezing phase. Picture (b) is a photo after the freezing.

frost bulb was almost the same as that anticipated by thermal analysis, and the final outside diameter of the frost bulb became about 150 mm.

The stress in circumferential direction on the inner surface of the pipe varies with the growth of the frost bulb. Figure 1 illustrates the change in circumferential stress with time, and it can be found that tensile stress is gradually increasing. The interactive stress between the pipe and the frost bulb will be discussed with the evaluation model introduced in the following section.

The pipe was set at the center before removing, and the front upper part of the specimen was cut out to confirm ice lens formation within the specimen. It is found that a concentric frost bulb was successfully formed.

Mechanical Model and Analysis

The cylindrical specimen including the pipe is completely axis-symmetric so that a quasi-one-dimensional model with polar coordinates on a horizontal plane was applied. Because the material is assumed homogeneous and isotropic, nonlinear large deformations such as tensile cracks cannot be evaluated. However, anisotropic property in frost heave ratio is considered by giving appropriate radial and circumferential strains for corresponding volumetric change.

Formulation for stress evaluation

It can be assumed that the displacement in circumferential direction is zero and no body force is acting. Then, the equilibrium equation is expressed by equation (1).

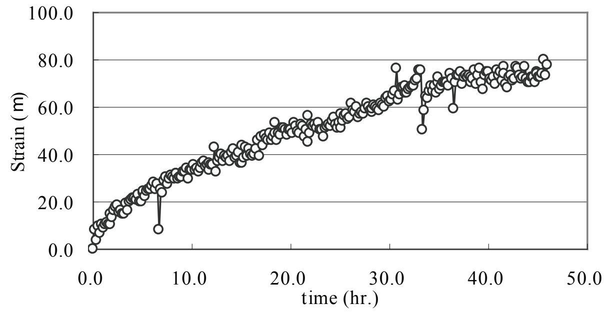

Figure 1. Change in circumferential stress on the inner surface of the pipe with the growth of the frost bulb.

$$\frac{d\sigma_r}{dr}+\frac{1}{r}\left(\sigma_r-\sigma_\theta\right)=0 \tag{1}$$

where r stands for the radial coordinate, and σ_r, σ_θ are stresses in radial and circumferential directions. The stress strain relation is given as follows.

$$\begin{Bmatrix}\varepsilon_r\\ \varepsilon_\theta\end{Bmatrix}=\frac{1+\nu}{E}\begin{bmatrix}(1-\nu) & -\nu\\ -\nu & (1-\nu)\end{bmatrix}\begin{Bmatrix}\sigma_r\\ \sigma_\theta\end{Bmatrix}+\begin{Bmatrix}\varepsilon_{rt}\\ \varepsilon_{t\theta}\end{Bmatrix} \tag{2}$$

ε_r, ε_θ are strains in radial and circumferential directions. E and ν are elastic modulus and Poisson's ratio, respectively. The strains are defined with displacements as equation (3).

$$\varepsilon_r=\frac{du}{dr},\ \varepsilon_\theta=\frac{u}{r} \tag{3}$$

Introducing equations (2) and (3) into (1), we can get the following equation (4).

$$\frac{d}{dr}\left[\frac{1}{r}\frac{d(ru)}{dr}\right]=0 \tag{4}$$

If equation (4) is integrated twice, the displacement u is described as a function of r with two constants.

$$u=\frac{1}{2}C_1 r+C_2\frac{1}{r} \tag{5}$$

Introducing a discrete model in the radial direction, the two constants can be related with the displacements at two nodes next to each other. The radial coordinates for those nodes are assumed as a and b respectively. The strains at r between two nodes are given by the following equation.

$$\begin{Bmatrix}\varepsilon_r\\ \varepsilon_\theta\end{Bmatrix}=\frac{1}{a^2-b^2}\begin{bmatrix}1/2 & -1/r^2\\ 1/2 & 1/r^2\end{bmatrix}\begin{bmatrix}2a & -2b\\ -ab^2 & a^2b\end{bmatrix}\begin{Bmatrix}u_a\\ u_b\end{Bmatrix} \tag{6}$$

In order to take the anisotropic property in frost heave ratio into consideration, parameter β, the ratio of inflation strain in θ direction to that in r direction, is introduced.

$$\beta=\varepsilon_{t\theta}/\varepsilon_{tr},\ \varepsilon_v=\varepsilon_{tr}+\varepsilon_{t\theta} \tag{7}$$

ε_v is the volumetric strain. Finally, we can get the following equation (8) for the discrete model.

$$\begin{Bmatrix}\sigma_r(a)\\ -\sigma_r(b)\end{Bmatrix}=[K]\begin{Bmatrix}u_a\\ u_b\end{Bmatrix}-\frac{\alpha}{1+\beta}\begin{Bmatrix}1-\nu(1-\beta)\\ -1+\nu(1-\beta)\end{Bmatrix}\varepsilon_v \tag{8}$$

Where

$$[K]=\alpha\frac{1}{a^2-b^2}\begin{bmatrix}a+(1-2\nu)b^2/a & -2(1-\nu)b\\ -2(1-\nu)a & b+(1-2\nu)a^2/b\end{bmatrix}$$

$$\alpha=\frac{E}{(1+\nu)(1-2\nu)}$$

Two boundary conditions are necessary for solving the discrete model. At the inner surface of the pipe, no radial stress is assumed because the pressure due to antifreeze is negligible. As another boundary condition, the constraining stress due to the membrane is adopted at the periphery of the specimen

Volumetric strain

If no water migration is considered, and contained water in the specimen is completely frozen, the volumetric strain is easily determined based on the water content and inflation ratio of ice. In this study, we applied Takashi's equation for estimating the volumetric strain. Takashi's equation was originally derived from numerous one-dimensional experiments to relate the frost heave ratio with the constraining stress and freezing rate as equation (9).

$$\xi=\xi_0+\frac{\sigma_0}{\sigma}\left(1+\sqrt{\frac{U_0}{U}}\right) \tag{9}$$

ξ : frost heave ratio, σ : constraining stress, U : freezing rate and ξ_0, σ_0 and U_0 are constants for the material obtained by experiment regulated by Japan Geomechanical Standard.

Though the frost heave ratio in Takashi's equation stands for volumetric change in one-dimensional frost heave, it is also introduced as volumetric strain ε_v in this study with the anisotropic parameter β. The constraining stress σ varies with the growth of the frost bulb. Then, it was calculated by the mechanical model with the growth and was applied into Takashi's equation to decide the volumetric change. The calculation conditions are tabulated in Table 2.

Evaluation of Results

Circumferential stress of pipe

The observed circumferential stress acting on the inner surface of the pipe has already been introduced in Figure 1. The estimated stresses by the mechanical model are added to the observation results as shown in Figure 2. In this figure, estimations with several variations in β based on Takashi's equation (case 1 to case 3) are illustrated, as well as the estimation results (case 0) in which in-situ freezing without water migration is assumed with isotropic inflation due to freezing. As shown in the figure, the estimation by Takashi's equation with β=0.0 shows good coincidence with the observation.

Table 2. Calculation conditions.

Radius	pipe		20 mm - 25 mm
	specimen		25 mm - 100 mm
Elastic Modulus	pipe		210 GPa
	specimen	unfrozen	150 MPa
		frozen	300 MPa
Poisson's ratio	pipe		0.3
	specimen	unfrozen	0.2
		Frozen	0.2
Number of element			76

Though the setting of appropriate β requires further study, it is understood that the estimation based on Takashi's equation may give satisfactory estimation for stress interaction.

Interactive stress between the frost bulb and the pipe

Figure 3 shows the estimation results for interactive stress in the radial direction between the frost bulb and the pipe based on Takashi's equation with β=0.0. It can be found that the radial interactive stress is tensile and is increasing with time. However, the amplitude of tensile stress is about 20% of the circumferential stress in the pipe. It may be that the frost bulb prevents stress transfer in the radial direction with its inflation. In this analysis, perfect continuity condition at the boundary for the interaction has been assumed, so that further discussion including adfreeze strength at the boundary may be necessary.

Figure 4 shows the stress distribution within the specimen estimated by the mechanical model. It is found that tensile stress in a radial direction is acting near the pipe, and its value reaches the maximum compression at the freezing front. On the other hand, circumferential stress is compressive in the frost bulb, and it becomes tensile in unfrozen soil.

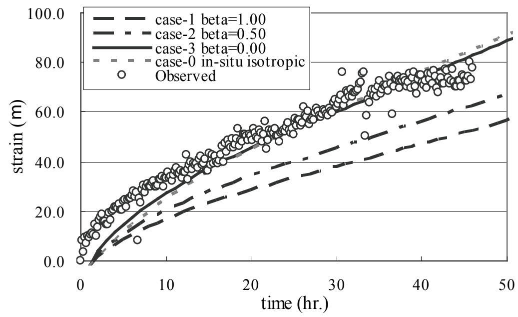

Figure 2. Estimated circumferential stress.

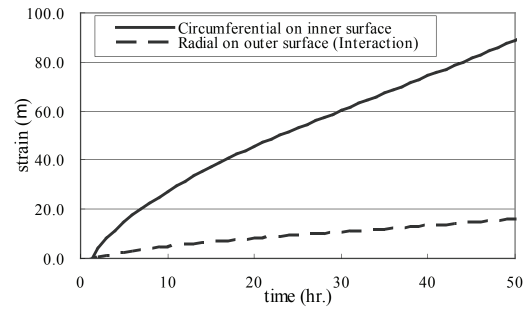

Figure 3. Estimated interactive radial stress.

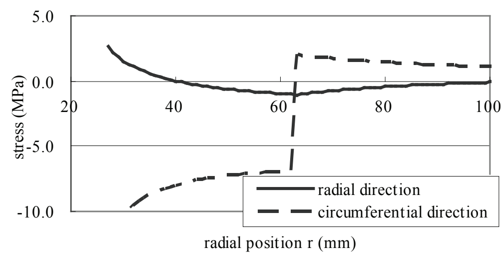

Figure 4. Stress distribution in the specimen (36 h after freezing).

Conclusion

Important findings obtained through this study are summarized as follows:

The newly-developed axis-symmetric freezing apparatus contributes to concentric formation of a frost bulb, and the interactive stress between frost bulb and pipe is successfully examined.

Evaluation of stress acting on the pipe shows good coincidence with the observation result by introducing Takashi's equation to the estimation of frost heave ratio.

In this study, introducing anisotropic property to frost heave yields better estimation in stress evaluation.

The interactive stress between frost bulb and pipe is tensile stress in the radial direction and is increasing with the growth of the frost bulb.

In this experiment, the specimen was covered with a rubber membrane, and the constraining stress due to the membrane was comparatively small due to its low spring coefficient. For further study, experiments under higher constraint pressure are preferable to scrutinize the interactive action.

Abstract

The mean annual ground temperature (MAGT) at two sites in the Mackenzie Delta, south of treeline, has increased by 0.3°C and 0.7°C over the past 40 years. This ground warming is less than reported from the adjacent tundra uplands. The hypothesis that MAGTs in the boreal forest region of the delta may have a reduced response to climate warming due to the thermal influence of numerous water bodies has been investigated with an equilibrium geothermal model. The model indicates that water bodies have a warming influence on MAGTs up to 750 m from the lake or channel. If lake-bottom temperatures do not respond to climate warming, or warm more slowly than ground surface temperatures, then MAGTs at sites close to water bodies will warm more slowly than sites located greater than 750 m away. This may partly explain the apparent dampening of ground thermal responses to climate change in the delta.

Keywords: climate warming; ground temperature; Mackenzie Delta; modeling; thermal regime; water bodies.

Introduction

This paper examines the sensitivity of permafrost to climate change in an area where different surfaces may vary in their response to warming. The southern and central Mackenzie Delta is forested, and approximately 40% of the area is occupied by water bodies (Mackay 1963, Emmerton et al. 2007) (Figs. 1, 2). The delta region is experiencing relatively rapid climate warming, and the annual mean air temperature has increased from about -10°C to -7°C between 1960 and 2005 (Fig. 3) (Environment Canada 2007). Ground temperatures at 24 to 29 m depth at three shrub tundra sites northeast of the delta have responded to this warming, increasing by 0.2°C, 0.4°C, and 0.8°C between 1990 and 2002 (Smith et al. 2005). We hypothesize that mean annual ground temperatures (MAGT) in the delta may differ in their response to climate warming from those in the tundra uplands due to the physical characteristics of the forest cover, and the thermal influence of the more numerous water bodies. Annual mean lake-bottom temperatures may be more stable over time than similar land-surface temperatures because the climatic warming is dominantly in winter, when lakes are ice covered and lake-bottom temperatures remain close to 0°C and are insensitive to fluctuations in air temperature (Maxwell 1997, Burn 2002).

In this paper we report recent ground temperature change in the boreal forest regions of the Mackenzie Delta. Ground temperatures measured in 2006 at two forested sites near Inuvik and Reindeer Station (Fig. 1) are compared with data collected in 1961 and 1969. Previous studies have acknowledged that ground temperatures are higher in the delta than in the adjacent tundra uplands due to the thermal influence of water bodies, and have attempted to remove this influence by situating ground temperature measurement sites away from water (Mackay 1974). In this study, an equilibrium model was used to determine the distance from water bodies at which the thermal disturbance is negligible, and a spatial analysis was conducted to quantify the area

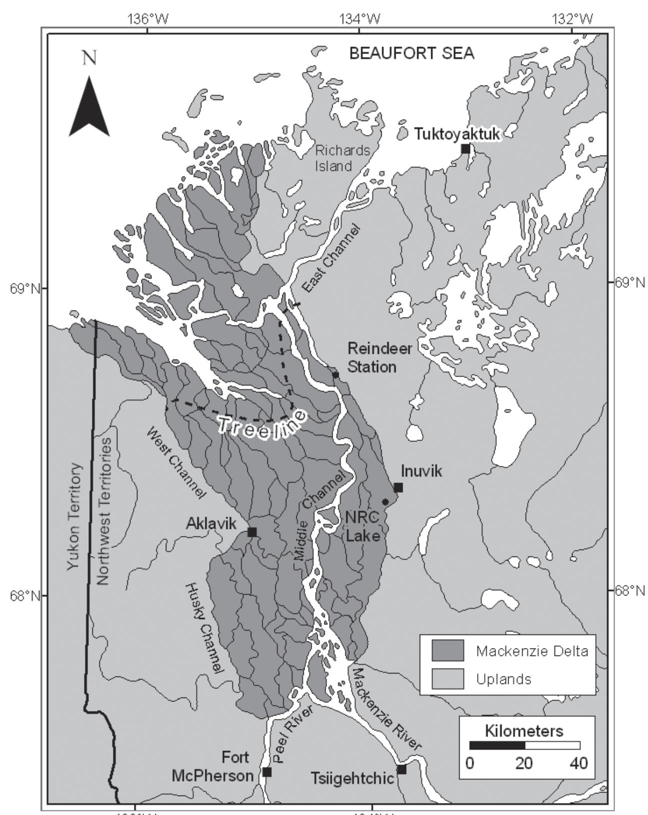

Figure 1. Mackenzie Delta region. Dark grey shading bounds the delta, and treeline is delimited by the dotted line (Mackay 1963).

Figure 2. Mackenzie Delta south of treeline. Land surfaces dominated by spruce forest are separated by channels and lakes.

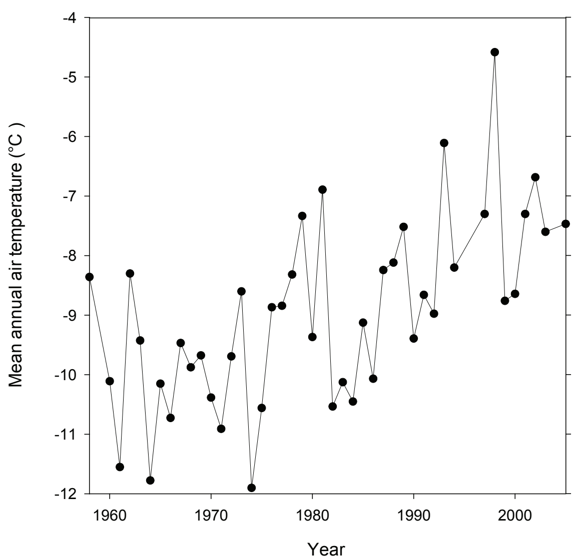

Figure 3. Mean annual air temperatures at Inuvik, 1958 to 2005. Data from Environment Canada (2007).

of the delta which is unaffected by the warming of water. We discuss whether ground temperatures in the delta will respond less to climate warming than in upland terrain, where there is a lower density of lakes.

The Mackenzie Delta Region

A variety of permafrost and terrain conditions exist in the Mackenzie Delta region, with a principal distinction between the alluvial delta and the shrub-tundra uplands to the east (Fig. 1). The delta is flooded annually by waters from the Mackenzie and Peel Rivers. Infiltration of flood water contributes to higher MAGT in the delta (-2°C to -4°C) than in the tundra uplands northeast of the delta (-6°C to -9°C) (Mackay 1974). The deposition of nutrients during the flood contributes to a northern extension of treeline, which forms the boundary between the central and northern delta (Fig. 1) (Mackay 1963).

The ground is warmer in the delta than in the surrounding uplands principally due to the high density of lakes and channels (Smith 1975). The late winter ice thickness on lakes in the central delta is less than 1 m, and most lakes do not freeze through (Mackay 1963, Marsh & Lesack 1996). As a result, an unfrozen talik forms in the sediments underneath most lakes of the Mackenzie Delta. The ground temperature beside lakes and channels is affected by heat flowing from the warmer sediments under the water body to the surrounding permafrost (Williams & Smith 1989).

South of treeline, white spruce (*Picea glauca*) communities occupy the majority of the land surface above the level of annual flooding. These communities are associated with colder permafrost than lower elevation sites because of surface conditions related to reduced flooding, including a thicker organic layer and a thinner snow cover due to canopy interception (Mackay 1974, Smith 1975, Pearce et al. 1988). The uppermost 1 to 2 m of permafrost in most spruce-forest communities are characterized by high ground-ice content, and, in places, syngenetic ice wedges (Kokelj & Burn 2005). Land surfaces of the central and southern delta located well away from water bodies have been used to measure ground temperatures that are relatively undisturbed by warming related to the presence of water (Mackay 1974).

Methods

Field methods

Ground temperatures were measured at two spruce-forest sites in the east central delta for comparison with data collected in 1961 and 1969 (Fig. 1) (Johnston & Brown 1964, Smith 1973). The site near Reindeer Station is located 101 m from the nearest lake, and 110 m from a channel, and the site at NRC Lake is located 77 m from the nearest lake and 72 m from a channel. These sites are representative of forested surfaces in the delta. Both sites were re-instrumented in 2004 by drilling a hole with a water-jet within 50 m of the original location and installing thermistors at comparable depths. Steel pipe was used to case the hole, which was filled with low conductivity silicone oil, and seven calibrated thermistors were installed at 0.5, 1.0, 3.0, 5.0, 7.0, 9.0, 11.0, 13.0, and 15.0 m depths. Steel pipe was used because it is sufficiently robust to withstand environmental stresses in the field. Temperatures at 15 m depth were of interest since this is near the depth of zero annual amplitude (Mackay 1974). It is assumed that the conductivity of the black iron pipe has a minimal influence at 15 m. The temperature at this depth corresponds with the MAGT and responds to long-term changes in air temperature or surface conditions, rather than seasonal fluctuations. Temperature measurements were made in 2006 to ensure that thermal equilibrium had re-established after drilling.

Analytical methods

The warming effect of water bodies on ground temperatures was modeled using equations developed by Lachenbruch (1957) and modified by Burn (2002). In the absence of water bodies, the undisturbed ground temperature profile is:

$$T_z = T_g + z/I \quad (1)$$

where T_z is the temperature (°C) at depth z (m), T_g is the mean annual ground surface temperature (°C), and I is the geothermal gradient (m°C^{-1}).

In the delta, the configuration of land and water can be modeled as a strip of a specified width of land that is bounded by a wide channel on one side, and a large lake on the other (Fig. 4). This is a conservative approach, as it assumes that the permafrost is a disturbance to ambient conditions governed by water bodies, not vice-versa. Many diagrams of the distribution of permafrost in the delta are consistent with this position (e.g. Smith & Hwang 1973, Fig. 4; Smith 1976, Fig. 14). This is a simplified representation of field conditions as modeled by Brown et al. (1964), who required a specific configuration for water bodies surrounding the site. In this paper, we are interested in a more general case. Under steady-state conditions, the ground temperature profile at a point on this strip of land is:

$$T_z = T_w + z/I + [(T_g - T_w)/\pi]\,[\tan^{-1}(H_{p1}/z) + \tan^{-1}(H_{p2}/z)] \qquad (2)$$

(modified from Burn 2002, eq. 4) where T_w is the mean annual water temperature (°C), H_{p1} is the width (m) of the strip of land from the lake to the point of measurement, and H_{p2} is the width (m) of the strip of land from the point of measurement to the channel. Current conditions are described by T_g = -3°C, T_w = 6°C, and I = 45 m°C^{-1} (Burn 2002). Ground temperatures were measured at 50 cm below the ground surface at the two delta spruce forest sites at Reindeer Station and NRC Lake between January 2005 and December 2006 to obtain T_g. The T_w was estimated from the mean annual lake-bottom temperature at NRC Lake, a small lake near Inuvik, measured from August 2005 to August 2007. NRC Lake is representative of the size and depth of most lakes in the delta (Johnston & Brown 1964, Marsh et al. 1999, Emmerton et al. 2007), and is representative of the flooding frequency of approximately 33% of lakes in the central delta, which is about once in five years (Marsh & Hey 1989). Smith (1976) reports less than 1°C difference between the T_w for a delta lake-bottom and T_w in channels.

A GIS analysis of topographic maps of the central and southern delta was conducted to determine the extent of terrestrial surfaces influenced by water bodies using ArcMap™ version 9.2. (Environmental Systems Research Institute 2007). National Topographic Database 1:50,000 scale vector data were used (Canada Center for Topographic Information, http://maps.nrcan.gc.ca), applying delta boundaries and treeline defined by Mackay (1963) (Fig. 1). Most aerial photographs used to generate the maps were taken during the early 1950s. Buffers were placed around channels and lakes in order to calculate the percentages of land in the delta located greater than 0, 50, 75, 100, 150, 300, 500, and 750 m away from a water body.

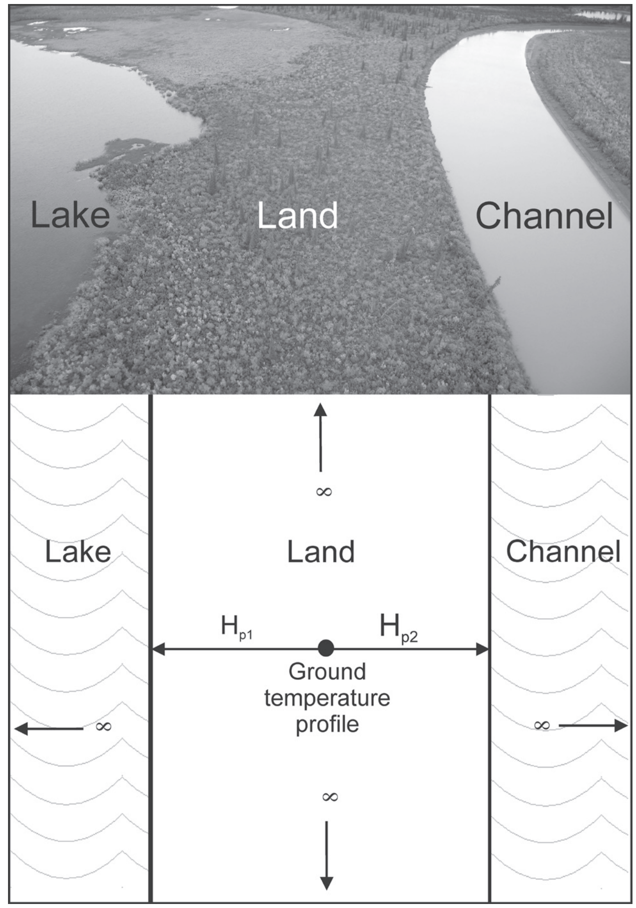

Figure 4. Configuration of ground and water bodies for simplified calculation of thermal disturbance from water in the delta environment.

Results

Field results

To characterize the current thermal regime, maximum and minimum ground temperatures recorded between January 2005 and December 2006 are presented in Figures 5 and 6. The 15 m ground temperature at the NRC Lake site increased from -3.5°C in May 1961 to -2.8°C in April 2006, a total increase of 0.7°C, or about 0.2°C per decade. At the site near Reindeer Station, ground temperature at 15 m depth increased by about 0.1°C per decade, from -2.3°C in September 1969 to -2.0°C in September 2006, a total increase of 0.3°C. Surface conditions at the time of the historical measurements were similar to those at present (Johnston & Brown 1964, Smith 1973); so it is likely that climate warming has contributed to the higher present day ground temperatures. Based on these two sites, it appears that ground temperatures in the delta have increased at a slower rate than on the adjacent shrub tundra (Smith et al. 2005). Data from the shrub tundra were obtained from below the depth of zero annual amplitude (24 and 29 m), and it is likely that even greater increases would have been recorded at the depth of zero annual amplitude.

Analytical results

Comparison of 15 m depth ground temperatures for various horizontal distances from water bodies with the undisturbed ground temperature are presented in Figure 7. The results indicate that in close proximity to water bodies (H_{p1}=H_{p2} = 0 to 200 m) the warming influence of the water decreases greatly as the horizontal distance from

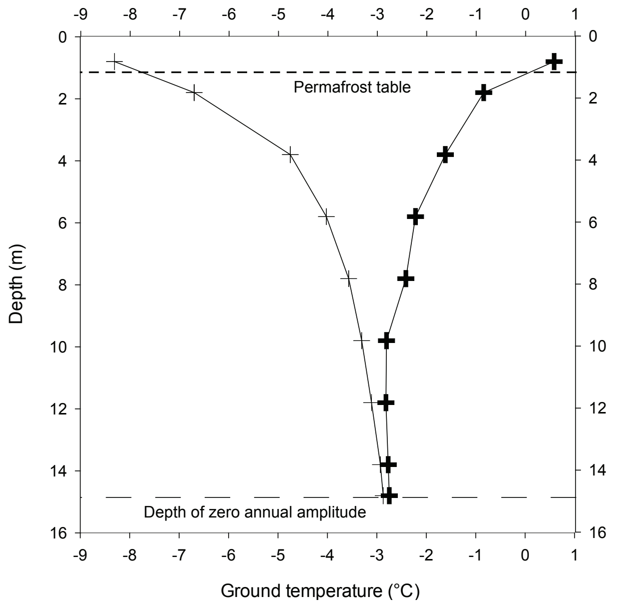

Figure 5. Ground temperature envelope from NRC Lake site, January 2005 to December 2006.

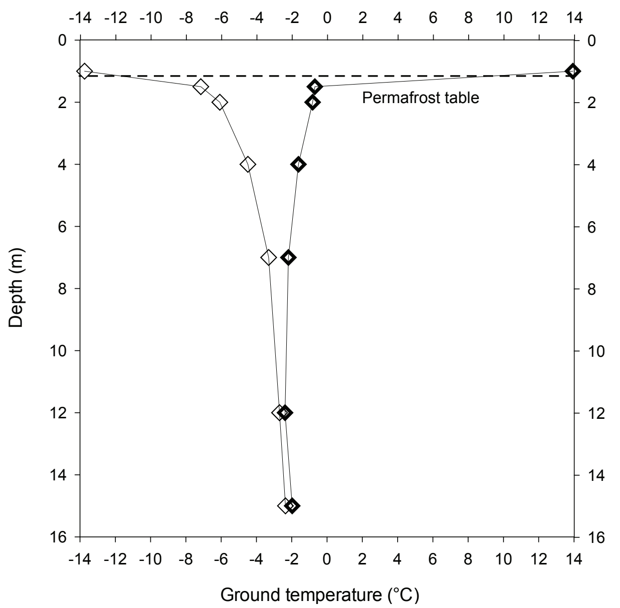

Figure 6. Ground temperature envelope from Reindeer Station site, January 2005 to December 2006.

water bodies increases. With further increases in horizontal distance (H_{p1}=H_{p2} = 200 to 1000 m), the ground temperature decrease is much reduced. If the distance from one water body remains small (H_{p1} = 50 m), as the distance from the second water body (H_{p2}) is increased, then the 15 m depth ground temperature remains above the undisturbed ground temperature despite further increases in H_{p2}, due to the close proximity of the first water body. The undisturbed ground temperature is approached where there is a large distance from both water bodies (H_{p1}=H_{p2} = 750 m).

Figure 7 shows that the difference between the disturbed and undisturbed ground temperature at 15 m depth is 0.1°C, 750 m from a water body. This difference approximates the precision of a thermistor, so at this distance the warming

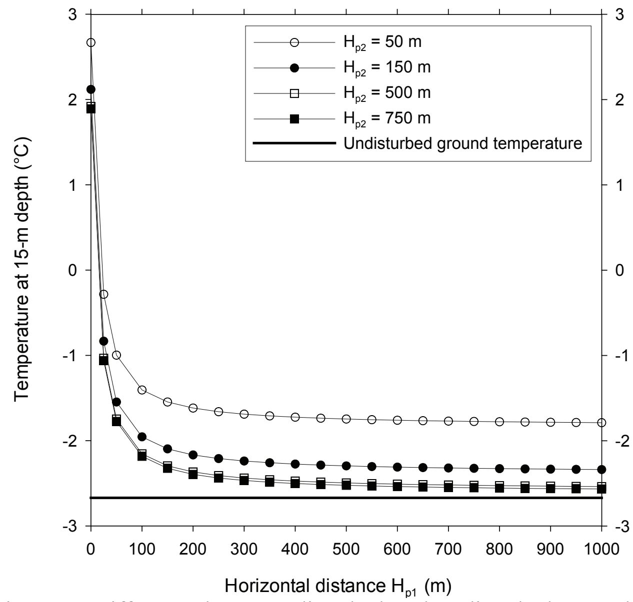

Figure 7. Difference between disturbed and undisturbed ground temperature as distances from channel and lake increase.

effect of water bodies is not detectable. The thermal influence of water bodies is detectable up to distances of about 750 m.

Spatial analysis of the central and southern delta indicated a total area of approximately 7900 km², of which about 58% is land. Only about 2% of land surfaces in the central and southern delta are located more than 750 m away from a water body (Fig. 8). This suggests that in the delta south of treeline, almost all ground temperatures at 15 m depth are affected to some extent by the thermal disturbance of water. The thermal effect is significant for most land areas, since a large proportion (81%) of terrestrial surfaces in the delta are located less than 150 m from a water body. The calculated 15 m depth ground temperature at a site located 150 m from a water body, given current T_g and T_w, is 0.6°C higher than the undisturbed ground temperature.

To test the hypothesis that ground where the temperature is affected by water bodies will warm less than unaffected ground, the equilibrium model was used to simulate the response of ground temperatures at 15 m depth to changes in T_g and T_w. Sites 50 and 150 m away from water bodies were used to simulate disturbed ground, and sites 750 m from water bodies to simulate undisturbed ground (Table 1). Data in Table 1 indicate that if the T_g and T_w are increased by the same amount, there is an equivalent increase in the temperature at 15 m depth, regardless of the horizontal distance from water bodies. So if ground and water temperatures respond to climate warming at the same rate, then MAGTs will respond uniformly throughout the delta.

The remaining scenarios simulate different responses of ground and water to climate warming. If T_g increases but T_w remains constant, the full increase in T_g is propagated to 15 m at sites located 750 m away from water bodies. However, the unchanged T_w is important at sites located 150 m or less from water bodies. The second scenario in Table 1 describes an increase of 1°C in T_g, and no change in T_w. At a site located 150 m from a water body, the temperature at 15 m depth is 0.1°C less than the corresponding temperature when T_g and T_w are both increased by 1°C. There is a reduction in the warming at 15 m depth, but at 150 m, this effect is comparable to the precision of measurement. A greater difference is produced when the T_g is increased by scenario, at 150 m from water, the 15 m ground temperature 3°C while the T_w remains unchanged (#4, Table 1). In this scenario at 150 m from water, the 15 m ground temperature is 0.2°C less than if T_g and T_w are both increased by 3°C. This is a physically significant effect since approximately 81% of land in the southern delta is located less than 150 m from a water body (Fig. 8).

The impact of no change in water temperatures is amplified at a distance of 50 m from a water body. At this distance, an unchanged T_w, coupled with a T_g increase of 1°C (#2, Table 1) leads to a 15 m ground temperature 0.2°C less than if the T_w also increased by 1°C. Similarly (#4, Table 1), under a T_g increase of 3°C, the 15 m ground temperature is 0.6°C less than if the T_w had also increased by 3°C. It appears that the response of water bodies to climate warming is physically significant at 50 m from a water body, and by implication, also at lesser distances. Such distances represent approximately 34% of the terrestrial area in southern delta (Fig. 8).

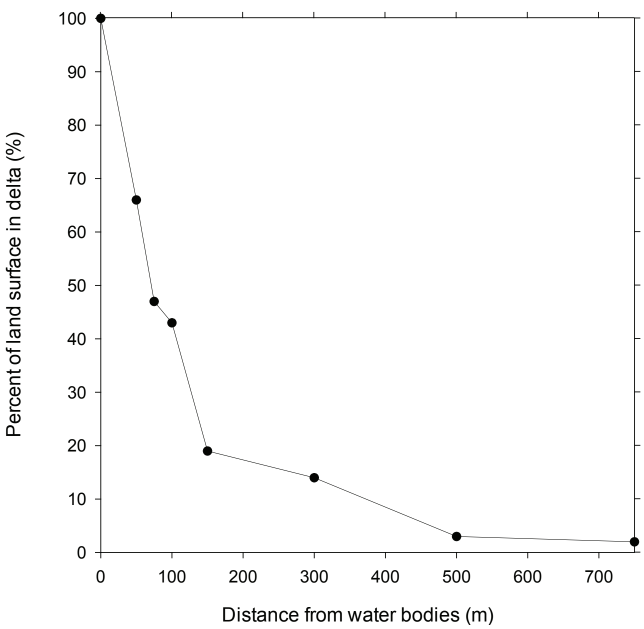

Figure 8. Percentages of land surface in the central and southern Mackenzie Delta that are located at distances greater than those specified from water bodies.

In the previous scenarios, T_w remained unchanged despite warming air temperatures in order to provide a distinction between the response of T_g and T_w to climate warming. It is perhaps more likely that water temperatures will respond to climate warming, but at a slower rate than ground temperatures. In the fifth scenario, the T_w was increased by half the change in T_g. The reduction in 15-m temperature of 0.1°C at 150-m distance may be undetectable due to instrument precision, but the reduction of 0.3°C at 50-m distance is measurable.

When water temperature warms more slowly than ground temperature, the modeling indicates that the thermal effect of water dampens the effect of climate warming, and that the dampening increases with proximity to the water body. In the Mackenzie delta, lakes are relatively static features, but the channels shift following bank erosion during the spring flood. There is a characteristic vegetation succession on point bars opposite cut banks which has been associated with various stages of permafrost aggradation (Smith 1975). Many sites within 50 m of channels may not support an equilibrium thermal regime, and at these locations the departure from undisturbed conditions will be greater than the equilibrium results presented in Table 1.

Conclusions

Field evidence from two sites in the forested Mackenzie delta indicates that recent ground temperature change in the delta, has been less than at three sites in the adjacent shrub tundra. Ground temperature modeling and spatial analysis indicate that almost all of the land in the delta is affected to some degree by water bodies. The reduced ground temperature changes measured in the delta may be related to the slow response of lakes to climate warming.

Based on the results that have been presented, the following conclusions are made:

1. Ground temperatures at 15 m depth have increased by 0.3°C and 0.7°C at two spruce-forest sites in the southern Mackenzie Delta since the 1960s. The warming rates of 0.1°C and 0.15°C per decade are slower than in the adjacent upland.
2. An equilibrium model for 15 m ground temperatures shows that the warming effect of water bodies extends to distances of 750 m from water bodies.

Table 1. Ground temperatures and ground temperature change in brackets at 15 m depth calculated at 50, 100, and 750 m from water bodies using equation 2, assuming different warming scenarios.

Horizontal distance from	Current conditions	1	2	3	4	5
Water bodies $H_{p1}=H_{p2}$ (m)	T_g=-3ºC T_w=6ºC (ºC)	T_g=-2ºC(+1) T_w=7ºC (+1) (ºC)	T_g=-2ºC(+1) T_w=6ºC (0) (ºC)	T_g=0ºC(+3) T_w=9ºC (+3) (ºC)	T_g=0ºC(+3) T_w=6ºC (0) (ºC)	T_g=0ºC(+3) T_w=7.5ºC (+1.5) (ºC)
50	-1.0	0.0 (+1)	-0.2 (+0.8)	2.0 (+3)	1.4 (+2.4)	1.7 (+2.7)
150	-2.1	-1.1 (+1)	-1.2 (+0.9)	0.9 (+3)	0.7 (+2.8)	0.8 (+2.9)
750	-2.6	-1.6 (+1)	-1.6 (+1)	0.4 (+3)	0.4 (+3)	0.4 (+3)

3. Spatial analysis indicates that about 2% of terrestrial surfaces in the delta are located at distances greater than or equal to 750 m from a water body, and therefore, almost all terrestrial sites in the delta experience the thermal influence of water bodies to some extent.

4. Results from an equilibrium model indicate that if lake-bottom temperatures do not respond to climate warming, or warm more slowly than ground surface temperatures, then mean annual ground temperatures at sites close to water bodies will warm more slowly than undisturbed sites. This may explain why ground thermal responses to recent climate warming appear to be damped in the Mackenzie Delta in comparison with the adjacent tundra uplands.

Abstract

Yellowknife, NWT, lies in the discontinuous permafrost zone, in the southern portion of the Slave Geologic Province of the Canadian Shield. There are few data on permafrost temperature from the Yellowknife area. Thermistors connected to miniature dataloggers were installed to measure air, near-surface, and permafrost temperatures at nine sites in four peatlands near Yellowknife, for two years. Annual mean ground surface temperatures were above 0°C at all sites, but annual mean temperatures in permafrost ranged from -1.9 to -0.2°C. The presence of permafrost at these sites is therefore due to the thermal offset, which ranged between 1.3 and 4.0°C. Annual mean air temperature was about 4.5°C higher in the second year and the surface offset declined by 2.6°C. The thermal offset increased by 1.2°C.

Keywords: n-factors; peatlands; permafrost; surface offset; thermal offset; Yellowknife.

Introduction

The city of Yellowknife, NWT, is located at the southern boundary of the Slave Structural Province of the Canadian Shield. The area is known for its Archean bedrock and the long history of mining. Currently, the region is experiencing rapid industrial development and the effects of global warming, which both affect and are affected by permafrost. Our understanding of permafrost conditions near Yellowknife is based largely on Brown (1973) and Wolfe (1998). The purposes of this paper are (1) to present field measurements of air and ground temperatures at several peatlands in the Yellowknife area for two consecutive years; and (2) to discuss the spatial variation in the surface and thermal offsets over the period of record. The field data presented in this paper were collected at sites along the Ingraham Trail up to 70 km east of the city.

Climate and Permafrost

The climate-permafrost system can be described by the difference between the annual mean temperatures of the air (Ta_a) and ground surface (Ts_a), the surface offset, and the difference between Ts_a and the annual mean temperature at the top of permafrost (Tp_a), or the thermal offset (Lachenbruch et al. 1988, Smith & Riseborough 1996). The surface offset is a function of the surface energy balance and therefore varies with vegetation, moisture, snow, and soil thermal properties (Klene et al. 2001, Karunaratne & Burn 2004). In winter, the surface offset is controlled by snow cover, and the latent heat released during ground freezing (Karunaratne & Burn 2004). The thermal offset is controlled by seasonal differences in the thermal conductivity of the active layer and the extent of winter cooling (Romanovsky & Osterkamp 1995, Riseborough 2002). The thermal conductivity of soil increases upon freezing because the thermal conductivity of ice is four times that of liquid water. Thus soil moisture content controls the difference between frozen and thawed conductivities of a soil, and thereby, the thermal offset as well. The thermal offset is negligible in bedrock and relatively high in peat. A large thermal offset can result in the presence of permafrost where annual mean surface temperature is greater than 0°C (Burn & Smith 1988).

Numerical models of the climate-permafrost relation have been developed that parameterize the surface and thermal offsets. The TTOP model, proposed by Smith & Riseborough (1996), represents the surface offset through freezing and thawing n-factors. The n-factor is a ratio of surface to air freezing or thawing indices (e.g., degree-days) (Karunaratne & Burn 2004). In the literature, thawing n-factors (n_t) range from 0.26 at a fen, to greater than 1.0 at open sites with well-drained mineral surfaces, and freezing n-factors (n_f) from 0.12 for wet sites with thick snow covers, to 0.48 for dry sites with little snow (Karunaratne & Burn 2004, Klene et al. 2001, Taylor 1995). The thermal offset depends on the ratio of thawed to frozen thermal conductivity (Romanovsky & Osterkamp 1995, Riseborough 2002), which can be estimated from soil characteristics.

Study Area

Yellowknife has a continental climate, with a mean annual air temperature (MAAT) of -4.6ºC (Environment Canada 2007). The mean daily maximum temperature for July is 21°C but can reach 30°C, while the mean daily minimum temperature for January is -31°C, and has dropped as low as -51°C (Environment Canada 2007). The mean total annual precipitation is 280 mm, of which more than half arrives as rain. Snow cover develops in October, persists until

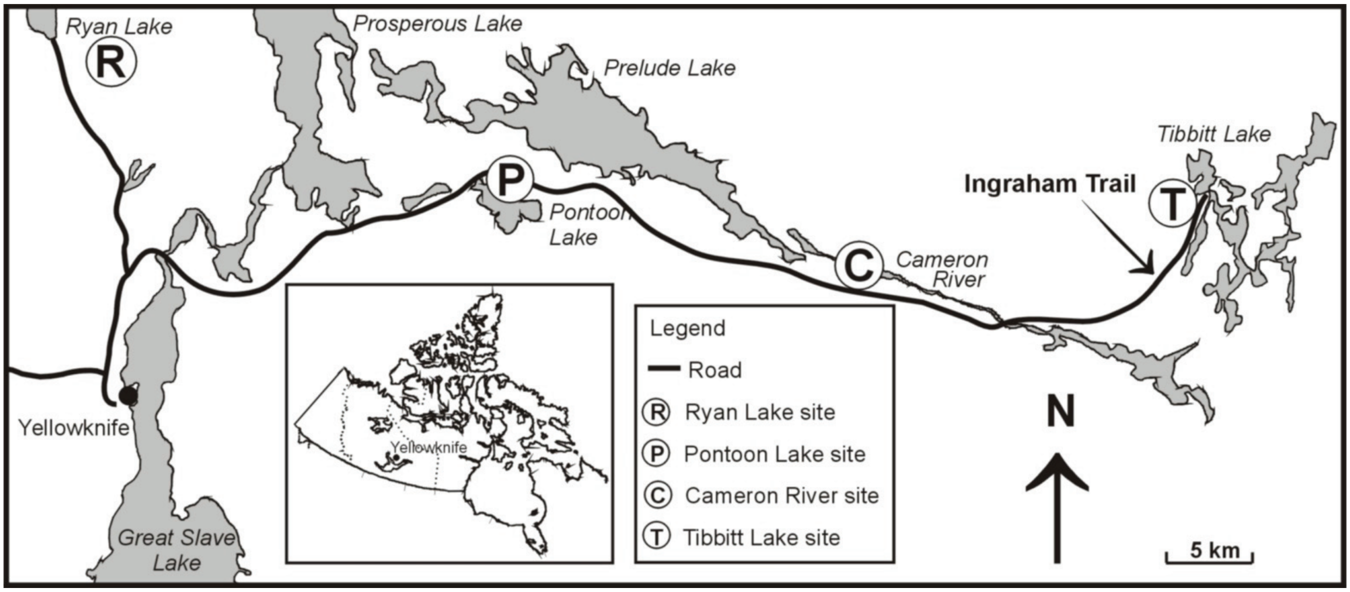

Figure 1. Location of peatland sites near Yellowknife.

the end of April, and approaches a depth of 40 cm in late winter (Environment Canada 2007). The terrain surrounding Yellowknife predominantly consists of peatlands populated by *Picea mariana*, and upland bedrock outcrops colonized by *Pinus banksiana*. The area lies in the extensive discontinuous permafrost zone (Heginbottom et al. 1995). Brown (1973) determined that permafrost is encountered near Yellowknife in peatlands, but not in outcrops or unconsolidated material. He recorded permafrost 50 m thick beneath a 30–cm active layer in a black-spruce peatland, and 30 m thick beneath a 68–cm active layer in a sedge peatland. In both cases the surficial peat was more than 1 m thick. Permafrost was absent in a nearby burnt peatland where the organic horizon was only 30 cm thick. Brown (1973) determined that mean annual ground temperatures were interannually variable, possibly due to differences in snow cover.

Study sites

Four sites were chosen along the Ingraham Trail east of Yellowknife to examine near-surface permafrost conditions. The sites were near Ryan Lake (R), situated 10 km north of Yellowknife, and at Pontoon Lake (P), Cameron River (C), and Tibbitt Lake (T), which were 30, 50, and 70 km east of Yellowknife respectively (Fig. 1). The sites were located in peatlands with *Sphagnum sp*. mosses and *Cladina sp*. lichens, and open-canopy *Picea mariana* forest. Low-lying shrubs commonly included *Ledum groenlandicum*, *Vaccinium vitis-idaea*, *Andromeda polifolia*, and *Empetrum nigrum*. *Rubus chamaemorus* was also ubiquitous. Although the peatlands are classified as basin bogs under the Canadian Wetland Classification System (1997), for the most part, the moss surface was dry, and the base of the active layer was commonly saturated. However, moisture conditions varied spatially and interannually.

Study period

The study period consisted of two years from October 2004 to September 2005, and from October 2005 to September 2006.

Precipitation differed between the years at the Yellowknife Airport. Summer 2004 was dry, receiving only 61mm of rain. The following summers were wetter, with 232 mm of rain in 2005, and 180 mm in 2006.

Snowfall was similar for both years but higher than normal, with maximum snow depth at the airport of 66 cm in both years.

Field Methods

Thermistors connected to miniature dataloggers were installed in 2003 and 2004 to measure air and near- surface temperatures at the peatlands. In total, nine sets of thermistors were installed at the four peatlands. Air temperatures were measured in radiation shields 1.5 m above the ground surface at peatlands T, C, and R. The thermistors measuring near-surface and ground temperatures were mounted on a wooden dowel and inserted into an augered hole. Near-surface temperatures were measured 2 to 5 cm beneath the living moss layer, and ground temperatures were measured at 50 and 100 cm depths. Temperature was recorded every 2 hours (Onset Computing, HOBO®, H08-006-04). The thermistors had a precision of ±0.38°C at 20°C, but random error associated with instrument precision is reduced in long-term averages because of the number of individual measurements (4380 measurements year^{-1}). The accuracy of the thermistors was reported to be ±0.5°C, but was found to be ±0.3°C of 0°C when they were calibrated in an ice bath.

In September 2006, soil samples of known volume were collected at each instrumented site at 10, 20, 30 and 50 cm depths. The soil samples were dried for 48 hours at 105°C to determine the volumetric soil moisture. Surveys of vegetation within 10 m^2 of each site were conducted in 2005, and included visual estimates of the canopy cover. Active-layer depths were determined at each of the instrumented sites in late summer by probing to resistance. In April 2005, snow depths were measured nine times along a 4x4 m cross-transect centered on the point of ground temperature measurements.

Permafrost at the Sites

Permafrost was established in the peat, but its thickness and that of the peat was unknown. Active-layer depths varied spatially and interannually and ranged from 40 to 70 cm (Table 1). The annual maximum temperature at 100 cm was below 0°C for both years at all the sites, indicating the presence of permafrost (Table 1). In 2004–05, the mean annual temperature at 100 cm (T_{100a}) ranged from -0.2°C at C-02 to -1.9°C at T-01; a difference of 1.7°C (Table 1). T_{100a} was between 0.7 and 1.0°C colder in 2004–05 than in 2005–06 except at C-02 and C-03 where it was nearly the same temperature in both years. At the coldest site, T-01, freezeback of the active layer did not occur until mid-January 2005 and until late February 2006, as indicated by a sudden decrease in the temperature at 50 and 100 cm depth (Fig. 2). At C-03, the warmest site, the temperature at 100 cm remained at -0.2°C throughout both years.

Air Temperature

Ta_a (October to September) at Yellowknife Airport (YZF) was -5.1°C for 2004–05, slightly below the MAAT of -4.6°C. The following year was warmer, with Ta_a of -0.6°C. The mean air temperature for the freezing (October to April) season (Ta_f) was 5.5°C lower in 2004–05 than in 2005–06, while the mean air temperature for the thawing (May-September) season (Ta_t) was 3.3°C lower in 2005 than in 2006 (Table 2). On average YZF was 0.9°C warmer than the study sites throughout the year, due to differences in microclimate conditions between the airfield and peatlands. The maximum difference between the peatlands for Ta_a and seasonal average temperatures (Ta_f and Ta_t) in both years was 0.8°C, but it was usually less than 0.3°C. The air temperatures at the study sites were similar, with differences in air temperature amongst the study sites, for the most part, within the accuracy of the instruments. Deviations in Ta_a beyond ±0.3°C were not consistent between sites, years, or seasons.

Table 2. Annual (October to September) mean air temperature (Ta_a), mean air temperature for the freezing season (Taf) and thawing season (Ta_t) for the Yellowknife Airport (YZF), and the Ryan Lake (R), Cameron River (C), and Tibbitt Lake (T) sites for 2004–05 and 2005–06.

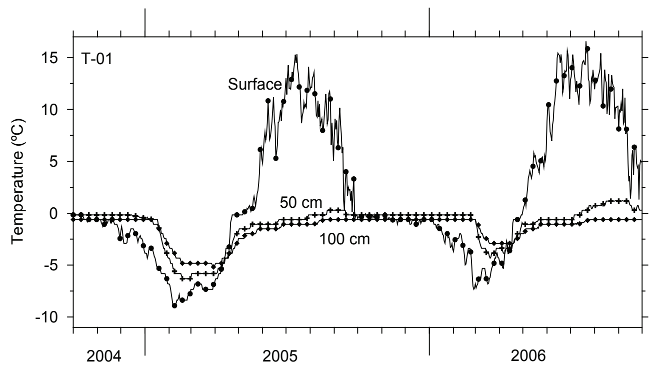

Figure 2. Mean daily surface and ground temperatures at 50 and 100 cm at site T-01 from October 2004 to September 2006. For clarity, the symbols are presented every 10 days while the plot is continuous throughout the two years.

Surface Temperature

The temperature of the surface is common to both the surface and thermal offsets and therefore is integral to the climate-permafrost relation. Surface temperature is measured at the base of the living mosses, approximately 2 to 5 cm from the ground surface to avoid radiative heating. This method is attractive because it positions the sensor close to the relatively warm ground surface during the summer, and is appropriate for measuring winter surface temperature,

Table 3. Mean near-surface temperatures for the year (Ts_a), freezing season (Ts_f) and thawing season (Ts_t), in 2004-05, and associated site characteristics.

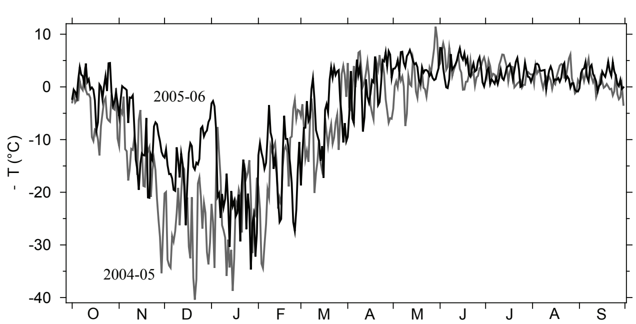

Figure 3. Difference between air and surface mean daily temperature at site C-02 for 2004–05 and 2005–06.

near the peat-snow interface. Such data can also be used to compare organic and exposed mineral surfaces.

Spatial variability of surface temperature

Annual mean and seasonal mean near-surface temperatures at each of the sites for 2004–05 are presented in Table 3, along with snow depth, mean volumetric soil moisture of the active layer, and estimated canopy cover. One measurement site was located in peatland T (T-01); three sites were in peatland C (C-02, -03, -04); two sites were in peatland P (P-05, -06); and three were in peatland R (R-07, -08, -09).

The range in Ts_a was 2.9°C among all nine sites, and 2.3°C among the sites at C and 2.4°C among the sites at R. Similarly, the variation in Ts_f, and Ts_t within peatlands C and R was no less than 60% of the total variation between peatlands. This suggests that the surface thermal regime was the same amongst the peatlands, and that variations in surface temperature among the instrumented sites were due to differences in microclimate.

The lowest Ts_a, and Ts_f, were measured at sites with over 50% canopy cover, and with thinner snow covers in winter due to interception of snow (Table 3). At sites where the snow depth was ≤ 45 cm, Ts_a were 0±0.5°C, and at sites with more than 50 cm of snow, Ts_a were between 0.8 and 2.4°C. The lowest Ts_t were also found at sites with high canopy cover, except at sites P-05 and P-06 which had the lowest soil moistures (Table 3). Canopy cover appears to control surface temperatures in peatlands through shading in summer and its influence on snow distribution in winter.

Interannual variation in surface temperature

Surface temperatures for 2004–05 and 2005–06 were examined at T-01, C-02, C-04, P-06 and R-09 to determine the year-to-year variability (Table 4). The surface temperature sensors at R-07, R-08, C-03, and P-05 did not produce reliable records in 2005-06 and were eliminated from this analysis. The average Ts_a, Ts_f, and Ts_t at the sites were 2.0°C lower in 2004–05 than in the following year (Table 4). The difference in annual mean surface temperature between the years was less than half of that for air temperature (Table 2). This is likely due to both the impact of snow cover in

Table 5. Surface offset (Ta_a-Ts_a), and freezing (n_f) and thawing (n_t) n-factors calculated from freezing and thawing degree-days at the sites.

Site	Surface Offset (°C) 2004-05	Surface Offset (°C) 2005-06	n_f 2004-05	n_f 2005-06	n_t 2004-05	n_t 2005-06
T-01	6.8	4.1	0.22	0.19	0.79	0.76
C-02	8.4	4.7	0.09	0.10	0.85	0.76

buffering the ground from variations in the air temperature regime, and to the impact of permafrost in restricting increases in surface temperature (Karunaratne & Burn 2004). The rank order of the five sites by Ts_a and Ts_t, was the same for both years (Table 4). The rank order of the sites by Ts_f, was similar for both years because the differences between four of the sites in 2005–06 did not exceed 0.3°C; the accuracy of the thermistors. Thus the interannual differences in surface temperature are consistent between the instrumented sites. Ts_a for all the sites was above 0°C for both years, except for R-09 in 2004–05. This indicates that the presence of permafrost in the Yellowknife area is due to the thermal, rather than the surface, offset. The thermal offset causes mean annual ground temperatures to decrease with depth through the active layer allowing permafrost to exist with mean annual surface temperatures above 0°C. Without the thermal offset, mean annual ground temperatures would increase with depth and therefore never extend below the mean annual surface temperature.

Surface Offset

The surface offset and the freezing (n_f) and thawing (n_t) n-factors were calculated for 2004–05 and 2005–06 based on surface temperatures measured at the sites and the average air temperature from T, C, R (Table 5). In 2004–05, the surface offset ranged from 5.3°C at R-09 to 8.4°C at C-02. The following year the surface offset was lower; between 3.7 and 4.7°C. The differences in surface offset between the two years can be attributed to differences between air and surface temperatures in early winter, since snow conditions were similar. In 2004–05, air temperatures had dropped below -20°C by mid-November, before the active layer had refrozen, which resulted in large differences between air and surface temperature (Fig. 3). In 2005–06, air temperatures were consistently higher than -20°C until the beginning of January, and thus closer to the surface temperature during freeze-back of the active layer.

Table 6. Thermal offsets calculated with ground temperatures at 50 cm (T_{50a}) and 100 cm (T_{100a}) for 2004–05 and 2005–06.

Site	T_{Sa}-T_{50a} (°C) 2004-05	T_{Sa}-T_{50a} (°C) 2005-06	T_{Sa}-T_{100a} (°C) 2004-05	T_{Sa}-T_{100a} (°C) 2005-06
T-01	2.5	3.3	2.7	3.8
C-02	2.4	2.7	3.0	4.0
C-03	1.1	-	2.2	-
C-04	1.8	2.8	1.8	3.2
P-05	1.9	-	-	-
P-06	1.9	3.0	1.6	2.8
R-07	2.6	-	2.7	-
R-08	2.0	-	2.3	-
R-09	0.8	2.3	1.1	2.4
Mean	1.9	2.8	2.2	3.2

Values of n_f ranged from 0.09 at C-02 and C-03 to 0.30 at P-06, and for n_t from 0.51 at R-09 to 0.93 at R-07 (Table 5). Both n_f and n_t for the study sites are within the range of n-factors reported in the literature for spruce peatlands (Jorgenson & Krieg 1988, Taylor 1995, Karunaratne & Burn 2004). Wet sites with thick active layers had the lowest values of n_f, and high values of n_f were calculated for sites with high canopy cover and subsequent thin snow covers. Values of n_t were related to canopy cover, with shaded sites having lower n_t than open sites. Sites P-05 and P-06 had higher n_t than their canopy cover would suggest possibly because of their low soil moisture. This suggests that moisture availability has a strong influence on n_t in peatlands.

Thermal Offset

The annual mean temperature at the top of permafrost (T_{Pa}) is required to calculate the thermal offset, but since the depth of the active layer varies spatially and interannually (Table 1), it is difficult to measure T_{Pa}. Fortunately, ground temperatures within the uppermost metres of permafrost can be used instead, as the ground warms very slowly with depth in this part of the temperature profile (Willams & Smith 1989), and temperatures several metres below the top of permafrost are similar to that at the top of permafrost. In 2004–05, slightly more than half of the sites had active layers thinner than 50cm, and the mean annual temperatures at 50 and 100 cm depths (T_{50a} and T_{100a}) were generally within 0.5°C, except at C-03 which had the deepest active layer (Table 1). The following year, most of the sites had active layers that were thicker than 50 cm, and the difference between T_{50a} and T_{100a} was 0.4°C higher than in 2004–05 (Table 1). The average difference in the thermal offset between that calculated with T_{50a} as opposed to T_{100a} was 0.1°C for the sites with active layers thinner than 50 cm, and 0.9°C for the sites with active layers thicker than 50 cm (Table 6). Thus the thermal offset calculated with T_{100a} is more appropriate to compare values between sites and years. The thermal offset (T_{Sa}-T_{100a}) was lower in 2004–05 than the following year for all of the sites; between 1.1 and 3.0°C in

2004–05 and between 2.4 and 4.0°C in 2005–06 (Table 6). The rank of the sites by the thermal offset was the same both years, with the highest value found at C-02 and the lowest at R-09. Sites with thick active layers had large thermal offsets (Table 1).

Conclusions

Air, surface and ground temperatures were measured in four peatlands near Yellowknife during 2004–05 and 2005–06. The following are the principal results of the study:

(1) The lowest annual mean surface temperatures were measured at sites with high canopy cover.
(2) The mean annual mean permafrost temperature among the sites was -1.3°C in 2004–05 and 0.7°C the following year.
(3) The mean surface offset among the sites was 5.9°C.
(4) The mean thermal offset among the sites was 2.6°C.
(5) Since the mean annual ground surface temperature in the peatlands was above 0°C, permafrost near Yellowknife is sustained by the thermal offset.

Acknowledgments

The research has been supported by the Natural Sciences and Engineering Research Council of Canada, and the Northern Scientific Training Program of Indian and Northern Affairs Canada. Field assistance from numerous individuals, especially Jesse Farlane and Krystal Thompson, is acknowledged with gratitude.

The Schmidt-Hammer as a Relative Age Dating Tool for Rock Glacier Surfaces: Examples from Northern and Central Europe

Andreas Kellerer-Pirklbauer
Institute of Geography and Regional Science, University of Graz, Austria

Abstract

This paper presents new data of measurements of Schmidt-hammer rebound values (*R*-values) on rock glacier surfaces and adjacent landforms from one site in northern Norway (Lakselv) and two sites in central Austria (Dösen and Weissenkar). The obtained *R*-values reveal long and complex rock glacier formation histories with initiations in the early Holocene. At least the large studied rock glaciers were formed continuously during most of the Holocene, whereas for small rock glaciers this is more difficult to prove. This implies that the Schmidt-hammer method seems to be a powerful tool in surface dating, particularly for large rock glaciers where multiple measurement sites along a longitudinal profile are possible to sample. *R*-values from such profiles enable the establishment of relative chronologies with high temporal resolution. Reliable absolute dating is possible when surfaces of known age with similar vegetation and climate history and comparable lithology are available. The more surfaces of known age are available, the better is a resulting age-calibration curve.

Keywords: Holocene landscape development; rock glacier formation; rock glacier surface dating; Schmidt-hammer.

Introduction

Rock glaciers originate from thick debris accumulations (talus and/or till) in high-relief environments that are under cryogenic conditions for a substantial period of time. Surface morphology, extent, and shape are the cumulative result of their entire genesis and thus climatic past. Temporal dates regarding their initiation and evolution period are the key to valuable palaeoclimatic information. Precise dating of rock glaciers is difficult but can be best achieved by applying an integrated approach, using a combination of relative—thereby distinguishing between fieldwork-based approaches (Schmidt-hammer rebound value, lichenometry, and weathering-rind thickness) and photogrammetry-based approaches (displacement rates and interpolated streamlines)—and absolute (luminescence, exposure/cosmogenic, and radiocarbon) dating methods (Haeberli et al. 2003). Absolute dating methods for rock glacier surfaces are still at an initial stage (Haeberli et al. 1999), are time-consuming, and have their own suites of assumptions and errors (cf. Shakesby et al. 2006), whereas relative dating methods are used more frequently (e.g., Haeberli et al. 2003, Frauenfelder et al. 2005, Kellerer-Pirklbauer et al. 2007). The combination of the Schmidt-hammer and photogrammetry-based approaches seems to be a powerful relative age-dating approach allowing—up to a certain extent—also absolute age estimations (Frauenfelder et al. 2005, Kellerer-Pirklbauer et al. 2007). However, Kellerer-Pirklbauer et al. (2007) pointed out that the main drawback of photogrammetry-based calculations of displacement rates and, derived from that, interpolated streamlines, is the crude assumption of constant velocity during the entire period of formation. Age estimations derived from Schmidt-hammer measurements seem to substantially reduce this drawback.

In this study the Schmidt-hammer method was applied at five rock glaciers and adjacent landforms in different environmental and geological settings. Results and age estimates are presented and compared with each other. The study areas are located at the following sites in Europe:

(1) One rock glacier near Lakselv, Gaissane Mountains, northern Norway (69°57′N, 24°47′E). Age dating based on cosmogenic isotope analysis is currently in progress from surface samples of a nearby rock glacier (LA-B in Fig. 1A) by Frauenfelder (pers. com.). No results are available so far.

(2) Three rock glaciers in the Dösen Valley, Ankogel Mountains, central Austria (46°59′N, 13°26′E). No detailed age estimations have been reported previously from there.

(3) One rock glacier in the Weissenkar Cirque, Schober Mountains, central Austria (46°57′N, 12°45′E). Crude age estimations were reported previously by Buchenauer (1990) suggesting a postglacial formation age.

Study Areas

Northern Norway – Lakselv

The study area near Lakselv, Gaissane Mountains, is characterised by a steep escarpment (caused by faulting) with some hundreds of meters in vertical dimension. This escarpment separates a high plateau from the broad glacially modified Balgesvag´gi valley (Fig. 1A). The high plateau is gently dipping towards the west with smooth summits reaching elevations above 800 m a.s.l. The bedrock at the study area consists of Precambrian and Palaezoic sandstones and silts. A number of gravitationally induced landforms can be identified at the foot of this escarpment reaching a lower elevation of ca. 380–400 m a.s.l. Such landforms are in particular two talus-derived, lobated rock glaciers (LA-A and LA-B in Fig. 1A) and four distinct avalanche boulder tongues (ABT in Fig. 1A). At this study area the intact (i.e. containing permafrost but presumably no current movement; Farbrot 2007), monomorphic and lobated rock glacier LA-A with a surface area of 0.09 km² was studied. For a detailed site description refer to Farbrot (2007).

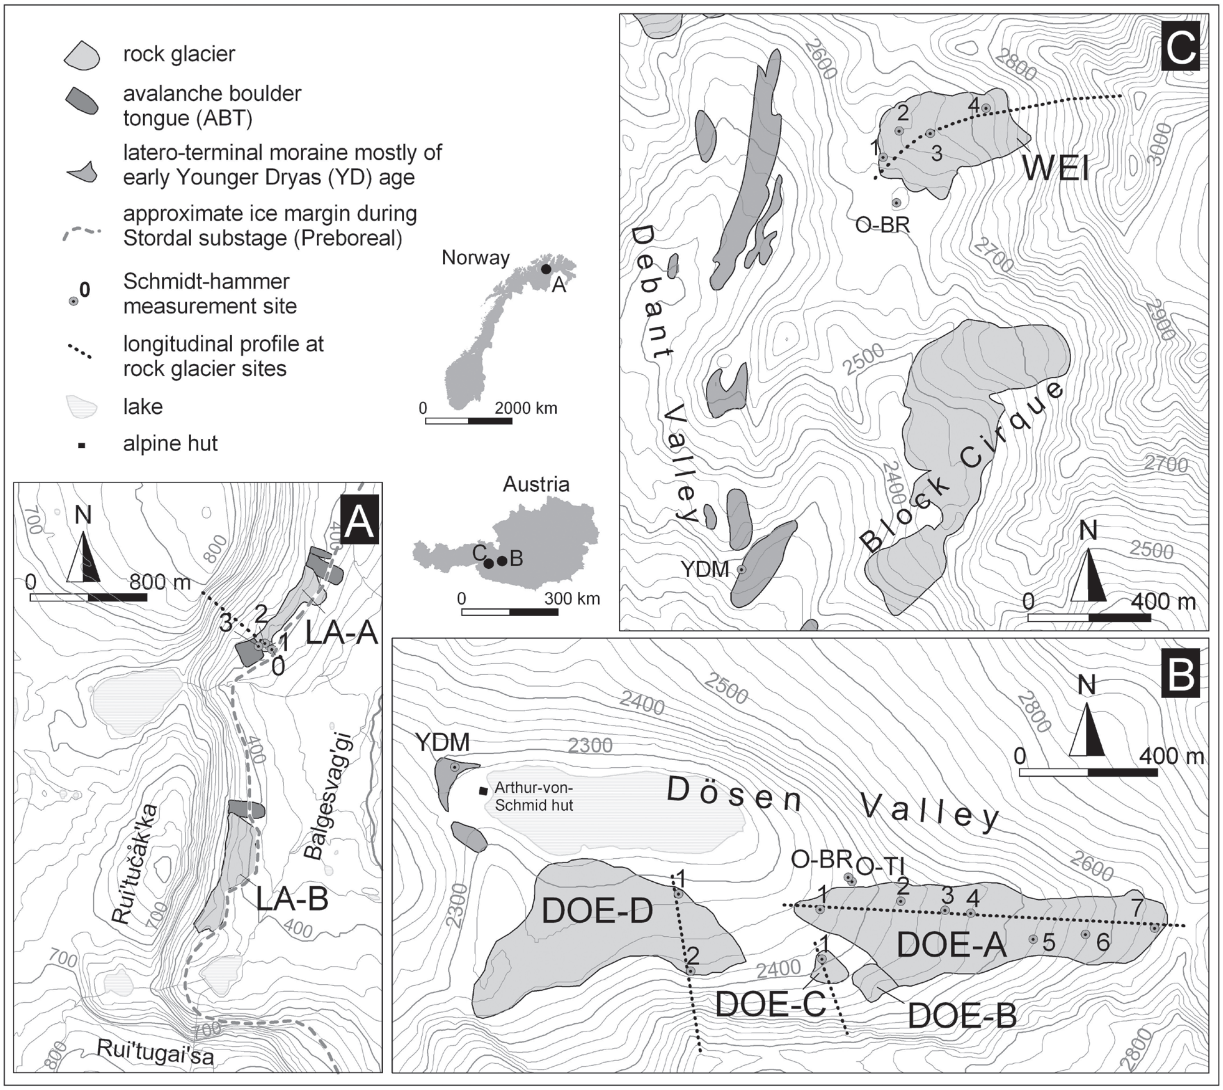

Figure 1. The study areas near (A) Lakselv, Gaissane Mountains in northern Norway and (B) Dösen Valley and (C) Weissenkar Cirque, both in central Austria: (A) Both rock glaciers (LA-A and LA-B=rock glacier Lakselv A and B) occur in close vicinity to avalanche boulder tongues indicating their close genetic relationship. Two Schmidt-hammer measurement sites are located at LA-A (1 & 2) and two nearby (0 & 3). The margin of the Fennoscandian Ice Sheet during the Stordal substage (Preboreal) was at the foot of the escarpment coming from east as indicated in the map. Age dating based on cosmogenic isotope analysis is currently in progress at LA-B. (B): Schmidt-hammer readings were carried out at two active, monomorphic, tongue-shaped (DOE-A and DOE-B) and one intact, monomorphic, lobated rock glacier (DOE-D) in the Dösen Valley. Dots at the rock glaciers, near rock glacier DOE-A (O-BR=bedrock outside rock glacier; O-TI=till boulders outside rock glacier) and at the terminal moraine of early Younger Dryas age (YDM) indicate sites of Schmidt-hammer measurements. (C) Schmidt-hammer readings were carried out at the surface of Weissenkar Rock Glacier (WEI), slightly outside the rock glacier at a roche moutonée (O-BR) and at a latero-terminal moraine ridge of early Younger Dryas age (YDM). Depicted landforms based on (A & B) field work and aerial photograph interpretation, and on (C) Buchenauer (1990). Dotted lines in the maps indicate longitudinal profiles.

Central Austria – Dösen

The second study area is situated in the Ankogel Mountains at the inner part of the glacially shaped, E-W trending Dösen Valley. This part of the valley is characterised by four north-to-west facing rock glaciers, a cirque floor with a tarn lake, and distinct terminal moraines (Fig. 1B). The moraines were presumably formed during the Egesen-maximum advance and are thus of early Younger Dryas (YD) age (Lieb 1996). The elevation ranges between 2270 m a.s.l. at the cirque threshold to more than 3000 m a.s.l. at the nearby Säuleck peak. The four rock glaciers predominantly consist of granitic gneiss (Kaufmann et al. 2007). Three of these rock glaciers (DOE-A, B, and C in Fig. 1B) are considered to be active, and one (DOE-D in Fig. 1B) is regarded as climatic inactive (Lieb 1996). In this study, the focus was on the two active and monomorphic rock glaciers, DOE-A (0.19 km²) and DOE-C (0.007 km²), and on the inactive and monomorphic rock glacier DOE-D (0.17 km²). Previous permafrost research—including velocity measurements—focused particularly on the rock glacier DOE-A (for details see Lieb 1996 or Kaufmann et al. 2007).

Central Austria – Weissenkar

The third study area is located in the Schober Mountains at a west-exposed cirque in the Debant Valley. As indicated by the high number of rock glaciers (n=126), the Schober Mountains provide suitable topoclimatic and geological (crystalline rocks) conditions for rock glacier formation (Lieb 1996). The cirque is dominated by the tongue-shaped Weissenkar Rock Glacier (WEI in Fig. 1C) which is fed by active scree slopes. Until the late 1990s, the rooting zone of WEI was occupied by a large perennial snow field. WEI consists of an active upper lobe overriding an inactive lower lobe. Different types of mica schist form the lithological component of the rock glacier. WEI is characterized by well developed furrows and ridges at its entire lower half, a lower limit at 2615 m a.s.l., a length of 500 m, and a surface area of 0.11 km². WEI creeps from the cirque to a plateau-like area composed of roches moutonées. Latero-terminal moraine ridges of Late Glacial age are frequent in the area. At this study area the rock glacier, one roche moutonée, and a distinct moraine ridge of supposed Egesen/early YD age located at the lower end of the Block Cirque were studied (cf. Buchenauer 1990, Lieb 1996, Kaufmann et al. 2006).

Methods

A Schmidt-hammer (or sclerometer) is a light and portable instrument traditionally used for concrete stability testing by recording a rebound value (R-value) of a spring-loaded bolt impacting a surface. Beginning in the 1980s (e.g., Matthews & Shakesby 1984, McCarroll 1989), this method has been increasingly applied in glacial and periglacial studies for relative rock surface dating. The obtained R-value is proportional to the compressive strength of the rock surface and gives a relative measure of the surface hardness and thus provides information on the time since surface exposure and the degree of weathering. High values are indicative of a lower age and vice-versa.

Analogue L-type Schmidt-hammers have been used at all three study areas using products of the companies "PROCEQ," Switzerland (Norwegian site) and "Controls," Italy (Austrian sites). On each of the larger rock glaciers (LA-A, DOE-A, DOE-D, and WEI), two to seven locations close to the central flow line between the frontal ridge and the rooting zone were measured. Sites were kept as small as possible. Measurements on rock glaciers were made on ridge crests and high spots to minimise the possible influence of late-lying snow on weathering rates.

Complementary measurements were carried out on a smaller rock glacier (DOE-C), on boulders at the active talus of the rooting zone of DOE-A, on an active ABT (LA-A3), and at outside sites located adjacent or down-valley from the rock glacier termini. These outside sites were located twice on bedrock (2 x O-BR: Dösen and Weissenkar) and four times on glacigenic boulders (LA-A0, O-TI and 2 x YDM: Dösen and Weissenkar). Sampled stable boulders and bedrock sites in each of the three study areas were selected on the basis of comparable lithology with dry, flat and clean surface, free of lichens, visual fissures and cracks (McCarroll 1989, Haeberli et al. 2003, Shakesby et al. 2006).

Arithmetic means of 50 individual readings (4 impacts per boulder; only the two middle values were noted) with 95% confidence interval were examined at all sites (Matthews & Shakesby 1984, Shakesby et al. 2006). Arithmetic means are representative for the effective hardness of the analyzed surface. The 95% confidence interval is indicative for the standard error and statistically significant age differences between measurement sites.

Results

The Schmidt-hammer results of all three study areas are summarised in Fig. 2A to 2C. Frequency distribution of only one sample shows low bimodality (LA-A3), and skewness is generally low to moderate. Negative skewness may point to a somewhat lower mean R-value (higher age) than observed; positive skewness may indicate a somewhat higher mean R-value (lower age) than observed.

Rock glaciers near Laksekv

Mean R-values range from 48.8 outside LA-A (LA-A0) to 54.8 at the active ABT (LA-A3) adjacent to the rock glacier with low 95% confidence limits. The four samples cover a R-value range of only 6.0. R-values taken at the rock glacier surface are significantly higher than the ones taken from the outside site close to a moraine ridge of Preboreal age, and they are significantly lower than the ones from the ABT.

Rock glaciers in the Dösen Valley

Mean R-values range from 29.7 at the YDM site to 47.7 at the active talus above DOE-A (DOE-A7) covering a R-value range of 18.0. The 95% confidence limits are generally below ±1.00. A decrease in R-values can be discerned at the inactive rock glacier DOE-D and, in particular, at the active rock glacier DOE-A (δR-value 12.3).

Rock glacier in the Weissenkar Cirque

Mean R-values range from 21.5 at the YDM site to 38.0 at site WEI4 located in the active rooting zone of the rock glacier covering a R-value range of 16.4. The rooting zone was occupied by a glacier during the Little Ice Age (~1850 AD) and a large perennial snow field until the late 1990s indicating a rather young age of the deposits at site WEI4. The 95% confidence limit at site WEI4 (1.77) is the highest of all 23 measured sites. A clear decrease in R-values can be discerned at the rock glacier WEI (δR-value 13.5).

Discussion

When analyzing Schmidt-hammer literature, it becomes obvious that R-value decrease over time is quite heterogeneous in alpine climates and in different lithologies. However, R-value differences of >10 suggest time periods of some thousands to more than ten thousand years even in competent rocks such as gneiss (e.g., Aa & Sjåstad 2000, Frauenfelder et al. 2005, Kellerer-Pirklbauer et al. 2007).

Rock glaciers near Lakselv

The formation of the studied rock glaciers in Lakselv

(LA-A) was initiated sometime after the retreat of the Fennoscandian Ice Sheet from the study area. During the YD period, the site of the rock glacier LA-A was situated well inside the glacier limit (Sollid et al. 1973). Marginal moraine ridge systems belonging to the Post-Main (Stordal) substages (Sollid et al. 1973) of suggested Preboreal age (9-10 ka BP, uncalibrated ^{14}C years; Andersen 1979) were deposited in very close vicinity to the present rock glaciers LA-A and LA-B (see Fig. 1A). Later these moraine ridges acted as natural barriers for the development of both lobated rock glaciers and were partly incorporated into them.

The interpretation of the obtained *R*-values is difficult, and the dating here is very speculative. Aa & Sjåstad (2000) calculated for a site in southern Norway that the *R*-value was reduced by 20.5 over a period of 9730 a. Their study site is to some extent climatically comparable to the Lakselv site but with different lithology (gneiss). They inferred a (hypothetical) linear surface weakening rate of 2.1 *R*-values per 1 ka. However, complications arise because the increase in the degree of weathering over time (i.e. weathering rind thickness) and the role of flaking of the weathering rind are not easy to quantify. Schmidt-hammer mean values seem to correlate with weathering rind thickness almost linearly (Laustela et al. 2003) allowing good comparison. Weathering rind thickness increases nonlinearly with time although this nonlinear weathering-time relationship seems to occur on very long timescales often exceeding 100 ka (Skakesby et al. 2006). The role of flaking of weathering rinds might be more important for shorter time periods (Etienne 2002). The *R*-value differences of 3.4 between LA-A1 and LA-A3 (site at the ABT) and 2.6 between LA-A1 and LA-A0 (site close to the Preboreal moraine ridge) is statistically significant. They allow the conclusion that the rock glacier surface is significant younger than Preboreal but significant older than the currently still active ABT. The low δR-value of 6.0 between the ABT site and the site adjacent to the moraine ridge also might be explained by occasional dispersing of rock material over the entire rock glacier LA-A and its foreland by powerful debris-charged snow avalanches. Judging from the morphology of the rock glacier itself, the glacial and periglacial landforms in close vicinity, and the considerations by Kääb (2005) – total age of rock glaciers might be 2–5 times higher than the minimum age obtained for the surface – a long and complex formation history and a rock glacier initiation soon after the Preboreal is suggested.

Rock glaciers in the Dösen Valley

The initiation of all rock glaciers in this study area occurred after the Egesen advance in the early YD period as indicated by the moraines downvalley from the four rock glaciers. In Austria, the early YD is 10Be-dated to around 12.3–12.4 ka (Kerschner & Ivy-Ochs 2007). Thus the maximum and the minimum R-values in this study area can be absolute dated to 12.3–12.4 ka at the YDM site and ~0 a at the active talus site DOE-A7. In this regard, one should not forget the time lag between initial crack formation in the rock face above the rock glacier (exposure to weathering) and the eventual release of a clast to the talus below. Quantification of this period is difficult.

By using a linear relationship between *R*-value and time, a tentative age-calibration curve with a mean decrease of 1.46

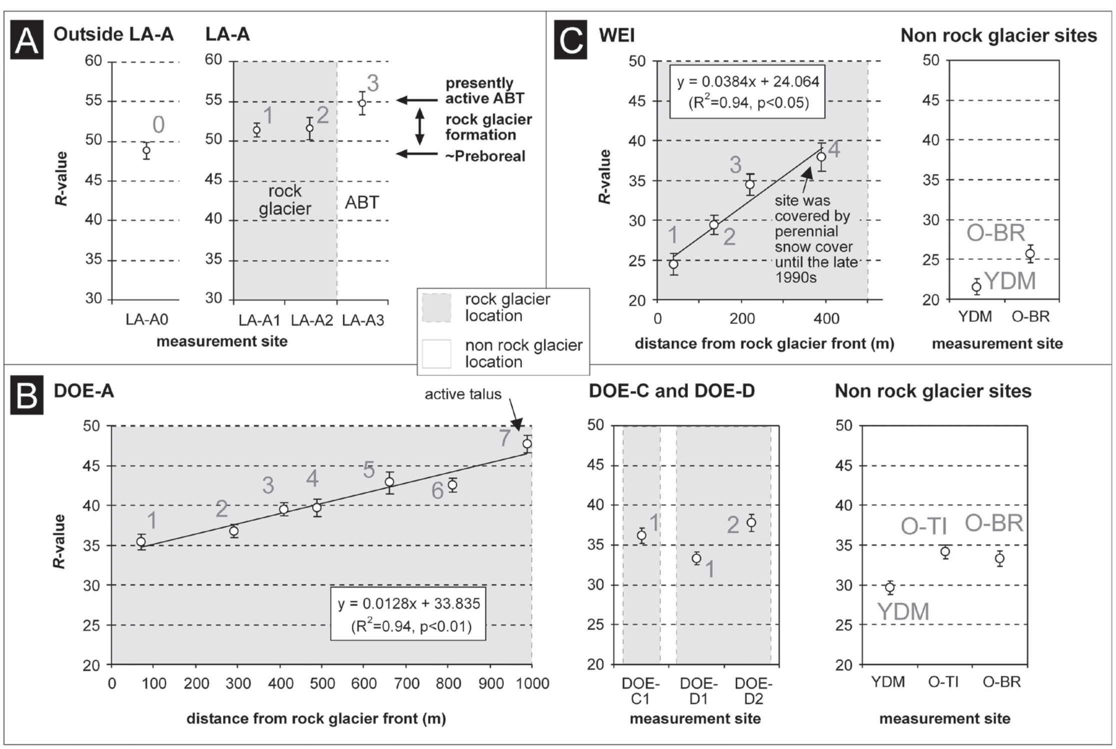

Figure 2. Results of the Schmidt-hammer measurements at the studied rock glaciers and nearby non-rock glacier locations in (A) northern Norway (LA-A) and (B-C) in central Austria (DOE-A, DOE-C, DOE-D and WEI): *R*-values show the arithmetic mean and 95% confidence limits at each measurement site. At the large monomorphic rock glaciers, DOE-A and WEI, *R*-values are plotted against distance from rock glacier front. Best-fit correlations are indicated. Numerals in the graph refer to locations in Figure 1. Estimated age ranges for (A) are given.

R-values per 1 ka can be inferred (Fig. 3A). Skakesby et al. (2006) introduced a simple method to investigate the likely size of error of the absolute age estimates derived by the linear relationship. According to their approach, error limits for the predicted ages are determined separately for the YD and present sites from the corresponding 95% confidence intervals of *R*-values by a straight line. The error limits in the predicted age based on this approach is ±607 years for YDM and ±774 years for DOE-A7. Thus a predicted age error of ca. ±0.7 ka for all sites should be considered.

A substantially and statistically significantly lower mean *R*-value at the YDM site compared to all other sites (δ≥3.6) suggests that during the YD and Preboreal periods, the head of the Dösen Valley was covered by a glacier terminating between the YDM and the present rock glacier front. The following glacier retreat deglaciated the bedrock site O-BR and deposited the coarse boulders at site O-TI. Identical *R*-values from site DOE-D1 suggest that the rock glacier DOE-D reached its lower end at a similar time. This further suggests that due to its lower position along the valley axis, this valley stretch was not glaciated in the preceding Preboreal period but allowed the formation of DOE-D.

The insignificant *R*-value difference between the outside site O-TI and the lowest site on DOE-A is difficult to interpret when considering the assumption that the total age of a rock glaciers is 2–5 times higher than the minimum age obtained for the surface (Kääb 2005). The obtained minor difference suggests that the surface and total landform age of DOE-A seems to be similar. The same seems to be true for DOE-C and DOE-D. Explanations might be: (a) a less effective "conveyor belt" mechanism (Haeberli et al. 2003), (b) debris-covered glacier tongues which were later incorporated in the rock glacier, (c) mineral variations in the bedrock, or (d) differences in the surface weakening rate between sites due to different vegetation /snow cover histories in the Holocene.

The regression line at DOE-A indicates that this rock glacier was formed continuously during most of the Holocene. Recent velocity data (1954–2005) from the rock glacier DOE-A show mean annual velocity rates of 13.4–37.4 cm a^{-1} (Kaufmann et al. 2007). If these velocities are taken as (questionable) constant over time and combined with the length of DOE-A, ages of 2.7–7.5 ka are calculated. These age values are lower than the age estimate of the lowest rock glacier site (DOE-A1) obtained by the tentative age-calibration curve presented in Fig. 3A (8.4±0.7 ka).

Rock glacier in the Weissenkar Cirque

The *R*-values from the third study area suggest a comparable landscape history to the one from the Dösen Valley. The initiation of the rock glacier WEI occurred after the Egesen advance in the early YD period as indicated by the YD moraines downvalley from the cirque. The linear relationship between the *R*-value of the YD moraine site (YDM: 21.5) and the uppermost measurement site in the rooting zone of the rock glacier (WEI4: 38.0) reveals a mean decrease of 1.33 R-values per 1 ka (Fig. 3B).

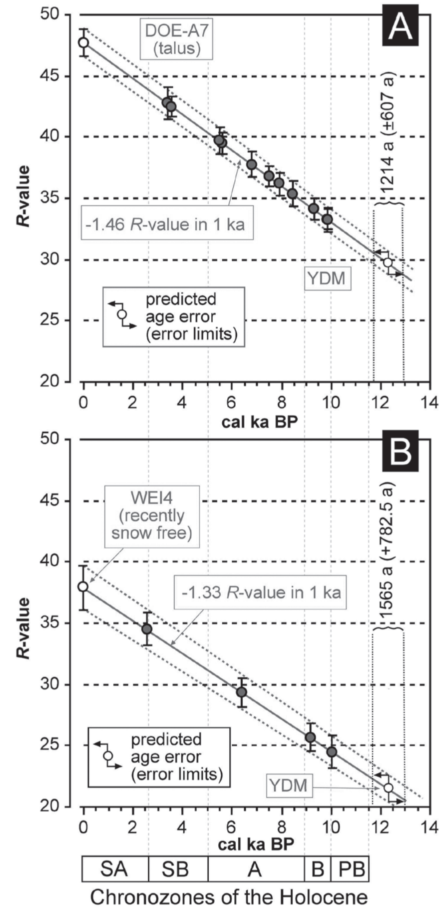

Figure 3. Tentative age-calibration curves for the *R*-values of the study areas Dösen (A) and Weissenkar (B) based on two surfaces of known age indicated as open circles. The calculation of predicted age error including error limits is illustrated for the YDM locations. Grey circles indicate calculated ages based on this approach. Holocene chronozones: SA=Subatlantic, SB=Suboreal, A=Atlantic, B=Boreal and PB=Preboreal.

This rate is only slightly less than the one from the Dösen Valley which indicates that the reduction in the mean *R*-value during the Holocene in central Austria was similar for granitic gneiss (Dösen) and mica schist (Weissenkar) despite substantially different absolute *R*-values.

At Weissenkar Cirque the bedrock site just outside the rock glacier (O-BR) suggests a younger age than the lowest site at the rock glacier (WEI1). Reasons for that might be explanations (a) to (d) presented above. The statistically significant decrease in R-values along a profile at WEI points to a long formation history of the landform starting in the early Holocene. At WEI, the lowest measurement site reveals an age of about 10 ka (cf. Fig. 3B). Therefore, WEI might be even older than the large rock glacier DOE-A in the Dösen Valley. Recent velocity data (1974–2004) from WEI were summarised by Kaufmann et al. (2006) showing low mean annual velocity rates of 1.6–11.6 cm a^{-1}. Assuming constant velocities and using a length of 500 m, rock glacier ages of 4.3–31.1 ka can be estimated. This maximum age is certainly far too high, highlighting the weakness of the assumption of constant surface velocity.

Conclusions

The Schmidt-hammer method seems to be a powerful tool in rock glacier dating, particularly for large rock glaciers where multiple measurement sites along a longitudinal profile are sampled. *R*-value data from such profiles enable the establishment of relative chronologies with high temporal resolution. For small and short rock glaciers this method is more difficult to apply, and additional palaeoclimatic information is required to constrain age estimates. At the study sites in Austria it was possible to estimate relatively accurately the age for Holocene features. However, possible incorporation of older clasts in the rock glacier surface or dispersing of "fresh" rock material by powerful debris-charged snow avalanches can lead to errors. Furthermore, mineral variations in the bedrock or differences in the rate of surface weakening between sites due to different vegetation/snow cover histories might significantly influence *R*-values. Reliable absolute surface age dating is only possible when surfaces of known age with similar vegetation and climate history, and comparable lithology are available. The more surfaces of known age are available, the better is a resulting age-calibration curve.

Acknowledgments

This study was carried out within the project ALP-CHANGE (www.alpchange.at) financed by the Austrian Science Fund (FWF) and by an international research scholarship by the Research Council of Norway. Research at the Weissenkar site was supported by students of my institute who are kindly acknowledged. The comments of both reviewer and the editor were highly appreciated.

Abstract

The technique of centrifuge modeling allows accurate simulation of full-scale geotechnical processes in small-scale models under correct self weight. Here we report results from two scaled 10 g centrifuge modeling experiments, designed to simulate solifluction processes associated with one-sided and two-sided freezing of an active layer of 1 m thickness at prototype scale. A distinct dry intermediate layer was observed in the two-sided experiment where only very small displacement and thaw settlement occurred. The overall rate of thaw in the two-sided model was significantly slower compared to the one-sided experiment. The total soil deformation profiles after five freeze-thaw cycles show a plug-like sliding component immediately above the permafrost table in the two-sided experiments, but shear strain decreasing with depth in the one-sided experiment. Data from these experiments are currently being used to calibrate and validate newly developed numerical constitutive modeling algorithms designed to predict soil behavior during solifluction.

Keywords: active layer; centrifuge modeling; solifluction.

Introduction

Here we present first results of scaled centrifuge simulation of solifluction processes associated with one-sided and two-sided soil freezing, allowing detailed comparison of hydrothermal processes and downslope displacement rates. These experiments are part of a research program designed to predict styles and rates of periglacial solifluction and their relationship to factors such as climate, hydrology, geology, and topography. New process-based numerical models are being developed and validated against well-controlled full-scale simulations (Harris et al., this volume) and reduced-scale centrifuge modeling.

Freezing and thawing of frost-susceptible, soil-covered slopes cause slow downslope soil movement which is highly significant to slope evolution. In areas of warm or no permafrost, seasonal freezing is from the surface downwards (one-sided freezing), whereas in cold permafrost areas, large thermal gradients in the uppermost permafrost layer can cause active layer freezing in two directions: from the permafrost table upwards and from the ground surface down (two-sided freezing) (e.g., Lewkowicz 1988, Shiklomanov & Nelson 2007). Bottom-upward freezing is most widespread where mean ground temperatures are below -5°C and usually precedes freezing from the surface (Shur 1988). In the case of one-sided freezing, ice lens formation occurs near the ground surface, but during two-sided freezing, ice lenses accumulate in a transition zone that includes the basal zone of the active layer and the upper part of the permafrost (Shur et al. 2005). Thaw penetration into this zone causes deeper soil movements and "plug-like" solifluction (Mackay 1981, Lewkowicz & Clarke 1998).

Numerous field studies of solifluction processes have emphasized the factors controlling spatial variability, and a global review is given by Matsuoka (2001). More detailed exploration of the mechanisms of periglacial solifluction under one-sided freezing has been achieved in large-scale laboratory simulations with controlled soil properties and boundary conditions (Coutard et al. 1988, Harris et al. 1996). The potential of using geotechnical centrifuge modeling technique for the simulations of mass movement processes in thawing slopes has been demonstrated in recent studies (Harris et al. 2001, Harris et al. 2003a,b, Harris et al. 2008). The present experiments were designed to simulate solifluction following one-sided and two-sided freezing conditions under correct slope self weight in the centrifugally accelerated gravity field and under well-controlled soil and boundary conditions.

Numerical Modeling

For stability problems in cold regions, such as periglacial solifluction, it may be difficult to accurately measure the field stresses in thawing soils with the limitation of current instruments and methods. The rates and styles of periglacial solifluction apparently depend to some degree on the depth at which ice lenses develop during frost heaving, (Matsuoka 2001). An accurate prediction of ice lensing is therefore of great importance to model the process of periglacial solifluction. A fully coupled thermo-hydro-mechanical numerical approach for modeling solifluction in freezing and thawing soils is under development, based on the existing software, COMPASS (Cleall et al. 2007). Numerical models will be calibrated against laboratory physical models, including centrifuge studies, and assessed via simulation of field data from monitored natural slopes in Svalbard and Norway (Harris et al. 2007).

Centrifuge Modeling Technique

Geotechnical centrifuge modeling allows detailed studies of real processes under defined boundary conditions, providing an excellent tool for verifying numerical methods. In the rotating centrifuge, a $1/N$ scaled model is subjected to a centrifugal force equivalent to N gravities (g) which increases the self-weight of the soil and thus generates a gravitational stress distribution in the model, which is equal to that in the prototype. In a centrifuge test at Ng, model linear dimensions scale as $1/N$, area $1/N^2$, stress 1/1, temperature 1/1, time for convective and conductive heat transfer $1/N^2$, and time for seepage force similarity $1/N^2$ (Croce et al. 1985, Savidou 1988). A 1/10 scale centrifuge model tested at 10 g therefore extrapolates to the correct prototype scale.

Accurate scaled modeling requires similitude in soil properties between model and prototype, which is achieved by using the same soil with the same stress history. In the present context, the thaw consolidation theory (Morgenstern & Nixon 1971) provides a framework for the analysis of effective stress within thawing ice-rich soils, the governing factors being thaw penetration rate (controlling rate of meltwater release) and consolidation rate (controlling rate of dissipation of excess pore-water pressure). Since time for seepage force similarity and for heat transfer both scale as $1/N^2$, no scaling conflicts arise in modeling the thaw consolidation process, and model time is reduced by a factor of N^2 (Harris et al. 2000, 2001).

However, the time scaling factor for viscous flow is 1/1, so potential temporal scaling conflicts arise if the dynamic response of the thawing soil to gravitational stress is a function of its viscosity. A series of "modeling of models" centrifuge experiments, in which solifluction processes were simulated at different scales and gravitational accelerations, showed virtually identical profiles of shear strain and identical soil transport rates in all models when scaled to prototype, leading to the conclusion that shear strains during solifluction reflect an elasto-plastic response of the thawing soil to gravitational stress, controlled by pore-water pressures, and not fluid flow controlled by viscosity (Harris et al. 2003a). Thus, no significant scaling conflicts arise during centrifuge modeling. An additional advantage of the method is that processes which would take many days or months at prototype scale can be simulated in a few hours.

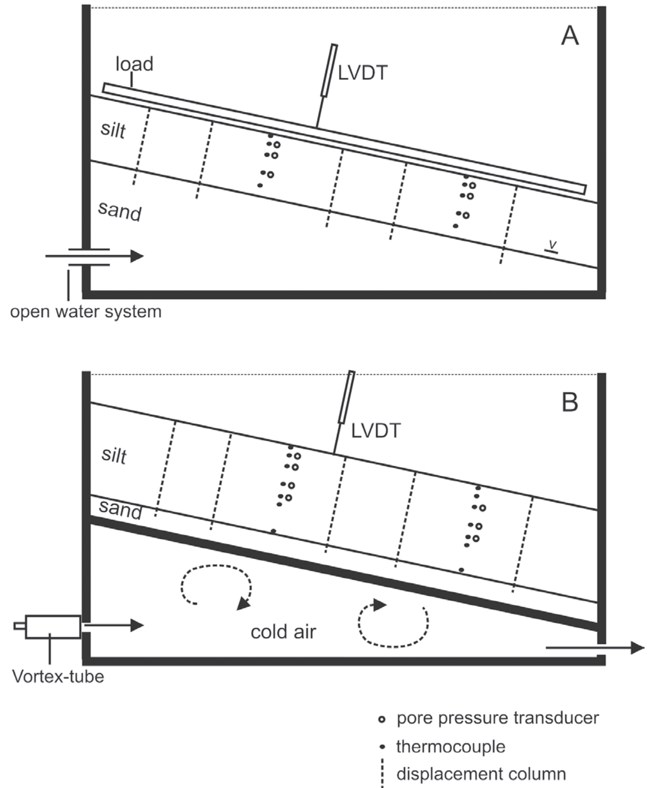

Figure 1. Experimental design during model freezing on the lab floor. (A) one-sided freezing and (B) two-sided freezing. The sides and base of the test box were surrounded in polystyrene insulation, and the surface temperature lowered to between -5°C and -10°C.

Design of Centrifuge Experiments

The Cardiff University geotechnical centrifuge consists of a beam centrifuge of 2.7-m radius for testing model packages of up to 1000 kg at an acceleration of up to 100 gravities. 1/10 scale slope models with gradient 12° were constructed in Perspex boxes of internal dimensions 0.74 m x 0.45 m x 0.44 m (Fig. 1) using the same silty soil that was used for equivalent full-scale laboratory simulations (see Harris et al., this volume). For this study, two different model types were prepared to simulate (a) the response of the thawing soil to ice distribution generated by seasonal one-sided freezing and (b) the response of the thawing soil to ice distribution generated by two-sided freezing under cold permafrost conditions. Soil was placed over a basal sand layer forming a 9-cm-thick model (scaling to 90 cm) for the one-sided experiments and a 14-cm-thick model (scaling to 140 cm) for the two-sided experiment.

In each, 2 vertical arrays of 5 and 7 type-K thermocouples, respectively, and three Druck pore pressure transducers were inserted. Thermocouples were placed at 5 cm above the box for air temperatures and at depths 0, 1, 3.5, 6, and 7 cm in the one-sided and at 0, 2, 3.5, 6, 8, and 9 cm in the two-sided model. Columns of 5 mm plastic cylinders were inserted perpendicular to the slope surface to measure soil deformation. A regular grid of 1 cm circular markers was distributed on the surface to monitor surface downslope displacement during thawing.

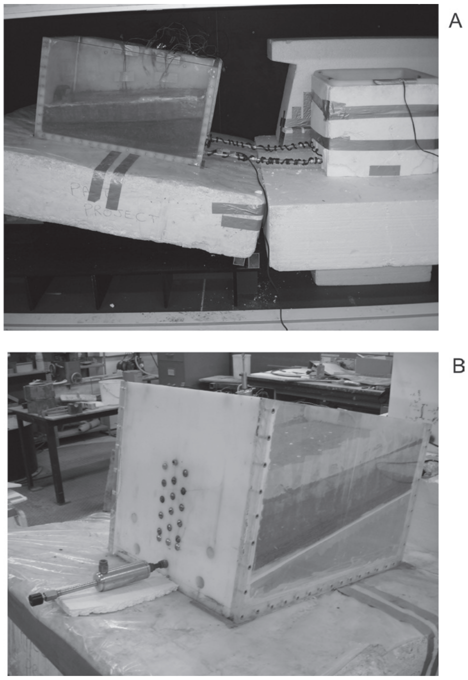

Figure 2. Model preparation. (A) One-sided set-up for freezing with an open-water system. (B) Two-sided freezing with a basal cooling system using vortex tubes.

Two linear voltage transducers (LVDT, LDC 1000C) were placed perpendicular to the soil surface to monitor frost heave during freezing. The model boxes were thermally insulated with polystyrene, and the soil slopes were frozen from the surface downwards at air temperatures between -5°C and -10°C in a freezing chamber under 1 g.

The one-sided model was frozen from the top under a confining load of 1.5 kPa and with an open-water system through the basal sand layer allowing ice segregation in the soil layer. During freezing, the model was tilted to give a horizontal soil surface, and water level was maintained at the sand-soil interface (Fig. 2A). In the two-sided model, a cold permafrost table was simulated using a basal cooling system of cold compressed air generated by three vortex tubes (Fig. 2B). During each cycle of two-sided freezing, summer heave was simulated by sprinkling water on the surface with air temperatures above 0°C and with the basal cooling system running, maintaining base temperatures around -3°C. Pore-water pressures, soil temperatures, air temperature, and frost heave were monitored through the data logger (Campbell CR1000).

The frozen model slopes were placed in the centrifuge gondola and thawed under a gravitational field of 10 gravities. Thawing was from the soil surface downwards at air temperatures between 10°C and 15°C and with an open drainage system. A laser (OADM20) was mounted above the slope surface to monitor thaw settlement. Every 30 minutes the grid of surface markers was captured by an automatic camera to trace the ground surface downslope displacement during thawing. During each freezing cycle, all sensors were monitored at 10-s intervals via the on-board centrifuge data logging system (Campbell CR10X). Each model was subjected to 5 freeze-thaw cycles.

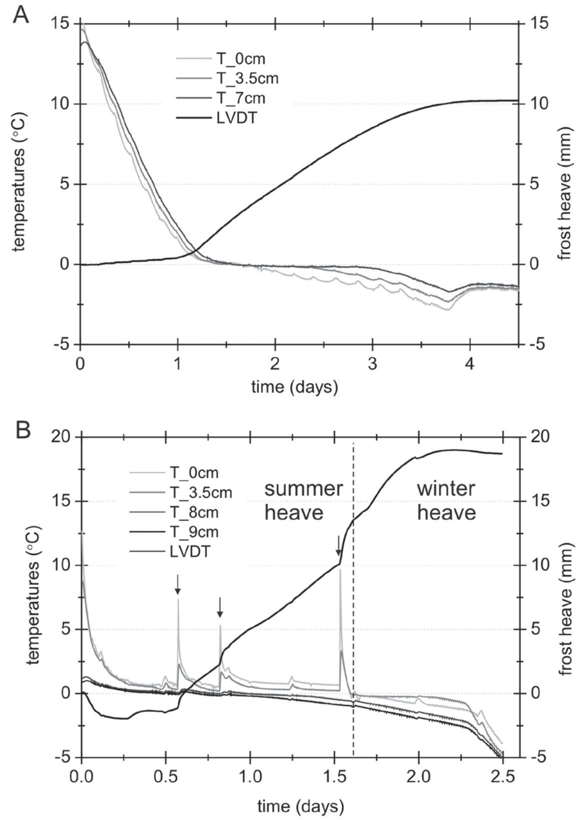

Figure 3. Frost heave and soil temperatures. (A) One-sided freezing experiment showing progressive frost heave over time and freezing from the surface downwards. (B) Two-sided freezing experiment in which heave can be divided into summer and winter components with active layer freezing from the surface downwards and from the permafrost table upwards. For summer, heave water was added to the surface (marked by arrows).

Results

Thermal regime and frost heave

During freezing of the soil models at 1g, the one-sided experiment showed a significant difference in frost heaving rate and thermal regime compared to the two-sided experiment, illustrated in Figure 3. Surface-downwards freezing of the one-sided model over a four-day period is indicated by the temperature-time series at depths 0, 3.5, and 7cm. Ice segregation occurred throughout the soil layer, reflected by uniform frost heaving rates (LVDT) over the freezing period (Fig. 3A). In the two-sided experiment, where basal temperatures were maintained below zero, active layer freezing took place over two days (Fig. 3B) and total heave was due (a) to summer heave with positive air temperatures and ice accumulation at the active layer base followed by (b) winter heave with active layer freezing from the surface downwards and from the permafrost table upwards.

A total of 10 mm (scaling to 10 cm at prototype) frost heave was measured in the one-sided and 19 mm (scaling to 19 cm) in the two-sided experiment. Heaving ratios (i.e., frost heave divided by thickness of the frozen layer) for different depths are listed in Table 1.

Table 1. Frost heave and thaw settlement measurements from the one-sided and two-sided experiment.

Test	Thaw depth (m)	Thaw settlement (mm)	Heaving ratio	Thaw rates (mm/hr)	Displacement (mm)	Ratio displacement/ settlement
1-sided	0	10.8	-	0.72	7.8	0.72
	0.1	31.3	0.24	0.33	9.3	0.30
	0.35	17.2	0.06	0.23	6.0	0.35

Thaw rates and thaw settlement

In Figure 4, thaw-penetration and thaw-settlement rates are shown during thawing at 10 g of the one-sided and the two-sided experiments in the centrifuge. Nearly linear thaw-settlement rates were monitored in the one-sided experiment. However, temperature profiles showed an apparent deceleration of thaw penetration close to the surface and between 0.6 and 0.7 m depths (prototype scale), associated with depths of slightly increased ice formation in the model. For each thawed layer (i.e., between two instrumentation depths), total thaw settlement, average thaw rates (i.e., thaw settlement per time), and heave ratio (i.e., thaw settlement per frozen layer thickness) are listed in Table 1. In the two-sided experiment, higher settlement rates were monitored near the surface and between depths 0.8 and 0.9 m (prototype scale) (Fig. 4B). In the relatively drier ice-poor layer (i.e., small heave ratios) between depths 0.35 and 0.6 m, lower rates of thaw settlement were measured. A very similar pattern was observed in recent field measurements on a permafrost solifluction slope in Svalbard (Harris et al. 2006) where moisture migration upwards and downwards during two-sided freezing had also left an ice poor central layer.

Rates of surface movement and displacement profiles

Table 1 shows surface displacement (at prototype scale) for each thaw depth during the one-sided and the two-sided experiment, based on time-lapse photographs of the displacement of one marker located in the center part of the model, where minimal boundary effects were expected. In the one-sided experiment, more than three-quarters of total displacement occurred during thaw of the uppermost 0.35 m, whereas in the two-sided experiment, most displacement occurred during thaw below 0.6 m. At these depths, highest ratios of displacement to thaw settlement were observed. However in the two-sided cycle, at depths between 0.2 to 0.6 m apparent upslope and downslope displacements were observed, which could have been caused by soil desiccation and crack formation during thaw progression into the relatively drier layers at these depths. From the displacement values in Table 1, and assuming that surface displacements were due to displacement of the thawed layer immediately

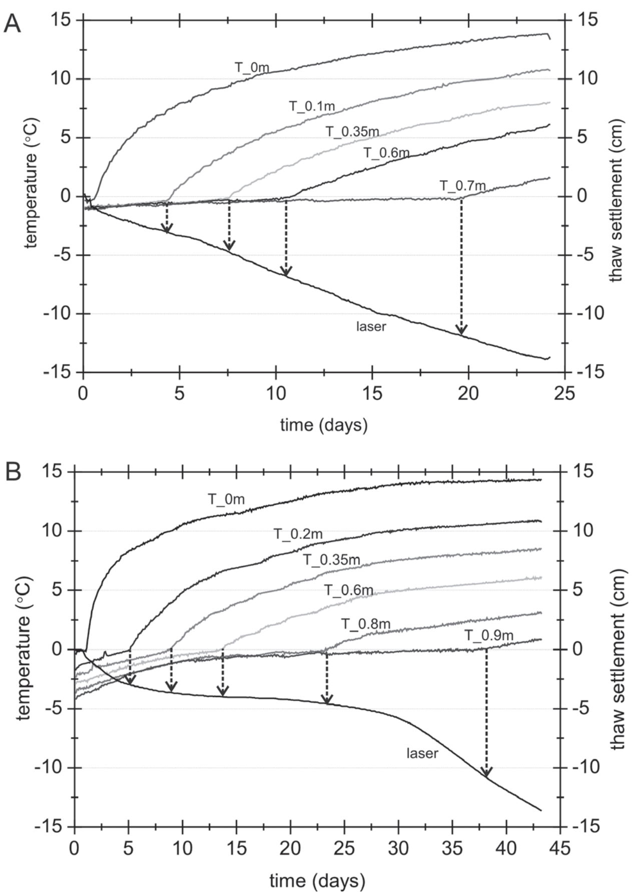

Figure 4. Temperature and settlement measured during thawing in the centrifuge for (A) the one-sided and (B) the two-sided experiment.

above the thaw front, subsurface displacement profiles were derived. Figure 5(a) shows profiles after one freeze-thaw cycle, (b) after five cycles of repeated freezing and thawing. The one-sided profiles show highest displacement near the surface, whereas in the two-sided experiment displacement occurs at deeper depths generating profiles similar to the plug-like movement of an active layer over an ice-rich basal shear zone as was described by Mackay (1981), Lewkowicz & Clarke (1998), and Matsuoka (2001).

Displacement columns were excavated after 5 freeze thaw cycles. Figure 6 shows an example for each experiment: the one-sided (a) and the two-sided (b). Although reflecting the generic shape of the calculated profiles (Fig. 5), the profile shapes exhibited by the columns also show some deviations especially for the two-sided experiment. This is due to the fact that the freezing cycles are not exactly reproducible: cycle-to-cycle variation in frost heave and depths of ice accumulation cause variation in total displacement and in the location of main displacement horizon (Fig. 6B). It should be noted that the active-layer thickness simulated in the two-sided freezing experiment was 9–10 cm model scale, 90–100 cm prototype. This is marked by an arrow in Figure 6B. Disturbance of the marker column below this depth reflects the final thawing of the model following the five-cycle experiment.

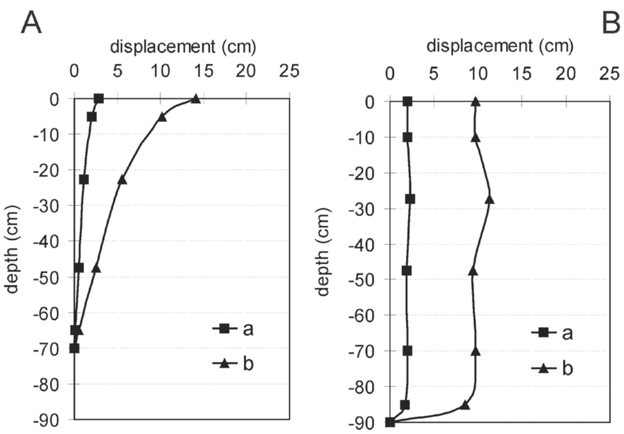

Figure 5. Calculated displacement profiles after (a) one freeze-thaw cycle and (b) five repeated cycles for (A) the one-sided and (B) the two-sided experiment.

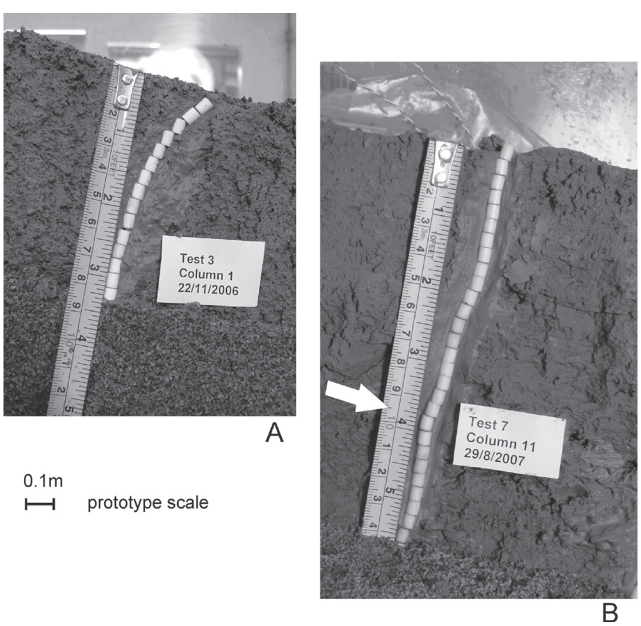

Figure 6. Observed subsurface displacement following five cycles for (A) the one-sided and (B) the two-sided experiment. The base of each column corresponds to the base of the model and top of the underlying sand layer.

Discussion

Subsurface displacement profiles resulting from the one-sided and two-sided experiments presented above exhibit significant differences regarding the depths where main displacement took place (Fig. 6). Matsuoka (2001) classified shapes of displacement profiles from field observations into four subgroups: needle ice creep, diurnal frost creep, annual frost creep with possible gelifluction, and plug-like flow. The typically convex shaped displacement profiles developed during five freeze-thaw cycles in our one-sided experiment (Fig. 6A) are similar to the one-sided seasonal freezing, gelifluction type of displacement profiles described by Matsuoka (2001). This profile shape typically originates from shear strain concentrated in the uppermost few centimeters to decimeters, depending on the duration of the freeze-thaw period which controls the depth of ice lens formation during freezing. In contrast, the two-sided experiments typically show concave-shaped profiles (Fig. 6B) similar to the plug-like displacement reported from cold permafrost areas where the basal active layer is ice-rich. In the two-sided freezing experiment (and in nature), the maximum summer active layer depth varied from cycle to cycle, leading to basal displacements occurring over a depth range of around 15 mm at model scale, or 15 cm at prototype scale, rather than being concentrated in one distinct layer. In general, the scaled experiments show similar shapes to those observed in full-scale experiments of one-sided and two-sided freezing and thawing (Harris et al., this volume). Scaled displacement rates and depths are in the same order of magnitude as field observations of solifluction in both seasonal frost and cold permafrost areas (see for instance Matsuoka & Hirakawa, 2000).

Conclusion

1. From these first results, we may conclude that the principle processes of solifluction associated with two-sided and one-sided active layer freezing were successfully physically modeled in small-scaled centrifuge experiments.
2. In the two-sided experiments, a distinct ice-poor intermediate layer was associated with very little thaw settlement downslope displacement.
3. Significantly different shapes of the one- and two-sided displacement profiles can be related to distribution of soil ice in the frozen models and subsequent consolidation during thaw. First qualitative comparisons indicate that scaled displacement rates and profile shapes are consistent with displacement profiles observed in field and full-scale laboratory experiments.
4. The geotechnical centrifuge modeling technique has proven an important tool for further systematic investigations of active layer behavior under controlled and repeatable conditions.
5. Further detailed validation through the principle of modeling of model analysis (Ko 1988) is in process and being produced in the near future.

6. Calibration and validation of numerical modeling with the scaled centrifuge physical modeling are in process, and further simulations of field monitoring and full-scale laboratory simulation experiments will be conducted.

Snow and Temperature Relationships on Polygonal Peat Plateaus, Churchill, Manitoba, Canada

G. Peter Kershaw
Department of Earth & Atmospheric Sciences, University of Alberta, Edmonton, AB, Canada, T6G 2E3

Abstract

Polygonal peat plateaus are a common landform in the Hudson Bay Lowlands and are diagnostic of continuous permafrost. The polygons are formed by ice wedge troughs that have different surface water and plant cover characteristics. In winter the low troughs accumulate more snow than the raised wind-deflated centers. This variation in snowpack drives temperature differences that can be dramatic. When thermokarst subsidence results from ice wedge melting, the snow accumulation is greater and the enhanced insulation traps more of the heat gained in summer. The mean annual temperature beneath the snow can rise above 0°C and the potential for a positive feedback occurs where further thermokarst subsidence traps more insulating snow. Ice wedges cease cracking and after degradation of the ice wedges, the raised polygon centres or baydjarakh have an external morphology that has resulted in them being mistakenly identified as palsas.

Keywords: baydjarakh; frost cracking; ice wedge polygon; microclimate; snowpack; temperature; thermokarst.

Introduction

Polygonal peat plateaus are relatively flat-topped features that have been dissected by ice wedge polygons and that often rise <2 m above the surrounding terrain (Brown 1970, van Everdingen 2005, Zoltai & Tarnocai 1975). The polygons are the ice wedge troughs that often have a different plant community from that which dominates the polygon centres.

One of the first descriptions of polygonal patterns was from Siberia by Figurin in 1823 (Washburn 1979). Since then they have been described from around the circumpolar North (French 1996, Mackay & Black 1973, Washburn 1979). They are formed by thermal contraction of the host sediments during winter followed by water entering the crack to freeze and form an ice veinlet that, given enough time for the cycle to repeat, develop into ice wedges (Fortier & Allard 2005, Fortier & Allard 2004, Kerfoot 1972, Lachenbruch 1966, Lachenbruch 1962, Leffingwell 1915, Mackay 1993, Mackay 1986, Mackay 1974, Mackay & Burn 2002, Mackay & MacKay 1974).

Thermal contraction has been observed with air temperature declines of 14°C d^{-1} over 34 h to 3.7°C d^{-1} over 102 h in peaty sands of northern Québec (Allard & Kasper 1998); 12°C d^{-1} over 18 h in peaty silts on Bylot Island, Nunavut (Fortier & Allard 2005); and 1.8°C d^{-1} over 96 h in ice-rich peat on islands in the Mackenzie Delta, NWT (Mackay 1993). In his 1993 paper Mackay concluded there was little correspondence between the mean daily air temperature and cracking of ice wedges; however, he noted that ice wedge cracking occurs when the mean minimum temperatures at 50 cm depth fall between -17°C and -23°C (the number and dates of readings were not specified).

Several factors can affect the magnitude and frequency of cracking, but there is a consensus that snowpack is a critical variable. One must be careful since in some studies the polygons are low-centered so that the snow insulates the polygon centres as well as the depressed ice wedge troughs (Allard & Kasper 1998, Fortier & Allard 2005). In high-centered polygons such as those at Churchill, the snowpack is thinner in the centers than the bordering ice wedge troughs. In general, a deeper, more continuous and long-lasting snowpack will insulate the ground against heat loss in winter (Goodrich 1982, Nicholson & Granberg 1973, Smith 1975).

Study area

The study features were ~2 km apart at similar elevation (~15 m a.s.l.) (Fig. 1). They were within the forest-tundra ecotone between the open forest and tundra near the Churchill Northern Studies Centre.

Excavations at one site in 1997 revealed ice nipples (Péwé 1962) extending from the tops of the larger ice wedges. These secondary wedges were more vein shaped—consistently ~2 cm thick and extending approximately 15 cm above the main wedge. Due to their morphology and lack of indications of

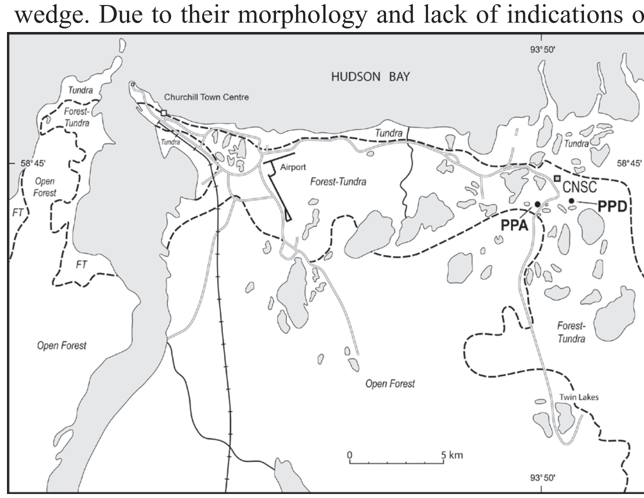

Figure 1. The study features were ~20 km east of the town of Churchill. Polygonal peat plateaus with degrading ice wedges (PPD) and aggrading ice wedges (PPA) were ~2 km south of the Churchill Northern Studies Centre (CNSC).

rapid peat accumulation, they were interpreted as evidence of active layer thinning and so can be classified as epigenetic ice wedges (Dostovalov & Popov 1966, French et al. 1982, Mackay 1974). The shallow (~20 cm) depressions over the ice wedges and the ice nipples are evidence of permafrost aggradation (Mackay 1976).

The ice wedges at the other site were degrading, as evidenced by the linear thermokarst depressions (0.8–1.5 m deep and 2–7 m wide) surrounding isolated remnant polygon centres (baydjarakhs). As with the aggrading site, the polygon centers were at the same height and flat topped. However, at the degrading site, the edges of intact and former ice wedge troughs were steep-sided, ending in a sedge wetland. When viewed from the air, the pattern of the original ice wedges was clearly polygonal. At both sites the polygons were 5–10 m in diameter. In 1997, and annually since 2002, ground-penetrating radar and coring at both sites have confirmed the presence of ice wedges within frozen peat of 1.25–2.5 m depth overlying marine sediments (clasts imbedded in a silty clay matrix) topped by a thin to 15 cm layer of poorly-decomposed marine algae. Coring confirms that the peat is dominantly well-decomposed to poorly-decomposed sedge peat with minor amounts of fine woody material, probably dwarf shrubs. Given the isostatic history (Dredge 1992), internal characteristics, basal marine algae deposits, and setting, the site history is probably much like reported for similar polygonal peat plateaus on Devon Island (Somr & King 1990).

Thaw depths were measured with a graduated probe in October 2007 at both sites. The polygon centers had 45.7 (n = 98) and 41.6 (n = 108) cm active layer on the polygonal peat plateau degrading and aggrading respectively. The mean active layer depth on the ice wedges at the aggrading peat plateau was 37 (n = 20) cm. Thaw depth in the troughs around the baydjarakhs could not be reliably determined since the underlying marine sediments were stony which prevented deep probing. Ground-penetrating radar surveys suggest a 10 to 12 m active layer between the remnant polygon centers.

In most cases the raised polygon centers were dominated by lichens (*Alectoria nigricans, A. ochroleuca, Cetraria nivalis, C. cucullata, Cladina* spp. and *Cladonia* spp.), dwarf ericaceous shrubs (*Ledum decumbens, Rhododendron lapponicum*) and the forb *Rubus chamaemorus*. The depressed ice wedge troughs on the aggrading permafrost site were dominated by mosses (*Sphagnum* spp. and *Dicranum* spp.), *Betula glandulosa*, *L. decumbens, Rubus chamaemorus* and *Salix* spp. On the degrading permafrost site the drier subsided troughs have similar plant cover to the aggrading site but where they extend to the water table the plants are dominated by wetland species (*Calliergon* spp. and *Carex aquatilis*).

Methods

Midwinter snowpack surveys were conducted over eight days in February each year from 2002 to 2007. Although the data collection included full snowpit stratigraphic descriptions, the data presented here are from the snow core (Adirondack) sampling. Sampling was stratified by microsite on the two polygonal peat plateaus–polygon centre and wedge troughs. Annual sample sizes varied between 30 and 132 and over the six years a total of 475 to 558 samples were taken on the four microsites–polygon centres and ice wedge troughs at both the aggrading and degrading polygonal peat plateaus.

Temperature was monitored with Campbell Scientific International CR10X data loggers and type T thermocouples connected through a multiplexer in the enclosure with the logger (AM416 or AM16/32) with reference junction on the 10X wiring panel. Readings were taken every 5 min with the mean daily temperature used in this analysis. Air temperature was recorded at 1.5 m height while surface temperatures were at 0 cm, shielded by moss or lichen. Near-surface permafrost temperature was measured at 80 cm depth; however, at the degrading permafrost site the sensor was severed by an animal after installation so no mean could be calculated for 2004.

A microclimate station was installed at the aggrading polygonal peat plateau in June 2001 and at the degrading polygonal peat plateau in June 2003. Mean annual temperatures were calculated for only those years where there was a full record: 2002–2006 and 2004–2006 for the aggrading and degrading sites, respectively.

A synthetic value was derived to facilitate comparison of the potential for heat conduction through the snowpack (Kershaw 2001). The Heat Transfer Coefficient (HTC) uses depth and density to estimate the potential heat loss from the soil; higher values indicate greater heat conduction and less insulation.

$$\mathrm{HTC} = k/d \quad (1)$$

where k is the thermal conductivity (Abel's 1893) of the snowpack and d is the snowpack depth

$$k = (2.94\ 10^{-6}\ \mathrm{W\ m^{-1}\ °K^{-1}})(\rho)^2 \quad (2)$$

where ρ is snowpack density (kg m^{-3})

Mean annual temperatures were calculated from the daily means during the year. Freezing degree-day totals were calculated by accumulating the mean daily values <0°C for the year.

Results

Interannual snowpack characteristics of depth and the potential for heat conduction were rarely significantly different (Figs. 2, 4). Consequently, comparisons among microsites were made with means of the six years of data.

Snowpack depth

Comparing microsites, snowpack depth varied little among years (Fig. 2). However, there were great differences between polygon centres and ice wedge troughs at both study sites. In the subsided ice wedge troughs at the degrading

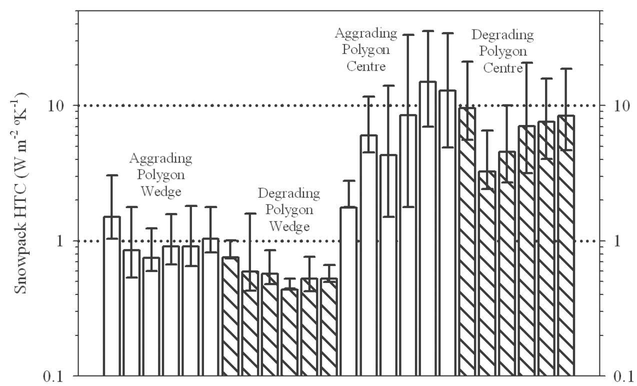

Figure 4. Midwinter snowpack heat transfer coefficient (HTC) (2002–2007) for the two ice wedge troughs and polygon centres on aggrading and degrading polygonal peat plateaus. Mean with capped lines for median (bottom) and standard deviation (top).

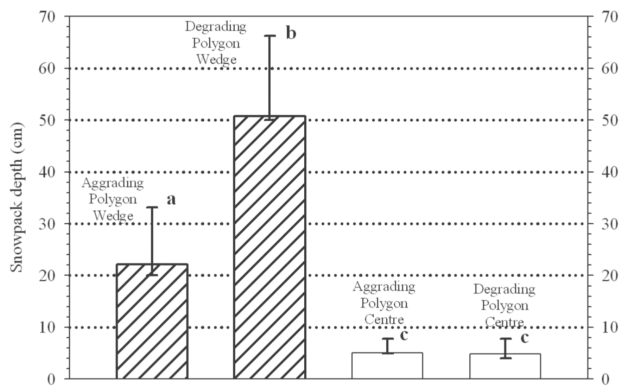

Figure 3. Midwinter snowpack depth (mean of six years) for the two ice wedge troughs and polygon centres on aggrading and degrading polygonal peat plateaus. Mean with capped lines for median (bottom) and standard deviation (top). Significantly different ($p < 0.05$) values have different letters.

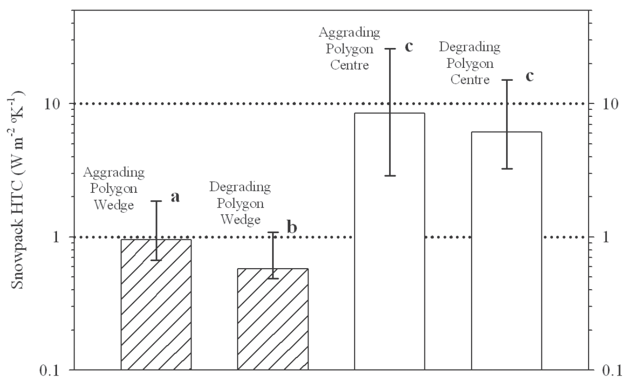

Figure 5. Midwinter snowpack heat transfer coefficient (HTC) (mean of six years) for the two ice wedge troughs and polygon centres on aggrading and degrading polygonal peat plateaus. Mean with capped lines for median (bottom) and standard deviation (top). Significantly different ($p < 0.05$) values have different letters.

polygonal peat plateau there was ~10x more snow than on the adjacent polygon centres. At the aggrading polygonal peat plateau there was 4x–5x more snow in the troughs. The polygon centre snowpack was similar between the two sites while the ice wedge troughs had significantly deeper snow (Fig. 3).

Snowpack heat conduction

Regardless of the year, there was ~10x higher potential for heat loss from the polygon centers compared to the adjacent ice wedge troughs (Fig. 4). The potential for heat loss from the wedge troughs on the degraded peat plateau was 40% lower that on the aggrading features (Fig. 5).

Temperature characteristics

Except for 2004, the mean annual air temperature was similar for the two sites (Fig. 6). Both the mean annual polygon centre surface temperatures and the near-surface permafrost temperatures were very similar. However, the mean annual surface temperatures of the ice wedge troughs differed by 5.5 to 6.5°C with the degrading ice wedges having mean annual temperatures well above 0°C at 2 and 3.5°C.

Freezing degree-days were greatest in 2004 and least in 2006 (Fig. 7). The polygon centres and the near-surface permafrost had similar values. Despite similar air temperatures, the ice wedge troughs were much colder on the aggrading peat plateau.

Discussion

The two study sites were close enough to share the same climatic characteristics and yet differed greatly in their geomorphic status—aggrading vs. degrading permafrost.

Snowpack – temperature relations

Snowpack on the polygon centres was similar in depth and potential heat conduction on the two sites (Figs. 3, 5). As a result, their surface temperature characteristics were similar with the same freezing degree-day totals (Figs. 6, 7). The mean annual temperature of the near-surface permafrost differed by only 0.2°C (Fig. 6).

The main difference between the sites was the snowpack and temperature characteristics of the ice wedge troughs. With at least double the snowpack and almost half the heat conduction, the degrading ice wedges had mean annual

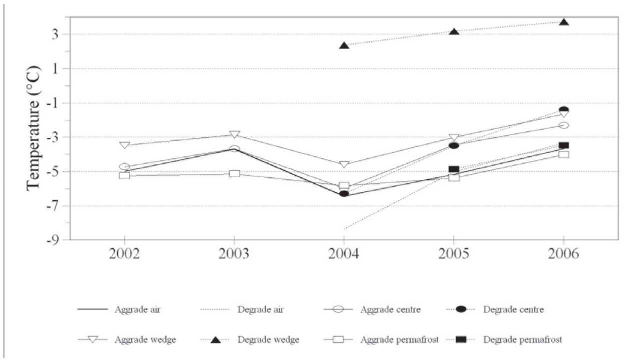

Figure 6. Mean annual temperature on polygonal peat plateau with aggrading permafrost (Aggrade) and degrading permafrost (Degrade). Temperatures measured at 150 cm height (air), ground surface of polygon ice-wedge trough (wedge) and ground surface of polygon centre (centre).

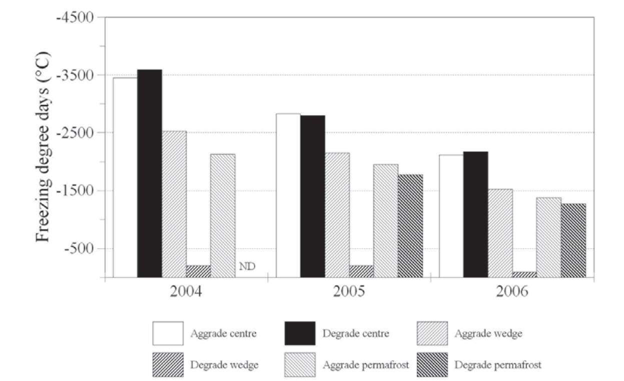

Figure 7. Accumulated freezing degree-days (<0ºC) on polygonal peat plateaus with aggrading permafrost (Aggrade) and degrading permafrost (Degrade). Temperatures measured at 150 cm height (Air), ground surface of polygon ice wedge trough (wedge) and ground surface of polygon centre (centre). No 2004 data available for near-surface permafrost on the degrading peat plateau.

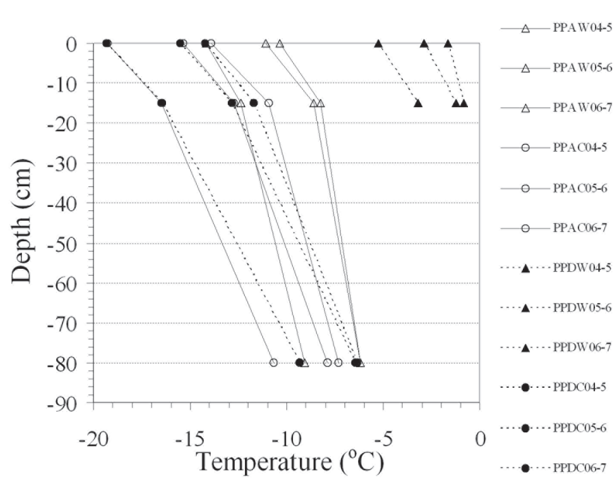

Figure 8. November to March mean temperatures for three winters (2004–2007) on polygonal peat plateaus with aggrading (PPA) and degrading (PPD) ice wedges (W) and their associated polygon centres (C). Measurements at the ground surface, 15 and 80 cm depth except for depressions associated with degraded ice wedges (PPDW).

surface temperatures above 0°C (Fig. 6). Winter temperatures (November–March) confirm that the degrading wedges were warmer than the polygon centres and the wedges on the aggrading site (Fig. 8). There was an average gradient of between 6.6°C and 10°C between the ground surface and 80 cm depth on the polygon centres.

The plant cover and near-surface peat characteristics were similar at both sites on the polygon centres but differed on the adjacent ice wedge troughs. The polygon centres had a thin snowpack with high heat conduction potential and consequently surface temperatures were similar to the air (Figs. 3, 5, 6). In 2003 open thermal contraction cracks were observed on the aggrading site but no cracks have ever been found at the degrading site. With no difference in polygon centre characteristics it must be the ice wedge trough characteristics that allow cracking to occur and the degrading site no longer possess these characteristics. The snowpack characteristics appear to set the limits to thermal contraction cracking.

Geomorphic implications

It is clear that the current state of the features is heavily influenced by surface topography interactions with snowpack and its thermal characteristics.

At the degrading site, it appears that a threshold has been achieved in the thermokarst depressions whereby thermal-contraction cracking has ceased. The snowpack prevents the magnitude and rate of cooling required for cracking of the residual ice wedges. It is also the case that many of the ice wedges have completely melted (Fig. 9). As thermokarst subsidence occurs the trough's ability to trap insulating snow increases and winter soil heat loss declines. Further degradation of the ice wedges eventually drops the surface to that of the surrounding fen and the local water table. The snow insulates so effectively that the mean annual temperature was from 7°C to 10.7°C warmer beneath the snow resulting in a mean annual surface temperature that was well above 0°C (Fig. 7). In contrast, on the aggrading site the difference was 1.9°C to 2.2°C with the mean annual surface temperature well below 0°C (Fig. 7).

Between ice wedge aggradation and complete degradation, there is a shift in snowpack characteristics over the wedges from offering little resistance to heat loss to effective insulation. At Churchill the study features provide examples of the two endpoints of this continuum. Given the dramatic differences between the two sites it might be that the switch between the two states occurred abruptly (a few years) after a threshold of snow thermal properties was achieved.

Conclusions

Two polygonal peat plateaus that were <2 km apart had similar plant cover, internal composition and mesoclimate; however, they differed in that one had degrading while the other had aggrading ice wedges. The ice wedge troughs in the baydjarakh field were often >1 m deeper than the aggrading site due to thermokarst subsidence.

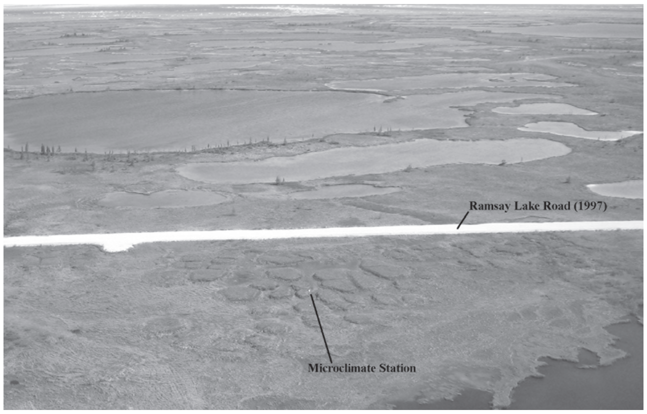

Figure 9. The former ice wedge pattern is still apparent at the degrading ice wedge site. The baydjarakh field developed as the original ice wedges degraded several decades prior to the construction of the Ramsay Lake Road. Hudson Bay is visible on the horizon.

The midwinter snowpack over the degrading ice wedges insulated against heat loss to the extent that the mean annual temperature was 2°C to 3°C above 0°C. Under these circumstances the ice wedges cannot reform. A new paradigm prevails at this site where the residual polygon centers remain elevated with shallow active layers and internal temperatures similar to the aggrading ice wedge site. The thermal contraction that would normally cause ice wedge cracking can occur on the raised mound of the residual polygon centre without affecting the area that surrounds it and which is under >50 cm of insulating snow. Under these circumstances the raised polygon centres are stable unless other processes such as change in plant cover or deflation of the peat lead to a change in their thermal state.

The residual polygon centres or baydjarakh (Czudek & Demek 1970) have been locally incorrectly identified as palsas. Their external morphology resemble palsas but their origin precludes this classification (van Everdingen 2005).

Polygonal peat plateaus are ubiquitous in the Hudson Bay Lowland (Dredge & Mott 2003) and are common throughout the rest of Canada (Tarnocai & Zoltai 1988, Zoltai et al. 1988). They are also common in Russia (Romanovskij 1985). Where they are sustaining thermokarst subsidence, interactions with increasing snowpack and its ability to trap summer heat could amplify the degradation process to the point that the ice wedges completely melt out. This positive feedback would be arrested if the polygon centre was lowered through such processes as deflation of the peat by wind (Seppälä 2004). However, it appears that progression of the process to a point whereby the ice wedges completely degrade is facilitated by snowpack interactions. In the area where polygonal peat plateaus are common and where future climate warming starts thermokarst subsidence, snowpack feedbacks could amplify the process and accelerate the effects of climate warming.

Acknowledgments

Earthwatch Institute volunteer teams along with students from the University of Alberta and Churchill Northern Studies Centre staff collected the snowpack data. In 1997 Dr. Michel Allard and Stewart Brown conducted initial excavations of the ice wedges and the first GPR surveys. Funding for this research has been through Earthwatch Institute, Churchill Northern Studies Centre, NSERC, IPY PPS Arctic Canada, and Canadian Circumpolar Institute.

Changes in Surface Topography and Active Layer Following Partial Gravel Removal in the Prudhoe Bay Oilfield, Alaska

Janet G. Kidd
ABR, Inc. – Environmental Research & Services, Fairbanks, AK, USA

Abstract

To promote the development of wetland plant communities on abandoned sites in the Prudhoe Bay Oilfield, Alaska, gravel has been partially removed to create suitable soil and hydrological conditions. This study focused on changes in surface topography and thermal regime following gravel removal at 6 sites over the past 17 years. We established transects across each site to monitor the relative surface elevation and depth of the active layer. The sites range in age from 4–16 years, and the depth of residual gravel fill varies from 8–60 cm. Results varied widely among the sites surveyed, with changes in surface topography and thaw depth ranging from minimal to extensive. In some cases, thaw settlement continued for more than 15 years after gravel removal. The deep thaw penetration likely was preserved due to the absence of an insulative surface organic mat. Despite the potential for promoting thermokarst, gravel removal is an effective approach for creating wetland ecosystems on disturbed sites.

Keywords: active layer; gravel fill; relative surface elevation; thaw depth; thermokarst; wetlands.

Introduction

Over the past 30 years, research has been conducted in the Prudhoe Bay Oilfield to develop strategies for rehabilitating land disturbed by oil extraction and oilfield operations (e.g., Mitchell 1979, Moore & Wright 1991, unpubl., McKendrick 1991, Jorgenson & Joyce 1994, Jorgenson 1997, Jorgenson et al. 2003a). Part of this effort has involved assessing the potential for restoring tundra wetland plant communities by removing gravel from abandoned sites and applying plant materials (Jorgenson & Joyce 1994, Kidd et al. 2004, 2006). Removing the gravel reestablishes a hydrologic connection with adjacent, undisturbed tundra communities and improves site characteristics for plant establishment and growth.

Although gravel removal can help facilitate the restoration of wetland plant communities on disturbed sites, the disruption of the thermal regime following gravel removal, and the resulting subsidence, can limit vegetation recovery in some cases (Jorgenson & Joyce 1995, Kidd et al. 2004, 2006). The absence of a thick, insulative gravel layer or tundra vegetative mat subjects the underlying permafrost to melting. In some cases, ponding is extensive, with water levels too deep to support emergent plant species. Compression of the underlying tundra soil by the weight of gravel fill also can result in the creation of impoundments (Kidd et al. 2004). When the gravel is removed, the depression that remains promotes the impoundment of water, which can further promote thaw subsidence by conducting and convecting heat away from the ground (Hopkins 1949).

To better predict the extent of changes in surface topography and permafrost following gravel removal and the effect on restoration efforts, we surveyed the relative surface elevation and depth of the active layer (thaw depth) of 6 gravel removal sites in the Prudhoe Bay Oilfield. The sites range in age from 4–16 years and include abandoned airstrips, access roads, an operations pad, and an exploratory well site (Fig. 1).

The survey sites are located in a variety of landscape settings, including Old Alluvial and Alluvial-Marine terraces and Basin Complexes (Jorgenson et al. 2003b, unpubl.). Adjacent plant communities include Moist Sedge-Shrub Tundra, Fresh Sedge and Grass Marsh, and Wet Sedge Meadow Tundra. Dominant plant species are *Carex aquatilis*, *C. bigelowii*, *Eriophorum* spp., *Arctophila fulva*, and *Salix* spp. Large waterbodies also are present near many of the sites. Based on data collected at Deadhorse and Prudhoe Bay (1990–2007), mean annual air temperature in the study area is -11°C, and mean annual total precipitation is 17.6 cm (National Climate Data Center 2007). The mean depth of the active layer in tundra ranges from 30.5–60.6 cm, based on measurements collected near West Dock (Fig. 1) and Deadhorse (1995–2005) (Streletskiy et al. 2008).

Methods

Prior to gravel removal, the gravel fill thickness at all sites was approximately 1.5 m, which is typical for roads and pads in the Prudhoe Bay Oilfield. After gravel removal, the residual gravel fill thickness ranged from 8–60 cm, except at the North Prudhoe Bay State No. 2 Exploratory Well Site (hereafter referred to as North State 2) and the Mobil W/Z airstrip. Shallow and deep basins were excavated in portions of these sites, resulting in complete gravel removal. Gravel was removed in winter or early spring, and the following summer, various plant cultivation treatments were applied. Treatments included applying fertilizer alone, seeding native-grass cultivars, transplanting tundra plugs, and seeding indigenous (locally collected) species. Fertilizer was applied with all the planting treatments. At one site, an area was left untreated as a control. Note that not all of the treatments listed above were applied at each site.

Relative surface elevations and thaw depths were measured from 1990–2006 along permanent transects established in each gravel removal area. The transects varied in number

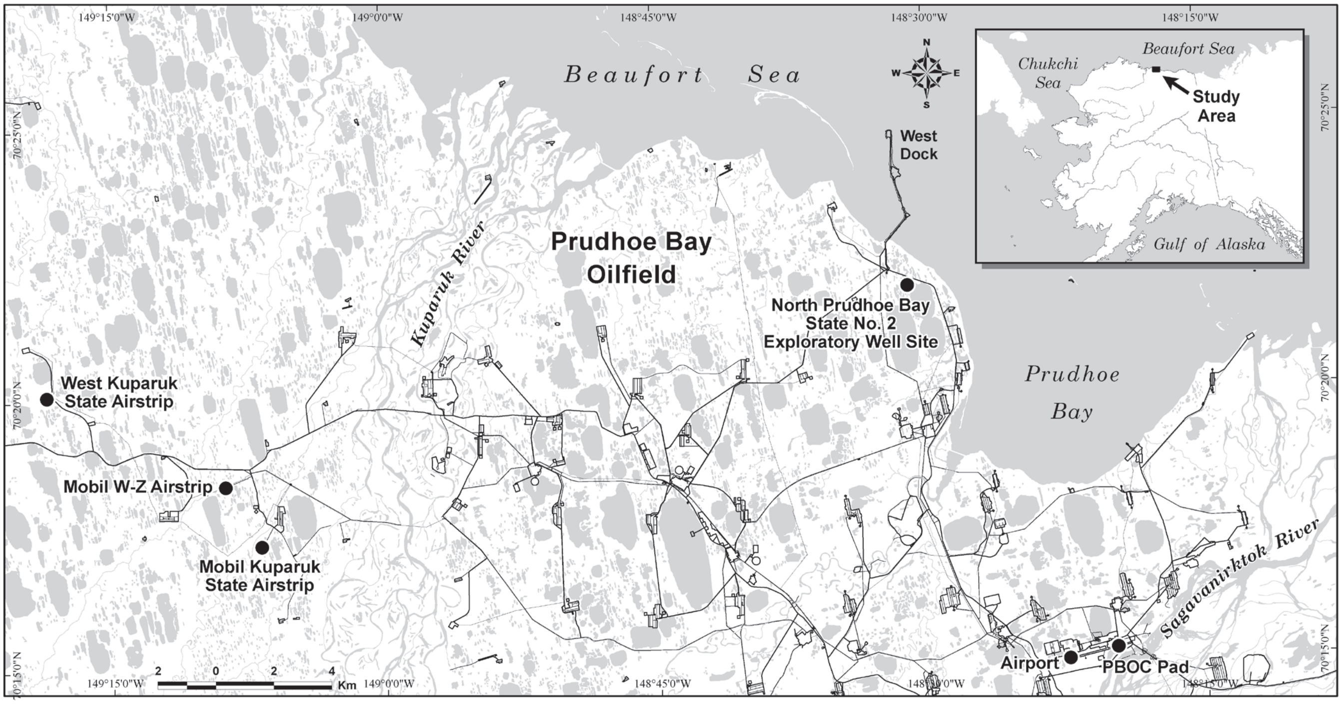

Figure 1. Locations of gravel removal sites surveyed for surface elevation and thaw depth, Prudhoe Bay Oilfield, Alaska, USA, 1990–2006.

and length, depending on the size of each site, and extended into the adjacent, undisturbed tundra approximately 5–10 m. Elevations were recorded at 1–2 m intervals along a meter tape using an auto-level or a laser level and survey rod. Thaw depths generally were measured every 5 m to the depth of resistance using a steel probe, which follows the methodology used in the Circumpolar Active Layer Monitoring (CALM) Program (Nelson et al. 1996). Additional thaw-depth measurements were made at prominent terrain breaks in the gravel removal areas and in the adjacent, undisturbed tundra in later years. The surveys were conducted in early to mid-August. Permanent benchmarks were not available at each location, so elevations were tied to the mean surface elevation of the adjacent, undisturbed tundra. Collection of geotechnical and ground temperature data was beyond the scope of this study.

Results and Discussion

Changes in surface elevation and thaw depth following gravel removal varied widely among the 6 sites surveyed, and were independent of site age (Figs. 2–5 & 7; Table 1). The greatest thaw settlement measured occurred at Mobil Kuparuk State Airstrip (-0.55 m, Fig. 2), where only 4 years had lapsed since gravel removal. In contrast, at North State 2, the southern transect only subsided 0.15 m in the 16-year period following gravel removal (Fig. 3). The topography of the 2 basins excavated also changed very little during this period. Changes in surface elevation on the northern transect were more notable, and included the development of several deep ponds.

The presence of deep troughs and depressions at Mobil Kuparuk Airstrip, the northern transect at North State 2, the Airport (Road 2, Fig. 4), and PBOC Pad (Fig. 5), indicate that ice wedges are present and in the process of melting. Flooded polygons form in response to the thawing wedges and are particularly evident at the Airport (Fig. 6). Elsewhere, more moderate subsidence has occurred (Fig.7), although the active layer is deep at all sites. Mean thaw depths range from 0.7–1.2 m (Table 1) and have yet to stabilize, even at the oldest sites (Airport, PBOC, North State 2). Mean thaw

depth in adjacent, undisturbed tundra in 2006 ranged from 0.49 m (± 0.02 m, n = 35) at Mobil W-Z to 0.73 m (± 0.03 m, n = 8) at the Airport.

The thawing and subsequent settlement of ice wedges at some of the sites is consistent with what has been observed elsewhere in terrain with similar characteristics. The 3 airstrips and the Airport access roads are all located in fine-grained, abandoned floodplain deposits, which are known to be ice rich (Jorgenson et al., 1996, unpublished). Compared with other terrain units in the region, the alluvial marine deposits associated with North State 2 are known to have some of the highest volumes of both ground and wedge ice (Pullman et al. 2007); this partly explains the extensive thermokarst on the northern half of the site. The southern

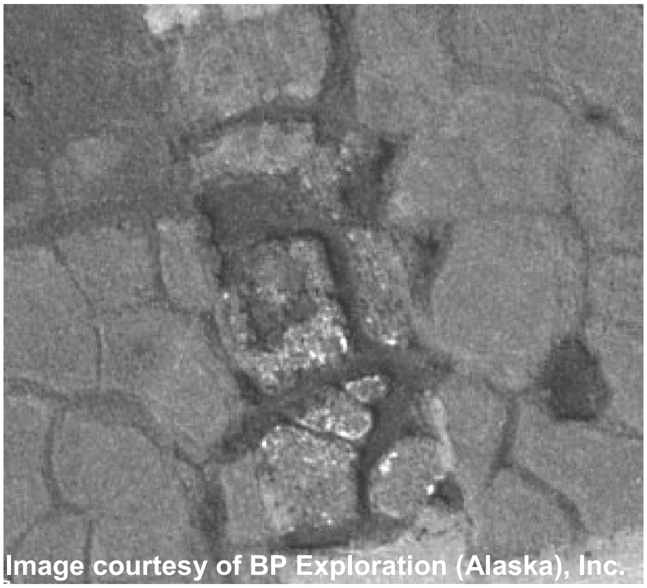

Figure 6. Aerial view of Road 3, Airport, showing deep, flooded polygon troughs, 2006.

half has experienced considerably less thaw settlement, however, suggesting that the processes governing surface stability at North State 2 are complex. The site is located in an old drained-lake basin, and the uneven thermokarst pattern probably reflects an irregular distribution of wedge ice in the sediments.

The differential settlement reveals the importance of varying types of ice. The settlement in the polygon centers between the ice wedges, which have varying forms of segregated ice, usually was only 10–30 cm. This is consistent with the thaw settlement estimates of 8–53 cm for a range of terrain types (Pullman et al. 2007). Settlement of the centers probably has achieved equilibrium with the new surface thermal regime. In contrast, the surface over ice wedges settled as much as 1.5 m. Ice wedges are particularly sensitive to disturbance (and climate change) because the wedge ice lies immediately below the active layer, and thus, there is little additional soil that can be thawed and added to the active layer to achieve a new stable equilibrium (Jorgenson et al. 2006). In addition, impoundment of water provides a positive feedback on heat gain and melting of ice. Jorgenson et al. (2006) found that aquatic sedges can rapidly colonize and stabilize the troughs within 30–50 yr, but troughs in the gravel removal areas are slow to vegetate. Consequently, they may be slower to stabilize until the wedge ice is almost completely melted out.

The absence of a deep organic soil layer has probably also played an important role in the maintenance of deep active layers and continued thaw settlement at these sites. Although productive communities of mosses and vascular plants have established in some of the treatment areas at the oldest sites, soil development has been minimal. The top 15–60 cm is still composed almost exclusively of coarse gravel, with varying amounts of sand. In addition,

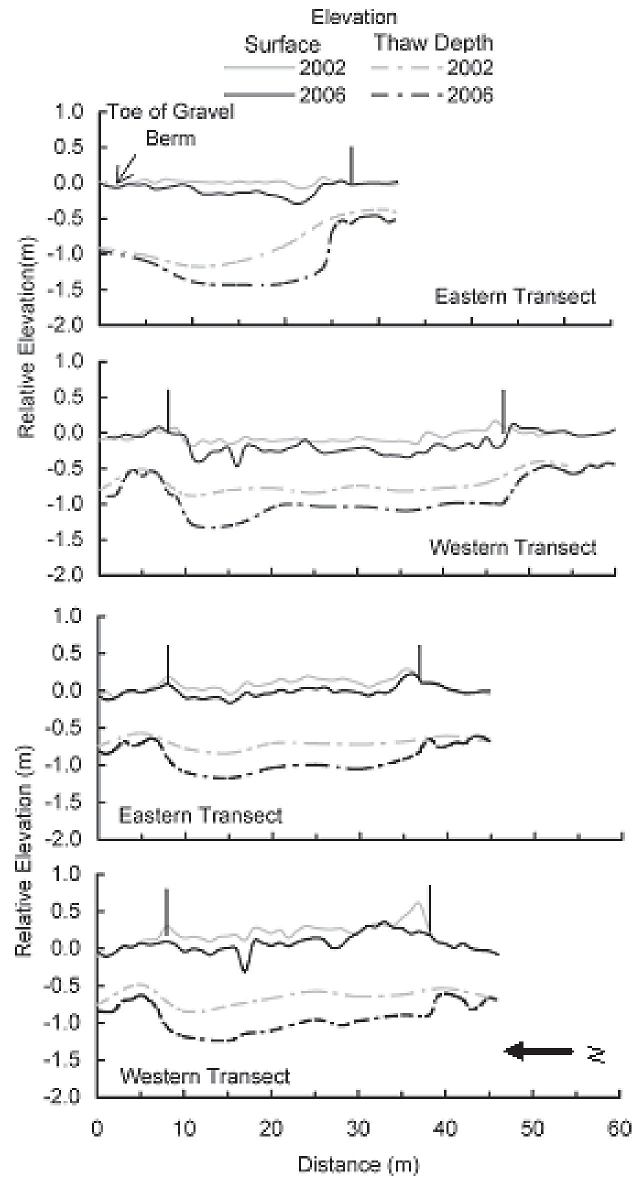

Figure 7. Profiles of relative surface and thaw depth elevation across Mobil W-Z (a) and West Kuparuk State (b) airstrips, 2002 and 2006. Brackets indicate boundaries between gravel removal areas and adjacent, undisturbed tundra.

plants have been unable to establish in deep ponds and troughs. As a result, during the relatively warm summers, heat can penetrate deeply into the exposed soil. The soils are saturated, and the high water content also serves as an excellent conductor of heat. Given the poor soil conditions and short growing season of the Arctic, it likely will be several decades before a sufficient moss and sedge peat mat develops on these sites to effectively insulate the soil. Consequently, we can expect that the volume of wedge ice will be substantially reduced before the sites become thermally stable.

Conclusions

The results of long-term monitoring of surface stability and permafrost of gravel removal sites indicate that the observed changes in the thermal regime are long lasting and should be considered when planning land rehabilitation efforts to promote vegetation recovery. At sites where the probability of extensive thermokarst and thaw settlement occurring is high, the application of plant-cultivation treatments should be postponed until conditions are relatively stable. This delay will allow plant materials to be established in areas where conditions are likely to remain suitable over the long term. This effort can be assisted by assessing the terrain characteristics and the pattern of change in surface topography at each site following gravel removal. For many sites, the network of ponds and troughs that form is apparent relatively soon after gravel removal (within the first 3 years), although determining the ultimate water depth of ponds and troughs is more challenging.

Despite the potential for promoting thermokarst, gravel removal is an effective approach for creating wetland ecosystems on disturbed sites, for several reasons. First, a hydrologic connection with the adjacent, undisturbed tundra is established, facilitating the exchange of nutrients, seeds, plant propagules, and soil microbes. Second, the wetland hydrology encourages colonization by tundra plant species, primarily sedges and grasses. Finally, the heterogeneous surface topography that results from thermokarst creates a range of site conditions from moist to wet to ponded, allowing for the establishment of a diversity of plant species, with varying life-history characteristics. This diversity helps ensure some plasticity in the plant communities that establish, allowing them to respond to changing surface conditions while the thermal regime stabilizes. A potential concern is that the thermokarst associated with gravel removal sites might destabilize adjacent areas. However, although some thaw settlement is evident along the margins of gravel removal sites, we have not observed any dramatic changes in the surface stability of these areas.

Acknowledgments

Funding for this study was provided by BP Exploration (Alaska), Inc., and managed by Bill Streever, Environmental Studies Leader. Initial financial support for data collection was provided by ARCO Alaska, Inc. Torre Jorgenson designed the land rehabilitation studies that are the sources of the long-term datasets and provided a valuable technical review. Sue Bishop assisted with fieldwork and reviewed the manuscript. Additional field support and graphical assistance was provided by Tim Cater, Kate Beattie, and Allison Zusi-Cobb.

Abstract

Excessive moisture is regarded as the main cause for the fall of Pleistocene tundra-steppe and the rise of modern tundra. The arctic tundra of Oyogos Yar is low in diverse plant species (ca 100). The floral composition is mainly the result of differences in moisture or drainage, respectively. We describe a vegetational profile recorded in August 2007 along a 10 km transect from the top of a yedoma ridge down to the adjacent alas depression between 40 m to 10 m a.s.l. Six main landscape units are described with respect to their floristic composition: yedoma top with thermokarst mounds, mud boils, yedoma slopes, small thermokarst ponds, thermo-erosional valleys, and the bottom of thermokarst depressions. Arctic thermokarst landscapes with yedoma ridges and alas depressions can be well-classified according to their vegetation. The main constituents of the plant cover at well-drained sites are grasses and polar willows, whereas excessively wet sites are occupied by sedges, cotton grass, and peat moss.

Keywords: alas depression; bioindication; moisture regime; thermokarst; tundra vegetation; yedoma elevation.

Introduction

The arctic vegetation cover reflects very well the small-scale periglacial landscape differentiation. Detailed surveys of plant associations are essential for the understanding of biotic responses to changes in permafrost landscapes. Around Beringia, the great influence of topography on arctic vegetation has been described from Alaska (Walker 2000, Kade et al. 2005) and from the Taymyr Peninsula (Matveyeva 1994). Such studies of modern tundra vegetation are, however, little-known from Arctic Yakutia. Within the frame of the joint Russian-German expedition, “Lena–New Siberian Islands 2007,” we studied relief-vegetation interactions at the coast of the Dimitrii Laptev Strait in August 2007.

Regional Setting

Oyogos Yar is the name of the mainland coast of the Dimitrii Laptev Strait (Fig. 1) between the mouth of the Kondrat’eva River in the east and Cape Svyatoy Nos in the west. This landscape is part of the Yana-Indigirka Lowland in Northeastern Siberia. Up to 500 m thick continuous permafrost and wide spread thermokarst characterize the coastal lowland. Oyogos Yar’s topography is dominated by extremely flat plains covered by mires and shallow lakes.

There are two main topographic elements: low elevations, so-called yedoma, which represent the Pleistocene ground level, and thermokarst depressions (alases), which formed as a result of thermal degradation of the ice-rich permafrost that constitutes the yedoma.

According to Aleksandrova (1980), Oyogos Yar belongs to the Sellyakh Inlet–Indigirka Delta district of the East Siberian province of the southern arctic tundra characterized by the dominance of *Alopecurus alpinus* and *Salix polaris*, the presence of *Carex ensifolia* ssp. *Arctisibirica,* and the absence of subarctic elements like *Betula nana* s.l. According to the Circumpolar Arctic vegetation map (CAVM Team 2003), the study area is covered with sedge/grass, moss wetland (W1) with *Carex aquatilis*, *Arctophila fulva*, *Dupontia*, and *Eriophorum* spp.

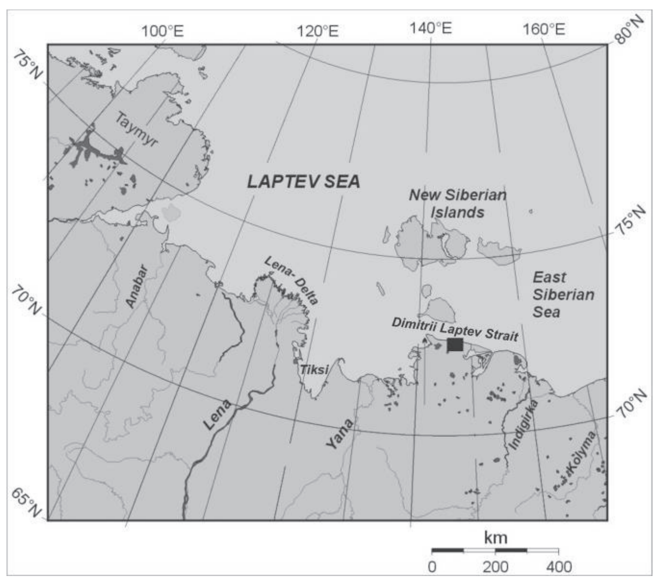

Figure 1. Position of the study area (black square corresponds to Fig. 2) at the mainland coast of the Dimitrii Laptev Strait.

The study area is located about 8 km west of the Kondrat’eva River mouth (Fig. 2) opposite to Cape

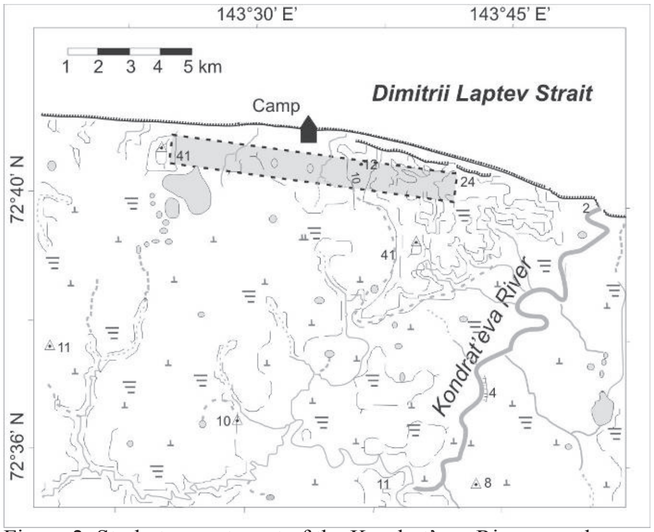

Figure 2. Study transect west of the Kondrat'eva River mouth.

Shalaurova, the eastern edge of Bol'shoy Lyakhovsky Island. The climate is characterized by cold winters, cool summers, and low precipitation. Climate data from the weather station Cape Shalaurova, about 80 km north of the study site, reflect a mean July air temperature of 2.8°C, a mean January air temperature of -32.2°C, and an annual precipitation of 253 mm (Rivas-Martínez 1996–2004).

Site Description

The study transect extends across the bottom of a large alas depression about 10 km in diameter (5 to 10 m a.s.l.) and the adjacent slope and top areas of a yedoma hill of up to 40 m in height (Figs. 2, 3). The alas bottom dominantly consists of polygonal wetland tundra with a 0.5 to 1.0 m thick peat cover. The thermokarst depression is cut by the coast of the Dimitrii Laptev Strait in the north, and additionally intersected by several thermo-erosional valleys that drained to the coast.

Within the recorded transect, the following six main landscape units are described with respect to their floristic composition: the yedoma with thermokarst mounds, mud boils, yedoma slopes, small thermokarst ponds, thermo-erosional valleys, and the bottom of thermokarst depressions.

Vegetation Characteristics

Thermokarst mounds on the yedoma

Thermokarst mounds are the best-drained habitats in the study area (Fig. 4). Their plant cover is mainly composed of *Salix polaris*, *Dryas punctata,* and *Alopecurus alpinus*. Other grasses, such as *Festuca brachyphylla* and *Deschampsia borealis,* and dicots, like *Potentilla hyparctica, Oxyria digyna, Papaver polare,* and *Valeriana subcapitata,* also occur.

Mud boils

Mud boils are the result of cryoturbation caused by frost pressing. In consequence, muddy soil flooded the ground.

Figure 3. View from the alas bottom to the yedoma hill.

Figure 4. Thermokarst mounds on the yedoma at Oyogos Yar.

The substrate is silty and well-drained. Mud boils occur at places most exposed and windswept on the Yedoma. Plants occur here only between such mud spots; the coverage is consequently very low with 20 to 40% (Fig. 5). *Potentilla hyparctica, Salix polaris,* and low growing grasses, and rushes like *Festuca brachyphylla, Deschampsia borealis,* and *Luzula confusa* are the main constituents of such habitats In addition, herbs such as *Lloydia serotina, Cardamine bellidifolia, Androsace triflora*, and *Tephroseris atropurpurea* occur in lower abundance.

This vegetation is similar in composition to cryptogam, herb barren (B1) or to the gramioid tundra (G1), described in the Circumpolar Arctic vegetation map (CAVM Team 2003).

Yedoma slopes

At yedoma slopes, the coverage is in general >80%. In the upper parts of slopes in SW exposition, *Dryas punctata* is one of the main constituents. *Salix polaris* and several grass species (*Alopecurus alpinus, Deschampsia borealis,* and *Festuca brachyphylla)* and *Luzula confusa* are characteristic of yedoma slopes. In lower parts of the slopes, where it is less drained and, consequently, moister, *Arctagrostis latifolia, Petasites frigidus,* several saxifrages (*S. nelsoniana, S. cernua, S. hieracifolia*) and other herbs (*Gastrolychnis apetala, Tephroseris atropurpurea, Ranunculus spp.*) are typical (Fig. 6).

Figure 5. Mud boil at the top of the yedoma visible in Figure 3.

Figure 6. Lower part of a yedoma slope with dominating *Arctagostis latifolia.* In the background, a thermo-erosional valley with reddish spectral signature (here: dark) is visible.

Figure 7. Thermokarst pond with dominating *Pleuropogon sabinei* growing immersed in the water (inserted photo).

Small thermokarst ponds

In small depressions on the yedoma, ponds with *Pleuropogon sabinei* and on the shore, *Arctophila fulva*, *Arctagrostis latifolia, Ranunculus hyperboreus, Dupontia fischeri*, *Eriophorum polystachion,* and *E. scheuchzeri* occur (Fig. 7).

Interestingly, genuine aquatics were widely lacking. Only *Hippuris vulgaris* was solitarily found in a sterile form. The white-flowered *Ranunculus pallasii* and *Caltha palustris* grew immersed in some ponds within the Alas depressions.

Figure 8. Thermo-erosional valley intersecting the yedoma of Oyogos Yar. Main constituent here is *Eriophorum scheuchzeri* causing a green spectral signature.

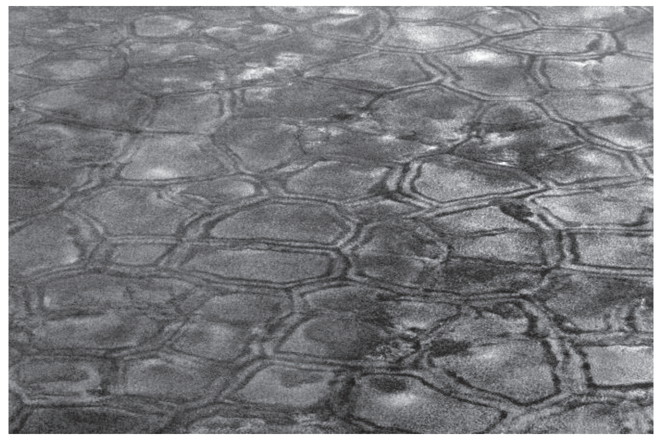

Figure 9. Bottom of a thermokarst depression with a water table above the ground. The polygonal surface patterns are visually strengthened by vegetational differentiation (compare Fig. 10).

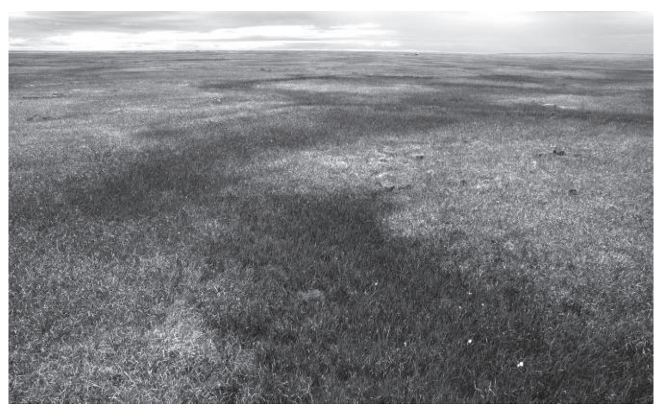

Figure 10. The wettest places in high center polygonal wetland tundra are the inter-polygonal trenches. Here, *Eriophorum polystachion* is the main constituent, causing a reddish (here dark) pattern.

Thermo-erosional valleys

Thermo-erosional valleys are permanently supplied by running water. They are characteristically colored and recognizable from a far distance (Fig. 6). Dark green and reddish signatures are mainly caused by different *Eriophorum* species: green – *E. scheuchzeri*, and red – *E.*

polystachion (Figs. 6, 8). Other plants of thermo-erosional valleys are *Petasites frigidus* and several crowfoot and grass species (*Dupontia fischeri, Calmagrostis holmii*).

Bottom of thermokarst depressions

The bottom of thermokarst depressions, alases, is in contrast to thermo-erosional valleys characterized by stagnant water and covered mainly with sedges (*Carex ensifolia* ssp. *arctisibirica*) and cotton grass (*Eriophorum polystachion*).

The vascular plant diversity here is the lowest in the study area. *Sphagnum* moss is widely present, causing irregular pale green spots in polygonal wetlands where the surface of water is above the ground (Fig. 9).

At sites outside water bodies, rushes (*Luzula nivalis, L. confusa*) cover large areas, together with several grasses (*Dupontia fischeri, Calamagrostis holmii, Poa alpigena,* and *Arctophila fulva*). The wettest places are almost exclusively occupied by *Eriophorum polystachion*, which produces reddish patterns on the ground indicating the water trenches between polygons from afar (Figs. 9, 10).

Conclusions

The main landscape units in thermokarst-affected landscapes can be well distinguished by their vascular plant cover.

Moisture or drainage, respectively is the most important ecological factor in the study area resulting in the strongest vegetation differentiation.

Subordinate factors are exposure and declination. There were no really dry places in the study area.

Excessive wetness is well-indicated by plants with characteristic spectral properties and, therefore, visible from far distances.

The plant species composition can alter quickly on short distances reflecting moisture changes resulting from the damming effect of the frozen ground.

The existence of such small-scale variations in the plant cover has important implications for the interpretation of palaeobotanical records.

Acknowledgments

We thank all participants of the joint Russian-German expedition, *Lena–New Siberian Islands 2007*, who helped us collecting, drying, and preparing the plants for the herbarium. The studies were supported by the German Science Foundation (KI 849/1).

A Two-Dimensional Numerical Heat Transfer Solution for Frost Heave Prediction Using the Segregation Potential Concept

Abstract

The Segregation Potential (SP) concept has been widely used to predict frost heaving for engineering projects, such as the design of buried chilled gas pipelines or ground freezing. It is of utmost importance for the SP concept to calculate an accurate temperature gradient in the frozen fringe. The authors developed a modified apparent heat capacity method using temperature-dependent unfrozen water contents. The model was implemented using the finite element method (FEM) with very fine mesh. The numerical results of the model have shown satisfactory accuracy as compared with the analytical solution. In addition, the model eliminates oscillations of the temperature gradient in the frozen fringe.

Keywords: chilled gas pipeline; frost heave; phase change; segregation potential.

Introduction

Frost heave is a mass and heat transfer phenomenon. The ice lens grows behind the freezing front. The transitional partially frozen zone between the ice lens and the unfrozen soil is called the *frozen fringe* (Miller 1972). Secondary frost heave theory (Miller 1978) is based on well-established principles of soil physics, hence it is the most popular theory. The secondary frost heave theory was successfully developed for numerical modeling (O'Neill & Miller 1985). However, the input parameters are difficult to obtain. Konrad & Morgenstern (1980, 1981) developed the Segregation Potential (SP) concept to overcome this problem. The SP concept succeeded in obtaining the overall frozen fringe characteristics including the suction gradient and the hydraulic conductivity through laboratory frost heave tests. The velocity of the pore water migrating to the frozen fringe, v, was proportional to the temperature gradient in the frozen fringe, gradT_{ff}, provided the suction at the pore-freezing front was constant:

$$v = \frac{P_w - P_u}{d} K_{ff} = \left(\frac{P_w - P_u}{T_s - T_f} K_{ff} \right) \mathrm{grad}T_{ff} = \mathrm{SP} \times \mathrm{grad}T_{ff} \tag{1}$$

where P_w = suction pressure at the active ice lens; P_u = suction at the freezing front; K_{ff} = overall hydraulic conductivity of the frozen fringe; d = thickness of the frozen fringe; T_s = segregation temperature; T_f = freezing temperature; and SP = segregation potential.

It was confirmed in a previous study by Konrad & Morgenstern (1982) that the SP value near thermal steady state is dependent on the following variables:

$$\mathrm{SP} = \mathrm{SP}\left(\dot{T}_f, P_u, P_e, etc\right) \tag{2}$$

where $\dot{T}_f$ = the cooling rate of the frozen fringe; P_e = confining pressure acting on the freezing front.

The cooling rates are very small in the field condition. It is reasonable to apply the cooling rates at the formation near thermal steady state obtained by constant temperature boundary frost heave tests for the field condition (Konrad & Morgenstern 1984). From Equation 1, the SP value decreases with increasing P_u. In most field conditions, P_u is fairly small as long as the freezing front is below the water table. Therefore, it would be reasonable to use the SP value determined by a laboratory frost heave test in which the warm plate temperature is close to freezing point, because the thermal boundary condition creates a small P_u value due to the short unfrozen soil length. The effect of P_e is taken into account empirically by Konrad & Morgenstern (1982):

$$\mathrm{SP} = \mathrm{SP}_0 \exp\left(-aP_e\right) \tag{3}$$

where a = a soil constant; SP_0 = the maximum value of segregation potential that occurs at zero external pressure.

Since the proposed model is based on the SP concept, the migrated water amount depends on the temperature gradient, the rate of cooling, and the stress state. To simplify the simulation process, numerically uncoupled temperature solution from the stress–strain analysis or mass transfer solution can be applied. For any particular time step, the non-linear temperature distribution is first calculated with an iterative procedure, and then this temperature solution is used to determine the location of the freezing front. With the freezing front position determined, the SP concept is then used to calculate the volume of water flow to the segregation freezing front.

The precise calculation of the temperature gradient in the frozen fringe is of utmost importance for the SP concept. Also, the coupled stress state has a strong dependence on thermal regime. Therefore, a numerical procedure for the transient heat transfer is first presented in this paper. Second, the verification of the developed heat transfer model is described. Finally, a new technique to calculate the temperature gradient in the frozen fringe is discussed.

Heat Transfer Model with Phase Change

Governing differential equation

The three basic modes of heat transfer are conduction, convection, and radiation. Heat conduction is the primary mode in soils (Konrand & Shen 1996). Although heat convection was considered in some models (e.g. Harlan 1973), it is usually negligible in soil heat transfer studies (Farouki 1981). Nixon (1975) reported that the convection component is two or three orders of magnitude smaller than the conduction component. Radiation components hardly contribute to the amount of heat transfer at all. Radiation accounts for less than 1% of the total heat transfer in sands and even less in fine-grained soils (Farouki 1981).

For the above mentioned reason, the developed two-dimensional heat transfer model with isotropic thermal properties is based on conduction only and is governed by the following equation:

$$C\frac{\partial T}{\partial t} + L = \frac{\partial}{\partial x}\left(k\frac{\partial T}{\partial x}\right) + \frac{\partial}{\partial y}\left(k\frac{\partial T}{\partial y}\right) \tag{4}$$

where C = volumetric heat capacity of soil; L = volumetric latent heat; T = soil temperature; t = time; and k = effective thermal conductivity of soil.

Alternatively, Equation 4 can be expressed as:

$$C_a\frac{\partial T}{\partial t} = \frac{\partial}{\partial x}\left(k\frac{\partial T}{\partial x}\right) + \frac{\partial}{\partial y}\left(k\frac{\partial T}{\partial y}\right) \tag{5}$$

where C_a = the apparent volumetric heat capacity.

The traditional apparent heat capacity is defined as:

$$C_a = C + \frac{L}{TI} \tag{6}$$

where $TI = T_f - T_s$: the temperature interval.

In this study, unfrozen water effect is taken into account in the phase change.

$$C_a = C + L'\rho_w\frac{\partial \theta_w}{\partial T} \tag{7}$$

where L' = latent heat of fusion per unit mass of water ($3.337*10^5$ J/kg); ρ_w = density of water (1000 kg/m^3); and θ_w = volumetric fraction of water.

This method is applied for fine-grained soils (Nixon 1983, Shen 1988). This method produces latent heat release over a range of subfreezing temperature.

Unfrozen water content in Fairbanks silt

Anderson and Morgenstern (1973) described a two-parameter power equation to determine unfrozen water content as:

$$w_u = m \times \left(T_f - T\right)^n \tag{8}$$

where w_u = unfrozen water content; m,n = characteristic soil parameters.

Michalowski & Zhu (2006) developed a first order exponential decay function:

$$w_u = w_1 + \left(w^t - w_1\right)\exp\left(\frac{T - T_f}{b}\right) \tag{9}$$

where w^t = the water content in an unfrozen state; w_1 = the asymptotic value; and b = the rate of decay.

With decreasing temperature, the unfrozen water content reaches the asymptotic value.

Equations 8 and 9 can describe the unfrozen water content of the soil, with which a clayey soil would be expected to have a relatively high unfrozen water content. However, the laboratory results of Fairbanks silt at the UAF pipeline experiment site showed a relatively low unfrozen water content and a very steep gradient around the freezing temperature (Huang et al. 2004). Therefore the authors applied a second order exponential decay given by:

$$\begin{cases} w_u = w_1 + w_2\exp\left(\dfrac{T - T_f}{t_1}\right) + w_3\exp\left(\dfrac{T - T_f}{t_2}\right) \\ w_1 + w_2 + w_3 = w^t \end{cases} \tag{10}$$

where t_1, t_2 = rate of decay.

Figure 1 shows the comparison between the calculated unfrozen water content curve and the measured results of Fairbanks silt at the UAF pipeline experiment site. The unfrozen water affects the soil's thermal properties.

Verification of Proposed Model

As shown in Equation 1, the precise calculation of the temperature gradient in the frozen fringe is the most important step for the SP concept. Nixon (1986) developed a two-dimensional geothermal model, named HAL, and conducted quadratic function fitting through three temperature points near the freezing front to determine gradT_{ff}. However, the proposed method produced oscillations of gradT_{ff} (Carlson & Nixon 1988). Coutts (1991) proposed that gradT_{ff} should be determined at the segregation temperature, which is the coldest temperature in the phase change range. This

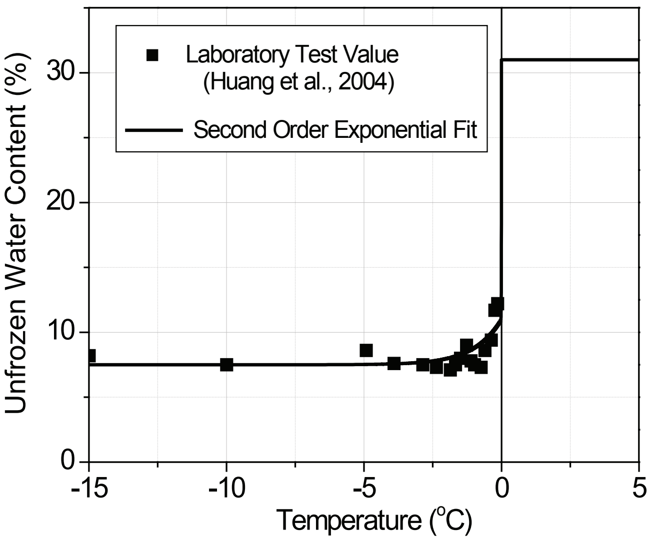

Figure 1. Unfrozen water contents of Fairbanks silt.

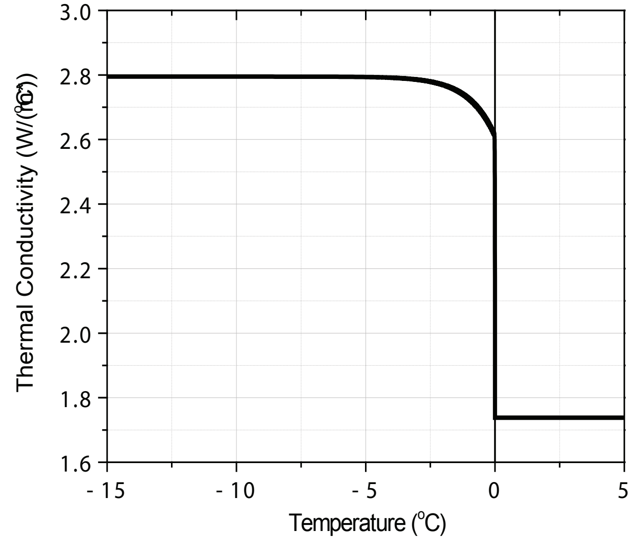

Figure 2. Thermal conductivity of Fairbanks silt for the proposed solution.

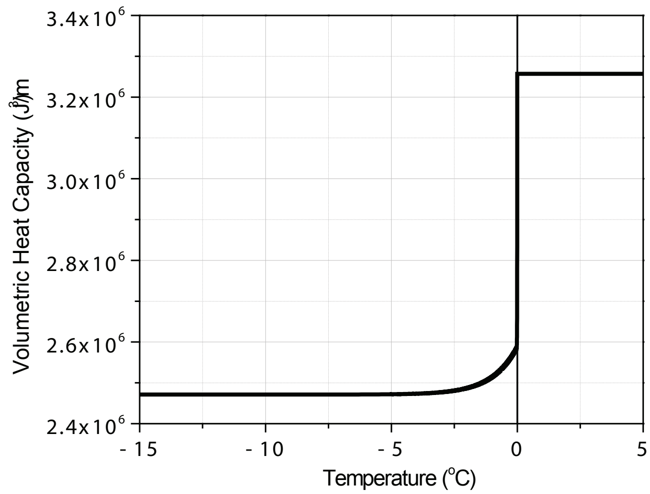

Figure 3. Volumetric heat capacity of Fairbanks silt for the proposed solution.

approach, however, could not eliminate oscillations. Konrad and Shen (1996) modified Coutts's model, and eliminated oscillations of gradT_{ff} using forced mesh adjustment. However, the procedure was very complicated to manage. Also, the adjusted mesh had numerical instability, because the stiffness term of the adjusted mesh had a very large range compared with that of the unfrozen or totally frozen mesh (Hawlader et al. 2004). The authors propose a new approach applying a fine mesh and considering the effects of unfrozen water.

The proposed model is implemented by ABAQUS/ Standard-6.7 finite element code. The soil geometry is a 0.0005 m by 10 m column. The two-dimensional four-node linear heat transfer element (DC2D4) is applied. The soil is divided into 0.0005 m square meshes. The mesh is only one element wide. The initial soil temperature is 1°C. The temperature boundary at the top is set at –1°C, and kept constant for 2000 hours. Zero heat flux is applied at the bottom and side boundaries. For the boundary conditions defined above, the two-dimensional heat transfer model is verified as a one-dimensional solution.

The unfrozen water contents shown in Figure 1 are taken into account in the thermal conductivities and volumetric heat capacities. Figures 2 and 3 show thermal conductivities and volumetric heat capacities of the Fairbanks silt at the UAF pipeline site, respectively. Thermal conductivity values were obtained by the thermal conductivity needle-probe method, then calibrated using the correlations of Johansen (1977). Those values are applied for the proposed model using the apparent heat capacity in Equation 7.

The proposed model is compared with the case using the traditional apparent heat capacity method with Equation 6, and verified against the Neumann solution. The Neumann solution is not valid for non-linear thermal properties but rather for materials that exhibit constant values in both the frozen and unfrozen states. Frozen thermal properties are determined at the asymptotic point. Latent heat generation was a concern in the frozen water amount from the freezing temperature to the asymptotic point (= w^t – w_1). The thermal conductivities of the frozen and unfrozen phase are determined as 2.79 and 1.74 W/(m*°C), the volumetric heat capacities were $3.26*10^6$ and $2.47*10^6$ J/(m^3*°C), respectively. The volumetric latent heat is $1.16*10^8$ J/m^3. Those constant properties are also used for the traditional apparent heat capacity method. The calculations are made by TI = 0.01°C, 0.05°C, and 0.1°C.

The freezing front penetration in each case is compared in Figure 4. While the traditional apparent heat capacity method for the case of TI = 0.01°C is identical to the result obtained from the Neumann solution, its accuracy is sensitive to the magnitude of TI. With increasing TI, the freezing front penetrates deeper.

Figure 5a shows the temperature profiles of Neumann and the proposed solution at 2000 hours. The proposed solution agrees

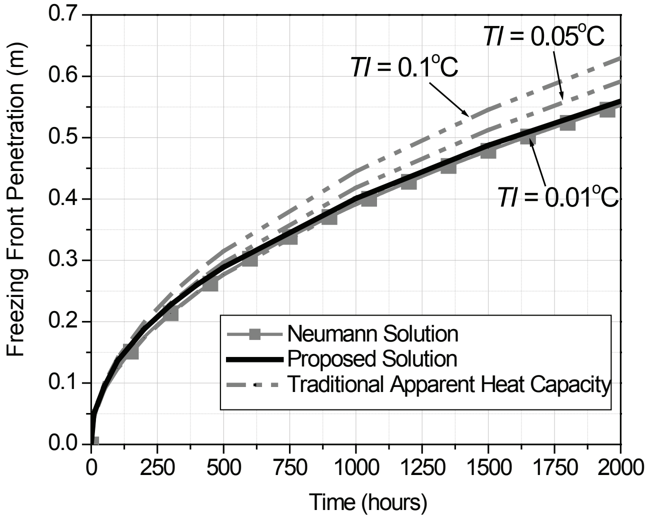

Figure 4. Comparison of freezing front penetration.

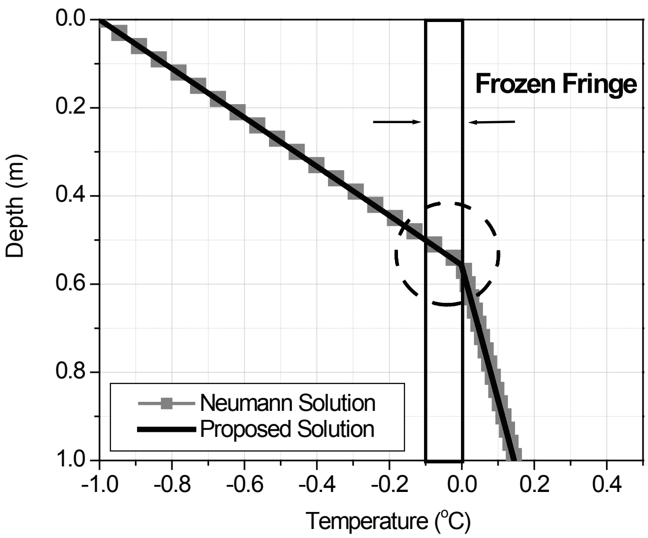

Figure 5a. Comparison of temperature distribution at 2000 hours.

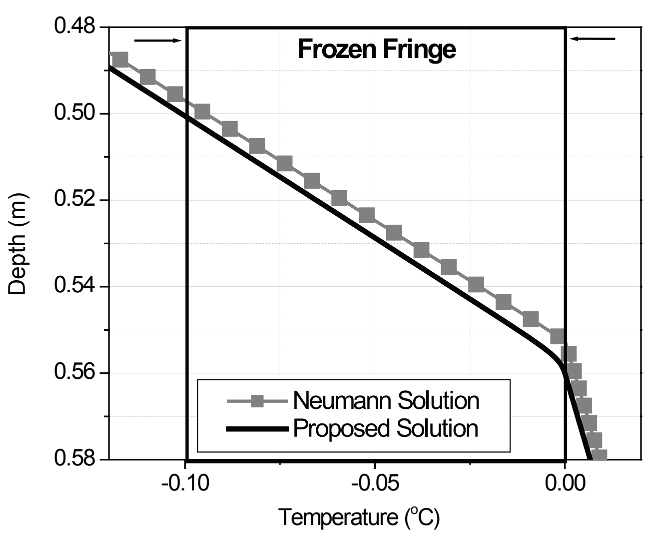

Figure 5b. Comparison of temperature distribution in frozen fringe at 2000 hours.

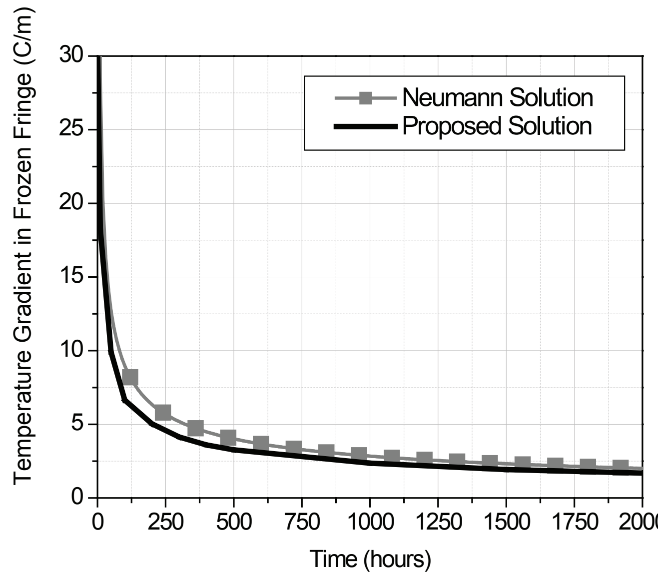

Figure 6. Comparison of temperature gradient in frozen fringe between Neumann and the proposed solution.

well with the Neumann solution. Figure 5b shows the close-up view of temperature distribution in the frozen fringe. T_s is assumed as –0.1°C to define the frozen fringe. Since the square mesh size is 0.0005 m, there are approximately 100 points in the frozen fringe. The effect of the fine mesh gives two advantages. First, it is the accuracy of the temperature distribution in the frozen fringe. The freezing front of the proposed solution is slightly deeper than that of Neumann solution as shown in Figures 4 and 5b. Also, the temperature distribution of the proposed solution is non-linear. This is due to the non-linear thermal properties of the unfrozen water content. The second advantage is the elimination of oscillations of gradT_{ff}. The history of gradT_{ff} between the proposed and Neumann solution is shown in Figure 6. The precision of the proposed solution is quite satisfactory and stable. Because of the precise and stable gradT_{ff}, it will be possible to adequately conduct water migration prediction using the SP concept.

It is true that the proposed solution requires considerable calculation time because of the fine mesh size. However, this issue was solved by using an IBM p690 computer at the Arctic Region Supercomputing Center in the University of Alaska Fairbanks.

The proposed solution was used to simulate the UAF frost heave experiment. Figures 7 and 8 show the finite element mesh and simulated temperature distribution with a deformed mesh in a steady state, respectively. The details of the mechanical model coupling and simulation results will be presented in a future paper.

Conclusion

A transient heat transfer model was developed to determine the temperature gradient in the frozen fringe with high precision using the SP concept. The proposed approach was implemented using a FEM model with a

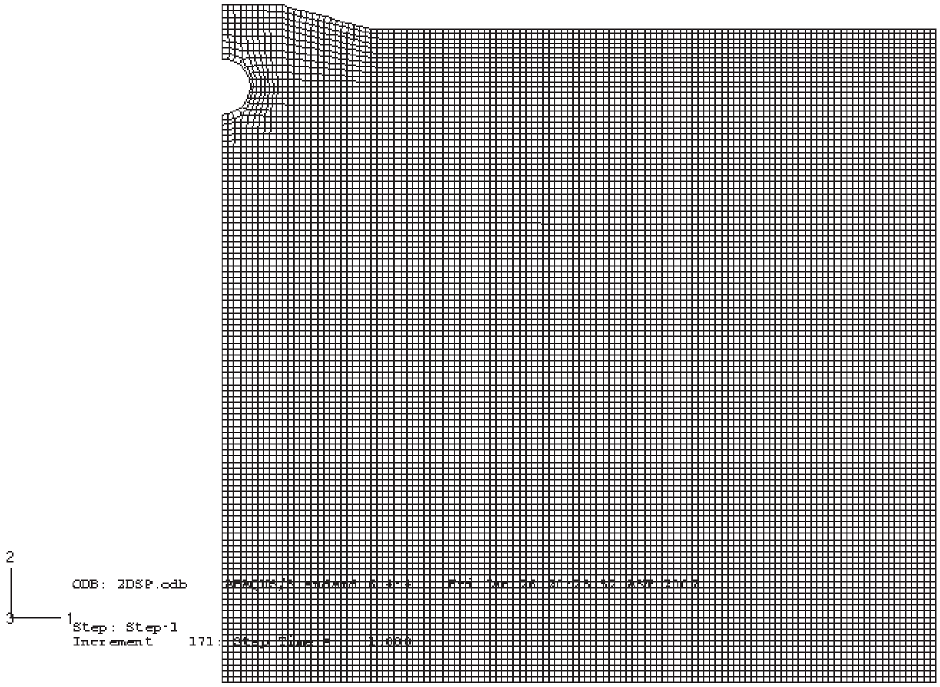

Figure 7. Finite element mesh for the simulation of the UAF pipeline experiments.

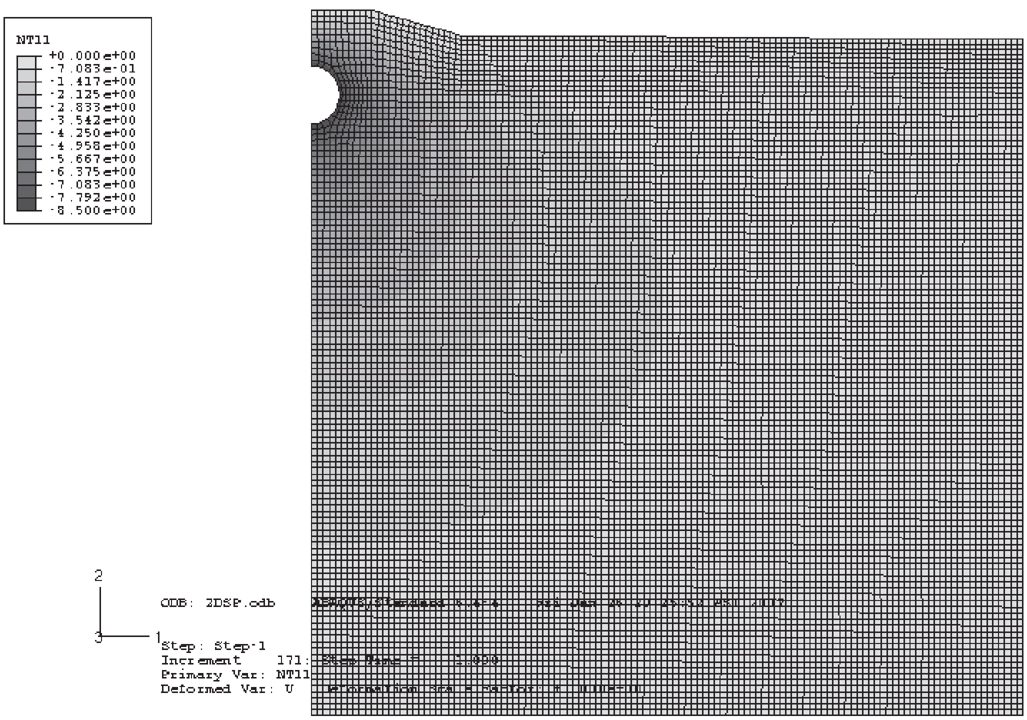

Figure 8. Simulated deformed mesh and temperature distribution in steady state.

fine mesh. A modified apparent heat capacity method considering unfrozen water contents was applied in the model. The model developed in this study has achieved the following improvements:

1. The proposed method can properly simulate the non-linear temperature distribution in the frozen fringe.
2. The calculated gradT_{ff} does not exhibit oscillations.
3. The simulated results agree well with the Neumann solution.

Acknowledgments

The numerical simulation of the study was supported by an Alaska EPSCoR Graduate Research Fellowship. The financial assistance is appreciated. The authors would also like to thank Dr. Xiong Zhang, University of Alaska Fairbanks, for his suggestions regarding the numerical simulation.

Abstract

Uncertainties in the carbon budget of high latitude ecosystems are partly due to difficulties in assessing the spatially and temporally highly variable methane emissions of permafrost soils. CH_4 contributes significantly to global warming. Arctic regions are most critically influenced by a changing climate. Modeling approaches are important tools to determine CH_4 fluxes of arctic environments. We present two process-based models to calculate methane emission from permafrost soils. Model forcing consists of ECMWF (European Center for Medium-Range Weather Forecasts) meteorological data which are validated against field measurements. Auxiliary input data is derived from satellite imagery and field measurements. A MERIS-FR land classification scheme is used to upscale emissions. Model results are validated using methane flux measurements on the landscape and small scale carried out in 2006 in the Lena Delta (72°N, 126°E) by Alfred Wegener Institute for Polar and Marine Research. The study site is characterized by arctic tundra ecosystems and continuous permafrost.

Keywords: Arctic; climate change; methane emissions; modeling; permafrost; tundra.

Introduction

Introduction

The radiative forcing due to methane—the second largest of the long-lived greenhouse gases after carbon dioxide—and its Global Warming Potential (GWP), which is about 20 times higher than the GWP of CO_2 (IPCC 2001), demonstrate the significant contribution of methane to warming of the atmosphere. The global atmospheric methane concentration has risen from a pre-industrial value of about 715 ppb to a current value of about 1774 ppb (IPCC 2007).

The observed increase in methane concentrations is very likely due to anthropogenic activity, mainly agriculture, burning of fossil fuels, and landfills. Contributions of further sources to the global atmospheric methane budget are not well determined yet (IPCC 2007) due to the difficulty in assessing the global emission rates of the natural sources, the strengths of which are highly variable in space and time (IPCC 2001).

Permafrost soils represent a large carbon reservoir, with an estimated carbon pool of about 900 Gt for frozen yedoma (ice-rich soils with high labile carbon content [Walter et al. 2003]) and non-yedoma soils excluding peatlands. The permafrost carbon reservoir exceeds that of the atmosphere (~730 Gt) and vegetation (~650 Gt) (Zimov et al. 2006).

Due to high sensitivity of the arctic soil carbon reservoir to increasing temperatures and to the large surface area, arctic regions are most critically influenced by changing climate. In thawed permafrost soils, methane is produced by specially adapted microbes under anaerobic conditions and released into the atmosphere. Extensive thawing of permafrost will release the carbon contained in the soils, hence further affecting the global carbon cycle. Model scenarios predict a severe degradation of permafrost in the Northern Hemisphere, including a northward shift of the permafrost boundary as well as an increase in active layer depth (Lawrence & Slater 2005, Zhang et al. 2007).

Studies on measuring methane flux on the landscape scale using the eddy covariance technique have been conducted by only by a few research groups (Fan et al. 1992, Friborg et al. 2000, Hargreaves et al. 2001, Harazono et al. 2006, Wille et al. 2007). Very few studies on modeling methane emission in Siberian permafrost regions on the regional scale have been performed (Bohn et al. 2007).

This study aims at modeling the methane budget of a high latitude permafrost-affected region for determining source strength, and at understanding emission patterns on a regional scale. Remote sensing techniques and ground-truth measurements are used to derive information needed as input for process-based models and to upscale modeling from single point to regional scale. We present a new approach where the methane model by Walter (1998) is modified for permafrost conditions and applied to a study site characterized by continuous permafrost.

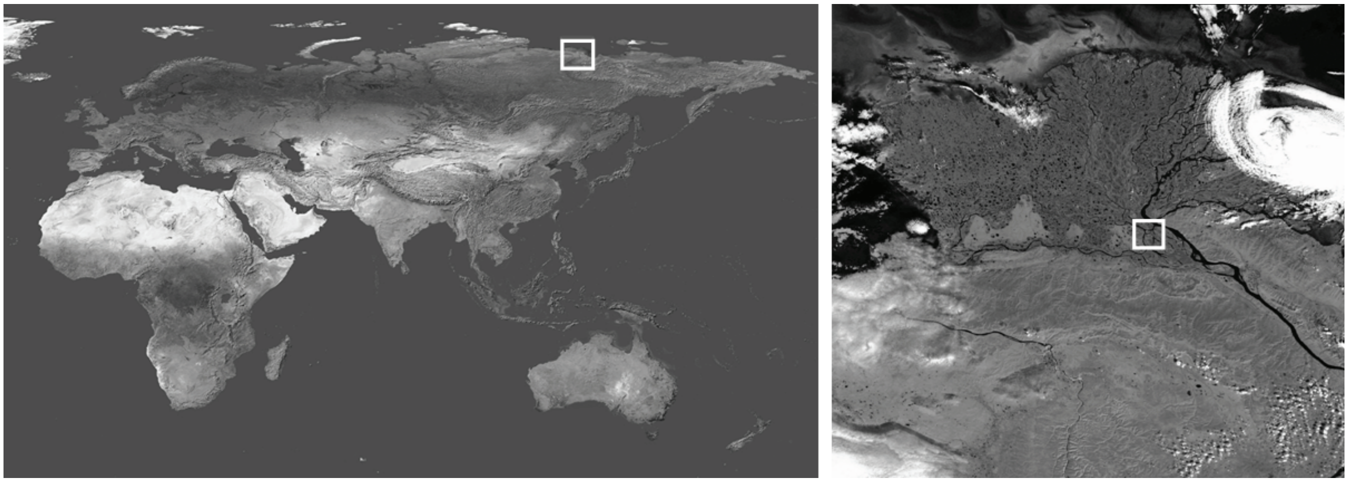

Figure 1. Geographical settings of the Lena River Delta and Samoylov Island shown in boxes (left panel: RGB composite of the globe based on MODIS data; right panel: RGB image for August 26, 2006, based on MERIS-FR data).

Materials and Methods

Study site

The Lena River Delta is located at the Laptev Sea coast in northeast Siberia (Fig. 1). It is considered a key region for understanding the underlying processes of the development and dynamics of permafrost in the Arctic under a warming climate. The region is characterized by arctic tundra ecosystems and is underlain by deep continuous permafrost.

The delta, situated at the north coast of Siberia, is the largest delta in the Arctic and one of the largest in the world (Walker 1998). It is characterized by a highly heterogeneous landscape of smaller and wider river branches and channels, as well as more than 1500 islands of various sizes on an area of about 32,000 km^2 (Walker 1998). Three major fluvial terraces with different geomorphological characteristics form the delta (Schwamborn et al. 2002). The 30-year (1961–1990) averages of mean air temperature and total precipitation measured at the meteorological station in Tiksi (eastern delta) are -13.5°C and 323 mm, respectively (Roshydromet 2004). The vegetation is mainly characterized by sedge/grass/moss wetland and sedge/moss/dwarf-shrub wetland, as well as dwarf-shrub tundra (CAVM Team 2003). The growing period is short, lasting for 60–80 days (Grigoriev 1993). The surface is characterized by wet polygonal tundra with a pronounced micro-relief (Wille et al. 2007).

Since 1998, yearly expeditions have been conducted by Alfred Wegener Institute for Polar and Marine Research, Potsdam (AWI) to study carbon dynamics and involved microbial processes and communities as well as the energy and water budget of Arctic tundra. Campaigns have been carried out on Samoylov Island (Fig. 1). Samoylov (72°22′N, 126°28′E) is representative of the active and youngest part of the Lena Delta and covers an area of approximately 7 km^2.

Model description

The methane emission model (Walter 1998) is a one-dimensional process-based climate-sensitive model to derive methane flux from natural wetlands. The processes leading to methane emission are modeled within a one-dimensional soil column which is discretized in 1 cm thick soil layers. Three different transport mechanisms that contribute to methane release from soils are taken into account and modeled explicitly; namely diffusion, ebullition, and plant-mediated transport.

Methane production strongly depends on the position of the water table (Roulet et al. 1992, Bubier et al. 1995), which is a measure for dividing the soil column into an anaerobic and aerobic zone (Fig. 2). Methane is only produced under the absence of oxygen and, hence, only in water-saturated parts of the soil column (Fig. 2a). The production of methane by methanogenic bacteria is a function of substrate availability, pH and temperature (Walter 1998). The temperature dependence of methane production rates can be described by Q_{10} values which depict the relative increase in activity after a temperature rise of 10°C (van Hulzen et al. 1999). The gas is then transported to the soil/water interface by molecular diffusion, ebullition and, if vascular plants occur, by plant-mediated transport. When the water table drops below the soil surface, oxygen can enter the soil pores, and the methane produced in lower, still water saturates (anaerobic) parts of the soil body and is transported upwards and oxidized in the aerobic zone by methanotrophic bacteria (Fig. 2b). Methane oxidation can be described by Michaelis-Menten kinetics (Bender & Conrad 1992).

The model is driven by meteorological data and needs auxiliary input data, such as vegetation and soil characteristics, land classification schemes, fraction of cover, and Net Primary Productivity (NPP). NPP is parameterized as a measure for substrate availability and, thus, is an important input parameter. Since the model was modified for permafrost conditions, many parameters are time-dependent with successive thawing of the soil body, and only a few fixed parameters are used in the simulation runs.

NPP of high latitude tundra ecosystems is calculated by the process-based vegetation model BETHY/DLR (Biosphere Energy Transfer Hydrology Model) (Knorr 1997,

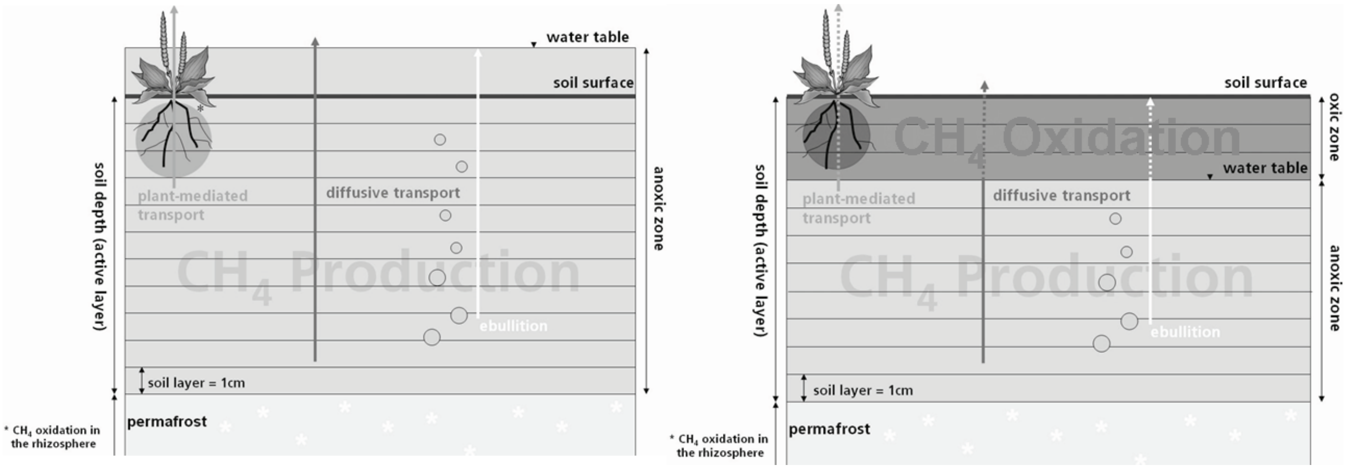

Figure 2. Schematic presentation of a soil column in the methane model. (a) Methane production and different transport mechanisms under water saturated conditions (anaerobic); (b) methane production and consumption as well as different transport mechanisms under partly aerobic conditions.

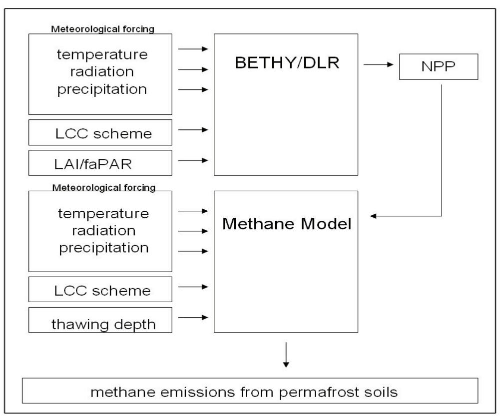

Figure 3. Flow chart illustrating the coupling of the BETHY/DLR model (NPP), the methane model, and their required input data.

Wisskirchen 2005). For simulations with BETHY/DLR, information about the state of vegetation is required; for example, time series of LAI (Leaf Area Index). Figure 3 shows the methodical structure of how the two models are coupled to work as a stand-alone package for modeling methane emission in permafrost regions.

Data

Both models need meteorological forcing data. Datasets provided by the European Centre for Medium Range Weather Forecast (ECMWF) are applied in modeling NPP and methane fluxes.

Auxiliary input data must be provided for both models. For simulations with the vegetation model BETHY/DLR, information about vegetation type and the state of vegetation (time series of LAI) is required. Running the methane model, additional input data such as vegetation parameters (e.g., rooting depth), soil characteristics (e.g., pore volume), land classification schemes (e.g., wetland distribution), fraction of cover, and NPP are needed.

Thawing of permafrost is described in the model by using measurements of active layer depth taken during field campaigns. Thawing/freezing is accounted for in order to characterize permafrost-related processes more realistically. The simulation starts with the first thawing of permafrost soil. Methane emission increases with increasing thawing depth, subsequently slowly decreases, and eventually comes to an end with permafrost re-freezing.

During the field campaign "System Laptev Sea – LENA2006" carried out from May to September 2006, Medium Resolution Imaging Spectrometer Full Resolution (MERIS-FR) data were acquired for the full growing season. MERIS-FR data were processed to derive information on vegetation characteristics needed as model input.

Vegetation characteristics

Vegetation characteristics play an important role in the presented modeling approach. In the vegetation model BETHY/DLR, LAI is used to describe the seasonal development of vegetation. It is needed as a continuous input variable to assess NPP.

In order to obtain realistic time series of LAI for the growing season 2006 of the Lena Delta, an approach using the MERIS Global Vegetation Index (MGVI), also called Top of the Atmosphere Vegetation Index (TOAVI), was used. FAPAR (Fraction of Absorbed Photosynthetically Active Radiation) can be retrieved by remote sensing techniques with acceptable accuracy using TOAVI values (Gobron et al. 2004) and can subsequently be used to estimate LAI. For homogeneous vegetation cover, LAI_{hom} is calculated using the equation (Monteith & Unsworth 1990):

$$LAI_{\mathrm{hom}_i} = LAI_{\max} \cdot \frac{\log(1 - FAPAR_i)}{\log(1 - FAPAR_{\max})} \tag{1}$$

$LAI_{\max}$ is chosen according to in situ measurements (Eq. 3). $FAPAR_i$ and $FAPAR_{\max}$ are derived from MGVI values.

During the field campaign 2006, field spectral measurements were taken using a portable ASD FieldSpecFR spectrometer (Analytical Spectral Devices Inc.). The spectrometer covers a wide spectral range from 350–2500 nm. Due to the highly heterogeneous surface patterns of wet polygonal tundra, different plant communities with different vegetation cover have evolved on a small scale in high and low center polygons and polygon rims, depending on changes in substrates and hydrologic regimes. Spectral measurements were taken in order to derive data on vegetation characteristics such as NDVI (Normalized Difference Vegetation Index) and LAI which can then be used to differentiate between plant communities as well as to validate satellite data.

Spectra have been processed using ENVI software. Processing is inevitable in order to correct for sensor properties and reference measurements using a spectralon panel. Biophysical indices (NDVI and LAI) were calculated and compared with NDVI and LAI values derived from MERIS-FR data.

NDVI was calculated from spectral data using the equation (Rouse et al. 1974):

$$NDVI = \frac{(R_{864} - R_{671})}{(R_{864} + R_{671})} \tag{2}$$

where R_{864} and R_{671} denote the reflectance at wavelengths 864 nm (near infrared) and 671 nm (red), respectively.
LAI was then calculated after Gardner & Blad (1986):

$$LAI = -1.248 + 5.839 * NDVI \tag{3}$$

LAI_{max} in equation (1) was set according to LAI values derived from equation (3).

Results and Discussion

Leaf Area Index (LAI)

Figure 4 shows results of the two approaches described above and presents a comparison between LAI calculated from field spectra and remote sensing data, respectively. The datasets compare reasonably well with slightly higher LAI values derived from in situ measurements. Additionally, a steeper slope can be observed in the in situ dataset. Possible explanations might be (1) an inaccurate atmospheric correction of MERIS-FR data due to high sun zenith angles and (2) the spatial resolution of MERIS-FR data (300 m) being unable to capture the high spatial heterogeneity of wet polygonal tundra.

However, it can be seen that the temporal variation of LAI during the vegetation period of 2006 is represented realistically. After slowly increasing at the beginning of the growing season, LAI reaches its maximum in mid-August (DOY 229) and then starts decreasing again. This agrees with ground truth observations from field campaigns in the delta.

Handling optical satellite data for high-latitude regions is often problematic due to high cloud contamination and high sun zenith angles. Here it is shown that for arctic regions like the Lena River Delta, information on vegetation characteristics can be retrieved from optical satellite-based measurements. Ground-truth data are useful for validating satellite-derived plant biophysical parameters. Working with

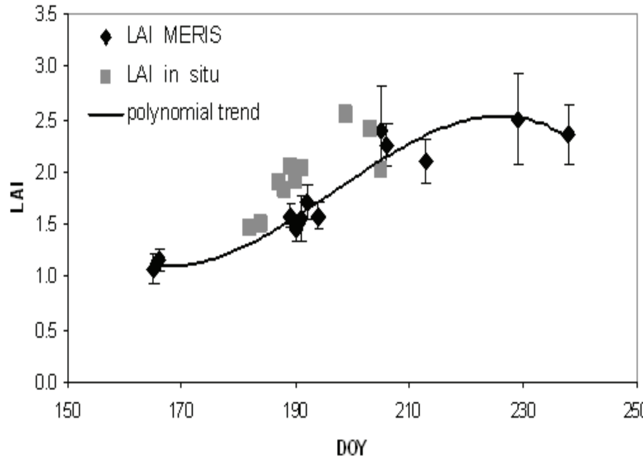

Figure 4. Time series of LAI for Samoylov Island for the growing season 2006. Diamonds: seasonal course of LAI derived from MERIS FAPAR values and polynomial fit, error bars indicate SD; triangles: LAI derived from field spectral measurements.

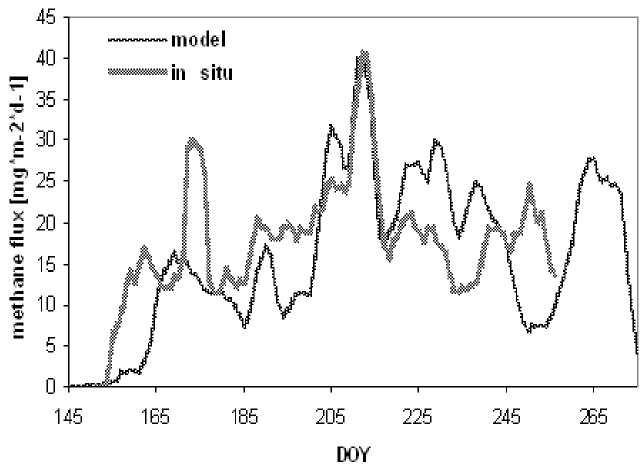

Figure 5. Measured and modeled methane fluxes (5-day running means) from a one-dimensional model run for the growing season 2006 and model coordinates 72°N, 126°E (Samoylov Island).

both ground-truth and remote sensing approaches as presented here provides a powerful tool to estimate vegetation characteristics on the small scale and to upscale these characteristics to the regional scale.

Realistic time series of plant canopy characteristics like LAI can be used as model input and to validate literature values when information about the state and seasonal variation of vegetation is required (BETHY/DLR).

Methane flux modeling

Methane flux was modeled one-dimensionally for the growing seasons of 2003–2006. Figure 5 shows a comparison of measured and modeled fluxes for the growing season of 2006. Flux measurements on the landscape scale using eddy covariance technique were carried out on Samoylov Island from June 9, 2006, through September 19, 2006, (Sachs et al. 2008). An eddy flux tower 3.6 m in height was used for methane flux measurements as well as for additional meteorological measurements. The seasonal course of modeled methane fluxes is limited by soil thawing and freezing.

In situ flux time series are used to validate the methane model and adjust model parameters, like Q_{10} values characterizing methane reduction and oxidation, to the study site. Between DOY 151 and 256, during overlap of the two curves, modeled methane flux is in good accordance with observed data. Flux integrals for both curves for the overlapping period are 1686 mg CH_4 m^{-2} (model) and 1895 mg CH_4 m^{-2} (measurements), respectively, which indicates a model underestimation of about 10%. This result agrees well with other studies using the same methane emission model; for example, when applied in Western Siberia (Bohn et al. 2007).

As can be seen in Figure 5, the time series of modeled methane emission shows less variation between days than the measured flux. This difference in seasonal fluctuation is due to the high variability of methane emission, both spatially and temporally (Joabsson et al. 1999, Wagner et al. 2003) and can be explained by the main factors controlling methane release. Wille et al. (2007) identified soil temperature and near-surface turbulence to be the driving parameters of methane emission in the Lena Delta.

The observed small-scale variability shown in the in situ data cannot fully be represented in the model results. Model input data on soil temperatures derived from ECMWF have a spatial resolution of 0.5°, and thus, variations in soil temperature due to the micro-relief of wet polygonal tundra cannot be taken into account.

Additionally, no data on wind distribution, wind direction, and wind speed are considered in the methane model.

However, since the project aims at quantifying methane emission on a regional scale, well-founded knowledge of small-scale process variability is an important factor for model understanding but cannot be fully implemented in the model.

Conclusions

For the growing season 2006, methane fluxes were modeled using two process-based models, a vegetation, and a methane emission model. Simulated methane fluxes are in agreement with in situ flux measurements ($r^2 = 0.63$). Time-integrated fluxes are 1686 mg CH_4 m^{-2} (model) and 1895 mg CH_4 m^{-2} (measurements), respectively. This indicates a model underestimation of about 10% which agrees with results of a study conducted in Western Siberia using the same methane emission model, where a model underestimation of about 10% was observed as well (Bohn et al. 2007).

Leaf Area Index needed as input for the vegetation model was calculated using two different approaches. LAI was derived (1) from satellite-based measurements and (2) by processing field spectral measurements. In situ data were applied in validating satellite data. It could be shown that information about the state and seasonal variation of the vegetation in arctic regions can be retrieved by remote sensing techniques. Used for deriving time series of LAI for the study site, the satellite measurements provide realistic results and compare reasonably well with LAI calculated from in situ spectral measurements.

The results demonstrate the important role of modeling techniques in assessing methane emissions for High Arctic permafrost-influenced ecosystems. Understanding of micro-scale processes studied through scientific field work is absolutely necessary when applying process-based models.

Acknowledgments

This project is conducted in the frame of the Helmholtz Research Network "Integrated Earth Observing System" (Helmholtz-EOS). Thanks to colleagues from AWI Potsdam for their in situ measurements and for getting the chance to participate in the LENA2006 campaign. Thanks to Dr. Dirk Wagner (AWI) who graciously provided data on Q_{10} values. The MERIS-FR data presented in this paper were acquired within the ESA-AO 3909.

Abstract

Hourly air and soil temperatures were monitored using arrays of miniature data loggers within eight 1-ha plots representing natural land cover types in northern Alaska's Kuparuk River watershed between 1995 and 2006. For each plot, mean daily air and soil temperatures were used to calculate mean winter *n*-factors, the ratio of seasonal freezing degree-day sums at the ground surface to those in the air. Mean 12 year *n*-factors ranged from 0.32 to 0.58 within the various plots, with ranges of 0.18 to 0.28 over the period of record. A distinct latitudinal gradient of *n*-factor values exists along this continentality gradient. Although direct measurements of snow cover are not available at the sites, temperature patterns indicate that snow cover is a major determinant of winter *n*-factor values.

Keywords: air temperature; Alaska; n-factor; permafrost; snow cover; soil-surface temperature.

Introduction

Transfer of heat between the atmosphere and ground in arctic environments can be complex. Large differences in vegetation and soil characteristics can occur over very short distances, leading to highly variable near-surface soil temperatures. In permafrost regions, however, it is often critical to be able estimate soil temperatures over large geographic areas. The *n*-factor, the ratio of freezing (or thawing) degree-day sums at the soil surface to those in the air at standard instrument height, was proposed (Carlson 1952) as a way of summarizing the seasonal winter (or summer) surface energy balance. Although the n-factor was introduced for engineering purposes, there has been considerable recent interest in its application to natural surfaces (Taylor 1995, Klene et al. 2001a, Karunaratne & Burn 2003, 2004, Kade et al. 2006). This, in turn, has led to its use in modeling exercises (e.g., Buteau et al. 2004, Juliussen & Humlum 2007).

Most previous studies have focused on series of plots in different latitudes, soil, and vegetation types over one or two seasons. This study utilizes multiple soil temperatures within a series of plots and examines the mean *n*-factor for each plot over 12 winter seasons to reveal information about interannual variability.

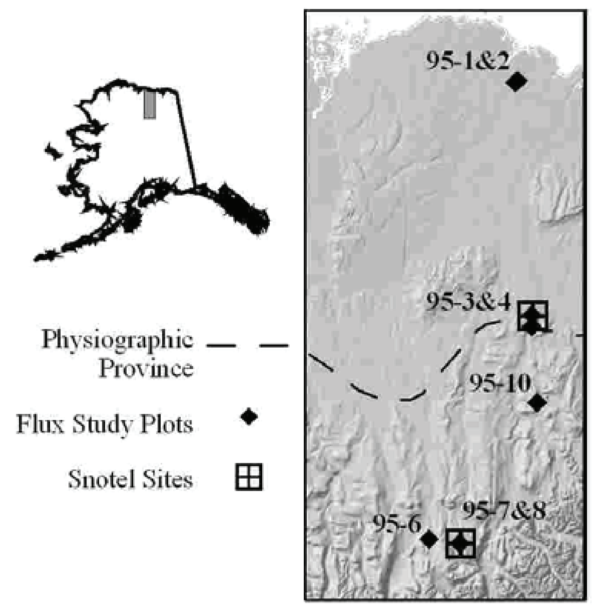

Figure 1. A shaded relief map of the study area showing locations of the Flux Plots, SNOTEL sites (see text), and the physiographic boundary between the coastal plain in the north and foothills in the south are depicted.

Study Area and Background

The Kuparuk River Basin of northern Alaska stretches from the Brooks Range to the Beaufort Sea, just west of the Dalton Highway (Fig. 1). This watershed was the focus of the U.S. National Science Foundation's (NSF) Arctic System Study Flux Project, an integrated mid-1990s study of the flux of greenhouse gases from terrestrial to atmospheric and marine environments (Kane & Reeburgh 1998).

Several of the projects utilized the "Flux Plots," a series of ten 1-ha plots arrayed along a climatic gradient from north to south. These plots were selected to represent common land-cover/soil associations and detailed vegetation and soil characterization was done on each. During the years the Flux Study was operating, these plots were incorporated into the NSF-funded Circumpolar Active-Layer Monitoring (CALM) program, allowing climate and active layer thickness measurements to continue in subsequent years. One plot on an island in the Sagavanirktok River was abandoned after flooding washed away the instrumentation, and another was discontinued due to difficulty in accessing a mountain top.

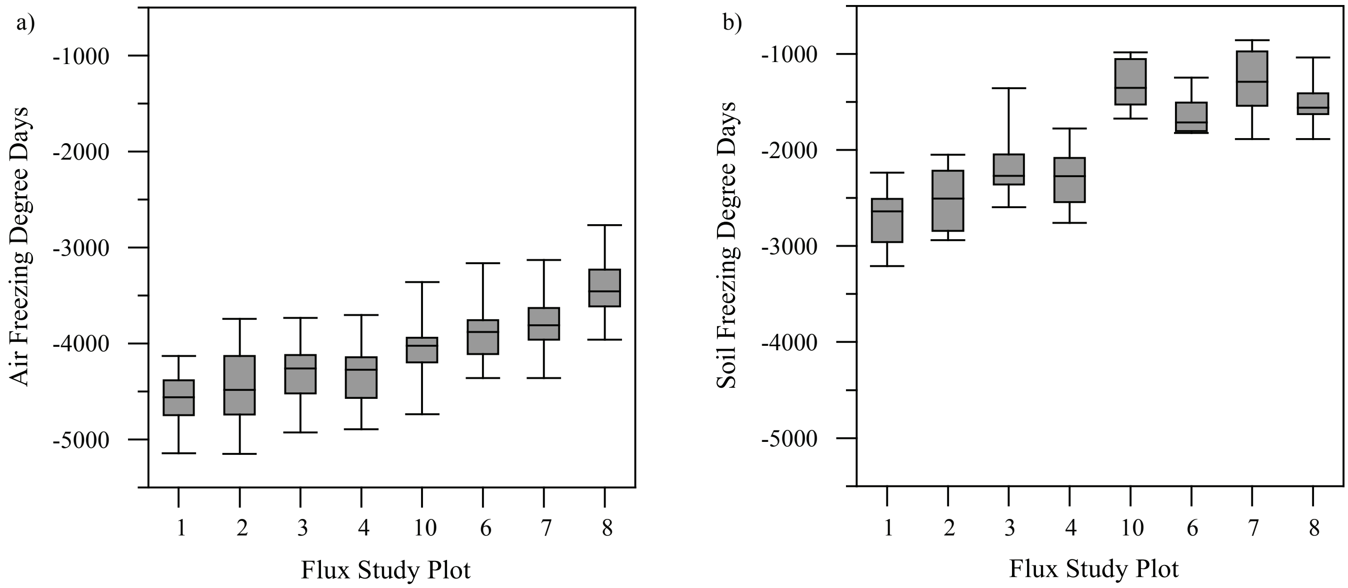

Figure 2. Box-and-whisker plots show the median, quartiles, and range of freezing degree-day sums in the air (a) and soil (b) at each of the eight Flux Plots observed between 1995 and 2006. Sites are arranged by latitudinal position; a distinct north-to-south (left-to-right) progression of values is apparent.

Elevations at the Flux plots used here ranged from 12 to 938 m a.s.l. Ten-year mean February and July air temperatures ranged from -18.3°C to -28.2°C and 7.3°C to 10.8°C, respectively, at the plots observed. Snow depths measured along a N-S transect in 1994–1996 varied from 0 m to 2 m within the basin (Taras et al. 2002). Permafrost underlies the entire region, with depths of about 600 m reported near Prudhoe Bay (Lachenbruch et al. 1982). Mean active layer thickness at the Flux Plots ranged from 42.2 cm to 60.3 cm during the 1995–1997 period (Klene et al. 2001). Vegetation was classified into four main categories: wet tundra, moist acidic tundra, moist nonacidic tundra, and shrublands (Walker & Bockheim 1995). Mean vegetation heights within the eight plots examined here ranged from 2.2 cm to 13.8 cm. Organic layer thickness ranged from 0 cm to 34 cm at the Flux Plots. Physiographically, the plots lie in the Arctic Coastal Plain province in the north and the Arctic Foothills province in the south (Wahrhaftig 1965). Observed soils included pergelic cryaquepts, cryorthents, cryoborolls, and histic pergelic cryaquolls (Walker & Bockheim 1995).

Klene et al. (2001) examined within- and between-plot variability of summer *n*-factors calculated for 1995–1997 at these plots. They found that mean n-factors within plots were robust when more than five soil-surface temperatures were available, and that the values were systematically related to land cover type. Mean summer *n*-factors calculated from 3 seasons of data ranged from 0.73 to 1.00 at the eight Flux Plots examined in this study (Klene et al. 2001).

Methodology

As part of the Flux Study, ten Stowaway© data loggers were installed at each Flux Plot in 1995. One monitored air temperature inside a six-gill radiation shield at standard screen height (1.8 m) while nine recorded soil-surface temperature in a range of microenvironments (Klene et al. 2001). The Stowaway loggers have gradually been replaced with five two-channel HoboPro© data loggers. The two-channel loggers have an accuracy of ±0.2°C and precision of 0.02°C at the freezing point. Thermistors at ground level were positioned approximately immediately below the ground surface to measure near-surface soil temperature. This placement was generally within an organic soil, though this varied from plot to plot. Water infiltration and animal damage led to high attrition rates initially, but recent records have generally been more reliable, although animal damage still causes losses each year. Observations were taken hourly until 1998, when a two-hour interval was adopted to extend battery life.

The hourly observations were summarized into daily means from which freezing degree-day sums (DDF) were calculated from air and soil records for the winter season, defined as 15 Sept to 15 May (243 days), following Hinkel et al. (2008). Adoption of this protocol results in inclusion of the entire snow cover period for most years. Statistics were computed for each winter season when more than 165 days with at least five of the nine soil-surface measurements were available at each plot. Freezing degree days (DDF) are calculated by summing mean daily temperatures for those days in which the mean was less than 0°C. Units are °C·days. Winter *n*-factors are based on freezing degree-day sums, thus warmer soil temperatures will lead to smaller winter *n*-factors, often attributable to the insulating effects of the snowpack. This is in contrast to thawing (summer) *n*-factors which are calculated using thawing degree days, which results in warmer soils leading to larger n-factors.

Snow depth is usually cited (e.g., Benson 1969; Goodrich 1982) as an important determinant of winter soil-surface temperatures and thus *n*-factors. However, snow depth records are rare in the Arctic. Two SNOTEL stations have

Table 1. Summary statistics for mean winter 1995–1996 through 2006–2007 at the eight Flux Plots.

Stand. Dev.	0.05	0.05	0.07	0.07	0.06	0.08	0.08	0.05

been operating within the study area over the period of record at the Sagwon Hills and Imnavait Creek. These sites are part of the SNOwpack TELemetry program run by the U.S. Natural Resources Conservation Program. Direct snow depth observations were unavailable but accumulated monthly precipitation has been archived (NRCS 2007). Precipitation was summed from October to May and used as a crude estimate of winter snowfall. Although this does not account for local variability resulting from vegetation, drifting, or scouring, it provides a basis for initial assessment.

Results and Discussion

The basic components of the n-factor are air and soil degree-day sums. These are plotted in Figure 2 to illustrate the variability of these parameters over the 12 winter seasons at each of the Flux Plots. The climatic gradient of colder air temperatures on the coastal plain and warmer inland temperatures is readily apparent (Fig. 2a). The air-temperature gradient is a simple manifestation of the north-south continentality gradient in the region; the fact that the surface-temperature gradient shows a corresponding trend indicates that air and surface temperatures are more strongly coupled than elsewhere on Alaska's North Slope (Hinkel et al. 2008).

The soil degree-day sums (Fig. 2b) are systematically warmer than the air temperatures by approximately 2000°C·days. Twelve-year mean differences ranged from 1897°C·days at Plot 1 to 2756°C·days at Flux 10. They also reveal a distinct warming from north to south. The four most southerly sites are more similar in their soil DDF ranges and means than were the air degree-day sums.

Analysis of mean winter n-factors at each plot revealed a substantial interannual variability considering that the soil temperatures were averages from multiple individual microsites within each 1-ha plot. Table 1 lists summary statistics. Mean values at the more northerly sites are larger (0.51 to 0.58) while the southerly sites have mean values of 0.32 to 0.44. Ranges in the mean winter *n*-factors at each plot varied from 0.18 to 0.28.

Box and whisker plots were calculated for the mean winter *n*-factors at each site and revealed, once again, a strong gradient from north to south (Fig. 3). A broader distribution of mean *n*-factors at the four southerly sites is reflected in the increased area within the quartile box. While the latitudinal

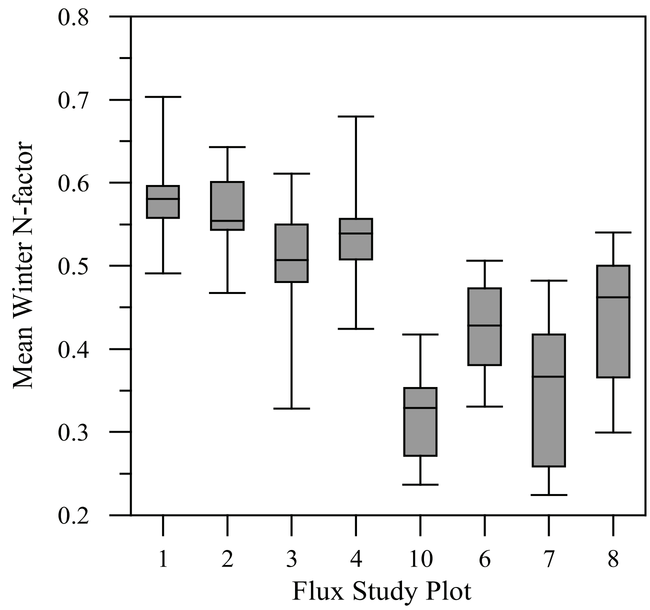

Figure 3. Box-and-whisker plots show the median, quartiles, and range of mean winter *n*-factors at each of the eight Flux Plots observed between 1995 and 2006.

gradient appears very distinct, snow depth at regional and microtopographic scales is an important factor determining ground temperature (Benson 1967, Gold 1967, Goodrich 1982). Vegetation should also be examined, as it can act to "trap" snow and prevent it from further displacement by wind gusts.

To examine these relationships, mean winter n-factors were plotted against the air and soil degree-day sums from which they were calculated (Fig. 4). DDF_{air} values show general trends of warmer air temperatures, leading to higher n-factors (Fig. 4a). The magnitude of the n-factor varies strongly by site (Plot 1 having the largest and Plots 6 and 10 the smallest) while DDF_{air} varies over a similar range. It is clear, therefore, that air temperature is not the sole determinant of the latitudinal gradient apparent in Figures 2 and 3.

The plot of DDF_{soil} (Fig. 4b) indicates that soil temperature constitutes a much stronger control over mean *n*-factor values. The data have an almost linear relationship, with warmer soils corresponding to lower *n*-factors. The data cluster tightly by plot, with northern sites having larger *n*-factor values and southern sites being lower.

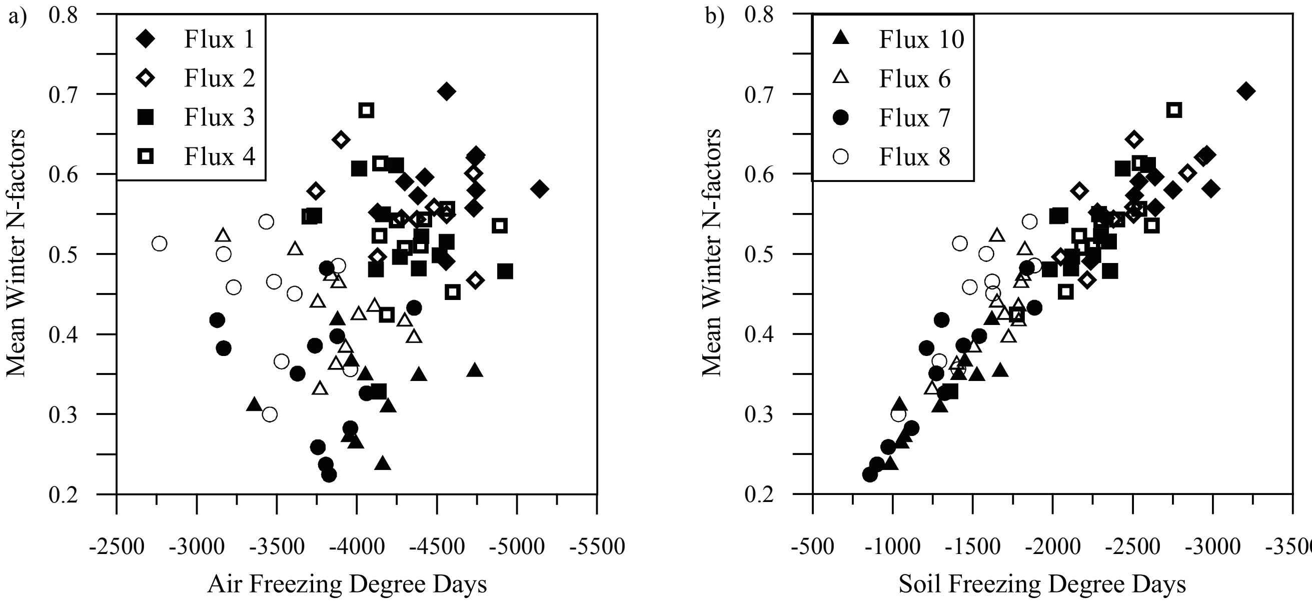

Figure 4. Mean winter air (a) and soil (b) degree days of freezing measured at each Flux Plot and graphed against mean winter n-factors. While air temperatures show no clear relationship, soil temperatures are directly related, reflecting the thermal influence of snow. X-axes have the same scale but different ranges.

Land cover within the region shows a general trend from moist nonacidic and wet sedge tundra complexes on the flat coastal plain, to a mix of acidic and shrub tundras in the foothills. The Flux Plots reflect these patterns (Walker & Bockheim 1995). Flux Plots 1 and 2 were chosen to include moist and wet complexes on the coastal plain. Plots 3 and 4 were selected as homogenous 1-ha areas of nonacidic and acidic tundra within close geographic proximity to each other (Walker & Bockheim 1995). The nonacidic tundra is characterized by the presence of Carex, Dryas, Eriophorum, and Hylocomium, while the acidic tundra has Eriophorum, Ledum, Betula, Hylocomium, and Salix with distinct tussock development (Walker & Bockheim 1995). Plots 6 and 8 are mixed acidic and shrub tundra and were included because of previous research done at those locations. Plot 7 is an acidic wetland. Site 10 was selected to represent a water-track, a shrubby wet first-order stream channel complex. The lower soil DDFs and n-factors at Plots 7 and 10 reflect their higher soil moisture contents. In the foothills, all 4 sites have the potential for drifting and scouring of snow, with slope angles ranging from 0° (Plot 7 in the bottom of a valley) to 15° at Plot 8. Sites 3, 6, 8, and 10 have slopes of more than 3°.

Taras et al. (2002) found that snow depth means and standard deviations were lower and less variable on the coastal plain than in the foothills. They were also able to categorize the amount of decoupling between air and soil temperatures using snow depth classes: 0–25 cm (highly coupled), 25–80 cm (coupled), and 80–200 cm (decoupled).

Although several studies have examined snow patterns on the North Slope, plot-level data were not available. Two SNOTEL sites, Sagwon and Imnavait, are located within the study area and have records covering the period 1995–2006. Each of these lies in close proximity to a pair of Flux Plots, in the Sagwon Hills (Plots 3, 4) and at Imnavait Creek (Plots 7, 8). Table 2 presents summary statistics of the accumulated precipitation (Oct–May) between 1995 and 2006 at these sites. While the mean winter precipitation at these sites is similar (approximately 8.7 cm), the range at Sagwon is just 1.0 while the Imnavait site range is 6.4 in.

Table 2. Summary statistics of the winter precipitation (Oct–May) accumulated at the available SNOTEL sites (cm). Seasons missing any monthly accumulation data were not used.

	Sagwon	Imnavait
N	6	10
Minimum	6.9	4.3
Mean	8.4	9.0
Median	8.8	7.2
Maximum	9.4	20.6
Range	2.5	16.3
Stand. Dev.	0.9	5.0

A crude assumption was made that the Sagwon site could represent general winter snow conditions in the northern portion of the study area while the Imnavait site would represent the southern. The Sagwon Hills are effectively the end of the coastal plain and beginning of the foothills province. Figure 5a shows the relationship between accumulated winter precipitation at Sagwon and mean winter n-factors at the four northern sites, while Figure 5b shows Imnavait and the southern sites.

Interestingly, the coastal sites furthest away from the Sagwon site seemed most closely related to interannual changes in snow depth. This presumably reflects that regional differences are important in areas that tend to be wind-blown with relatively shallow snowpack. In the south, no clear relationship is apparent. The documented variability of snow depth in the foothills (Taras et al. 2002) resulting

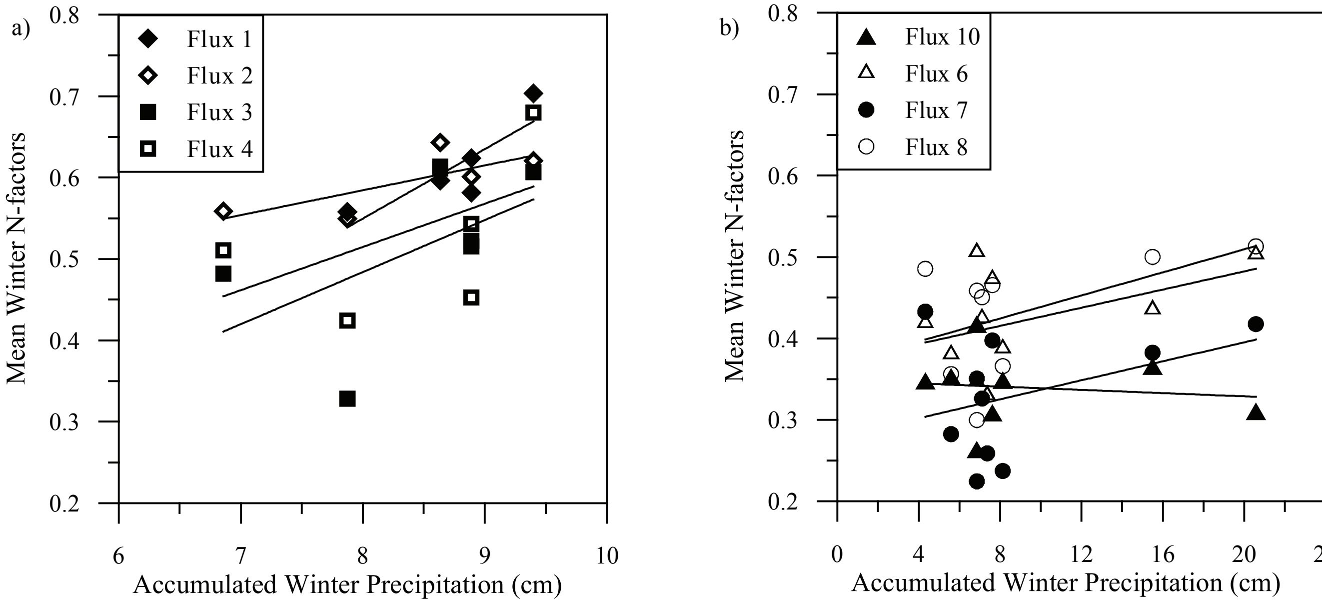

Figure 5. Accumulated winter precipitation (Oct–May) at SNOTEL sites plotted against mean winter *n*-factors in the northern (a) and southern (b) portion of the study area, represented by the Sagwon and Imnavait SNOTELs, respectively. The *x*-axes differ in scale.

from microtopography, vegetation, and wind-action is obfuscating the general interannual variability in snowpack conditions.

In comparison to previous work, the mean winter n-factors are higher than those found by Carlson (1952) and Taylor (1995) in central Alaska and the Mackenzie River Valley but similar to those observed by Karunaratne and Burn (2003, 2004) and Kade et al. (2006) in the Yukon Territory and northern Alaska. Snow depths may be thicker at Carlson's and Taylor's sites. In the study by Karunaratne and Burn (2003) in the Yukon between 1997 and 2000, n-factors ranged between 0.3 and 0.5 while the mean maximum snow depth observed ranged from 19–28 cm. Kade et al. (2006) calculated n-factors at a transect of three sites in northern Alaska overlapping the central and northern portions of the study area and found values of 0.3 and 0.6 at tundra sites bracketing the locations of Plots 3 and 4 and Sites 1 and 2.

Conclusions

The unusual set of geographically diverse observations used in this study allowed interannual quantification of n-factor variability at a range of tundra sites over 12 winter seasons. The latitudinal gradient in mean winter *n*-factors values are related not just to air temperatures, but also to vegetation and snow depth, as previous work and theory suggest. However, the lack of in situ snow depth measurements prevents further detailed analysis of within-plot variability. Future work should consider methods for improving quantification of snowpack characteristics, both spatially and temporally in the region.

Geophysical Mapping of Isolated Permafrost Lenses at a Sporadic Permafrost Site at Low Altitude in the Swiss Alps

Christof Kneisel
Department of Physical Geography, University of Würzburg, Germany
Daniel Schwindt
Department of Physical Geography, University of Trier, Germany

Abstract

Results of geophysical mapping of isolated permafrost lenses at a vegetated scree slope below the timberline using electrical resistivity tomography and refraction seismics are presented. In total, 20 geoelectrical and 10 seismic surveys were performed. Using 5 m spacing, survey length resulted in 175 m and 265 m arrays for the geoelectrical surveys and 115 m for the refraction seismic surveys. With respect to the large heterogeneity of the permafrost distribution, tomographic inversion schemes were used for data analyses and interpretation. Both electrical resistivity and refraction seismic surveys showed isolated anomalies of high resistivity and high velocity within the subsurface, especially in the lower parts of the scree slope. P-wave velocities of the isolated anomalies were between 1700-4300 m/s in a host material with velocities between 1000-1500 m/s. In most cases these locations coincide with the high-resistivity anomalies of the 2D resistivity tomography.

Keywords: electrical resistivity tomography; geophysical mapping; isolated permafrost; refraction seismics; scree slope; Swiss Alps.

Introduction

The Upper Engadine is one of the mountain regions in Switzerland with widespread alpine permafrost occurrence. Discontinuous permafrost is encountered above 2400 m a.s.l. Below the timberline, sporadic permafrost is assumed to exist only at very shaded sites. One of these special places is situated in the Bever valley, which represents one of the few sites in Switzerland where isolated permafrost lenses could be confirmed by several geophysical techniques (Kneisel et al. 2000, Kneisel 2003, Kneisel & Hauck 2003). For a detailed geophysical mapping of the sporadic permafrost distribution joint application of electrical resistivity tomography and seismic refraction surveys have been applied.

There are several publications concerning joint application of geoelectrical surveys and refraction seismics for sounding of rock glacier permafrost using one-dimensional techniques (e.g., Vonder Mühll 1993, Wagner 1996, Ikeda 2006). Similar to electrical resistivity tomography, a tomographic variant of seismic refraction which has become increasingly important in the past few years can be applied yielding two-dimensional velocity distributions of the subsurface (e.g., Musil et al. 2002, Kneisel & Hauck 2003, Hauck et al. 2004, LeBlanc et al. 2004, Maurer & Hauck 2007).

With respect to the known small-scale heterogeneity as many as 20 geoelectrical and 10 seismic surveys were performed, of which characteristic profiles are shown. This paper significantly extends the earlier studies presented by the author (see above) by introducing a larger number of 2D geophysical surveys using tomographic inversion schemes for data analyses allowing for more detailed interpretation and conclusions.

Site Description

The sporadic permafrost site below the timberline is located in the Bever Valley, a trough-shaped valley with bottom elevation between 1730 m and 1800 m a.s.l. at its lower end. Both the north- and south-exposed valley sides are wooded. At present the upper timberline is between 2200 m and 2300 m a.s.l. Larch (*Larix decidua*) and cembra pine (*Pinus cembra*) are the dominant tree species of the forest. Most parts of the scree slopes which occur below the rock walls are well covered with vegetation (Fig. 1). The soils are poorly developed and covered by an organic layer up to 30 cm thick. Below the organic layer, only a few centimeters of mineral soil exist. Mean annual air temperature at a nearby climate station in the Bever village at 1710 m a.s.l. is +1°C.

Methods

Electrical resistivity tomography (ERT)

Since geoelectrical methods are most suitable for

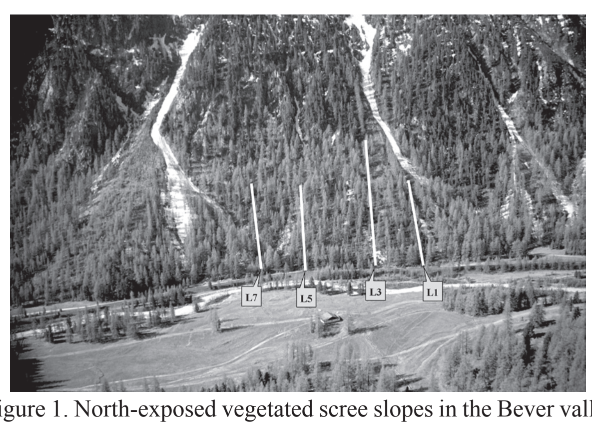

Figure 1. North-exposed vegetated scree slopes in the Bever valley. Lines indicate location of survey profiles.

investigating a subsurface with distinct contrasts in conductivity and resistivity, geoelectrical soundings constitute one of the traditional geophysical methods which have become standard in permafrost research to detect mountain permafrost. Since a marked increase of the electrical resistivity occurs at the freezing point, the method is expected to be most suitable to detect, locate, and characterize structures containing frozen material. Based on the number of scientific publications in the last decade and the large variety of applications, the tomographic variant of the method (electrical resistivity tomography, ERT) is maybe the most universally applicable method in mountain studies (Kneisel & Hauck 2008).

Resistivity values of frozen ground can vary over a wide range depending on the ice content, the temperature, and the content of impurities. The dependence of resistivity on temperature is closely related to the amount of unfrozen water. Perennially frozen silt, sand, gravel, or frozen debris with varying ice content show resistivity values between 5 kOhm.m to several hundred kOhm.m (e.g., Haeberli & Vonder Mühll 1996, Hauck & Kneisel 2008).

For the presented research the two-dimensional (2D) electrical surveys were performed using the Wenner and Wenner Schlumberger configurations with 5 m spacing and an IRIS SYSCAL Junior Switch resistivity-meter. The measured apparent resistivities are used to build up a vertical contoured section showing the lateral and vertical variation of resistivity over the section. The conventional method of plotting the results for the interpretation is the so-called pseudosection which gives an approximate image of the subsurface resistivity distribution. High gradients in the subsurface resistivity distribution usually indicate interfaces between different layers. The measured sets of apparent resistivities were inverted using the software package RES2DINV. This inversion software tries to reduce the difference between the calculated and measured apparent resistivity values by adjusting the resistivity of the model blocks. Topographic corrections can be incorporated into the inversion algorithm which is an essential point for studies in alpine periglacial environments with often complex and heterogeneous topography. Further details on different array geometries and data processing are given for instance in Reynolds (1997) and Kneisel (2006).

Refraction seismics

Similar to the resistivity investigated by electric methods, the sharp increase of the seismic primary wave (P-wave) velocity at the freezing point is used to differentiate between frozen and unfrozen material. The P-wave velocity distribution can be used as a complementary indicator to resistivity for the presence of frozen material. The method is especially useful to determine the top of the permafrost layer, as the contrast for the P-wave velocity between the unfrozen top layer (= active-layer, 400-1500 m/s) and the permafrost body (2000-4000 m/s) is usually large. On the other hand, the values for most common rock types (e.g., gneiss or granite) are similar to the values for ice, so the detection of mountain permafrost is often difficult by using refraction seismic data alone. From this it becomes clear that for some permafrost applications refraction seismic has to be combined for instance with electric methods, in order to get unambiguous results in terms of permafrost delineation. A Geometrics Geode 24-channel seismograph and a cable with 5 m spacing were used for data acquisition. A total number of 10 shot points enabled the data set to be inverted with tomographic inversion schemes. The Pickwin and Plotrefa software was used for data processing and analyses. To create the starting model for each profile a 1D-time-term inversion was performed. The tomographic inversion scheme is based on a least squares algorithm. Topographic corrections were incorporated into the inversion algorithm. Further details on seismic data analyses are given in Palmer (1986) and Reynolds (1997).

Results and Discussion

Profile L1 is situated in a clearing (Fig. 1) where the thickness of the organic layer varies between 15 and 25 cm. Two isolated high resistivity anomalies with a thickness of 10-15 m and a horizontal extent between 10-20 m are present in the ERT (Fig. 3). Maximum resistivities of more than 160 kOhm.m point to permafrost. This interpretation is confirmed by the results of the refraction seismic tomography with P-wave velocities of 4300 m/s for the lower anomaly. Though the upper anomaly shown in the ERT is not completely displayed in the refraction seismic tomogram, relatively warm permafrost (-0.2°C) is confirmed by temperature measurements in an 8 m deep borehole at this location (Fig. 2).

Both tomograms show a thin active-layer of 2-4 m depth, which is due to the isolating properties of the thick organic layer. This modelled active-layer depth compares well with the temperature measurements in the borehole. Measured in late October 2006, the maximum thaw depth had been reached.

High velocities and resistivities usually indicate high ice

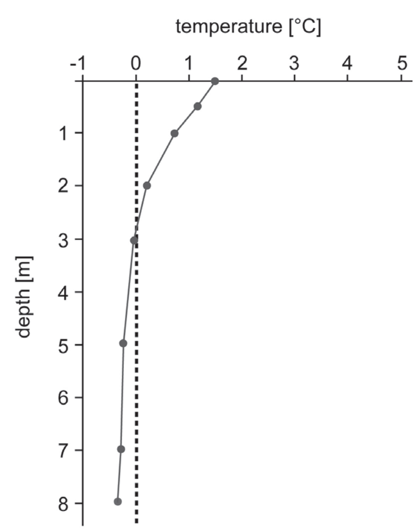

Figure 2. Borehole temperatures measured on 25.10.2006.

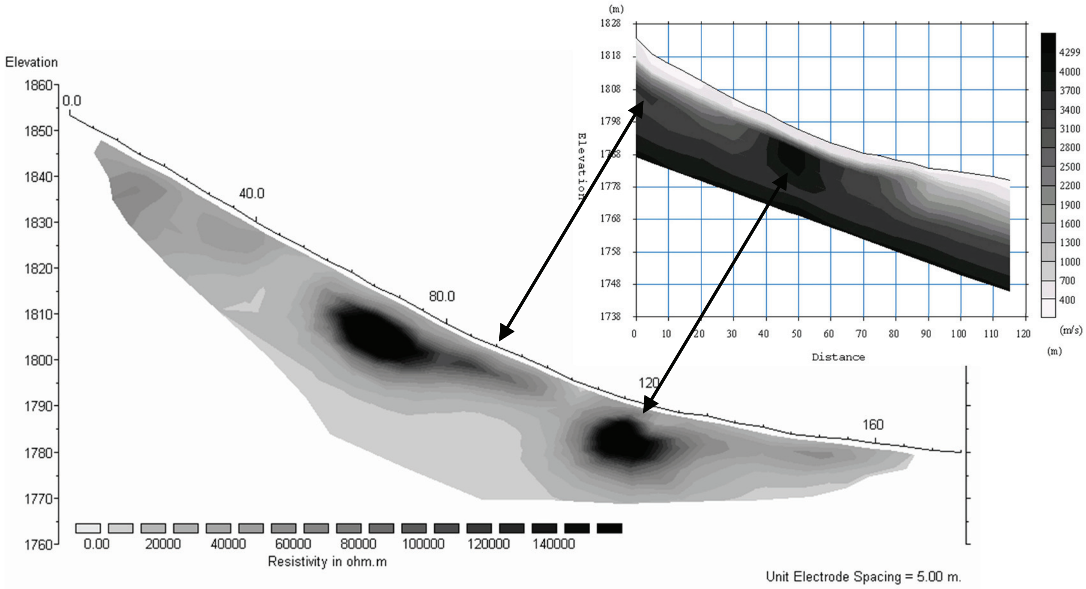

Figure 3. Electrical resistivity and refraction seismic tomograms of profile L1.

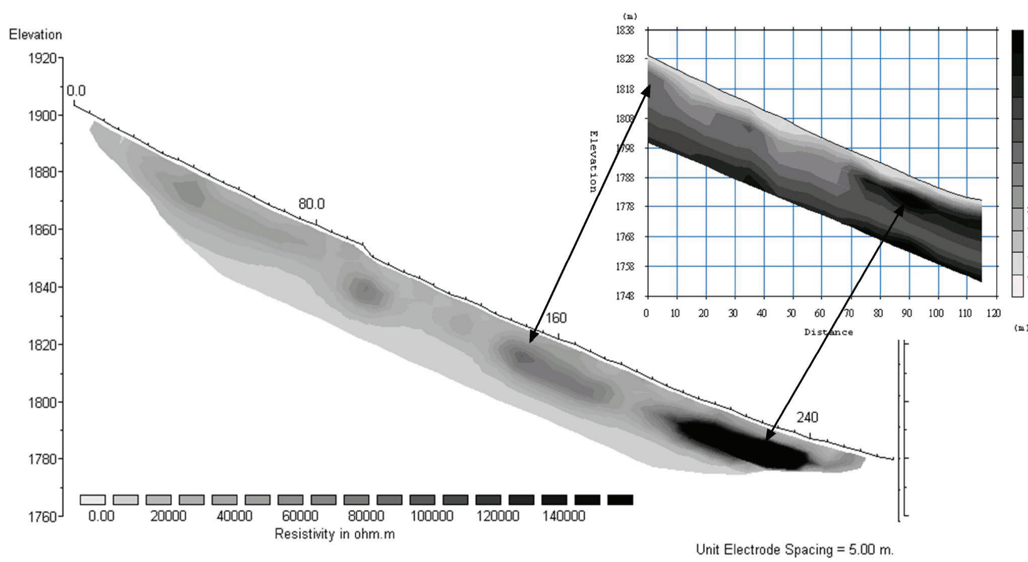

Figure 4. Electrical resistivity and refraction seismic tomograms of profile L3.

contents. Despite permafrost temperatures of only -0.2°C, the unfrozen water content is assumed to be relatively low, in the areas of the high resistivity and high velocity anomalies. The nearly linear decrease of resistivity values at greater depth indicates increasing unfrozen water content due to rising temperatures.

The ERT profile L3 (Fig. 4) shows two elongated high resistivity anomalies in the lower part of the scree slope. With resistivities of more than 160 kOhm.m the anomaly between 205 and 240 m of the ERT array is, situated in an area of coarse blocky material with low rates of fine grained material, covered with a thick organic layer of up to 30 cm. Despite relatively low P-wave velocities of 1900-2000 m/s this anomaly is assumed to represent permafrost. Low P-wave velocities at this place are most likely due to high contents of air filled voids. Profile L3 is assumed to be situated at the margin of a permafrost lens (Fig. 7). This is supported by results of a cross- and a parallel-measured profile, not shown in this paper.

The anomaly between 145 and 180 m of the ERT array and resistivities of 80-100 kOhm.m can be correlated with two anomalies in the refraction seismic tomogram. Unlike the lower parts of the profile, this area can be characterized by higher rates of fine grained material and an organic layer of about 20 cm. Despite of low P-wave velocities between 1500-1600 m/s permafrost can be assumed. If the high resistivities in this area were only due to air filled voids, seismic velocities should be much lower.

Without further research the anomalies above 1820 m a.s.l. in profile L3 cannot clearly be confirmed as permafrost, however the high resistivities are probably due to air filled voids and permafrost also in the upper parts of the scree slope.

The organic layer thickness in the area of profile L5 is comparatively thin, varying from 10-15 cm. In the ERT of profile L5 (Fig. 5) three anomalies with comparatively low resistivities of 60-100 kOhm.m are shown. The lower anomaly between 90 and 150 m can be compared with a more homogeneous area of high velocities (3000-3200 m/s) in the refraction seismic tomogram, hence are interpreted as permafrost. Below a depth of 10-15 m resistivities decrease nearly linear, indicating a decrease in ice content and/or increasing unfrozen water content. Ice rich, but "warm" permafrost can be assumed. High P-wave velocities exclude high amounts of air filled voids. The lower resistivities as compared to the other profiles could be due to comparatively higher unfrozen water content. Due to comparable conditions, concerning surface and subsurface properties, permafrost can also be assumed for the anomalies in the upper parts of the profile.

Very shaded conditions and a homogenous subsurface, with higher amounts of blocky material and an organic layer of about 20 cm is found in most parts of profile L7. Both, the ERT and the refraction seismic tomogram of profile L7 show an elongated high resistivity/high velocity anomaly between 1780 and 1815 m a.s.l., confirming probably ice-rich permafrost (Fig. 6). A thin active-layer of less than 2 m is

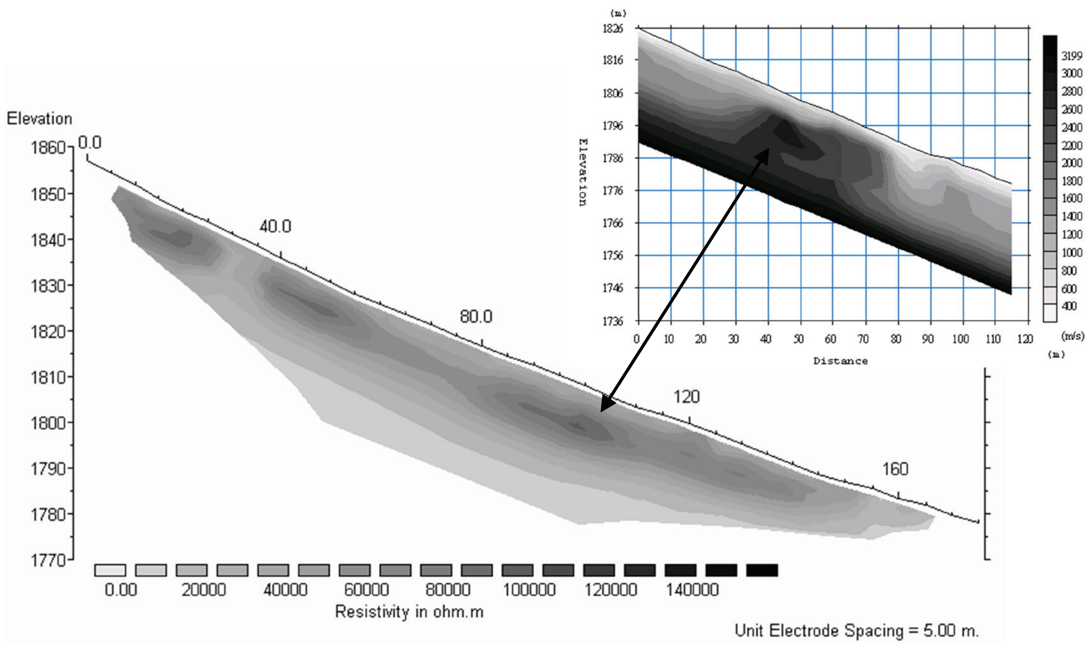

Figure 5. Electrical resistivity and refraction seismic tomograms of profile L5.

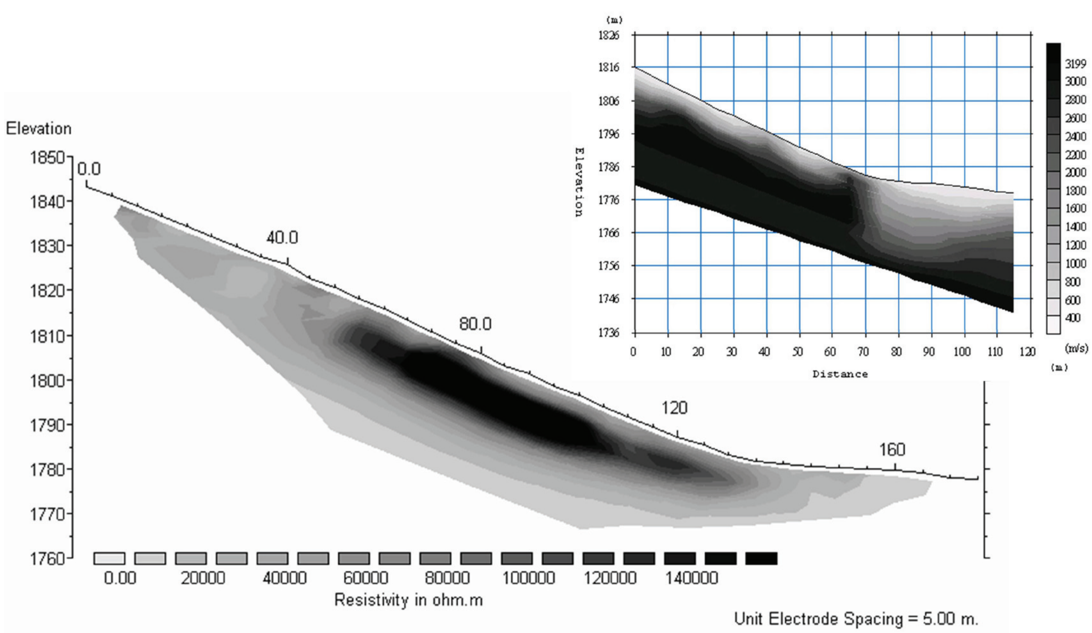

Figure 6. Electrical resistivity and refraction seismic tomograms of profile L7.

detected. However, these profiles had been measured in May 2007 and maximum thaw depth had not yet been reached. In contrast to the ERT, where resistivities slowly decrease up and down slope from the center of the permafrost lens, a sharp decrease to lower velocities is shown in the refraction seismic tomogram. Low resistivities and gradually increasing low P-wave velocities in the gently inclined lower parts of the profile could point to higher amounts of fine grained material in the subsurface.

Permafrost has been detected all over the investigated scree slope below 1840 m a.s.l. by extensive geophysical mapping (Fig. 7) however, permafrost distribution and characteristics are heterogeneous. In profiles L1 and L7 high resistivity/high velocity permafrost is present (Table 1, Fig. 7). Ice-rich permafrost with low amounts of unfrozen water and air cavities can be assumed. Lower resistivities but high P-wave velocities in profile L5 can be interpreted as ice-rich but warm permafrost with higher amounts of unfrozen water reducing the electrical resistivity. High resistivity/low velocity permafrost is to be found in profile L3. Due to very low amounts of fine grained material between the boulders many air cavities lead to high resistivities but low P-wave velocities.

Table 1. Comparison of maximum resistivities and P-wave velocities.

Profile	maximum resistivity (kOhm.m)	maximum P-wave velocity (m/s)
L1	>160	4100
L3	>160	1900-2000
L5	90-100	2900
L7	140->160	3100

Conclusions

Joint application of electrical resistivity and refraction seismics has proven to be a useful approach at this heterogeneous permafrost site as they provide complementary information about the subsurface. With respect to the large heterogeneity of the permafrost distribution, tomographic inversion schemes were used for data analyses and interpretation for both methods.

Both, electrical resistivity and refraction seismic surveys showed isolated anomalies of high resistivity and high velocity within the subsurface, especially in the lower parts of the scree slope. P-wave velocities of the isolated anomalies were between 1700-4300 m/s in a host material with velocities between 1000-1500 m/s. These locations coincide with the high-resistivity anomalies of the 2D resistivity tomography. Due to the P-wave velocities between 1700-4300 m/s, the high-resistive anomalies can be characterised as permafrost lenses, because air cavities would result in much smaller P-wave velocities. In most cases the results of both techniques coincide very well. Results of the refraction seismic tomography also point to a thin active-layer, especially in the lower parts of the scree slope. This can be due to the isolating properties of the thick layers of organic material which is, among other factors, responsible for the occurrence of this sporadic permafrost at low altitude.

The ground thermal regime is assumed to be a result of the interaction of climatic conditions with topography (northern exposure, small amount of incoming radiation, frequent temperature inversions in winter, distribution and duration of snow cover) as well as surface and subsurface factors (organic layers, coarse blocky material).

Abstract

Temporal variation in the late summer water quality of 21 small tundra lakes in the Mackenzie Delta region was investigated from 2003 to 2007. Ten lakes were undisturbed, eight had thaw slump scars in their catchments, and three were impacted by highly active thaw slumps. The electrical conductivities (EC) of lake waters from 2003–2007 varied significantly between most lakes. The greatest differences were between the disturbed lakes with elevated EC and undisturbed lakes with relatively low EC. Over the study period, the lowest and highest late-summer lake water EC were recorded in 14 of 21 lakes in association with the wettest preceding year (2006), and driest preceding winter (2003), respectively. This suggests that the chemistry of small tundra lakes is sensitive to variations in the annual water balance. Over time, the greatest relative variation in EC within lakes was associated with undisturbed lakes with unique catchment characteristics and lakes with large active thaw slumps. Intense slumping caused lake water EC to increase, and stabilization was associated with a decreasing trend.

Keywords: climate change; lake chemistry; Mackenzie Delta region; retrogressive thaw slumping; tundra lakes.

Introduction

Impacts to northern aquatic systems are anticipated with climate warming due to the modification of hydrological processes, increases in water temperature and terrestrial biomass, and intensification of disturbance regimes (Rouse et al. 1997, Jorgenson et al. 2006, Lantz & Kokelj, 2008). It is well documented that water in small tundra lakes is generally low in ionic concentration because runoff derived from snowmelt and rainfall is rapidly transported through a thin nutrient-poor active layer (Quinton & Marsh 1999, Kokelj & Burn 2005). Interannual variations in precipitation and catchment runoff should then influence the chemistry of these lakes (Rouse et al. 1997). Furthermore, there is a geochemical contrast between the leached active layer soils and the underlying ion-rich permafrost so that degradation of near-surface permafrost due to -active layer deepening or thaw slumping (Fig. 1) may modify the chemistry of soils, slope runoff, and waters in adjacent lakes and ponds (Kokelj & Lewkowicz 1999, Kokelj et al. 2002, Kokelj et al. 2005, Keller et al. 2007).

The physical and chemical characteristics of small lakes affected by retrogressive thaw slumps and adjacent undisturbed tundra lakes were described by Kokelj et al. (2005), and here we examine temporal variations in the electrical conductivity (EC) of water in these lakes from 2003 to 2007. Since runoff from areas affected by thawing permafrost is solute-rich (Kokelj & Lewkowicz 1999), we hypothesized that the ionic concentrations as indicated by EC would increase with time in lakes affected by active thaw slumps, whereas the stabilization of a slump may cause lake water ionic concentration to stabilize or decrease. It is reported that solute concentrations in lakes with stable thaw slumps are elevated with respect to undisturbed lakes (Kokelj et al. 2005), but relative interannual variability of the two populations may be similar due to the influence of regional climate conditions. To test these hypotheses, the chemical characteristics of water in the ten undisturbed lakes and the 11 lakes affected by recently stabilized and active slumps between Inuvik and Richards Island were evaluated in late summer from 2003 to 2007 (Fig. 2). Temporal patterns in EC are examined with respect to precipitation patterns and disturbance status. The implications of climate-induced permafrost degradation on lake chemistry are discussed and variability in water quality conditions is considered with respect to defining baseline water quality conditions for assessing environmental impacts of northern development.

Environmental Setting

The study lakes are in upland terrain east of the Mackenzie River Delta between Inuvik and the Beaufort Sea coast (Fig. 2). Kokelj et al. (2005) described the study area so that only a brief overview is provided here. The region is characterized by thousands of small lakes and ponds, most of which occur in glaciogenic deposits derived from carbonate and shale bedrock of the Mackenzie Basin (Rampton 1988, Mackay 1992, Burn 2002). As a result, calcium and sulphate are dominant ionic constituents of lake water (Kokelj et al. 2005).

Figure 1. Large, recently stabilized retrogressive thaw slump, Lake 10B. The thaw slump scar is about 7 ha in area. Note active slumps are developing in the scar zone in the upper part of photograph.

Lakes occupy between 10 and 20% of the landscape in the vicinity of the study lakes and median lake areas are on the order of a few hectares (Kokelj et al. 2005). Terrain is underlain by ice-rich permafrost and thaw slumps are common throughout the region (Fig. 1) (Mackay 1963, Rampton 1988). From 8 to 17% of water bodies in the vicinity of the study lakes are influenced by thermokarst slumping (Kokelj et al. 2005).

Study Lakes

Twenty-one study lakes between Inuvik and Richards Island were selected following analysis of aerial photographs and field reconnaissance in 2002 (Fig. 2). Small lakes with first-order catchments were selected (Table 1). Catchment, lake. and thaw slump disturbance areas were estimated by digitizing respective parameters on georeferenced, orthorectified, 1:30,000 scale, colour aerial photographs from 2004. Field reconnaissance and re-correction of aerial photographs has resulted in minor modifications to the aerial estimates of catchment and disturbance areas reported in Kokelj et al. (2005) (Table 1).

The lakes are in shrub and low shrub tundra environments in rolling terrain (Ritchie 1984). The small lakes (1 to 18 ha) are within headwater catchments that range from 7 to 92 ha. Eleven of the catchments (Lakes 1B to 11B) contain retrogressive thaw slumps, which occur on slopes surrounding the study lakes and occupy from 4 to 35% of the respective watershed areas (Fig. 1, Table 1). Lakes 5B, 9B and 10B were impacted by highly active slumping for at least a portion of the five-year study period. Slumping at 5B and 10B stabilized in 2004 and 2003, respectively, with activity at 10B increasing again in 2007. Lake 9B had a large and highly active slump for the first three years of study, but as the slump grew upslope, the headwall diminished and activity decreased in 2006 and 2007. Ten undisturbed lakes (Lakes 1A to 11A) are situated near disturbed catchments (Fig. 2). Time series data were not available for Lake 7A. The

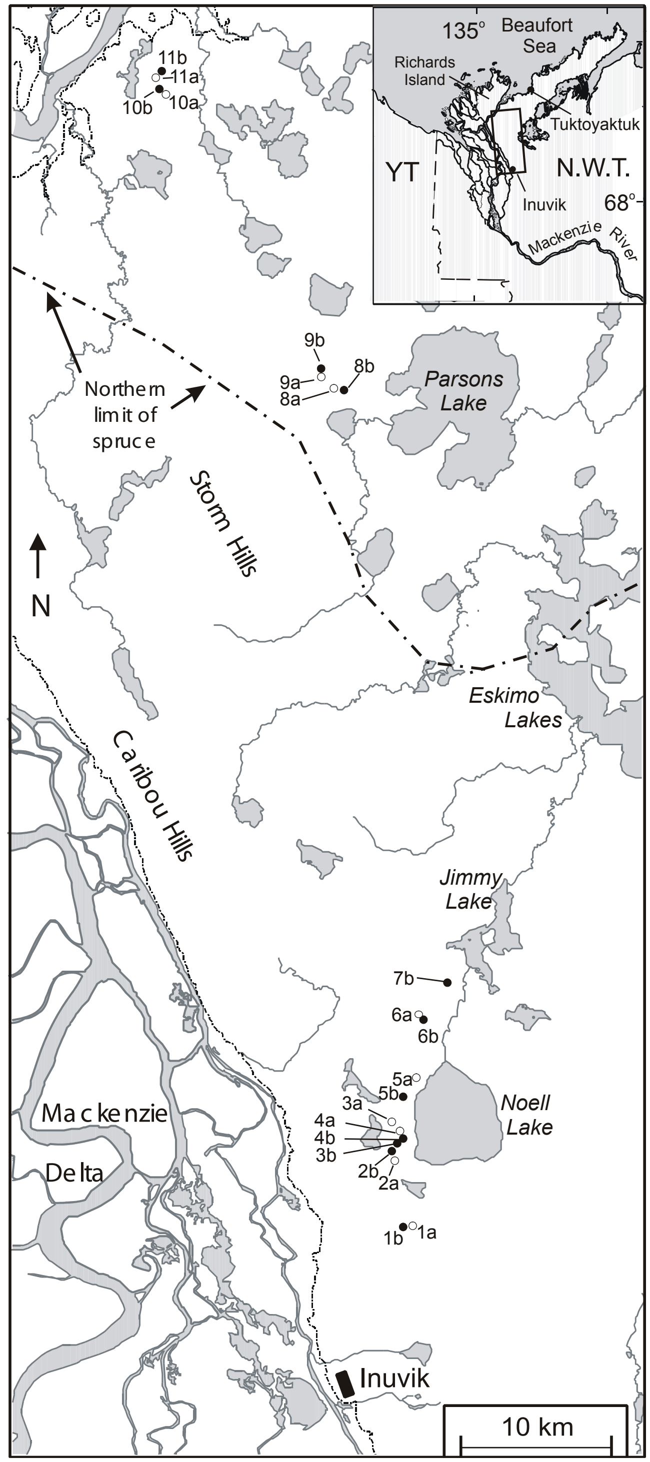

Figure 2. Map of tundra upland study lakes east of Mackenzie Delta, NWT.

southern portion of the study area was burned by wildfire in 1968, affecting catchments 1A, 1B, 2A, 2B, 3A, 3B, 4A, and 4B (Landhäuser & Wein 1993, Mackay 1995). Burned areas are colonized by dense alder and willow bush and active-layeractive layer thicknesses are generally greater than in the nearby tundra (Landhäuser & Wein 1993). Lake depth, determined at the centre of each lake, ranged from 11.3 m at Lake 3B to 1.6 m at Lake 8A, but the deepest parts of small lakes and ponds may be located away from the centre. Maximum late winter ice thickness in 2003 and 2007 did not exceed 1.5 m, and therefore, even the shallowest lakes did not freeze to the bottom. Profiles obtained during late summer surveys suggest that portions of lakes over about 6 m deep may be thermally and chemically stratified in late summer (Kokelj et al. 2005, Fig. 3).

Methods

From 2003 to 2007, during late August or the first week of September, surface water samples were obtained from the centre of each lake using a helicopter equipped with floats. Water samples were collected in 1 L polyethylene bottles rinsed three times with sample site water prior to collection. Sampling depth was about 50 cm. Following collection, sample bottles were placed in a cooler with ice packs and returned to the laboratory for analysis. Water samples were analyzed following standard methods taken from Clesceri et al. (1998). Specific EC and total alkalinity were measured on unfiltered samples in the laboratory using a Titralab radiometer. Anions and cations were evaluated by ion chromatography and hardness was calculated as the sum of inorganic calcium and magnesium using:

$$\text{Hardness (mg/L)} = 2.497 \times \text{Ca(mg/L)} + 4.117 \times \text{Mg(mg/L)}$$

Potential effects of lake and year on EC in undisturbed and disturbed lakes were tested using a randomized complete block design with years as blocks (Sokal & Rohlf 1995) followed by *post hoc* multiple comparisons using Tukey's test to control the experiment-wise Type 1 error rate. As lakes were not replicated, the interaction between year and lake could not be tested. Since multiple comparisons of means among lakes collapse data over years, the assumption of no year-lake interaction must be met if there is a significant effect. Although this assumption could not be tested, time series graphics of EC by lake provide no evidence of lake-year interaction. Residual diagnostics including Shapiro-Wilk's test of normality, visual assessment of leverage, plot residuals versus observed values, and a plot of fitted versus observed values indicate no concerns with assumptions of the statistical model (Sokal & Rohlf 1995). Relative variation in the conductivity of individual lakes over time was described by the coefficient of variation (CV) (Sokal & Rohlf 1995). Relations between water quality parameters and temporal variation in EC between lakes were explored using Spearman's rank correlations (Sokal & Rohlf 1995). Interpretation of the correlation results were regarded as tentative due to the likely low power of the between-lake EC tests because of small sample size and the large number of tests which adversely affect Type 1 error rate. Statistical analyses were conducted in R (R Development Core Team, 2007).

Results

Lake water ionic concentrations, 2003–2007

Electrical conductivity (EC) in late summer surface water samples collected from 2003–2007 was strongly correlated with major ions (Ca, Mg, K, Na, and SO_4; $P < 0.0001$) (also, see Kokelj et al. 2005; Table 3). This indicates that EC is a good descriptor of ionic strength in the water of the study lakes. In the undisturbed lakes, the highest late summer conductivities from 2003–2007 were observed in Lake 3A (160 to 185 µS/cm), which is one of the more southerly catchments and was burned in 1968 (Fig. 3). The lowest conductivities over this period were observed in Lake 9A (38.9 to 44.2 µS/cm), located in hilly upland tundra on the eastern slope of the Storm Hills (Fig. 2). The mean EC of undisturbed lakes from 2003 to 2007 was 104.5, 94.7, 93.2, 87.2, and 96.7 µS/cm, respectively. Analysis of variance shows that EC in undisturbed lakes varies significantly with year and lake, with the largest variation being associated with between lake differences (Table 2a, Fig. 3). Tukey's honest significant difference procedure indicates that, with four exceptions, the disturbed lakes, across years, are significantly different from one another. The *post hoc* testing also showed that in 2003, the mean EC of undisturbed lakes was significantly higher than in 2004 through 2006, but not 2007, and that EC in 2006 was significantly lower than that in 2007.

Ionic concentrations in lakes affected by retrogressive thaw slumping were always elevated with respect to undisturbed lakes (Figs. 3 & 4) (Kokelj et al. 2005). Lake 10B, had the highest lake water EC of any disturbed lake

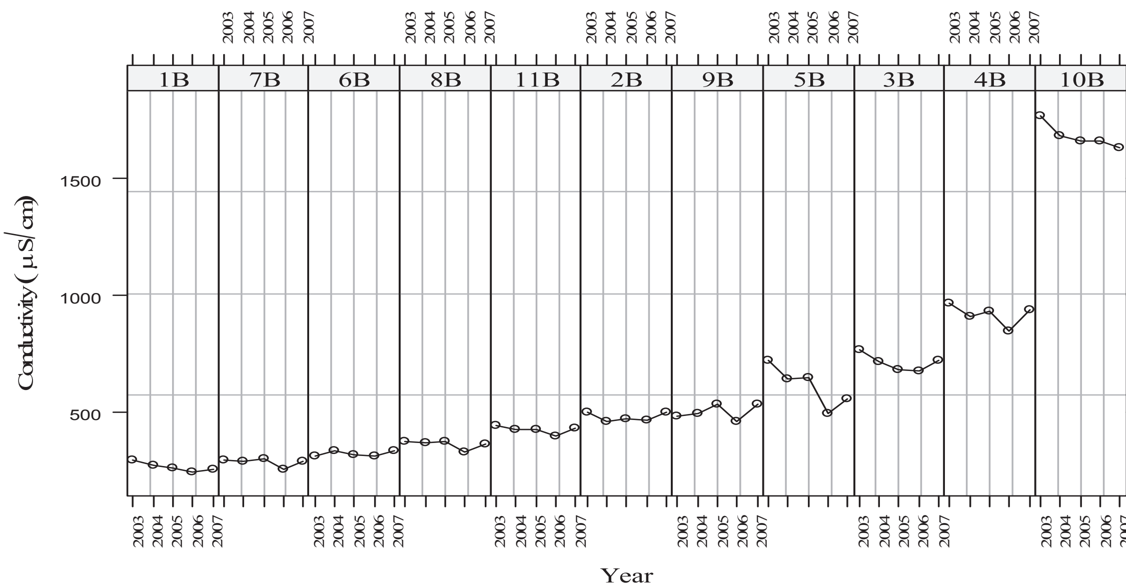

Figure 4. Electrical conductivity of lake water, lakes affected by slumping 2003–2007, Mackenzie Delta region.

and the greatest proportion of catchment area affected by slumping (Fig. 4, Table 1). The most southerly lake, 1B, had the smallest proportion of catchment area influenced by slumping and the lowest EC values. Yearly mean EC of the 11 lakes impacted by slumping from 2003 to 2007 was 631.7, 600.8, 602.5, 561.0, and 597.0 µS/cm, respectively. Table 2b shows that both lake and year are significant factors describing conductivity in the disturbed lakes and as expected the effect of lake (Kokelj et al. 2005) is much larger than that of year. The *post hoc* testing indicated that most lakes are significantly different from one another and that conductivity in 2006 is significantly lower than in 2003 through 2005.

Spearman's rank correlations of late summer lake water EC from 2003 to 2007 indicated significant positive associations between 36 pairs of lakes (Figs. 3, 4). It is also interesting to note the highest late summer EC was measured in 2003 for 14 of the 21 lakes, and the lowest lake water EC was also measured in 14 of 21 lakes in summer 2006 (Figs. 3, 4). Variability in late summer EC over years was described for each of the 21 lakes by calculating their CV (Table 1). Electrical conductivities of lakes 6A and 11A had the highest CV for the undisturbed population. The EC of lakes affected by retrogressive thaw slumping appear to be less variable than the undisturbed lakes, but this is due to the much higher ionic concentrations in disturbed lakes (Figs. 3, 4, Table 1) (Kokelj et al. 2005). Among the disturbed lakes, the highest CV for EC occurred in lakes 5B, 9B, and 1B. The first two lakes were characterized by large areas of highly-active slumping, and Lake 1B is in the largest study catchment and has a relatively large slump that reactivated in 2006 (Table 1).

Discussion

In the study region, tundra lakes are characterized by low ionic concentrations typically less than 100 µS/cm (Pienitz et al. 1997, Kokelj et al. 2005). Local variations in terrain and catchment conditions contribute to between lake differences in the EC of lake water (Figs. 3, 4, Table 2). For example, amongst undisturbed lakes, the highest lake water EC (1A, 2A, 3A) was associated with catchments that were burned in 1968 (Kokelj et al. 2005). Active layer deepening and thawing of near-surface permafrost can release soluble materials which may be transported to the lakes by surface runoff. Amongst the undisturbed lakes, the greatest relative variation in late summer EC (Table 1) was associated with lakes that possess unique catchment characteristics, including the influence of periodic icings and flooding by a nearby stream (6A), and large catchment areas which may experience interannual variation in contributory areas (11A).

End of summer EC from 2003–2007 covaried between many disturbed and undisturbed lakes (Figs. 3, 4). Although we interpret these results cautiously, the correlations suggest the influence of a regional driver. Mean conductivities of both disturbed and undisturbed lakes were notably high in 2003 and low in 2006. The minimum end of summer EC occurred in 14 of 21 lakes in August 2006, which was preceded by the wettest summer and year (Fig. 5). In contrast, EC highs in 14 of 21 individual lakes were recorded in August 2003, which was preceded by the driest winter. These observations suggest that the ionic chemistry of these lakes is sensitive to annual variations in the seasonal water balance.

Regardless, Table 2 emphasizes that between-lake differences have a greater relative influence over EC than does year. Figures 3 and 4 highlight the importance of permafrost degradation on between lake differences in EC as well as on the temporal variations in the chemistry of disturbed lakes. Lakes affected by retrogressive thaw slumping possess elevated ionic concentrations and EC with respect to undisturbed lakes because soluble materials released from thawing permafrost are transported to the lakes by surface runoff (Figs. 3, 4) (Kokelj et al. 2005). The intensity of ionic effects on lake water is positively associated with the proportion of catchment area affected by disturbance (Kokelj et al. 2005). Slumping also appeared to influence temporal variability in lake water EC. The highest coefficients of variation in late summer EC of disturbed lakes were associated with lakes affected by active slumping (Table 1). As hypothesized, intense slumping activity was associated with increasing EC (9B, 2003–2005) because thaw slumping exposes soluble materials that may be transported from disturbed slopes to the lake by surface runoff (Kokelj & Lewkowicz 1999). Stabilization of large active slumps was associated with a decreasing trend in EC, likely because the source of soluble materials is diminished with time (5B, 2005–2007; 10B, 2003–2007) (Fig. 4). It should be pointed out that temporal variation in ionic strength of water in the lakes 9B and 10B did not correlate with any of the other study lakes. In these lakes, effects of slumping subsumed the effects of a regional driver which appears to be influencing the EC of many other study lakes.

Permafrost temperatures are rising in response to 20th Century climate warming in Alaska and northwestern Canada and the frequency and magnitude of terrain disturbances associated with thawing permafrost is increasing (Serreze et al. 2000, Jorgenson et al. 2006, Lantz & Kokelj, 2008). An acceleration of thermokarst activity in conjunction with the geochemical response of lakes to slump growth (Fig. 4) suggests that permafrost disturbance could grow in importance as a driver of lake water chemistry.

In addition to anticipating impacts of climate change on tundra lakes, understanding factors that influence temporal variation in water chemistry is critical to establishing baseline water quality conditions for aquatic effects-monitoring programs. These programs are becoming regulatory requirements for assessing impacts and determining effectiveness of mitigations associated with resource development projects in Canada's North. The study lakes highlight the importance of considering catchment characteristics such as thaw slumping and lake sensitivity to interannual variations in the water balance when selecting reference lakes for the establishment of baseline conditions.

Conclusions

From these results the following conclusions are drawn:

1. Small lakes affected by thermokarst slumping have elevated EC relative to undisturbed lakes.

2. The largest degree of temporal variation in ionic strength of undisturbed tundra lakes occurred in association with unique catchment characteristics.

3. Patterns of variation in late summer EC appeared to be similar amongst many small tundra lakes. End of summer lake water EC may be sensitive to the annual water budget.

4. Amongst the disturbed lakes, those influenced by active slumping showed the greatest degree of variability in lake water EC. Increasing lake water EC was observed in a lake with a large rapidly growing slump and a decline in lake water EC was observed in lakes where large slumps have recently stabilized.

Abstract

The primary conceptualization of a cryolithosphere on Mars and a thickness of frozen rocks were introduced by Kuzmin (1983), Krass and Merzlikin (1990), and Clifford and Parker (2001). All evaluations of thickness of the Martian cryolithosphere were based on a stable temperature field model. The thickness of frost rocks (H_m) was found following the profile of gradual temperature distribution with depth for one- and two-layered lithological models. The average annual surface temperature, temperature of phase transition for water, temperature of heat transfer, and heat flux to the lower permafrost boundary were taken into account. The revised estimates of the frozen rock thickness are much reduced.

Keywords: cryolithosphere; heat transfer; modeling; temperature field; thermal conductivity coefficient.

Introduction

The greater distance of Mars from the Sun (1.5 times more than Earth) and strong rarefaction of the Martian atmosphere determines the existence of a large region with negative temperatures—a cryosphere. It begins at a height of 130–140 km above the surface, and extends deep inside across the entire planet. Many relief forms can be interpreted by the presence of a thick layer of frozen rock and consequent cryological processes. The relief is characterized by highly elongated forms which are up to 10 times larger in size then their terrestrial analogues. Considerable differences in the ice formation processes within the frozen rocks, and the scale of ice-saturated layers destruction on Mars and on Earth, could possibly explain such a significant difference in size.

Current ideas about the cryolithosphere of Mars and a frozen rock layer are mainly based on the work of Kuzmin (1983), Krass and Merzlikin (1990), and Clifford and Parker (2001). It has been estimated based on a stable thermal field model.

The thickness of a massive frozen rock layer ($H_м$) was found by the profile of stationary distribution of temperature T (K) with depth for models with one- and two-layered lithological cross-sections. The average surface temperature T_{av} and the temperature of phase transition of water, T_{ph} , and values of heat flux to the lower boundary of the cryolithosphere, q, are known. The main differences in these calculations were caused by the choices the various authors have made for the following parameters.

Coefficient of thermal conductivity (λ) for the upper rock layers. λ_m=1.8 W m^{-1} K^{-1} according to Merzlikin, and λ_m = 2.0 W m^{-1} K^{-1} according to Parker. In both calculations, a correction for the influence of temperature on the thermal conductivity of ice and upper layer porosity (0.35±0.15) has been used. Kuzmin set an average of λ_m=2.1 8 W m^{-1} K^{-1}, and using λ_{min} =0.59 and λ_{max} =3.47 8 W m^{-1} K^{-1}.

The magnitude of heat flux from depth (q) is 0.04 W m^{-2} or q = 0.03 W m^{-2} according to Krass and Clifford, respectively. q = 0.039 W m^{-2} (minimum = 0.022; maximum =0.055 W m^{-2}).

The average surface temperature (T_{av}) is equal to - 63°C. T_{av} = -29°C at the equator and T_{av} = -90°C at the poles in the works of Kuzmin, while T_{av}= - 82.5°C; T_{av} = -55°C at the equator and T_{av}= -119°C at the poles in the work of Clifford and Parker.

The presence of water-saturated layers in a cross-sectional model was considered by Kuzmin, Clifford, and Parker in their last publications.

The resulting average thickness of frozen rock varies from 2.7 km (Krass & Merzlikin 1990) to 3.23 km (Kuzmin 1983), changing from 1.5 km to 2.3–4.7 km in equatorial regions to 5 km (Kuzmin 1983) to 6.5–13 km (Clifford and Parker) under the polar caps.

According to the data of remote probing obtained recently (Mars Climate Database of the European Space Agency), and according to our ideas, it seems reasonably to precict the depth of the cryolithosphere and to reduce the estimated thickness of the frozen rock layer on Mars.

For the final evaluations, the following data were taken into account: (a) corrected means of surface temperature observed along meridians; (b) the pressure of upper layers on the lower boundary of frozen rock; (c) the presence on the surface of a dehydrated regolith layer with a thickness from 0.2 to 2.0 m. This layer is characterized by extremely low thermal conductivity (thermal resistance of a 1.5 m thick layer of regolith is equal to 5–10 m of freshly deposited snow); and (d) mineralization of pore solutions, taking the presence of highly mineralized solutions on Mars as a vital hypothesis. There appear to be salty “crusts” in study areas observed by landing craft such as Viking 1 and 2, and the Mars Pathfinder. Also, x-ray spectrometer (APXS) in the

Ares valley, and spectrometer Mossbauer in Gusev crater, registered high salinity in areas where the Mars Rovers, the Mars Pathfinder, and the Spirit landed.

The actual thickness of the frozen rock cryolithosphere on Mars is estimated to average around 2300 m, which is less than what was earlier assumed and similar to values observed on Earth. Frozen rocks contain cryohydrates that have no analogues on Earth.

For the analysis and interpretation of properties of Martian surface rocks, a set of laboratory experiments was carried out for terrestrial samples across a wide range of negative temperatures (from -60 to -120°C); these included measurement of thermal conductivity, heat capacity, and coefficient of linear expansion.

Discussion

Temperature conditions on the surface of Mars

The Martian Global Database (MGD) (www.lmd.jussieu.fr/mars.html) was used for evaluation of spatiotemporal mutability of components of surface energy (radiation-heat) balance, the surface temperature, and the temperature of the near-surface atmospheric zone for high latitude regions of Mars based on General Circulation Models (GCM) to model climate and atmosphere circulation. GCMs are also widely used for weather predication and climate research on Earth.

The Martian version of GCM is the result of cooperative work of LMD (Laboratoire de la Meteorologie Dynamique du CNRS, LMD, Paris) and AOPP (Atmospheric, Oceanic and Planetary Physics, Department of Physics, Oxford University, Oxford, England UK). They are based on actual data received from orbital stations and landing rovers from Mars Pathfinder, Mars Global Surveyor, and Viking 1 and 2.

The influence of atmosphere dustiness and dust storms were taken into account by adding some corrections for different scenarios: "dust" year and "clear" year, average and strong global dust storms The database is an information-searching system equipped with a calculation module for receiving current data on climatic parameters and during a period for a precise site, region, or across the planet.

The analyses of temperature conditions on the surface and in the near-surface atmosphere layers show that the dynamics of seasonal temperature have some characteristic features (Table 1). Maximum temperatures were observed at the end of the Martian summer, while the warmest season is autumn (for the North hemisphere).

Winter temperature tends to decrease with some variations for different areas. It is the coldest period for the region 64°N, 48°E with the peak of negative temperatures at -128.9°C. The coldest time for more southern areas 58°N, 48°E, as well as for 64°N, 30°E, is spring with the temperatures around -123°C.

In the extremely cold period (Ls = 330–360), diurnal temperature fluctuates within 1°C for the area 65°N, 68°N, within 50°C for the latitudes 47°N, and reaches the most significant values up to 100°C at latitude 43°N. Diurnal surface temperature for latitudes 65°N, 68°N achieve a minimum at 10 a.m. and a maximum at 12 p.m. The lower latitudes 43°N, 47°N are characterized by a minimum at 8 a.m., while maximums are differentiated according to the albedo. The lowest temperatures on the Utopia area (43°N, 91°W), for example, were observed at mid-day and the highest temperature at 18 a.m.; with 100°C of temperature fluctuation. In the areas of low albedo, temperatures are minimal at 8 a.m. and maximal at 14–16 p.m., and vary some 40–50 degrees.

Existence of dry soft regolith on the Martian surface

In accordance with data from the High Energy Neutron Detector (HEND) (Feldman et al. 2002), there is a dry soft regolith layer on the surface of Mars. The depth varies from 0.2 m close to the polar caps to 1.5–2.0 m on the equator. It was formed by physical weathering and has andesite or andesite-basaltic composition. The regolith layer at the Viking-1 landing site is composed mainly of clay particles or dusty fraction up to 60% (from 0.05–0.001 to less 0.001 mm), and by a sand fraction of up to 30% (from 0.1 to 2 mm). Some stone-like rounded inclusions with a size of 3–4 cm were noticed.

The thermal inertia (I) is the main thermal parameter of rocks, where $I = (\lambda C_{vhc})^{1/2}$. Here, C_{vhc} is the volumetric heat capacity in J cm^{-3} K^{-1}). Maps of thermal inertia compiled with the help of MCD and the data received by rovers (Jakovsky et al. 2000) allows generalizing a character of varying thermal inertia.

In particular, a significant increase of *I* values was observed from background values 100 J m^{-2} K^{-1} $s^{-1/2}$ (for 80% of the surface) to 400 J m^{-2} K^{-1} $s^{-1/2}$ for areas in northern latitudes from 86ºN, and to 2000 J m^{-2} K^{-1} $s^{-1/2}$ for some regions in the Southern Hemisphere.

As the data on thermal inertia is a *sine qua non* condition for regolith thermal conductivity, some experimental data obtained by differential scanning calorimetry (Komarov 2003, Isaev et al. 2006) for terrestrial samples were used in mathematic modeling of the thermal fields.

Values of volumetric heat capacity (C_{vhc}) do not depend on rarefaction and forces of gravitation. Samples of rocks were tested in an air-dry state because analyses of spectral lines of water in the short-wave part TES spectrums of the Martian surface showed that the amount of water in regolith is less than 0.1–0.2 weight percent (Christensen et al. 2001).

According to the data from neutron spectroscopy collected by the Mars Odyssey (Feldman et al. 2002), the total water content in the regolith layer on Mars is only up to first percents. Therefore, it appears to be chemically bound water.

Values of thermal inertia (I) vary between 330–380 J m^{-2} K^{-1} $s^{-1/2}$, the rock density (ρ) between 1.0–1.6 g cm^{3} for areas of Viking-1 and 2 landings. Taking into account the magnitude of the volumetric heat capacity (C) as 0.42 kJ kg^{-1} K^{-1}, and the dependence of C on the temperature, theoretical values of the thermal conductivity coefficient λ were in the range of 0.12 to 0.2 W m^{-1} K^{-1} were realized.

These estimates are similar to those actually evaluated on Mars by landing stations. For other sites located in middle and high latitudes of the Northern Hemisphere, values of λ are between 0.07–0.15 W m^{-1} K^{-1}.

Therefore, in spite of the shallow thickness and owing to the low thermal conductivity, the thermal resistance of the regolith layer is very high and could be compared to the resistance of a fresh snow on the Earth with a thickness of 3–5 m.

Results of laboratorial measurements of properties of terrestrial rocks at subzero temperatures

For the analysis and interpretation of rock properties of the subsurface layer on Mars, along with the data on heat capacity (C) obtained for terrestrial samples, it is possible to use experimental measurements of thermal conductivity and the coefficient of linear expansion (Komarov 2003, Isaev et al. 2006). It was determined for a wide range of negative temperatures (down to -120°C) by calorimeter and dilatometer equipment. Values of thermal conductivity for terrestrial rocks were re-estimated in accordance with the average value of near-surface atmospheric pressure (6 mbar). An account was based on the method of Dulnev and Zarichnyak (1974) under the conditions of transitional mode of gaseous medium flux ($2 \geq Kn \geq 0.1$, where Kn os the Knudsen criterion). The coefficient of accommodation was taken for the CO_2 – SiO_2 system (for the Martian atmosphere the main constituent is CO_2 – 95%).

This, with some corrections for rarefaction, corresponds to the coefficient of thermal conductivity of dusty particles.

According to our point of view, the thermal conductivity of the subsurface layer corresponds to coefficient values for dusty particles with a density in the range of 1.15 ± 0.15 g cm^{-3}. The density of surface rocks evaluated by orbital stations, and based on thermal inertia, is 1.2 g cm^{-3}. According to polarimetric analysis, it is 1.0 g cm^{-3} for the layer of some part of mm. Radar shows 1.4 g cm^{-3}, while the analyses of dielectric permittivity estimates 1.2 cm^{-3} for waves in the range of 3.8 to 70 cm.

Calculated evaluations of the thermal conductivity of ice-saturated rocks on Mars by Clifford and Parke were based on the generalized conductivity method. It was taken into account the dependence of ice thermal conductivity on the temperature which is, by far, significantly increased with the lowering of temperature. In our opinion, the value of λ was dramatically overestimated and, as a consequence, the thickness of permafrost was overestimated as well. As provided by experimental data ,some increase of λ can be noted exclusively for the pure hexagonal polycrystalline ice in a volume.

Among the possible explanations for actual decrease of λ in spite of the increase in conductivity of ice, are the following reasons:

(1) Loss of plastic properties of ice and formation of micro cracks within the body of ice starting at -12°C;

(2) Under low temperatures, a different coefficient of linear expansion (α) for ice and for mineral structures plays an important role, resulting in the formation of micro cracks at the mineral-ice interface; and

(3) A coefficient of linear expansion (α) specific to different minerals leads also to the formation of micro cracks.

The total effect of these processes becomes dominant and drives to decreasing of bulk thermal conductivity λ (Komarov 2003, Isaev et al. 2006).

The upper boundary of frozen rocks and ice content in the upper layers

The upper boundary of the frozen rocks was determined by the "impact method" developed in the analyses of surface images of Mars (scale from 1:5000000 to 1:250000) that were collected by Mariner-9, Mars-5 and Viking-1 and -2. This method is based on geomorphologic criterion. Morphological impact features revealed an alteration of upper layers of frozen rocks at different latitudes.

Thus, it was found that geologically young impact sites are often surrounded by radial fluid-like fluxes. It seems to be a result of a melting process in the underlying ice-saturated rocks that appeared after meteoritic explosion in ice-containing rocks. Evaluation of comparative ice-content was proposed by Kuzmin & Zabalueva (2002), who set up the ratio of the debris flow area to the diameter of the impact crater itself. A depth of frozen rock confining layers was also mapped (Kuzmin & Zabalueva 2002). Along with the data from the HEND equipment collected during the Mars Odyssey mission (Feldman et al. 2002), it has been used in our work for the evaluation of ice content in the frozen rocks.

This data shows a significant decrease of epithermal neutrons flux (energy rate 1eV - 0.1 MeV) in the areas of high latitudes caused by the presence of water ice within the subsurface rocks. The water content in a 2 m surface layer was evaluated as 40% by weight for Northern Hemisphere and 23% for Southern hemisphere (for 1-layer model), and to 55% (for two-layer model where dry regolith layer with 2% of water content overlies the subsurface strata).

Influence of overlying rock layers on the occurrence of low margin of frost rocks

Due to well-known peculiarities of ice formation in capillary-pore medium and in independent volume, a modified equation of Claiperon–Clauzius was used for evaluation of pressure (P) on temperature of phase transfer between water and ice. The equation takes into account the possibility of phase equilibrium for the phases under different pressure. In other words, it was assumed that ice of water can be liberated under the Martian atmospheric pressure while the water is subjected by the pressure of overlying layers.

This situation is characteristic for Mars, where strongly dissected basalts and andesites are abundant in subsurface layers due to impact activity. High rarefaction on Mars results in increasing density in liquid and solid phases during the process of degassing, though it makes a negligible correction in evaluations. Therefore, in the estimation of

the temperature on the low margin of frozen rocks and cryolithosphere, terrestrial values were taken for the density of ice and water. The effect of low gravitation on Mars was taken into account when the pressure of overlying strata was evaluated. By operation of the additivity rule, the influence of overlying layer pressure and mineralization of pore solutions could be calculated. The possibility of potential presence of gas hydrates within the frozen rocks was not appreciated.

Effect of mineralization of pore solutions (based on the hypothesis of the existence of brines at depth on Mars)

Salt crusts found by Viking 1 and 2 and by Mars Pathfinder evidence the existence of brines close to the surface. It is characterized by high chlorine and sulfur content in comparison with background rocks. Salt crust formation can be explained by the mechanism of capillary inflow of salty solutions up to the layer subjected to summer temperature fluctuations, as well as by irregular frost penetration. The latter leads to the formation of closed volumes of mineralized brines.

This formation is accompanied by increasing hydrostatic pressure and by subsequent cracking of frost rocks under mechanical stress. Mineralized solutions can be discharged on the surface forming salty crusts after evaporation.

Mineralization of surface layers was observed by Mars Pathfinder and Spirit rovers equipped by alfa-proton spectrometer (APEX) (Rieder et al. 1997) and by Mossbauer spectrometer in Ares valley and in the area of the Gusev impact.

Seasonal monitoring of radar reflectivity in the area of Solar Gulf also confirms the presence of brines in the frozen rocks.

In our opinion, the mechanism of formation of "martian cryopegs" is similar to the terrestrial analogues observed in regions of Central Yakutia, where considerable cryogenic concentration of pore solutions was taking place due to strong evaporation. Salt migration down along the sequence is forced out by frost penetration as a result of the "piston mechanism". Accumulation of mineralized solutions leads to the formation of cryopegs characterized by high salt concentrations that exceed 250 ml/l.

The composition of these brines is presumably magnesium-chlorine-sulfate: ice H_2O + $CaCl_2$ x $6H_2O$ + $MgCl_2$ x 12 H_2O

(the point of the eutectic is around 217K). This isotherm (217K) can be selected as a potential boundary between the zone of frozen H_2O- ice contained and frost cryohydrate contained rocks. It has no analogues on Earth.

The existence of mineralized waters set conditions for the zone of cooled rocks with no ice-content close to the low boundary of frozen rocks which is determined by the 273K isotherm. The upper boundary can be evaluated as additive value of temperature of ice to water phase transfer - 258 K (overlying rocks pressure and mineralization of pore solutions were taken into account).

Conclusions

Based on the estimated values of rocks which are tabulated (Table 2), it is concluded:

1. The average thickness of the frozen rock layer (cryolithosphere) is 2300 m, with some corrections caused by heat flux inflow. This value exceeds the terrestrial analogue but is significantly less than assumed earlier. A hypothesis of the existence of highly mineralized brines on Mars, the influence of the thermal resistance of a dry surface layer of regolith and overlying rocks on the temperature of water-ice formation, was taken into account.

2. The sequence is constrained by layers (from surface): frosty (thickness up to 300 m), frost (thickness up to 3900 m); cooled rocks (thickness up to 600 m) and thawed rocks. Within the frost rocks a cryohydrate-contained layers were identified. It has not been observed on Earth.

The presence of gas hydrates in the frozen rocks of Mars was not discussed due to lack of data.

Geocryological Problems Associated with Railroads and Highways

V.G. Kondratiev
TransEGEM, Moscow, Russia

Abstract

Over the last 10 years, significant new construction of railroads and highways has occurred in Transbaikal and the adjacent territories, including China. Examples of geocryological problems associated with selected railroad and highway locations are presented. Operational reliability, assessment, and monitoring needs are discussed. Emphasis is given to providing comprehensive geocryological exploration efforts, utilizing innovative and intelligent design solutions, allowing for timely and quality construction procedures as well as making provisions for necessary ongoing maintenance. Experience with anti-deformation measures, used for both the Russian and Chinese railroads and highways, utilizing both active and passive methods for strengthening the embankments on ice-rich permafrost, is also presented. In addition, technical solutions involving anti-frost heaving devices for electrical contact-line railway and power line tower supports, is reviewed.

Keywords: embankments; geocryological monitoring; highways; permafrost; railroads; thaw settlement.

Introduction

The history of railways constructed in permafrost regions exceeds more than 100 years: Transbaikalian, Amur, Alaska, Norilsk, Gudson, Labrador, Baikal–Amur (BAM), Amur–Yakut (AЯМ), Yamal, and some other railways in Russia, the USA, and Canada. Construction of each of these railroads provides examples of frozen-ground construction and attempts to provide stable subgrade soils in areas of permafrost and deep seasonal freezing.

Construction in China of the Qinghai–Tibet Railway along the Golmud–Lhasa segment occurred in 2000–2006. This is the newest stage of major railway construction, involving conditions of permafrost and deep seasonal freezing of the soils. The project has included new, large-scale attempts to solve some of the specific problems.

The author was involved with Chinese experts on addressing problems of geocryological concerns along the Qinghai–Tibet Railway and the Qinghai–Tibet Highway over the last 14 years, and in Russia, has been actively engaged in these problems since 1986. Results of his research are reflected in more than 60 technical papers and reports, as well as 5 monographs published in the USSR, Russia, the USA, Canada, Norway, China, Japan, and Finland. Information from these projects and various studies are briefly reviewed in this paper.

Geocryological Problems Associated with Railroads

There has been very limited success in building a railway line that would not undergo deformations resulting from thawing of ice-rich soils or frost heave, induced by freezing of wet foundation soil. These problems are characteristic for all railroads regardless of the length of time in operation. The Transbaikalian Railroad has been in operation more than 100 years, the BAM and the Amur–Yakutsk Main Line, well over tens of years, and the connecting lines Chara–Cheena and Ulak–Elga, only several years. The Qinghai–Tibet Railway has only recently been completed.

Figure 1. Deformations of a track and power line tower support along an electrified section of the Transbaikalian Railroad, km 6278, November 2006.

One of the major problem areas on the Transbaikalian Railroad, located at route segment 6277 to 6278 km, is shown in Figure 1. This segment is known as the “golden” kilometer. At this location, continuing deformation of the embankment and rail-sleeper grating have been occurring since 1949. Train speed limitations of 40 km/h, and sometimes as low as even 15 km/h, have been imposed since 1969, while addition of ballast and rail adjustments are executed annually.

In some places, the ballast has already subsided 5 to 6 m, and subsidence of the railbed has not ceased. This condition is expected to continue for many years, since the embankment was constructed on permafrost soils having a thickness of 25 to 30 m.

On the East Siberian Railroad, in the region of the Kazankan sidings at 1374 km on the BAM, major railway track deformation has been taking place for nearly two decades. From the original four-track lines on this segment, only one remains in service; however, as shown in Figure 2, it also requires nearly-continual maintenance and recurrent refitting. For the last 7 years, 360 million rubles (about 15

Figure 3. Track and power line tower deformation along the Chara–Cheena Railroad, October 2003.

million dollars) have been spent to refit this section of the railroad, but the problem of stabilization remains unsolved. Train speeds are still limited to 15 to 40 km/h, since the threat of unacceptable deformation of the track on this side hill-slope remains. Since this segment of the BAM is electrified, it is critical that the electric contact net and supporting power line towers be repaired as well.

To the north of the Transbaikalia, the Chara–Cheena Railroad was constructed in 2001. The route extends over an area having extremely complex engineering-geocryological conditions involving ice-rich permafrost. In some areas, the underground ice has a thickness of 5 to 10 m. An example of this railway track deformation, occurring under the adverse influence of cryogenic warming processes, is shown in Figure 3.

Sun-Precipitation Protective Sheds

The thawing of permafrost soil under railroad and highway embankments is usually caused by: 1) increased absorption of solar radiation into the subgrade when compared to the natural surface; 2) the infiltration of precipitation through the embankment; 3) an increase in the thickness of snow cover at the base of the embankment and adjacent area; and 4) the migration of surface and subsurface water into the body and base of the subgrade in side-hill slope areas.

Figure 4. Sun-precipitation protective sheds on the Qinghai–Tibet Railway, August 2006.

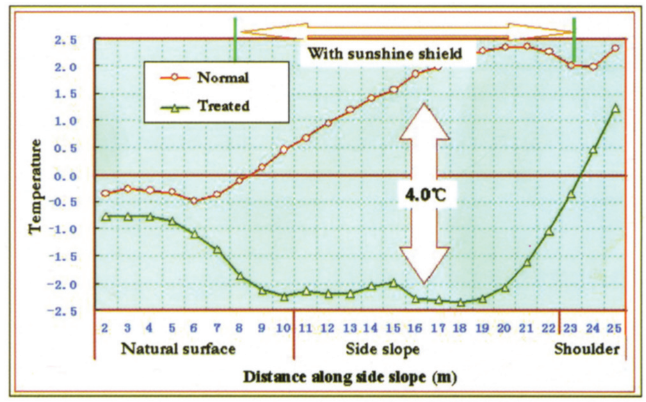

Figure 5. Cooling influence of the sun-precipitation protective sheds, constructed on the embankment slopes of the Qinghai–Tibet Railway.

Several methods of strengthening the base of embankments on ice-rich permafrost have been developed. These methods cause a decrease in the average annual temperature of soils and assist in preserving the permafrost state in a way that reduces warming and improves cooling impacts.

These technical solutions have been presented in articles, reports, and monographs, both in domestic and foreign publications (Kondratiev 1994, 1996, 1998, 2002, 2004, & 2006). The solutions have been applied on experimental projects while constructing the Amur–Yakutia trunk line and the connecting Ulak–Elga Railroad, and while preparing a feasibility study of stabilization measures for use on the Transbaikalian Railroad. Some of these solutions have been applied also on the Qinghai–Tibet Railway in China. An example of the sun-precipitation protective shed applied to side slopes is shown in Figure 4. Data from observations at the full-scale site indicates temperature reductions ranging from 3 to 5ºC in the subgrade soil. This cooling influence, as shown in Figure 5, serves to improve the stability of the subgrade soil on the highly ice-rich permafrost soil (Niu & Shen 2006).

Application of sun-precipitation protective sheds has also been accomplished on Russian railways and highways. On the Amur–Yakut Railway at the approach to the Lena River for tens of kilometers of the railroad, there exists a so-called ice complex, having a thickness of several tens of meters. Excavation or mechanical pre-thawing of this ice thickness is considered to be impractical. Therefore, it has been concluded that this section should be protected from thawing during all periods of railroad operation.

In 2007, a technical study of the application of sheds for preventing degradation of ice-rich permafrost, at the base of an embankment along the Tommot–Kerdem Railway, was initiated at five separate sites. These involved three embankments having heights of 3.48, 6.64, and 7.31 m and two excavations having depths of 2.38 and 5.5 m.

For comparison, at the same sites, thermotechnical calculations of the cooling influence of convective stone/rock covering on the embankments and excavated slopes were executed. Results were found to show a higher efficiency with the sun-precipitation protective sheds for cooling soils in the subgrade of an embankment and prevention of degradation in the underlying permafrost soil, particularly when used in combination with dolomite powder (light-reflecting painting) placed on the surfaces of the basic platform and employment of an antifiltering membrane underneath. Results further indicate that:

- On slopes of both embankments and excavations, the shed-only application provided a decrease of 10 to 31% (average 22.4%) in the depth of the bedding and cover over the permafrost soils along the axis in comparison with the rock covers.
- On the slopes of both embankments and excavations, use of sheds in combination with dolomite powder painted on the surface of the basic platform provided a 25 to 35% (average 30.6%) decrease in the depth of the bedding and cover over the permafrost soils along the axis in comparison with the rock covers.
- On the slopes of both embankments and excavations, use of sheds in combination with the dolomite power painted on the surface of the basic platform and with placement of an antifiltering membrane underneath provided a 28 to 40% (average 34.6%) decrease in the depth of the bedding and cover over the permafrost soils along the axis in comparison with the rock covers. In this case, cooling of the embankment and subgrade soil occurs more rapidly than at sites having rock covers. After only 5 years, the subgrade soils and a substantial part of the body of the embankment exist in the permafrost state, whereas under the rock covers the embankment remained unfrozen, and complete freezing will only occur after 50 years.

Thermotechnical calculations for the Amur–Yakut Highway, as well as experimental research in Tibet, demonstrate that sun-precipitation protective shed applications represent an effective treatment as an anti-deformation device for embankments on railroads and highways at sites containing icy permafrost soils. The positive effect of the shed application is accomplished by both allowing the intensive winter cooling of the embankment and its subgrade, and by both the reduction in infiltration of summer precipitation and the exclusion of direct solar radiation. This helps to preserve the higher strength properties of the frozen soils in the subgrade during all periods. Thus, the design of an embankment becomes simpler, traffic volume and safety improves, and maintenance and repair needs decrease.

Figure 6. Adverse deformation of power line tower supports along the electrified section of the Transbaikalian Railroad, August 2001.

Operational Reliability and Monitoring

Operational reliability of railways and highways in regions of permafrost is predetermined by the choice of constructive-technological solutions and methods of effective execution during construction and subsequent maintenance operations. Constant protection of roads from adverse engineering-geocryological processes, particularly in areas of ice-rich soil, is important in order to provide stability and maintain traffic design speeds. To be most effective, such protection needs to be carried out systematically with emphasis on engineering and geocryological monitoring of the routes. This includes providing regular reviews and controls, technical analysis, and estimations and forecasts of changes in freezing conditions. Such a procedure allows detection and mitigation of undesirable and adverse cryogenic processes. The concept of such a monitoring system was developed for the constructed Berkakit–Tommot–Yakutsk Railroad (Kondratiev and Pozin 2000). In 2001, the concept and process were presented in Beijing and then applied to the Qinghai–Tibet Railway route.

Anti-Frost Heaving Tower Supports

The provision and effective utilization of basic facilities of railways in areas of a permafrost and deep seasonal soil freezing is associated with significant difficulties. As an example, on the Transbaikalian Railroad during the past 10 years (1997 to 2006) at least 17,192 power line tower supports required corrective repairs and 3,294 were replaced. In most cases deformation of support structures were caused by frost jacking within wet friable sediments of seasonally thawed (STL) or seasonally frozen (SFL) layers. Figure 6 provides an example of the extent of tower deformation.

In responding to this problem, a patented solution for an anti-frost heaving measure was developed for the purpose of decreasing the influence of frost heaving forces. This is accomplished by the simultaneous increase in lateral forces on the tower support in STL by freezing and by cooling within long-term frozen soils by means of (a) thermosyphon support in STL, inserted into a hollow reinforced concrete support or metal base; (b) wrapping of an anti-frost heaving sleeve made of nonfreezing grease and a protective casing

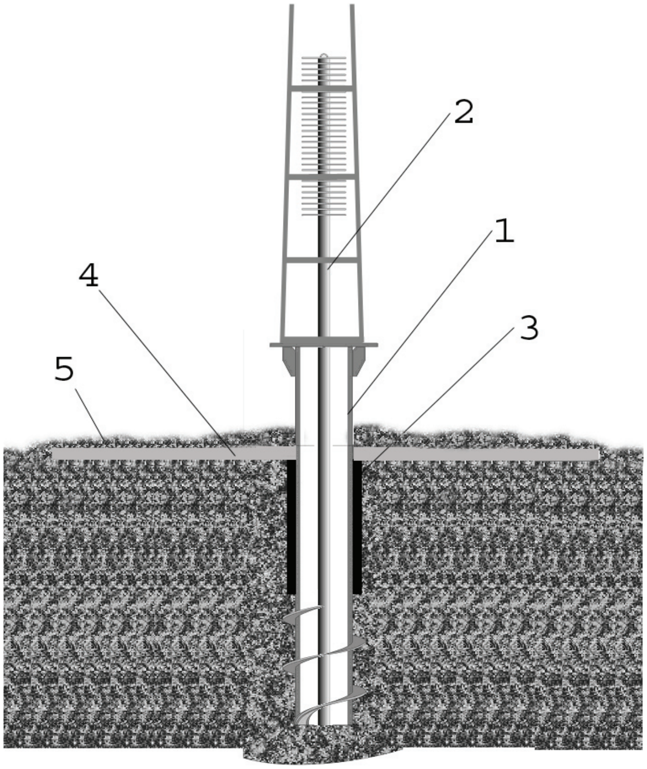

Figure 7. Metal support with screw base (1), with thermosyphon inset (2), anti-frost heaving sleeve (3), thermal insulation (4), and a covering soil layer (5).

made of frost-resistant material; (c) placement of heat and hydroinsulation at the soil surface around the support; and (d) inclusion of a sun-precipitation protective shed around the support and anti-frost heaving sleeve (Kondratiev, 2005).

The anti-frost heaving device design for a metal tower support having a screw base (as shown in Fig. 7) consists of three basic elements: the thermosyphon, the thermal insulation, and the anti-frost heave sleeve.

In October 2003, anti-frost heaving devices consisting of the thermosyphon structure and a 1.25 m long anti-frost heaving sleeve were installed on five tower support pile bases along the Erofey–Pavlovich–Sgibievo segment of the Transbaikalian Railroad.

Work on placing the insulation layer around the support bases and protective soil cover was performed in April 2004, after allowing maximum winter freezeback of the soil around the metal support bases. The elevated portion of the supports was then painted with a white cover.

Analysis of the data recovered since November 2004 shows that, owing to the cooling influence of the thermosyphons, soil freezing near the base (at 0.1 to 0.2 m from the surface) occurred more quickly than at 0.55 to 0.65 m. Around one support, the frozen soil mass, which normally thaws to a depth of 2.5 to 4 m by late autumn, was found to preserve the soil in a constantly-frozen state around the lower portion of the support at a depth of 1.5 to 3 m.

Periodic level surveys were conducted on the top part of the tower supports and have shown that the tower bases having anti-frost heaving devices have remained stable under varying conditions of soil freezing and thawing cycles. Measurements indicate that the vertical movement does not exceed 10 mm, based on a measurement accuracy of a Class III level survey. Whereas, 20 to 30% of the tower bases not having anti-frost heaving devices have begun to heave after 2 to 3 years following installation. Their vertical moving for 5 annual cycles of freezing-thawing have ranged from 10 to 280 mm.

Following verification of the experimental anti-frost heaving devices for the tower support bases, applications have now been extended to electrified rail line projects such as the Karimakaya–Borzya, Burinda–Magdagachi, Mogocha–Amazar, Chernovskaya, and Karimskaya stations. This solution also has the potential for use on other types of tower structures such as signal system devices, high voltage transmission lines, communication structures, and elevated pipelines which are exposed to the negative influence of soil frost heaving.

Geocryological Problems Associated with Highways

Problems with embankment stability of subgrade soils are characteristic for highways within permafrost regions as well. Particularly for the newer “Amur” Highway extending from Chita to Khabarovsk (shown in Figs. 8–10) and the Qinghai–Tibet Highway (shown in Fig. 11).

The federal “Amur”–Chita to Khabarovsk Highway is one of the largest contemporary construction efforts in Russia. Construction of the road, having a length of 2165 km, began in 1978 and is planned for completion in 2010. However, even now, many sections of the road are subject to constant repairs that are not always successful. As an example, the high embankment on the “Amur” Highway, where it passes over Chichon Stream at 247 km, is presented. Here, the uneven subsidence of the 20 m high embankment has been observed since May 2001, soon after the delivery of this highway section. Since that time, as shown in Figure 8, subsidence of the road surface in some places has approached about 2 m, in spite of the periodic addition of soil and the re-leveling to profile grade.

Both transverse and diagonal cracks, having widths of up to 15 to 20 cm, are opening within the roadway, shoulders, and embankment slopes. The pavement surface is also highly deformed. This highway section is in a very distressed condition. The traffic speed for vehicles is now limited to 40 km/h for this section, while the designated design speed is 100 km/h.

During September 2006, the innovative repairs of this 200 m of failing section, as shown in Figure 9, was completed.

Almost 10 million rubles have been spent on repairs to date; however, as shown in Figure 10, deformation of the embankment section continues. The subgrade soil in this section consists of 15 to 20 m of permafrost, with the larger part being ice-rich soils that settle and flow upon thawing. As a result, permafrost degradation and corresponding deformation of the road under the prevailing conditions is expected to continue indefinitely.There are a number of other such examples along the “Amur” Highway. Since much of the route passes through the southern fringe of discontinuous permafrost and also lies within a region of deep seasonal soil freezing, it is evident that an ongoing change in permafrost conditions and deep seasonal freezing will continue. Thus, it is important to identify permafrost conditions along the route, develop systematic means to address or control the cryogenic dynamics that adversely influence elements of the roadway, and initiate the timely application of protective measures. Therefore, in order to provide for a more effective operation of this highway, the system of engineering-geocryological monitoring of the “Amur” Highway was developed under the designation SIGMA “Amur.”

In 2006, the TransEGEM organization developed and submitted to Rosavtodor the concept of SIGMA “Amur.” Following is a summary of the developed concept (Kondratiev et al. 2007):

- The SIGMA “Amur” structure includes information gathering, processing and analysis of information, assessment and information storage, forecasting and projection of protective measures, and application of protection (implementation of protective measures).
- The operating scheme of SIGMA “Amur” provides for a number of regular procedures arranged into cycles for data gathering and processing, assessment of hazardous engineering-geocryological processes, forecasting their future development, and management of unfavorable processes.
- The operating structure of SIGMA “Amur” consists of several subsystems designed for different purposes: hierarchical, project monitoring, and operating subsystems, productive work, and methodical and technical support.
- Primary subjects of SIGMA “Amur” engineering-geocryological inquiry consists of three interrelated parts: geology-geographical, permafrost, and highway conditions.
- The overall program of the SIGMA “Amur” organization emphasizes optimal structure and consistency in practical operations, both with regard to organization and function.
- The plan is to implement a complex program with the aim to set up SIGMA “Amur.” The program has three stages: preliminary stage, setup of information database, and the SIGMA “Amur” operation stage.
- Address proposals on the organization of SIGMA “Amur” operation.

The early creation and functioning of SIGMA “Amur” was intended to provide a more reliable and safe highway that will reduce less unproductive expenditures and improve its operations. Without application of such a concept, the “Amur” Highway will be subject to continuing repairs, constant traffic speed limitations for vehicles, and major financial and material losses.

Figure 11. Deformation and displacement of an embankment slope on the Qinghai–Tibet Highway as a result of permafrost degradation outside the influence area of the thermosyphons, August 2006.

In the 1950s the Qinghai–Tibet Highway was constructed with a gravel-crushed stone coating. In the 1980s, it was reconstructed, and in may sections, asphalt pavement was applied. This black pavement surface accelerated degradation of permafrost within the subgrade, producing significant surface deformations in those sections having ice-rich soils. Also, those subgrades having frost heaving soils were adversely impacted (Wu et al. 1988). Recently the highway was reconstructed to meet contemporary high-speed vehicle standards. The highway, in essence, traverses parallel with the Qinghai–Tibet Railway. The highway has a hard-surfaced pavement and utilizes anti-frost heaving measures in the sections having ice-rich soils. At some of these locations, thermosyphons have been placed in the form of one or two lines along roadway shoulders; however, as can be seen in Figure 11, some embankment problems have begun to occur. It is also expected that the thermosyphons will not protect the road from thermokarsts because of their limited radius of cooling.

Conclusions

In conclusion, it is felt that the above information again demonstrates that, in order to achieve stable and reliable transportation routes in regions of permafrost and deep seasonal frozen soils, it is critical that a system be utilized which provides comprehensive geocryological exploration and evaluation, uses innovative and intelligent design solutions, allows timely and quality construction procedures, and provides for necessary ongoing maintenance.

Abstract

This paper presents the results of investigations on interannual variability of seasonal thaw depth in the taiga landscapes on the Lena-Kenkeme watershed in the vicinity of Yakutsk (East Siberia). The results of our investigations indicate that the depth of seasonal thaw is more strongly related to the interannual variation of winter ground heat loss than to the interannual variation of air thawing index or total summer precipitation.

Keywords: active layer; ground heat storage; ground temperature; seasonal thaw depth; soil moisture content.

Introduction

The necessity of considering wintertime heat losses from the ground when analyzing seasonal thaw patterns is dictated by the specifics of the heat balance of the ground layer in contact with the atmosphere. The greater the winter heat loss from the ground (within the entire depth of annual heat exchange), the larger the amount of heat required for preliminary ground warming in the summer. Correspondingly, there will be some reduction in the proportion of the heat expended on phase transformation of soil moisture, and hence less energy will be available for deep summer thawing of the soil.

The winter heat loss from the ground shows strong variations from year to year. It is greater in years with thin snow cover and lower in those with deep snow. There are, however, no accurate methods for measuring or estimating this quantity. The intensity of winter cooling can be qualitatively characterized by the mean annual ground temperature at the active layer–permafrost boundary (t_ξ), because in permafrost areas the winter season plays a decisive role in the development of the ground thermal regime. Compared to the amount of ground heat exchange, t_ξ is easier to determine experimentally and is found by standard measurements with temperature sensors permanently installed in the ground. The t_ξ value is lower in the years of increased winter heat losses from the ground and is higher in years with reduced winter heat losses. Thus, the effect of variations in the winter ground heat loss on summer thaw depth can be estimated by investigating the relationship between thaw depth and interannual variation in mean annual ground temperature.

Methods

A modified design of the Danilin-type frost gage developed for Russian weather stations was used in this study. This device determines the 0°C isotherm within the ground from the position of the thawed/frozen interface in the measuring tube with distilled water, which is removed for reading from the pipe that is permanently installed in the ground. The Danilin frost gage has two important advantages. First, determination of the 0°C isotherm in the surrounding ground from phase change of water in the measuring tube provides a sufficiently reliable measurement, requires no preliminary calibration, and has virtually unlimited time stability. Even if there is some difference between the position of the 0°C isotherm determined by the frost gage and the actual position of the phase boundary (or the top of plastic frozen soil in clay material) due to different freezing points of the soil and the tube water, this will not affect statistical parameters of the time series since the error will be systematic. Second, the use of the frost gage ensures that measurements are made at the same location each year; this eliminates the potential effects of spatial variation.

Many years of experience have shown that the Danilin frost gage provides accurate estimates of thaw depth, but that it is not satisfactory for the study of active layer freezing. Therefore, a considerably simplified design of the Danilin frost gage intended exclusively for determination of summer thaw depth has been used in this study. This design does not use an extractable measuring tube, eliminating air convection into the soil. The simplified version of the frost gage consists of a polypropylene tube with an outer diameter of 25 mm and an inner diameter of 20 mm, whose length exceeds the maximum possible thaw depth at a site. The tube is waterproof and sealed at the bottom. The sealed bottom is lowered into a small-diameter hole drilled for thaw depth measurement. The annulus is backfilled and thoroughly compacted. Then the tube is filled with distilled water to the ground surface level. The position of the 0°C isotherm in the ground is determined by a metal tape whose end is lowered into the frost gage tube to the water/ice interface at the time of measurement.

Experimental investigations were conducted in taiga landscapes in the vicinity of Yakutsk (East Siberia, 62°N, 129°E). The thermal research program was initiated in 1996 (Konstantinov et al. 2001, Konstantinov & Fukuda 2001, Fedorov et al. 2003).

Experimental sites 1, 2, and 3 are located on the erosional plain (southern part of the study area) where the active layer consists predominantly of fine-grained sands (dry density 1100-1800 kg/m^3; 75%–85% sand, 8%–11% silt, and 6%–15% clay) and silty sands (dry density 1200–1750 kg/m^3; 61%–67% sand, 25%–29% silt and 6%–10% clay). Sites 4, 5, and 6 are located in the erosional-aggradational plain (northern part of the study area) where the soils consist mainly of silts (dry density 960-1700 kg/m^3; 19%–47% sand, 41%–66% silt, and 7%–20% clay).

Experimental site 1: Middle part of a long, gentle north-facing slope. Soils: sands and silty sands. Vegetation: *Laricetum arctouso-vacciniosum*.

Experimental site 2: Ridge crest. Soils: sands. Vegetation: *Lariceto-pinetum limnoso-arctostaphylosum*.

Experimental site 3: Upper part of a long, gentle north-facing slope. Soils: sands and silty sands. Vegetation: *Lariceto-betuletum limnoso-vacciniosum*.

Experimental site 4: Inter-alas surface surrounded by mature and growing thermokarst depressions. Soils: silts. *Mixtoherboso-graminosum* meadow.

Experimental site 5: Dry area on the bottom of a large thermokarst depression (alas). Soils: silts. *Mixtoherboso-graminosum* meadow.

Experimental site 6: Inter-alas surface. Large clear-cut area in larch forest where tree stands were removed in the early 1990s. Soils: silts. Vegetation: secondary growth of grasses and fragments of the low-shrub layer.

Results

The values of basic meteorological variables for the period of investigation are presented in Table 1, using a provisory year starting from 1 October and ending on 30 September, so that one winter season would not fall in two different calendar years. Double figures are used; e.g., 1997/1998, 1998/1999, etc. The data indicate that the main meteorological parameters have strong interannual variability in the study area, resulting in significant interannual variations of mean annual ground temperature (Table 2). The maximum difference in t_ξ has been 1.5°C–3.2°C in absolute values.

Interannual variations in maximum annual thaw penetration at experimental sites are given in Table 3. For the observation period, the standard deviation of thaw depth is 0.07–0.14 m, and the coefficient of variation is 0.04 to 0.09. As is seen, seasonal thaw depth is less variable than mean annual ground temperature, whose coefficient of variation is 0.25–0.47 for the same period. This fact imposes more stringent requirements on the instruments and methods used in field experiments. The use of only mechanical probing or soil temperature profiles in the study of interannual variation in seasonal thawing can result in errors, since these methods give less accurate estimates than the frost gage. This is especially critical in southern permafrost regions where active layer thicknesses exceed 1 m.

Tables 1 and 3 show that there is no obvious relationship between the active layer thickness and the air thawing index. Data for the period 2005–2007 confirm this conclusion. Interannual variations in the degree-days sum at the ground cover surface (May-September) are plotted in Figure 1. It is seen that the surface thawing index decreased in 2005–2007, but the depth of thaw and the mean annual ground temperature increased.

There is also no strong relationship between the seasonal thaw depth and the total summer precipitation. The years with the deepest (1999/2000) and shallowest (2000/2001) thaw penetration had total summer rainfall of 126 and 68 mm, respectively. The effect of precipitation on seasonal thaw depth appears not to be a major determinant here with this small difference in precipitation totals, considering that their range over the observation period was 68 to 256 mm. A distinct relationship between thaw depth and summer precipitation was only observed at Site 1 located in the middle part of a long, gentle slope with a larch stand on sandy soils (Tables 1, 3). In 1998/1999, 2004/2005, 2005/2006, and 2006/2007 high suprapermafrost groundwater flow occurred at this site after heavy rains, resulting in the deepest thaw.

Tables 2 and 3 and Figure 1 show that seasonal thaw depth increased in years with higher mean annual ground temperatures (1999/2000, 2004/2005, 2005/2006, and 2006/2007) and decreased in years with lower t_ξ (2000/2001, 2001/2002, 2002/2003, and 2003/2004). During the period of observations, t_ξ was warmest in 1999/2000. In that year most sites experienced maximum thaw depths, while air thawing indices and rainfall totals were within the average range of the series variation. The best agreement between the interannual variability of thaw depth and that of mean annual temperature was observed at sites with the minimum t_ξ difference over the observation period (Site 6).

If we compare thaw development in four years with the coldest ground temperatures (2000/2001, 2001/2002, 2002/2003, and 2003/2004), it is seen that the depth of thaw was not shallowest in the coldest year 2002/2003. This discrepancy can be explained if one compares pre-summer soil moisture contents in these years, which were 1.5–1.8 times higher in 2000/2001 and 2003/2004 compared to 2001/2002 and 2002/2003 (Fig. 2). This is the reason for minimum thaw in 2000/2001 and 2003/2004: greater heat loss is required for phase change of soil moisture under the conditions of increased seasonal ice content in the active layer. Shallower thaw depth at Site 2, which experienced warmer ground temperatures in 2006/2007 compared to 2005/2006 can also be attributed to the effects of variations in seasonal ice content. Many investigators have shown that opposite trends in thaw depth can occur over short distances. One possible explanation is the effect of seasonal ice content in the active layer, because ground conditions vary greatly over

space. Adjacent sites can therefore experience very different thaw rates if they show dissimilar variations in seasonal ice content from year to year. These examples demonstrate that soil moisture is an important consideration in the study of interannual variability of seasonal thaw depth.

Data on the effect of winter factors on active layer thickness are available mostly for the regions with a continental climate, such as Central Yakutia and northern Tian Shan (Blagoobrazov 1964, Skryabin et al. 1998, Marchenko 2002, Konstantinov et al. 2006). For the coastal regions of the permafrost zone, the depth of thaw has been found to be more sensitive to summer factors, mainly the thawing index (Brown et al. 2000, Leibman 2001, Fedorov-Davydov et al. 2004, Mazhitova & Kaverin 2007).

Conclusions

The results of our investigations indicate that in the taiga landscapes of the Yakutsk area, the depth of seasonal thaw is more strongly related to the interannual variation of winter ground heat loss than to the interannual variation of the air thawing index or total summer precipitation. This suggests that in years with warmer summers, the heat surplus at the ground surface is largely expended to increase eddy heat flux and latent heat flux, with only a small portion spent on heat flow into the soil. One of the major factors controlling seasonal thaw depth is soil moisture content in the active layer, which deserves a more in-depth study to develop a better understanding of the problem.

The findings of this study and other studies indicate that the relationship of active layer depth to winter factors is much stronger in the continental areas than in the coastal regions.

Abstract

Distribution of natural and man-made chemical elements in soils and vegetation of modern landscapes of the Lower Pechora floodplain and the adjacent terrace was studied along landscape transects crossing the floodplain and terrace zones at different distances from the coast (Bolvansky Cape) to the settlement of Bol'shaya Sopka to reveal peculiarities due to landscape structure and natural migration processes. River water was characterized by low salinity (35–131 mg/l) and hydrocarbonate-calcium composition, while groundwater was comparatively enriched in magnesium, sodium, chlorine ions (39, 26, 31 meq%) and water-soluble organics (peaty areas, 540–2450°, Pt-Co scale). The concentration of ^{137}Cs in soils and vegetation was within the global fallout level, but varied considerably (2.5–215 Bq/kg and 24–365 Bq/kg dry weight, correspondingly) in relation to hydrological, landscape, and soil features of the area, the plant species enabling discussion of the recent history of migration processes in landscapes after man-made contamination.

Keywords: ^{137}Cs in soils and plants; landscape geochemistry; Lower Pechora; radioecology; radionuclide profiles.

Introduction

Draining vast areas, the rivers of the Arctic basin play an important role in its material balance on its margins rich in bioresources. The Pechora River basin belongs to an area with minor man-made impact and is, therefore, of interest for monitoring global man-made contamination and its history in high-latitude permafrost regions. Being a ubiquitous artificial marker of contamination, ^{137}Cs has been included in natural processes for more than 50 years and can serve as the tracer of spatial transformation of aerial contamination in modern landscapes. The objectives of this study were to reveal landscape heterogeneity and peculiarities of ^{137}Cs redistribution in the Lower Pechora area. The two main morphological elements, namely the floodplain and terrace area, were selected to compare the river transport and in situ migration with permafrost impact.

Study Area and Methods

Field studies were performed in the area of the Lower Pechora basin in 2003 and 2004. The strategy of investigation was similar to that applied in the Lower Yenisey reaches (Korobova et al. 2007). A series of landscape transects crossing the floodplain and terrace zones were located at different distances from the coast: Cape Bolvansky, Yushino settlement on the right river side, the upper delta Ekushnaky (EK) and Kermundei (KM) Islands, the right river side near Naryan Mar, and on the left high terrace near Bol'shaya Sopka (Table 1). Soil, water, and plant samples were taken at the selected sites characterizing the two main geomorphological levels. They correspond to terraces and flooding zones in order to compare radiocesium distribution in landscape components under atmospheric water migration and river transport. The location of study sites in a meridional seaward direction was to follow the marine impact and the delta island formation.

Soil profiles were sampled continuously, with sampling increments ranging from 2–10 cm to a depth of 40–100 cm. Vegetation was described by species composition and abundance and sampled at 0.25 m^2 plots located over the soil profiles. Surface and groundwater samples collected at selected points of the cross section were filtered, sealed, and preserved in a dark freezer (-5°C) for transportation to the laboratory. Ion composition of water samples was determined with the help of ion selective electrodes (NO_3^-, Cl^-), titrimetry (HCO_3^-), nephelometry (SO_4^{2-}), photometry (NH_4^+, PO_4^{3-}) techniques and AES-ICP (cations). Accuracy of determination did not exceed 5%.

^{137}Cs and ^{40}K were determined in soil and plant samples with the help of a Canberra gamma-spectrometer with an HPGe detector. ^{137}Cs determination error equaled on the average 31% and 33% (soils and plants), ^{40}K – 19% (soils), correspondingly, depending upon the concentration level.

Chemical Composition of the Surface and Ground Water on Terrace and Flood Plain

Water samples were analyzed to characterize ^{137}Cs water migration conditions (Sanchini 1988). Salinity and colority of water, as well as suspended load, considerably varied in their type, landscape position, and distance from the sea

(Table 1). The Pechora River water was characterized by neutral pH value, low salinity (0.07–0.13 g/l) and colority except for its deep inlet at Kermundej Island (Table 2). Water salinity was the highest in the soil water on Cape Bolvansky terrace (0.193 g/l) close to the sea aquatory. The adjacent terrace foot and the lower floodplain groundwater were much fresher (<0.06 g/l) due to river impact. Low water salinity not exceeding 0.05 g/l was observed on the peaty watersheds upstream, while soil water of the islands and the river water were two times the value. Salinity correlated

with pH (r=0.701, n=14) and water hardness (r=0.895). A tendency of negative relation was observed between salinity and colority (r=-0.528, n=13).

Peaty areas were noted for enhanced colority of water (up to 2450º, Pt-Co scale) due to soluble organic substances most abundant in the active layer of tundra humic gley soils. Suspended load determined varied from 0.1 to 0.8 g/l and increased in the groundwater of organic soils (Tables 1, 2).

Ion composition

Ion composition of ground-water presented in Figure 1 proved considerable leaching of the former marine sediments developed on Cape Bolvansky terrace. However, relatively high chlorine, magnesium, and low hydro-carbonate ion content indicate the marine contribution. The Pechora water near Cape Bolvansky was relatively enriched in sodium. A higher percentage of sodium and potassium ion content was found in the groundwater of Yushino soils. Pechora River water was relatively enriched in chlorine (up to 0.4 meq/l) and sodium (maximum 0.28 meq1/l) as compared to groundwater collected from soil cuts on the adjacent coastal zone and terraces (0.23 meq/l and 0.17 meq/l correspondingly). Chlorine, sulphate ions, and strontium content in the river water slightly decreased upstream, while potassium concentration in river water increased upstream (from 0.6 mg/l to 1.1 mg/l) being in general lower as compared to groundwater (up to 1.7 mg/l in the latter).

Terrestrial water compared to the river was noted for enhanced content of NH_4^+ (0.4–2.6 mg/l) and PO_4^{3-}, the highest nitrate ion amount NO_3^- (0.03–013 meq/l), and a large value of chemical oxygen demand (130–433 mgO_2/l,) in

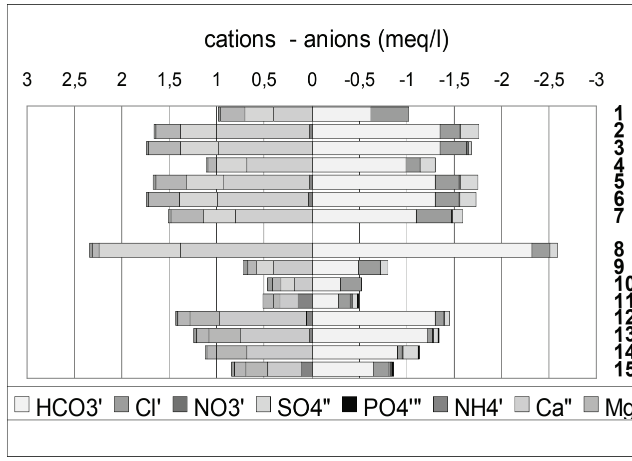

Figure. 1. Chemical composition of water samples positioned in southward direction. 1–15 - sampling places, see Table 2.

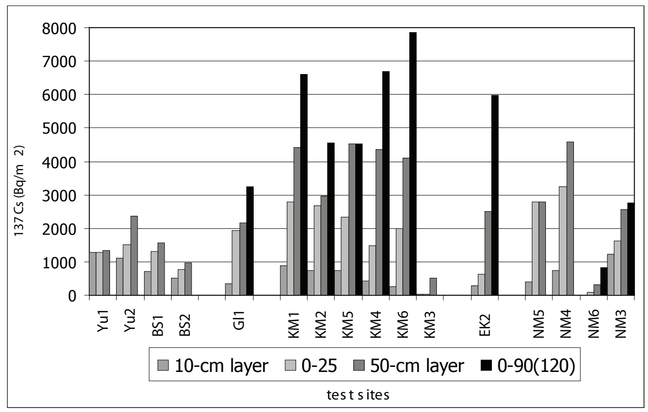

Figure 2. ^{137}Cs inventory in soil layers of different thickness. Sampling plots indices – see Table 1.

water of the peaty terraces (Pechora–17 mg/l, determination by V. Filonenko). It was at least twice as rich in silicon and iron as compared to the river. Performed analysis showed chemical signatures of the increasing influence of the marine environment that can be direct (aerial and water) and indirect (marine sediments) on both the terrace landscapes and river water and a considerable enrichment of the Pechora tundra terrace soils in water-soluble organic compounds and mobile iron. Similar water migration conditions due to vicinity of the sea seaward increase of salinity, chlorine and sodium in water and soil water extractions) and cryogene concentration of salts (enrichment of the tundra soils in water-soluble organic compounds and iron) were found earlier for the Lower Yenisey landscapes (Ivanov & Vlasov 1974, Korobova et al. 2003, 2004).

^{137}Cs Distribution in Soils

^{137}Cs inventory in soils

^{137}Cs activity determined in 203 samples collected from different soil layers was within the global fallout level and varied from 0.58 to 215 Bq/kg (dry weight – dw).

Radiocesium contamination density varied within sixteen studied plots from 0.8 to 7.8 kBq/m^2, V = 57% (Fig. 2). Mean

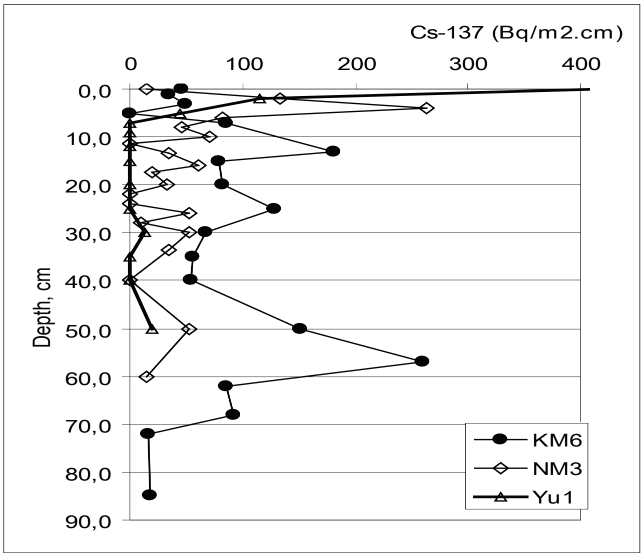

Figure 3. Three main types of ^{137}Cs profiles at the studied in Lower Pechora region. Sampling plots indices – see Table 1.

value equaled 4.8 ± 0.6 kBq/m^2 that corresponded to the data published in the *Atlas of Radioactive Contamination of Russia* (*Atlas* 1998, Wright et al. 1997, Strand et al. 1998).

Topsoil layers were most contaminated at watersheds (over 1 kBq/m^2, plots Yu1, 2; NM3, terrace landscapes). However, the contamination density within the total sampled depth was found the highest for the floodplain plots. The floodplain soils appeared to contain in total several times the amount of ^{137}Cs determined in the active layer of the terrace soils (Kermundej Island, Fig. 2).

^{137}Cs is known to be easily adsorbed by clay particles via ion exchange of interlayer cations or on the mineral edge defects (Evans et al. 1983, Cornell 1993, Bostick et al. 2002). Therefore, it seemed interesting to compare its inventory with that of natural ^{40}K since in sands, potassium concentration is in general three times lower than that in clay sedimentary rocks.

^{40}K inventory was the lowest in fresh sandy deposits of the medium-level sandy bars (KM3, NM6). In the organic soils of the peaty terraces, especially most distant from the coast (plot BS), ^{40}K inventory was the lowest. Positive correlation was established between ^{137}Cs and ^{40}K in 10–25 cm soil layer for all plots (0.760, n=14), in the lower (50–130 cm) mineral layers (0.640, n=8) and the total layer (0–130 cm, 0.708, n=9) in floodplain landscapes. In the top 10–cm layer of floodplain ^{137}Cs and ^{40}K relation was negative, while in watershed top organic horizons it had a positive tendency (r=0.653, n=5).

^{137}Cs profiles in terrace and floodplain soils

Our earlier investigations performed in the Lower Yenisey River basin showed that distribution in soil profiles significantly depended upon the origin of contamination (global fallout or regional river discharge) and geomorphological position of the plot (Korobova et al. 2004, 2007). In the Lower Pechora reaches the highest ^{137}Cs values were characteristic for terrace landscapes (215 Bk/kg, Yu2; 65–120 Bq/kg, NM3). Specific ^{137}Cs activity of the floodplain soil layers did not exceed 20 Bq/kg, reaching maximum in the buried layers sampled on Kermundej Island

*1- <1mm; 2 - 1–.25 mm; 3 - >0.25 mm.

Concentration peaks in the terrace undisturbed tundra peaty and humus-peaty gley soils corresponded to the top 2-cm layer, to the boundary of the organic and gley mineral horizons (from 20 to 45 cm), and to the bottom of the active layer (40–60 cm) with the maximum radiocesium specific activity in the top organic horizon.

In the southern part of the study area, where the terrace soils are subjected to strong wind erosion and sand deposition, the soil profile (NM3) consisted of a sequence of organic layers or lenses interlacing with pure sands. Easy leaching of these horizons cause formation of podzolized, illuvial organic and ferric layers forming beneath the humic one. The most pronounced ^{137}Cs peak corresponded to the top organic layer (13–29 Bq/kg). Below the ^{137}Cs curve acquires a saw-tooth character with double increase in the buried humus horizon (5.5 Bq/kg). Contamination density of each layer reduced to its thickness allowed compare the horizons of the terrace and floodplain soils by ^{137}Cs fixation ability within the volume unit and demonstrated that maximum ^{137}Cs fixation in floodplain and terrace soil layers are of similar order (Fig. 3).

To study ^{137}Cs fixation in particles bound to organic matter, we undertook dry sieving of samples from profile NM3 and measured ^{137}Cs in fractions >1, 1, 1–0.25 and <0.25 mm. The coarse fraction consisted mainly of organic debris (litter, bark, roots) in various stages of decomposition. Fraction 1–0.25 mm, referred to as coarse and medium sand fraction according to U.S.D.A (Shaetzl & Anderson 2006), was a mixture of humified organic debris and organo-mineral aggregates which were separated visually into two parts: one enriched in organic debris and one not enriched. The smallest sandy fraction was

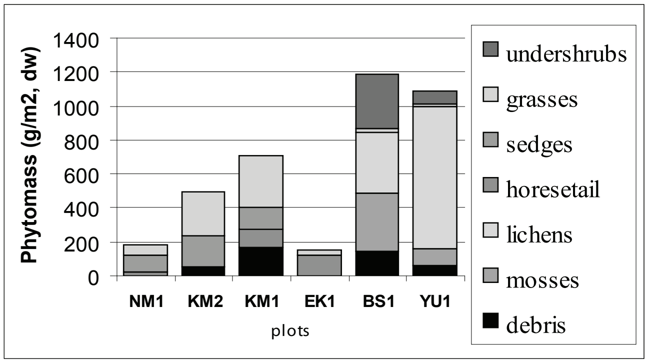

Figure 4. Phytomass of the selected plots and its composition. Plots indices – see Table 1.

mainly mineral. However, organic and ferric coating and charcoal particles were also present.

Fraction <0.25mm dominated by weight throughout the whole pedon (Table 3). Fine fraction played the main role in ^{137}Cs fixation in the top, newly formed organic horizon. In the buried organic lenses the major radionuclide portion (73%) was associated with slightly decomposed and humified organic debris. Mineral grains and aggregates 1–0.25 mm in diameter, enriched in ^{137}Cs, were found in textured illuvial horizons with humus and ferric iron accumulation. In transition to parent alluvium and sandy alluvium, all cesium supply was retained in this mineral fraction. Such distribution clearly showed that the organic matter is able to conserve ^{137}Cs for a long time. The form of the curve below the buried horizon and the low value of ^{137}Cs concentration give reason to suggest periodic deposition of slightly contaminated sediments by wind or water. However, a simple downward radionuclide migration in highly permeable sandy soils cannot be excluded.

Floodplain soils had several peaks of ^{137}Cs at definite depths (KM6, Fig. 3). On Kermundej Island, most profiles had three peaks, that is, 1, 15, and 30 cm in the silty gley soil on low-level floodplain (KM1) and 8–13, 25–30 and 52–57 cm on the medium level (KM4, KM5, KM6). The primitive sandy soil of the riverside high ridge (KM3) had the first pronounced peak at the depth of 50–60 cm. Similarity in radiocesium curves suggests synchronic sedimentation of the layers with the corresponding depth peak concentration. Higher ^{137}Cs deposition during flooding is usually explained by river erosion of the contaminated sediments and soil layer over vast areas. Using hydrological data helps to reconstruct maximum local flooding periods and to evaluate erasing and depositing capacity of the river.

The low contribution of the Chernobyl accident cannot be separated out from the total contamination using our data. However, this does not contradict the suggestion that the upper peak in soil profiles includes the Chernobyl contribution.

Three cuts were investigated on the left bank of Ekushansky Island severely eroded by the Pechora opened (1) old peaty deposits 1.5–3 m thick, (2) the young soddy sandy soil of the medium level floodplain, and (3) a fresh sandy alluvium. In old peat deposits ^{137}Cs was detected fragmentally (3 to 9 Bq/kg) to the depth of 23 cm. In the young soddy soil the layer with 13–14 Bq/kg of ^{137}Cs was buried at the depth of 62–75 cm under the less contaminated ones. In sandy alluvium only

*leaves, Cape Bolvansky

a minor amount (2–2.5 Bq/kg) was determined in horizon 70–100 cm deep.

Performed analysis revealed roughly two to three contamination levels of the alluvial soil layers: (1) small (2–5 Bq/kg) or close to small (7–10 Bq/kg) and (2) medium (16–18 Bq/kg). The depths of the layers with similar sequence of contamination levels were believed to correspond to similar contamination events either due to direct aerial deposition or secondary deposition during flooding. An additional analysis of the appropriate hydrological data would help to reconstruct the flooding and to estimate sedimentation rates at the study plots.

^{137}Cs Accumulation in Vegetation Cover and Plant Species

Vegetation cover of the studied plots, described in Table 1, varied in total biomass from 0.15 to 5.77 kg/m^2 dw (excluding the tree layer at plots NM2 and NM3). The largest phytomass (mostly presented by willow shrubs - 81%–95%) developed on the medium and high level floodplains. Willow biomass sequentially increased from locations of the young rare willow growth pioneering high ridges (1, 2 kg/m^2, KM3) to mature willow thickets at the head of Gluboky Island (maximum value, GL1). In woodless areas the main mass contribution in floodplain landscapes belonged to mosses (30%) and lichens (up to 75%) on high terraces and to grasses and sedges (20%–53%) (Fig. 4).

Mean concentration of radiocesium in plant groups formed the row: mosses>horsetail>lichens (Table 4). High variation of the mean value within a group (62%–89%) was caused by considerable diversity in contamination level, landscape conditions, and species composition.

Site-specific ^{137}Cs accumulation by plant species

Radiocesium values exceeding 100 Bq/kg were found in plant species collected on the high terrace landscapes on Cape Bolvansky (mosses, horsetail, willow, grasses) near Yushino (Yu2, peaty soil, mosses) and Naryan Mar under old spruce forest (NM2, moss).

The moss species growing on terraces formed a row: *Hylocomium splendens>Pleurozium schreberi≥Sphagnum sp.* The highest ^{137}Cs accumulation was found in *Hylocomium* growing on Cape Shaitansky (365 Bq/kg). Sphagnum sampled in 5-cm layers in marshy depression near Yushino contained maximum ^{137}Cs amount in the top layer (95 Bq/kg against 45–49 Bq/kg down to 20 cm) that moss and lichen growing on Cape Bolvansky and near Yushino, as well as horsetail species collected on the floodplain were at least twice richer in ^{137}Cs as compared to Naryan Mar and Bolshaya Sopka sites. At Naryan Mar and Bolshaya Sopka sites, radiocesium content in the upper litter layer did not exceed 45%, while on Plot Yu2 it reached 80%. This can be caused by a difference in precipitation between the forest-tundra and tundra zones, leading to better leaching of the upper layers. The age of the ecosystem was also significant for ^{137}Cs fixation by plant species. Both *Hylocomium* and *Cladonia* species were 3 and 5 times richer when collected on plot NM2-03 located in old spruce forest with highly developed overgrown cover as compared to young coniferous forest near Naryan Mar (NM3). Correlation between ^{137}Cs-specific activity in the plant and the top 10 cm layer was significant for horsetail (r=0.710; n=11). Unlike the Lower Yenisey, ^{137}Cs content in horsetail increased seaward. This supported our earlier conclusion that horsetail is a suitable species for monitoring purposes (Korobova et al. 2007).

Conclusion

Low ^{137}Cs specific activity of soils and plants in the Pechora delta terrace and floodplain landscapes proved the global character of contamination. ^{137}Cs maximum content in terrace landscapes and their topsoil layer indicated aerial pollution that was higher in the soils and moss cover of the northern plots. Despite different water migration conditions and a pronounced marine influence increasing seaward that can be followed in chlorine content both in river and groundwater samples, ^{137}Cs fallout was strongly fixed by organo-mineral soil particles, reflected in maximum concentration of radiocesium in the undisturbed terrace organic horizons and particles enriched in organic debris, ^{137}Cs depth peaks in floodplain soils. Floodplain accumulation of ed ^{137}Cs was comparable and exceeded the inventories on the adjacent terraces that could occur due to both the direct fixation by dried surfaces and secondary accumulation of contaminated sediments. The most pronounced ^{137}Cs peaks in the lower layers covered by clean sandy alluvial or wind deposits are likely to correspond to the period of maximum ^{137}Cs global fallout (the year of 1963; Walling & He 1999). In case of constant flux, this allows a rough comparison of the deposition rates. Similar to the Yenisey, the Pechora terrace soils had pronounced minor ^{137}Cs peaks at the bottom of the active layer water, presumably due to ^{137}Cs sorption by suspension during concentration of water solution above the permafrost table due to freezing.

Abstract

The thermal state of the permafrost of the Eastern Arctic lowlands lying between the Lena Delta and the mouth of the Kolyma River is described in this paper. Three datasets were considered: (a) soil temperature from 12 federal weather stations at 0.2 to 3.2 m depths, (b) the thawing depth dynamics from 20 various environmental Circumpolar Active Layer Monitoring (CALM) sites, and (c) the permafrost temperature of the upper 25 m measured in about 100 boreholes. The stability of the permafrost's thermal state during the last 25–30 years was revealed. In spite of the slow increase in the mean annual air temperature (0.01°C/yr to 0.02°C/yr), only cyclic fluctuations in soil temperature and depth of thawing rather than notable trends were observed.

Keywords: active layer; boreholes; climate change; soil temperature; thermal state of permafrost.

Introduction

Monitoring of the thermal state of ground outside the permafrost zone is performed occasionally according to special needs only. The necessity of such activities in the area of permafrost expansion (at 20% of the land) increases due to the projected permafrost response to climate change. Since the thermal capacities of the upper permafrost are controlled by climate, the climatic change tendencies are believed to be spatiotemporally reflected in the thermal state of permafrost. This study concerns the permafrost response to these changes during the last quarter of the 20th century, which was the period of global warming.

Object of Study

The thermal state of permafrost is known to respond to climate fluctuations by changes in the upper layers, as follows (Fig.1):

I. The active (seasonally thawing) layer, matching with the profile of modern cryosol, and is characterized by above-zero temperatures during summer and below-zero temperatures during winter. It ranges from ground surface to maximal depth reached by the thawing front in a given year by the end of the warming period. The maximal depth referred to as the active layer thickness (ALT) is usually implemented to models.

II. The layer of annual temperature oscillations. The temperature oscillations penetrate into the layer allowing the temperature to redistribute along the vertical axis in accordance with the basic Fourier conduction law. The bottom of the layer is referred to as the depth of zero annual amplitudes of temperature (H), which usually varies from 15 to 20 m depending on the thermal capacities of the ground and soil covers. The temperature fluctuations gradually lower to the bottom, and the temperature at the H depth is thought to represent the mean annual temperature of the permafrost (T_0).

III. Deeper layer of constant annual temperatures, where upper boundary condition changes are reflected with attenuation. It changes non-linearly and is believed to reflect the decadal to centennial fluctuations of soil temperature (Lachenbruch & Marshall 1986). The lower boundary is the permafrost bottom. The thermal pattern in this layer is usually characterized by the geothermal gradient (g) taken from the slope of the temperature curve.

Study Area

Investigations were carried out at Seaside Lowlands in the eastern Arctic in tundra, forest-tundra, and north taiga between the Lena Delta and the mouth of the Kolyma River (125–162°E, 65–72°N) at elevations up to 100 m above sea level. They spread up to 400 km latitudinally from the coasts of the Laptev and East-Siberian Seas to the mountainous areas of the Verkhoyansk and Cherskogo Ranges and the Yukagir Plateau (Fig. 2).

The topography of the study area is as follows: (a) drained watersheds composed of the late Pleistocene Ice Complex, (b) alas depressions, the result of subsidence of watersheds in the Holocene, (c) river flood plains, and (d) sand plains (like Khallerchinskaya Tundra) in the lower streams of the Indigirka, and Kolyma Rivers and the Lena Delta. The climate at the lowlands is arctic continental. According to Cherskii, Chokurdakh, and Tiksi weather stations the mean annual air temperature varies from -10°C to -16°C; the mean temperature of the warmest month (July) varies 8°C to 12°C, and that of the coldest month (January) varies -32°C to -34°C. The transition to above zero mean daily temperatures usually occurs in the second half of May, and the thermal

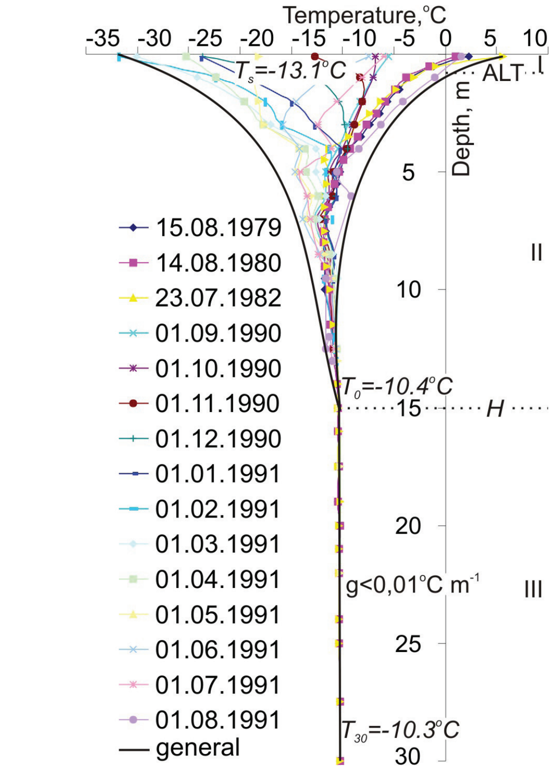

Figure 1. Temperature regime of the drained tundra watershed (Chukchee River, 69.48°N, 147.04°E). I-active layer; II-layer of annual temperature oscillations; III-layer of constant annual temperature. Data on every measurement are provided to assure the "general" envelopes are lined adequately; g was counted by dividing the difference in permafrost temperature, T_0, and the deepest temperature measured by the difference in depths of both measurements.

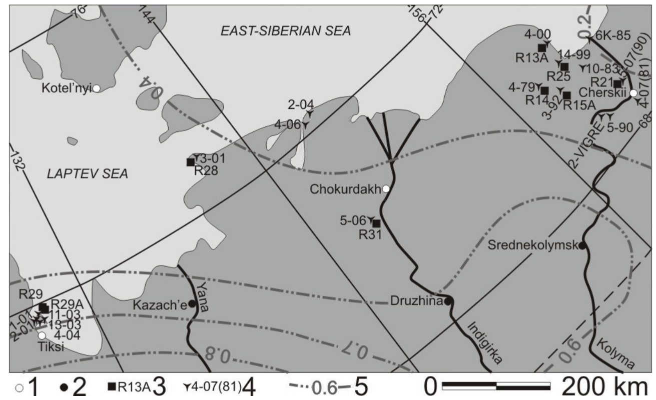

Figure 2. Locations of federal weather stations, boreholes and active layer monitoring sites considered in this paper. Key: 1–air temperature monitoring sites; 2–soil temperature monitoring sites; 3–active layer monitoring sites according to the CALM program numeration, with A designating the alas depression sites; 4–permafrost temperature monitoring in boreholes; the number after the dash is the year of drilling, which would be the starting year of the measurements if the other is not shown in brackets; 5–the current air temperature increase trends (Pavlov & Malkova 2005).

regime reverts to dominantly subzero temperatures at the end of September. The duration of the period with positive mean daily air temperatures is about 115–140 days. The mean annual atmospheric precipitation is 200–300 mm, with 80–130 mm of the total occurring during the warm season.

Snow cover is present from the end of September to mid-June having a maximal thickness of 30–70 cm, increasing eastwards, with more snow accumulating in depressions.

Continuous permafrost occurs to 290–420 m depths along the Kolyma River valley as found by Russian Geological Survey drilling in taiga at the southern margin of the study area and goes to 600–800 m along the Arctic coast in tundra, as calculated from the mean annual temperature and the geothermal gradient.

Materials and Methods

To estimate the thermal state of permafrost in the last 2–3 decades, three independent datasets were used:

1. ALT measured in variously located Circumpolar Active Layer Monitoring (CALM) sites, where observations have been held during the last 10–15 years since 1989.

2. The long-term soil temperature records at 0.2–3.2 m depth from the federal weather stations network, which represent long-term soil temperature observations since the 1960s. They characterize both the active layer and the upper part of the layer of annual temperature oscillations in permafrost.

3. Permafrost temperature measured in boreholes since the 1970s. It characterizes both the layer of annual oscillations and the layer of constant annual temperature down to 25–50 m.

Soil temperature data are available for 12 weather stations located in taiga north of the Polar Circle, surrounding the area of study. They can be obtained from the Frozen Ground Data Center (http://nsidc.org/fgdc/). Srednekolymsk, Druzhina, and Kazaché are located at Seaside Lowlands (Fig. 2). Kazaché operated in the 1930s–1950s and further data are absent, though it was excluded from our consideration. The Druzhina and Srednekolymsk stations, located in taiga, have records continuous enough to consider. Soil temperature measurements were made with outtake mercury thermometers (for detailed description of the measurement technique see Gilichinsky et al. 1998, 2000; Zhang et al. 2001, 2005; Frauenfeld et al. 2004; Bykhovets et al. 2007). In spite of being out of date, the monitoring system has distinctive preference of long-term continuous observations. The Srednekolymsk and Druzhina sites measure soil temperature since 1960 more or less constantly. The longest datasets of mean annual soil temperature have been chosen at 0.4 and 1.6 m depths. Gaps in the datasets were interpolated from neighboring depths, when the temperature correlation exceeded 0.7 (n>10; n – number of years). Ten-year averaging gave poorly representable results, and thus to acquire reflection of the 11-year sun cycle we used the 5-year running averages to compile the dataset for each depth.

ALT was measured at the CALM sites. All sites consist of the square net of regular observation points occupying 1 ha. Sampling points are arrayed with 10 m spacing in rows aligned with the cardinal directions and probed according to the CALM protocol (Nelson et al. 1996). The resulting datasets consist of 121 values for each site. Data are available at http://www.udel/geog/CALM. There are 20 sites located at the study area (for detailed site description see Brown et al. 2000, Fyodorov-Davydov et al. 2004). The detailed analysis of spatial and temporal patterns of seasonal thawing at the area under study could be found in the paper of Fyodorov-Davydov et al. in these proceedings. Only the sites having permafrost temperature boreholes in the vicinity were taken into account in this paper, as follows: R14 - tundra watershed on Chukochya River, R15A - alas depression on Kon'kovaya River, R21 - shrub tundra growing at sandy plain near Akhmelo Lake were measured since 1996, and R25 at the watershed residual hill slope near Yakutskoe Lake did from 1999. Site R13A - alas at Chukochii Cape was established in 2000. Several sites were established after 2000, as follows: R28 – polar tundra watershed at Svyatoi. Nos Cape measured only once in 2001; R29 and R29A at Bykovskii Peninsula in the Lena delta at watershed and alas, respectively, introduced in 2003, and R31 site at the left bank of the Indigirka River valley measured since 2004.

Single temperature measurements in boreholes started in 1979 according to the Techniques of Permafrost Survey (1979), as a rule to the depth of 25 m, using copper resistance thermometer strings and DC bridge (Russia) at each 0.5 m to 5 m depth, 1 m - from 5 m to 15 m depth, and 2.5 m down to borehole bottom. Boreholes diameter varied from 78 mm in the top to 63 mm in the bottom. Liners were installed to three meters only to prevent water leaking from the permafrost table. Later the resistance thermometers were replaced by thermoresistors with the same accuracy of ±0.1°C, but the measurements still were carried out once per year during 4–5 years. To determine the depth of constant annual temperatures with these means is possible in deep holes. Thus the necessary depth of the boreholes was not less than 25 m, and the period of observation has to be several years at least. The shallower of several measurements at neighboring measuring depths showing similar temperature were considered the depth of zero annual amplitudes. Since the mid-90s the boreholes have been step-by-step equipped by dataloggers for continuous year-round observations. At the moment two and four channel HOBO Pro series dataloggers with 0.25°C accuracy and ten-channel loggers with 0.01°C accuracy (LPC, Geomonitoring, Russia) are used. One sensor is usually installed at the surface, the others at various depths inside the borehole. Temperatures were measured four times per day.

The study area had more than 100 monitoring boreholes in 1979–92. Unfortunately most of them are lost nowadays. The new boreholes were drilled since 2000 at the same places and equipped with modern instruments for temperature measurements to re-involve the old data and quantitatively estimate the changes in the thermal state of permafrost. The changes were estimated using the 25-year old temperature records and the recent data.

Geothermal gradient measurements were measured to the depth 250 m in Geological Survey parametric borehole 2-VIGRE in 1979.

Results and Discussion

Soil temperature

Soil temperature measured at Srednekolymsk and Druzhina stations are shown in Figure 3. Two synchronous for both measuring depth and station periods of warming roughly at 1970–1975 and 1980–85, and those of cooling during 1975–80 and 1985–87 were revealed. The 1990s warming started earlier at more continental and cold Druzhina. The mean annual soil temperature in Srednekolymsk is -1.5±0.3°C (n=25, 1969–94) at 0.4 m (within the active layer), and 2.4±0.3°C (n=25) at 1.6 m (within permafrost). The mean annual soil temperature in Druzhina is -5.2±0.5°C at 0.4 m (active layer), and -4.6± 0.6°C (n=25) at 1.6 m (permafrost). The maximal difference in soil temperature during cold and warm periods reached 1°C in Srednekolymsk and up to 2°C in Druzhina. The soil temperature seems to be stable in Srednekolymsk, experiencing cyclic fluctuations during the study period of 1969–94. So does soil temperature in Druzhina at 0.4 m, while at 1.6 m it was warming with the rate of 0.03°C/yr.

Analysis of soil temperature trends at 0.4, 0.8, 1.6, and 3.2 m depths at 10 surrounding-the-lowlands weather stations located in Larix taiga north of the Polar Circle showed the maximal trend being 0.027°C /yr at 1.6 m in Druzhina, with most of thee stations having negligible (less than 0.01°C/yr) trends, while 3 stations showed even slightly negative trend. Chudinova et al. (2006) analyzing trends in soil temperature to the east of Lena River found a variety of tendencies for soil temperatures at 0.2–3.2 m depths have concluded the least soil temperature increase during 1960s–1990s beneath all the Federal weather stations. It could only be explained by the active layer having successful amounts of summer moisture and winter cold to discharge supplementary heat through the phase transitions. We let alone the discussion on reasons of trend variability in the study area. Above mentioned results confirm the fact that no significant changes occurred in soil temperature during the last 30 years.

Monthly time series of soil temperature at 0.4 and 1.6

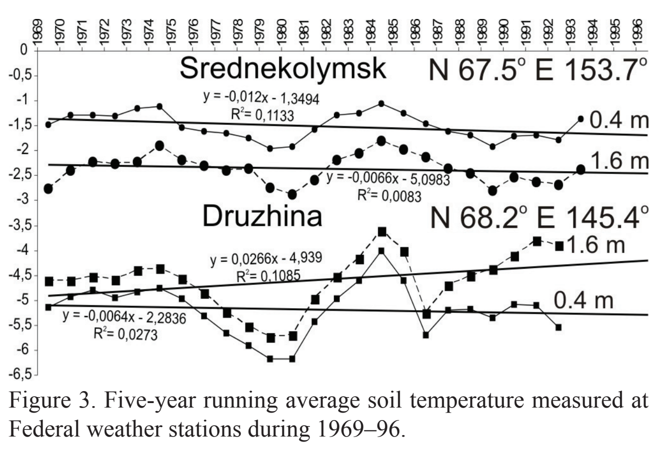

Figure 3. Five-year running average soil temperature measured at Federal weather stations during 1969–96.

Table 1. Mean annual soil temperature at the drilling sites according to monthly monitoring data.

	1981		Sep 1990-Aug 1991	
	active layer 0.4 m	perma-frost 1.6 m	active layer 0.4 m	perma-frost 1.6 m
Flood plain (4-07)	-4.7	-4.5		
Sand plain (5-07)			-0.9	-1.1
Watershed (4-79)			-11.9	-11.6
Srednekolymsk	-1.6	-1.3	-0.7	-2.0
Druzhina	-7.2	-6.7	-4.5	-3.7

m depths in our boreholes in tundra conducted in 1981, 1990–1991 correlate well ($r2>0.9$, $5<n<12$) with those made at the weather stations in taiga. Mean annual soil temperatures on tundra watersheds are much (more than 5°C) lower than in taiga (Table 1). Thermal regime of soils in taiga flood plain is colder than Srednekolymsk, while warmer than the Druzhina, lying south and characterized as more continental, having severe winters and less precipitation (data not shown). Borehole 5-07 showed abnormal, high soil temperature which is a subject of discussion below. However, the data are insufficient to reproduce the temperature, in our boreholes from the years of measurements at the weather stations only.

Active layer observations

Mean values of active layer thickness in the northern part of the Kolyma lowland vary significantly (see Fig. 4).

The largest discrepancies within tundra are associated with texture of parent materials. Sand plain tundra thaws two to three times deeper than wetter loams of watersheds. Besides the influence of lithology, the effect of locally higher permafrost temperatures, which promote deeper thawing, can be observed (Fyodorov-Davydov et al. 2004). Significant latitudinal differences within single topographic levels occurred only in 2005, when the deepest thawing occurred at all watersheds but the westernmost R29 site at Bykovskii Peninsula and R31 at the left bank of the Indigirka valley. The least ALT occurred in 1998 when only three of the sites were in operation. The longest dataset available is for the sand plain R21 site (see Fig. 3 in Fyodorov-Davydov et al., these proceedings). It shows the cyclic fluctuations of ALT. Decreasing of the ALT occurred through the 1990s, when the soil temperature remained relatively stable or even slightly decreased at both weather stations (Fig. 3). However, passing the highest value in 2004-05, the curve in 2007 returns to 1990s 101 cm ALT.

The influence of latitudinal irradiance on the spatial pattern of ALT is rather obvious in watersheds having relatively homogeneous texture (Table 2). Active layer thickness increases from north to south. At the R28 and R29 sites in grass-dominated tundra the ALT was 32±5 cm. Shrub tundra of R31, R14, and R25 had the mean ALT of 42±7 cm. Thaw depressions formed by thermokarst are usually waterlogged and accumulate peat, leading to a decrease of ALT. Thaw depths in alas are similar or slightly lower than on watershed.

In the area of study the close correlation between active layer thickness and thermal characteristics was observed at Site R25 ($r2>0.7$ for air temperature) and all other sites for the sum of summer above-zero temperature, but for R13A (Fyodorov-Davydov et al. 2004; see also Fyodorov-Davydov et al., these proceedings).

Permafrost temperature

The data on permafrost temperature at the depth of zero annual amplitudes are presented in Table 3. The depth of zero annual amplitude (H) was found at various depths: 8–10 m in alas depressions, 12–15 m at loamy watersheds, and 18–20 m within ice wedges and at the sand plain.

Temperature measurements conducted show the mean temperature on tundra watersheds of -10.5±0.9°C (n=8). The temperature rises up to -6.2°C in taiga watershed (5_90). Watershed permafrost temperature has significant negative correlation with latitude ($r2$=-0.79, n=8) designating the falling of permafrost temperature with latitude.

Alas depressions show the mean of -9.2±1.0°C (n=6), with the lowest temperature found at the highest alas at Chukochii Cape. The correlation with latitude is -0.55 (n=6),

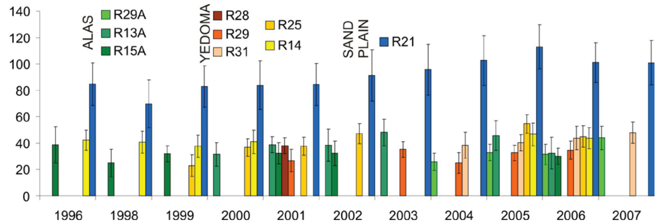

Figure 4. Mean annual ALT data (cm) monitored at the CALM sites. Green, red-yellow and blue colors represent different topographic levels. Sites are listed according to latitude southwards. Bars indicate ±1 standard deviation of 121 to 600 measuring points annually.

Notes: 1980s involve temperature measurements made before 1990, while the 2000s include measurements made after 1995.

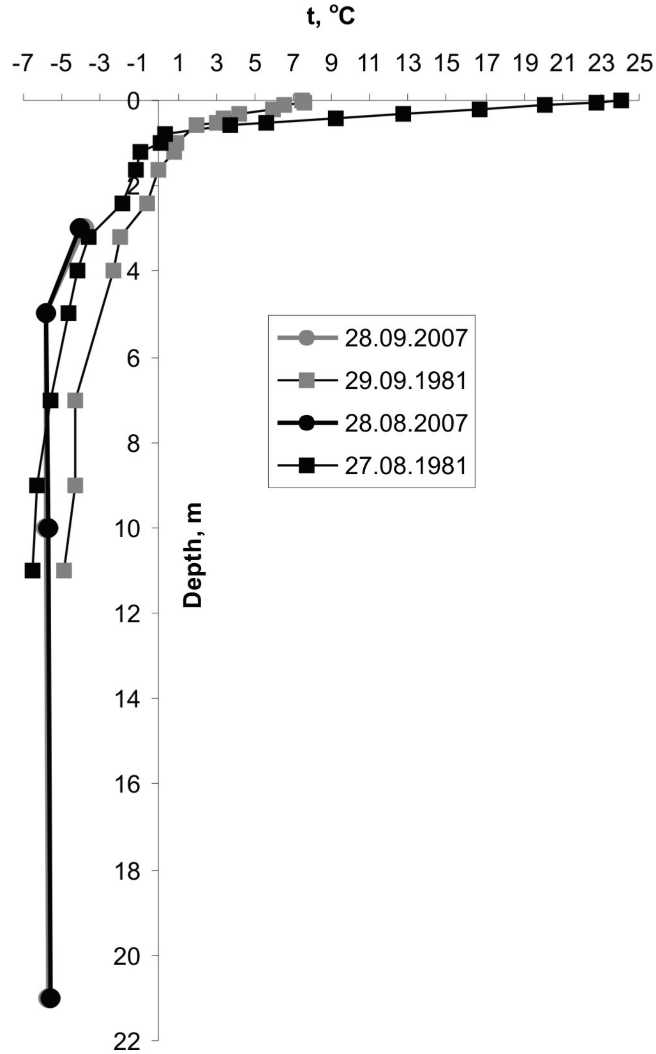

Figure 5. Temperature regime in 4_07 borehole at the Kolyma River flood plain.

which suggests other controls on permafrost temperature like wetness, relative depth of alas depression within the watershed, and peat thickness.

Permafrost temperature at levels experiencing present day sedimentation and syncryogenic formation of permafrost at flood plains and in Kamenka Island in the Kolyma delta is -5.9±0.2°C (n=2).

Measurements of permafrost temperature performed in the 1980s and 2000s differ by 0.1°C at watersheds and flood plains (Fig. 5), about 0.5°C in alas depressions.

From the bottom of the layer of zero temperature amplitudes (H) to 100 m depth g = 0, followed with the stepwise temperature rise, giving the mean g of 0.015°C /m.

Sand plain temperature is -9.4°C at the northernmost site, while it was suggested to be out of order at the 5_07 borehole representing the thermal anomaly site (see Tables 1, 3). Having the data on surface thermal capacities change through the years, we suppose the location of the borehole above the geological fault where the heat flux from the earth crust warms permafrost up to about -4°C. 3_92 borehole drilled in the very deep alas depression to 55 m depth shows positive gradient g down from the depth of zero annual amplitudes, which allows us to suggest the alas continuing to thaw having the long period heat wave penetrating to permafrost. Hence the temperature increase of 0.5 in alas depression is thought to be measured in atypical environment.

Permafrost warming was reported for many surrounding regions. For example Osterkamp (2005) reported on recent warming of Alaskan permafrost. The mean annual temperature of Eastern Arctic permafrost is in equilibrium with present-day climate. Long-term measurements do not reveal significant changes in permafrost temperature or even the timing of thermal wave penetration through the soils. We should not forget the stability of permafrost in the study area during Pleistocene. Even when regional permafrost degradation has occurred during climatic optimums, it was stable in the study area. However, as temperatures rise faster in the high-latitude continental regions, permafrost could be greatly impacted.

Conclusion

Today depths of seasonally thawing, soil and permafrost temperatures on wide eastern Arctic lowlands indicate the stable thermal state of permafrost during the last 30 yrs. The periods of warming of nearly 1970–75, 1980–85, 1989–93, and since 1999 till present, are reflected in the increase of less than 20% in ALT and 1°C–2°C in soil temperature.

This stability allows us to use data of single measurements in characteristics of permafrost thermal state in the Eastern Arctic. It is as follows.

Upper soils, permafrost temperature, and ALT are subject to change latitudinally, with the highest change occurring at sandy drained plains and between tundra and taiga. Watersheds usually have around -11°C temperature of permafrost and less than 0.6 m ALT. Widespread alas depressions have -9°C cold permafrost and nearly the same depth of seasonal thawing as watersheds. Flood plains characterize with -6°C cold permafrost.

The study area had more than 100 monitoring boreholes in 1980s with the network being recreated currently. Extensive temperature monitoring of permafrost allows the exclusion of temperature anomalies from modeling of thermal response of permafrost to climate changes. Reconstruction of old borehole networks gives the most precise evidence of permafrost thermal state change.

Rock Permafrost Geophysics and Its Explanatory Power for Permafrost-Induced Rockfalls and Rock Creep: A Perspective

M. Krautblatter
Institute of Geography, University of Bonn, Germany

Abstract

Rockfalls and rock creep in permafrost-affected bedrock are an increasing hazard in high mountain areas. Besides temperature measurements and physically-based temperature modeling, geophysics in permafrost rocks provides a new methodology for investigating spatial and temporal patterns of permafrost rocks. First examples of 2D electrical resistivity tomographies and refraction seismic tomographies in permafrost rocks are displayed as well as 3D electrical tomographies. ERT time-lapse inversion routines allow for a direct comparison of subsequent time-sections and provide insight into temporal phenomena of heat propagation and permafrost aggradation and degradation. This article aims to show that in the case of ice-filled discontinuities and hydrological pressures geophysical results can potentially be linked to parameters that control rock stability.

Keywords: ERT; ice-mechanics; permafrost; refraction seismics; resistivity; rock creep; rockfalls.

Introduction

Degrading permafrost in rock walls is hazardous, partly due to the amount of potential energy that is released in case of instabilities (Harris et al. 2001). In 2002, the Dzhimarai-khokh rock/ice avalanche (Russian Caucasus) detached approximately 4 million m³ from a 1 km wide starting zone and caused more than 140 casualties (Haeberli, 2005, Kääb et al. 2003). Even smaller permafrost rockfalls, such as the 2003 Matterhorn rockfall, are considered major hazards in densely populated high mountain areas (Gruber et al. 2004). Inventories show that the frequency of these rockfalls has considerably increased in the warm 1990s and was boosted by the hot summer of 2003 (Schoeneich et al. 2004). Moreover, slow rock creep in permafrost rocks causes significant damage especially to tourist infrastructure in high mountain areas.

Besides temperature logger data, borehole information, and rock temperature modeling approaches, the geophysical applications described here provide a new tool for the spatial and temporal analysis of rock permafrost. In some cases, information on the thermal state of permafrost reveals sizeable information for stability consideration (Davies et al. 2001), but changing hydrological properties of ice, such as water content, may also play a vital part in decreasing resistive forces of ice-contained rock masses (Gruber & Haeberli 2007). This paper combines a review of existing geophysical techniques that are applicable in permafrost rocks and a perspective on how these can contribute to understanding mass movements in permafrost-affected bedrock in future. It will address three questions:

(1) What geophysical methods can be applied in permafrost rocks? (2) What properties do they detect? (3) What is their explanatory power for permafrost-induced mass movements?

Investigation Sites

Methods described in this article were tested at three investigation sites: the "Steintälli," a N-S exposed crestline (Matter/Turtmann Valleys, Switzerland) at about 3070–3150 m a.s.l. with slaty paragneiss (see Fig. 1); the North Face of the Zugspitze limestone summit (Wetterstein Mountains, Germany/Austria) at about 2800 m a.s.l., and the gneissic Gemsstock crestline (Switzerland) at 2900 m a.s.l. in collaboration with Marcia Phillips. Figure 1 shows a typical arrangement of a 2D-ERT in steep, permafrost-affected bedrock. More detailed site characteristics can be sourced from Krautblatter and Hauck (2007) and Gude and Barsch (2005). Problems associated with the comparison of different field sites and extrapolation of results are discussed in Krautblatter & Dikau (2007).

Geophysical Methods for Rock Permafrost and Detectable Properties

Surface-based geophysical methods represent a cost-effective approach to permafrost mapping and characterisation (Harris et al. 2001). Hauck (2001) provided a systematic comparison of different geophysical methods for monitoring permafrost in high-mountain environments. However, the application of geophysical methods to permafrost rock walls just began in 2005 (Krautblatter & Hauck 2007). This section will give a quick overview of methods that have successfully been applied to permafrost rocks in the last three years. Data used for Figures 2, 6, and 8 were previously published in Krautblatter & Hauck (2007) and are described there in detail.

Electrical resistivity tomography (ERT)

ERT is a key method in permafrost research, as freezing and thawing of most materials are associated with a resistivity change that spans one order of magnitude, which is, in turn, easily detectable. The first approach to derive spatial information from rock faces by ERT was applied by Sass (2003). In subsequent studies he provided further evidence that ERT measurements are capable of measuring the degree of rock moisture (Sass 2005) and temporal and spatial variations of freeze and thaw limits (Sass 2004) in rock faces. These ERT measurements were confined to the monitoring of the upper weathering crust (centimeter- to decimeter-scale) of non-permafrost rock faces. Krautblatter and Hauck (2007) extended this method to a decameter-scale and applied it to the investigation of active layer processes in permafrost-affected rock walls.

Arrays with centimeter-long steel screws as electrodes were drilled into solid rock (see Fig. 1) and were measured repeatedly with high voltages (mostly 10^2–10^3 V) to improve the signal to noise ratio. A detailed survey of hardware and software adaptations and a systematic discussion of error sources is provided by Krautblatter and Hauck (2007). Errors associated with different ERT-arrays were assessed along with the impact of topography and other geometric error sources (Krautblatter & Verleysdonk 2008a). The Res2DInv software was chosen, as it is capable of topographic correction and "real" time-lapse inversion of subsequent measurements. To cope with high resistivity gradients, inversions models with mesh size smaller than the electrode distance and robust inversion routines provide better results. Resistivity values that correspond to the transition between frozen and thawed rock were measured repeatedly at the rock surface along different arrays and yielded evidence that the transition occurs between 13 and 20 kΩm for the gneissic rocks at the Steintälli (Krautblatter & Hauck 2007) and are in the same range as those established for carbonate rocks at the Zugspitze by Sass (2004) and our own measurements (Krautblatter & Verleysdonk 2008b). Figure 2 shows an ERT that was measured close to Figure 1 at an east-facing part of the rock crestline between Matter and Turtmann Valleys. It shows a 3 m thick thawed surface layer of rock above a constantly frozen permafrost layer; a plunge in temperature following August 14th is evident due to frozen rock close to the surface in all parts of the transect. Resistivity–temperature patterns of rock samples of all field sites are currently tested in a freezing chamber in the laboratory.

The relation between measured resistivity and rock temperature is straightforward. For temperatures below the freezing point, resistivity (p) depends mainly on unfrozen water content until most of the pore water is frozen. In Alpine environments resistivity can be calculated based on a reference value p_o as an exponential response to the temperature below the freezing point (T_f) according to McGinnis et al. (1973):

$$\rho = \rho_0 e^{b(T_f - T)} \tag{1}$$

The factor b in Equation (1) determines the rate of resistivity increase and can be derived empirically (Hauck 2001, Hauck 2002). Short-term changes in resistivity can be attributed to changes in pore water content and temperature, while changes in porosity and water chemistry can be neglected over daily to monthly measurement intervals in low-porosity rocks. Due to the exponential response of resistivity to temperatures below 0°C, freeze-thaw transitions correspond to an increase in resistivity by one order of magnitude and are thus a very sensitive method for detecting the state of rock permafrost close to 0°C. On the other hand, deeply frozen bedrock (below -5°C) along the measured transects causes problems for the electrode contact.

Refraction seismic tomography (RST)

The application of refraction seismics in permafrost studies is based on the interpretation of refracted headwaves that indicate the transition of a slower, unfrozen top layer

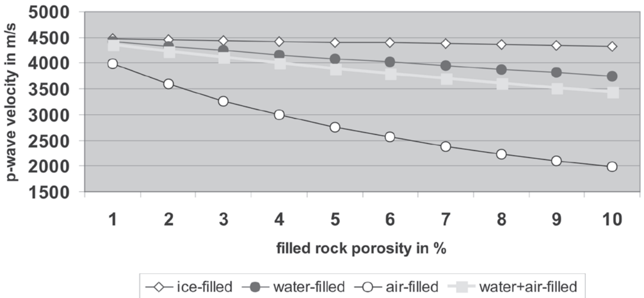

Figure 4. Estimation of P-wave velocities of rock with different porosity and pore content.

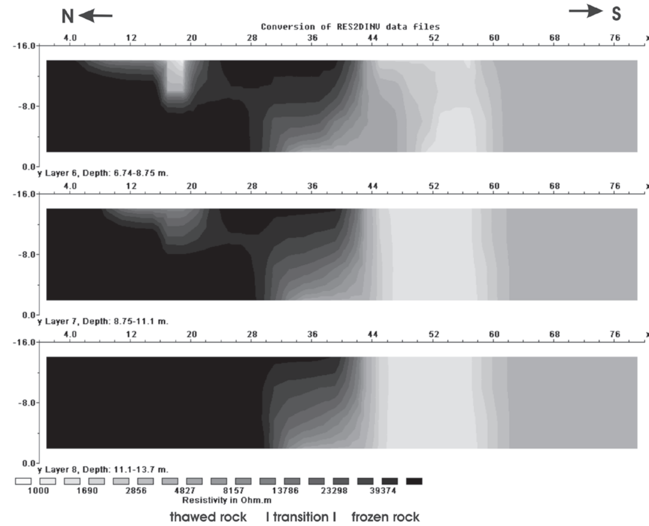

Figure 5. 3D-ERT cross sections at three different depths cutting the Turtmann/Matter Valley crestline N-S. Measured with ca. 1000 datum points from ca. 200 electrodes at September 5–9, 2006.

to a frozen layer with faster P-wave propagation below. Recent approaches apply tomographic inversion schemes (Otto & Sass 2006) often based on high-resolution datasets (Maurer & Hauck 2007, Musil et al. 2002). Seismics are also applied to determine 2D and 3D rock mass properties and potential instabilities (Heincke et al. 2006). Preliminary results from Krautblatter et al. (2007) indicate that refraction seismics are applicable for permafrost detection in solid rock walls, even if they provide less depth information than ERT measurements. On the other hand, it appears that they resolve small-scale features such as ice-filled clefts in more detail. For instance, Figure 3 shows a cross-cut through the E-W trending Steintälli crestline at Transect 9. Thoroughly frozen rock aligns along ice-filled discontinuities indicating the good thermal conduction (k = 2.2 W/(m*K)) without latent buffers in the readily frozen ice in clefts.

In practice P-Waves were stimulated with a 5 kg sledgehammer. Per transect, 24 drilled geophone positions in bedrock and 40 marked and fixed shot positions were arranged in line with the ERT transects so that RST and ERT were measured simultaneously (Krautblatter et al. 2007). A direct comparison of ERT and RST showed that frozen high-resistivity rocks in the ERT typically have P-wave velocities significantly above 4000 m/s (see section below) while wet and dry rock masses indicate a significantly slower propagation. As P-wave velocities of frozen and thawed rock differ only by a few hundred m/s in velocity, it is important to define the geometry of shot and recording position exactly, which was done using a high-resolution tachymeter. High P-wave velocities in rock necessitate high temporal resolution of geophone signals. Surface waves are not decelerated by a soft surface layer, such as soil, and thus often disturb signals recorded by geophones close to the shot position. We applied REFLEXW, Version 4.5 by Sandmeier Scientific Software, with model settings, such as initial P-wave velocity assumption, adjusted to bedrock conditions.

Air-, water-, and ice-filled pores in rock lead to significantly different attenuation of P-wave velocities. This is especially true for air-filled porosity. Figure 4 shows theoretical P-wave velocity for different pore-fillings and rock porosities derived from mixing laws. However, it appeared in simultaneous ERT and RST measurements that carefully conducted RST can resolve the difference between water and ice-filled rock even in low-porosity (2%–3%) bedrock, and that velocity differences are larger than expected from mixing laws for certain rock porosities. This could be due to the fact that melting in low-permeability rocks leads to a small gas content in pores to compensate the ice-water volume reduction or that the seismic velocities provide a more integral signal that includes ice in discontinuities in the rock mass.

The third dimension: 3D ERT and RST

ERT and RST can be conducted in 3D. Figure 5 shows three horizontal sections cut at depths of 7–9 m, 9–11 m and 11–14 m with N-S orientation that indicate a sharp divide between frozen rock to the north and thawed rock to the south at meter 44. Problems that arise when conducting three-dimensional geophysics in permafrost rocks are time-consuming measurements (ca. one week of uninterrupted measurements), the necessity of highly precise topographic information, and the required high resolution due to the enormous resistivity/seismic velocity gradients present in permafrost rock systems. Moreover, traditional 3D arrays (e.g., Pole-Pole or Dipol-Dipol ERT) result in bad signal to noise ratios (Krautblatter & Verleysdonk 2008a) and electrode/geophone spacing and arrays must be adjusted to local conditions. Therefore, the first 3D ERT and 3D RST array in permafrost rocks, which was conducted in 2006, relied on a very close (2 m) arrangement of geophones (120), electrodes (205), and shot positions (200) (Fig. 6) (Krautblatter et al. 2007) and is based on Wenner-arrays that yield much better signal to noise ratios than Pole or Dipole-type arrays.

The fourth dimension: Time-lapse ERT

The installation of permanent electrodes and modeling of subsequent resistivity datasets within the same inversion routine (so-called time-lapse inversion) allows for a direct assessment of spatial and temporal permafrost variability (Hauck 2002, Hauck & Vonder Mühll 2003). Figure 6 shows the freezing of the previously thawed surface rock up to 3 m

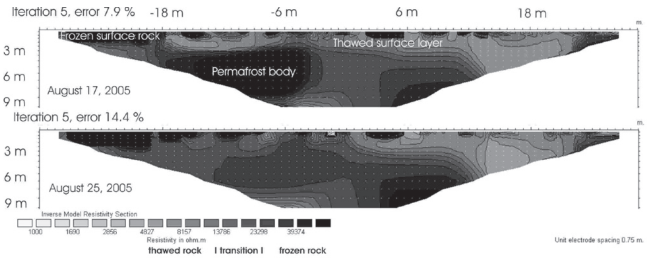

Figure 6. Freezing of surface rock from August 17 (top) to August 25, 2005 (bottom) due to a severe drop in air temperature recorded at the Steintälli E-transect (3130 m a.s.l., Matter/Turtmann Valleys, Switzerland).

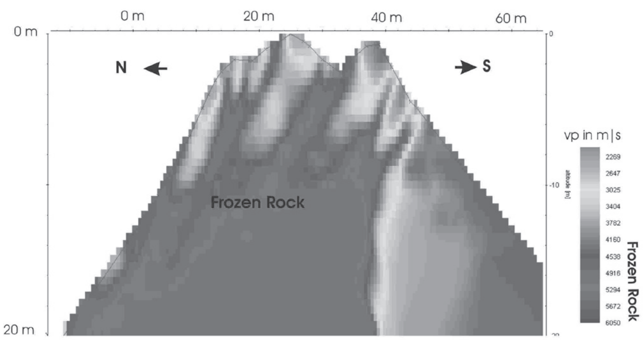

Figure 7. RST – north-south transect 7 (August 31, 2006) of the Matter/Turtmann Valleys crestline, 3150 m a.s.l. Mention the disposition of the frozen discontinuity zones as possible detachment zones with daylighted bedding.

depth following a plunge in temperature after August 14, 2005. While time-lapse routines for ERT are already in place, time-lapse routines for RST are still more difficult to perform.

Time-lapse inversion of subsequent measurements provides insights into short-term and long-term freeze-thaw thermal regimes (Krautblatter & Hauck 2007), response times (Krautblatter & Verleysdonk 2008b), changes in hydrological rock conductivity, and permafrost aggradation and degradation (Krautblatter 2008). Moreover, changes in subsequent time sections can definitely be attributed to changes in rock moisture or the state of freezing, while changes in geological properties can be ruled out for short-timescales.

Explanatory Power for Permafrost-Induced Mass Movements

We define permafrost-induced mass movements as those whose kinematical behavior is at least partly influenced by ice mechanics and permafrost hydrology. The most common types are rockfalls and rock block creep. These are usually explained (1) by a reduction of the resisting force, e.g., shear-strength in ice-filled clefts (Davies et al. 2001, Davies et al. 2000) or (2) an increase in the driving force, e.g., hydrological pressure (Fischer et al. 2007).

Ice-filled discontinuities

Figure 7 shows a cross-cut through the E-W trending Steintälli crestline. Geometrical position, orientation, and

persistence of ice-filled clefts in the upper 10 m can be well detected in RST surveys. It is assumed that ice-filled discontinuities react according to stress-strain behavior of weight-loaded polycrystalline ice. The deformation of ice at constant stress is characterized by four phases: (1) elastic deformation that is followed by permanent deformation, first at a decreasing rate (2) primary creep, then at a constant rate (3) secondary creep, and finally at an increasing rate (4) tertiary creep (Budd & Jacka 1989). Mostly secondary creep and tertiary creep occur at speeds relevant for mass movements. The flow relation for secondary creep relates the shear strain rate ε_{xy} to the shear stress τ_{xy},

$$\varepsilon_{xy} = A\tau_{xy}^{n} \tag{2}$$

where A depends mainly on ice temperature, anisotropic crystal orientation, impurity content, and water content, and n increases at shear stresses greater than 500 kPa (Barnes et al. 1971). Crystal orientation, impurity content, and shear stresses remain more or less constant over short timescales. In contrary, ice temperature and water content in mass movement systems are subject to major annual and interannual changes. Thus, for temperatures above -10°C, A can be approached by

$$A = A_0 \exp(-\frac{Q}{RT}) \approx A_0 \exp(-\frac{16700}{T}) \tag{3}$$

where A_0 is independent of temperature, R is the universal gas constant, and Q is the activation energy (Weertman

1973) and A_{0t} for tertiary creep

$$A_{0t} = (3.2 + 5.8W) * 10^{-15} (kPa)^{-3} s^{-1} \quad (4)$$

can be related to the percentage water content W. It must be stressed that the water content strongly decreases with temperature. Paterson (2001) states -2°C as the lowest temperature at which the effect of water in the ice is relevant for the stress-strain behavior.

Equations (3) and (4) show that both ice temperature and water content play a dominant role in the mechanical behavior of ice-filled clefts at temperatures close to -0°C. Assuming moderate water content of 0.6%, the creep rate at 0°C is three times the rate at -2°C (Paterson 2001), which has serious effects on displacement rates and factors of safety considerations of mass movements.

As has been shown above, ERT and refraction seismics are highly susceptible to water/ice content inside the rock system just below the freezing point. Thus, the susceptibility range of seismic velocity and resistivity (ca. -0°C to -5°C) corresponds to the most important changes in ice-mechanical properties. This means the values temperature and water content, which are relevant for stability considerations in well-jointed permafrost rocks, are targeted by ERT and refraction seismics and combined interpretation strategies.

Hydrological pressure

Figure 8 shows light-colored, low-resistivity cleft water zones percolated by glacial meltwater that were observed to persist over several years and to limit the spatial extension of permafrost bodies (Krautblatter 2008). While pressure effects only have a small effect on the stress-strain behavior of ice itself (resisting force) (Weertman 1973), the reduction of applied normal stress and the increase in shear stress (driving force) may play a key role in preparing and triggering mass movements (Fischer et al. 2007, Terzaghi 1962). According to Wegmann (1998), permafrost degradation and aggradation in rocks in response to altered hydraulic conductivity occurs at all depths and quickly responds to annual melting patterns. He could also show that rock deformation quickly responds to spatial changes in permafrost rock conductivity.

Unfrozen cleft zones can easily be detected at the surface with RST and with ERT measurements possibly up to the maximum depth of the applied array (e.g., 80 m at the Zugspitze, 400 m Schlumberger-array). As shown in Figure 8, resistivity in water-filled cleft zones and frozen rock typically differs by 1–2 orders of magnitude and is, thus, easily detectable even at greater depths (Krautblatter & Hauck 2007). This opens up a whole range of new possibilities e.g., for the investigation of rock permafrost hydrology (Wegmann 1998), glacier-permafrost inter-connectivity (Moorman 2005), and rock deformation processes that are closely linked to freeze-thaw processes by latent heat transfer in clefts (Murton et al. 2006, Wegmann 1998).

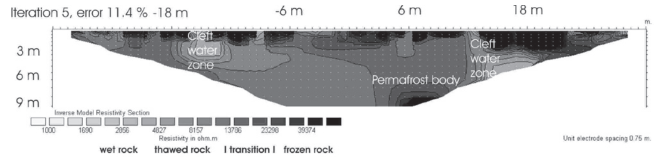

Figure 8. ERT of Transect NE (September 13, 2005). Mention the persistently thawed deep- reaching cleft water zones.

Conclusion

Resistivity monitoring may provide indications on temperature changes and water saturation, while refraction seismics help to gain insight into discontinuity zones and exact geometric properties of instable bodies. Repeated time-sections reveal interannual, annual, and multiannual time-patterns as well as response times, the fourth dimension of rock permafrost systems.

For permafrost-induced mass movements, with secondary and tertiary creep of ice close to -0°C, three highly-variable forces play a key role in unbalancing resisting and driving forces. The resisting force of ice-creep in clefts is mainly controlled by (1) temperature and (2) water content in the ice. Due to the laws of electrolytic conductivity, resistivity values assessed by ERT react sensitively to both parameters, and water content is a key control for P-wave velocity. The highly variable driving force, (3) hydrological pressure, is well detectable in ERT time-sections as pore and cleft space supersaturation lead to a plunge in electrolytic resistivity. However, many other anisotropic factors distort ERT and seismic measurements, and further field and laboratory experience is needed for the allocation of their influence and for the “suppression” of such noise.

Abstract

Temperature data from three boreholes located on an ice-cored moraine near sea level are analyzed. One of these boreholes was drilled 6 m from the shore and shows significantly higher temperatures than the holes about 150 m from the shore. Using meteorological data and measurements of water temperatures, we model the permafrost distribution into the fjord as well as the influence of the sea on permafrost temperatures near the shore. The model results suggest that permafrost, as defined solely on temperature, is present beneath Van Mijenfjorden.

Keywords: borehole temperatures; coastal; geothermal modeling; permafrost; subsea permafrost; Svalbard.

Introduction

Permafrost on Svalbard is classified as continuous. It is more than 500 m thick in the highlands and less than 100 m near the coasts (Humlum et al. 2003). While considerable knowledge of permafrost conditions in the mountains exists from the extensive coal mining, little has been published on the permafrost in the shore areas of Svalbard. Exceptions are Gregersen & Eidsmoen (1988) that compares deep borehole temperatures at the shore with inland boreholes in Longyearbyen and Svea, and Harada & Yoshikawa (1996) that uses DC resistivity soundings to estimate the permafrost thickness of marine terraces at the shore of Adventfjorden near Longyearbyen.

The aim of this paper is to describe the permafrost conditions in the ice-cored moraine, Crednermorenen,a peninsula in Van Mijenfjorden in central Spitsbergen (Fig. 1). Since April 2005 temperatures have been logged every two hrs in three boreholes on the moraine each with 16 thermistors down to eight m. One of the boreholes is located only six m from the shoreline. Permafrost conditions in the shore area are important since the permafrost here is "warm" and thin. When constructing in such areas, particular attention must therefore be given to the permafrost conditions. In most other parts of Svalbard, permafrost is thicker, colder and more stable.

Due to the few previous studies of near-shore permafrost on Svalbard, an attempt was made to model both the effect of the sea on the onshore permafrost as well as the possibility of subsea permafrost. We use a transient 2D finite element geothermal model (TEMP/W from Geoslope International, Calgary, Canada; Krahn 2004) that is forced with meteorological data and measured water temperatures as boundary conditions.

Field Site

Crednermorenen is a lateral moraine deposited by a surge of the tidewater glacier Paulabreen (Fig. 1) around 1300 A.D. (Hald et al. 2001). The moraine forms a peninsula (1x3 km),

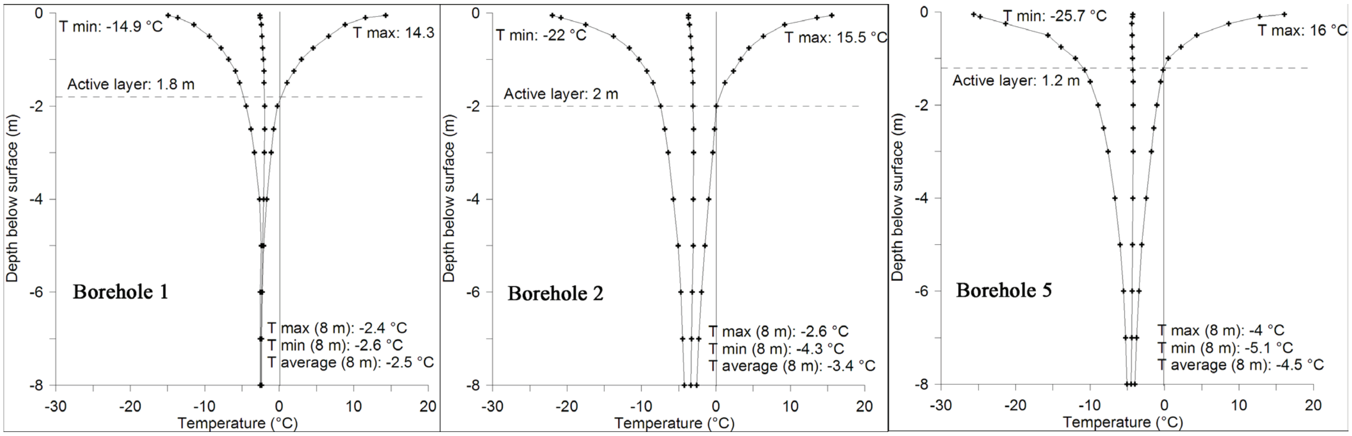

Figure 2. Maximum, minimum, and average temperatures in all depths from 10 September 2006 to 9 September 2007 for Boreholes 1, 2, and 5.

Table 1. Average annual temperature at the ground surface, at the top of the permafrost (TTOP).

	(Air)	Hole 1	Hole2	Hole 5
T surface (°C)	-4.6	-2.6	-3.7	-4.2
TTOP (°C)		-2.0	-3.1	-4.3

partly ice-cored and partly consisting of proglacially pushed marine clays (Kristensen et al., in press). It is surrounded by water on three sides and in its northern part lies a 1 km long lagoon, —Vallunden—that, is connected to the sea by a 15m-wide channel near Borehole 1. The water in Vallunden is salty as the tide flows in and out through the channel.

The oceanography in Van Mijenfjorden is strongly affected by an island at the fjord mouth, Akseløya (Fig. 1A), which nearly blocks the water exchange between the fjord and the warmer Atlantic water outside (Nilsen 2002). The water column is thus dominated by cold local water. Shore-fast ice is usually present from December to June. Bottom water salinity is around 34‰ (Hald et al. 2001), and July temperatures of -1.53°C and and -1.27°C have been measured in two basins in Van Mijenfjorden at 112 m and 74 m depth (Gulliksen et al. 1985). The climate in Sveagruva is slightly colder and more humid than in Longyearbyen 45 km to the NNE, but the meteorological record is shorter and more irregular. Mean annual air temperature close to sea level was -5.4°C in the period 1997–2006, and precipitation in the period 1995–2002 was on average 244 mm/y (www.met.no).

Temperature Measurements in Boreholes

Four 10 m deep boreholes (Fig. 1B) were drilled on Crednermorenen in March 2005 using an air pressure driven drilling rig. Coring was not possible, but the pulverized blown up sediment was collected from three of the holes, described and analyzed for water content and salinity. Borehole 1 was located two m above sea level and six m from the channel that connects Vallunden with Sveasundet. Borehole 2 was drilled into the ice-cored part of the moraine 17 m a.s.l. and 150 m from Sveabukta. Borehole 5 was established on top of the moraine ridge 145 m from Vallunden and 20 m a.s.l. Hole four was located on the marine clay part of Crednermorenen, but was destroyed by a bear in October 2006, and therefore no data are presented from that hole. In each borehole an eight m thermistor string (EBA Engineering, Edmonton, Canada) with 16 thermistors at decreasing spacing towards the surface was inserted. The uppermost sensor in each hole was placed at roughly three cm depth, and was measuring the surface temperature in this paper. Temperatures have been logged every two hour using Lakewood dataloggers; the accuracy of the thermistors is around 0.1°C. The annual temperature envelopes recorded in the three boreholes are shown in Figure 2. The maximum surface temperature for holes one and five occurred on 16 July 2007, and for hole two on 18 June 2007. The maximum temperature was very similar for the three holes, probably indicating that the barren surface provided similar summer conditions. The minimum surface temperature for all three holes occurred on 23 January 2007, which was contemporary with the minimum air temperature (-32.9°C) being recorded. The minimum surface temperature was much lower in hole two and five than in hole one. The latter had usually a snow cover of around 20 cm whereas both holes two and five were usually snow-free in winter due to wind redistribution in these more exposed sites. In Borehole 1 the seasonal temperature fluctuation became insignificant (0.25°C) below six meters depth, whereas the difference between annual maximum and minimum temperature at eight m in Boreholes 2 and 5 were 1.7°C and 1.1°C respectively.

Table 1 shows that all ground surface temperatures in the investigated period were higher than the mean air temperature. Hole one was warmest, reflecting the thickest snow cover during winter. The snow insulated the surface against cold winter temperatures creating a positive surface offset as demonstrated by, for example, Smith & Riseborough (1996). Hole 5 had the smallest surface offset as this site is usually never snow covered.

Smith & Riseborough (1996) also demonstrated that, due to higher thermal conductivity in frozen ground than in unfrozen, temperatures will tend to decrease from the ground surface to the top of the permafrost table (TTOP). Table 1 shows

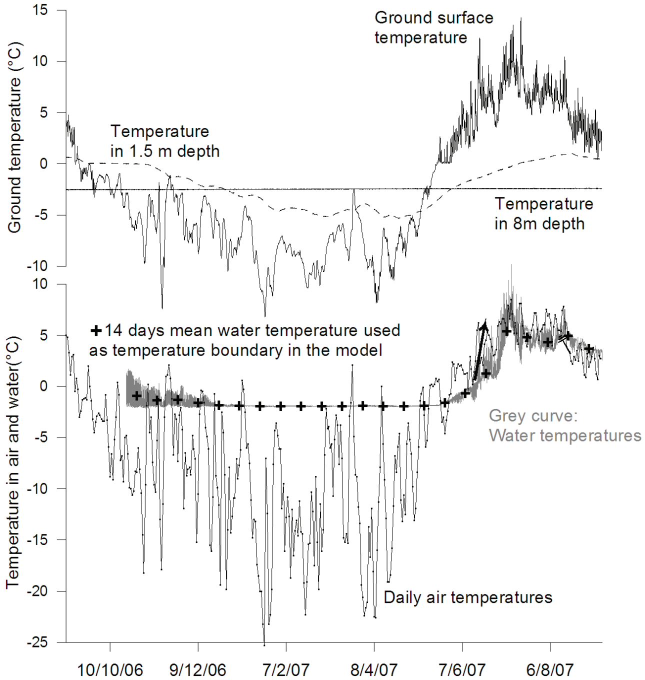

Figure 3. Upper part: Temperatures in Borehole 1 at the surface, in 1.5 m depth (dotted line) and in 8 m depth (no variation). Lower part: Air temperatures and water temperatures.

that in Boreholes 1 and 2 TTOP was higher than the surface temperature whereas in hole five it was practically the same. The active layer offset therefore seemed not to be important for the ground temperatures on the moraine, whereas snow depth in winter certainly was.

Tide and Water Temperature Measurements

Water temperatures in the narrow and shallow strait Sveasundet were measured and recorded every 20 min from 10 October 2006 to 9 September 2007 by a tidal gauge placed at two m water depth. The data can be seen in Figure 3 together with temperature measurements from Borehole 1 from three selected depths and air temperature measurements over the same time interval.

The freshwater from Kjellstrømsdalen passes the Sveasundet strait, and strong tidal currents flowing in and out of Braganzavågen ensure mixing of salt and fresh water here. For this reason the summer water temperatures were high compared to what has been measured in the deep basins in the fjord during summer. Winter temperatures however appeared to be constant around -1.93°C in most of the fjord.

The measured water temperatures can be divided in three distinct periods:

1) An autumn period when the temperature fluctuated in relation to the tide between -1.9 and +1.7°C lasting from 21 October to 26 December. Temperatures rose when the tide was moving through Sveasundet into the tidal flat Braganzavågen and fell when the tide flowed out again. This is consistent with observations that sea ice started forming in Braganzavågen before other places in the fjord. An example

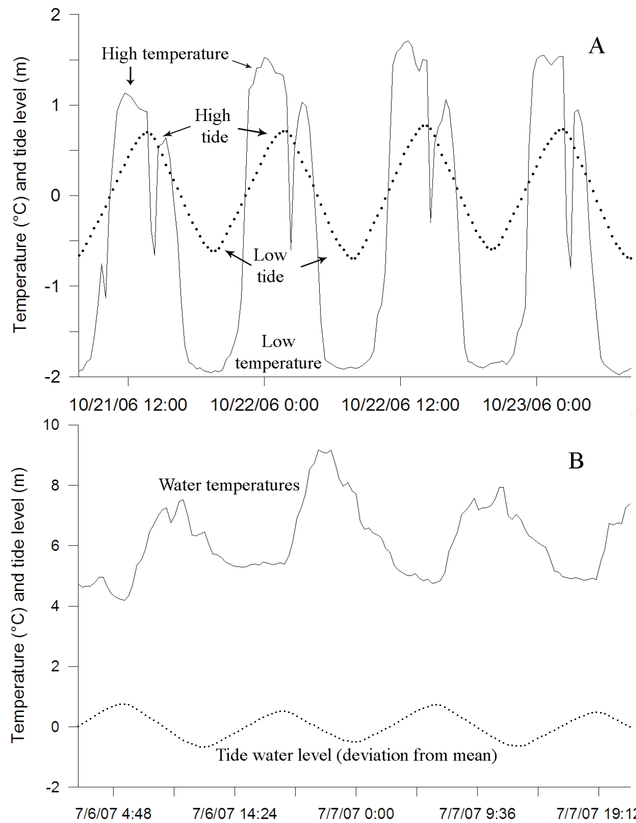

Figure 4. Examples of the relationship between water temperatures and the tide. A: Autumn conditions when the first sea ice forms, B: summer conditions.

of the coupling between tide and temperatures in the autumn can be seen in Figure 4A**.** November 28 was the last time the temperature rose above zero.

2) A winter period from 26 December to 22 May 2007. The temperature was nearly constant around -1.93, and no temperature fluctuations with tide were observed. The temperature corresponded to the freezing point of sea water and the fjord was covered by ice throughout this time. This winter period with constant water temperatures is easily identifiable in Figure 3.

3) A summer period from 22 May 2007 to the end of the measurements. Here the water temperatures increased and gradually approached the air temperature. The water temperature rose above zero for the first time on 13 June 2007. The temperature fluctuations were again controlled by tidal currents and were opposite in phase to those of the autumn. Now rising tide was associated with lower temperatures and falling tide with increasing temperatures (Fig. 4B). The reason is that water was now heated in the tidal flat Braganzavågen, where it was cooled during the autumn.

Modeling the Effect of the Sea on the Permafrost Temperatures

Studying the measured borehole temperatures, one can see that Borehole 1 deviated significantly from Boreholes

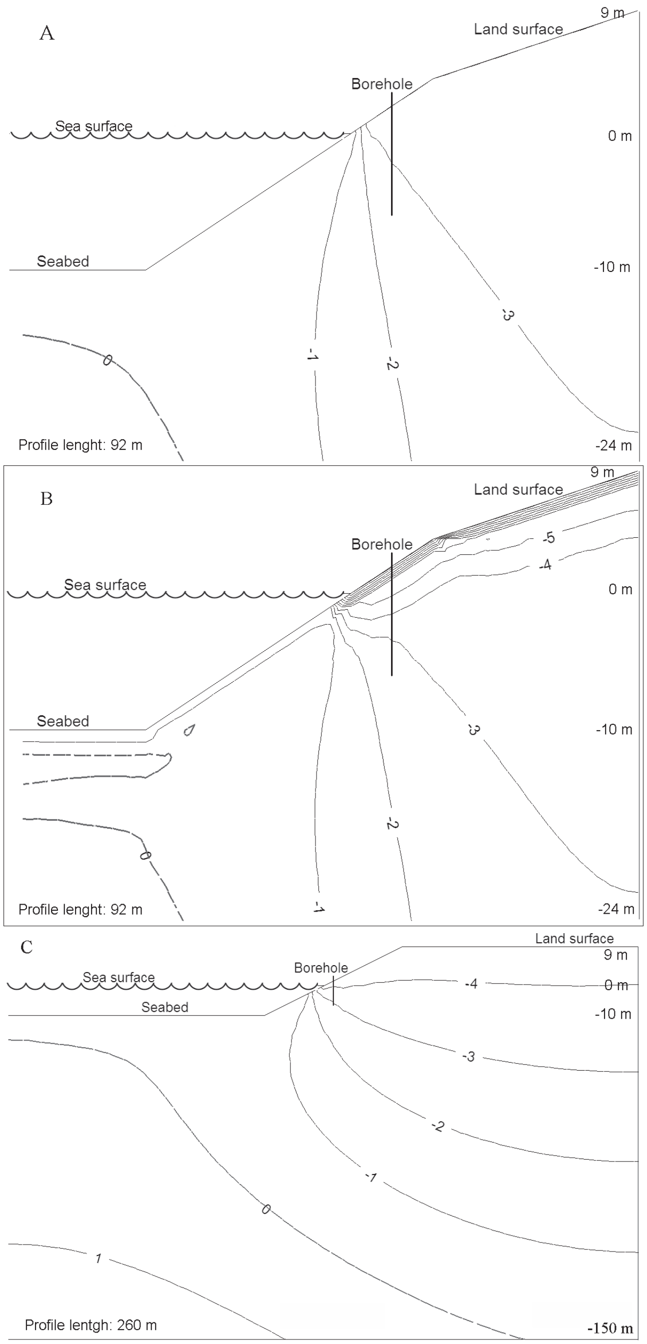

Figure 5. Three model output results. A: Steady state simulation of the ground temperatures in the immediate shore area. B: The same section but run in a transient mode forced with measured climatic data and sea water temperatures. Snapshot from 7 April 2007. C: Steady state simulation of a wider and deeper section with the boundary conditions the same as in A.

2 and 5 in respect both to the thermal regime and the depth of zero annual amplitude. While some of this deviation can be explained by a thicker snow cover during winter, most likely the proximity (6 m) to the sea affected the permafrost temperatures here. Located two m a.s.l. and being eight m deep, most of the borehole also lay below sea level. At eight m depth in Borehole 1, the temperature was -2.5°C. This indicates that permafrost probably extends into the seabed

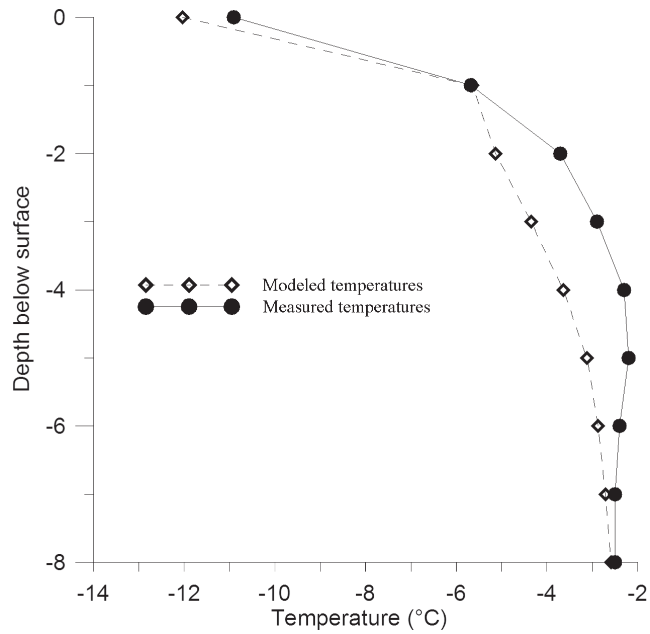

Figure 6. Comparison of the temperatures measured in Borehole 1 on 7 April 2007 and the modeled temperatures on the same day.

from the shore. An attempt was made to model both the effect of the sea on the onshore permafrost temperatures as well as the possibility of subsea permafrost existence. Gregersen & Eidsmoen (1988) previously tried to model the possible subsea permafrost in the area, but they had no information on the water temperatures in the fjord.

Model description and input

A 2D finite element program (TEMP/W) was used to model the permafrost thickness in Crednermorenen and the extent below the fjord bottom. The model is described in detail by Krahn (2004). Two temperature-dependent input functions (unfrozen water content and thermal conductivity) and overall water content are laboratory data from a nearby moraine, Damesmorenen, four km from hole 1, published by Gregersen et al. (1983). Volumetric heat capacity was set to 2000 and 3000 kJ/(m^3 x K) for frozen and unfrozen states respectively. Only one set of thermal properties was supplied to the model. It is obviously incorrect to assume homogeneous subsurface conditions, but we have no other thermal properties data available nor information on the subsea stratigraphy. A geothermal gradient of 35 mW/m^2 was set as a flux boundary condition at the bottom of the profiles. The vertical profile sides were set as zero flux boundaries.

To obtain a first estimate of the subsurface temperatures, the model was initially run in a steady state mode (Figs. 5A, 5C) using an estimated annual surface temperature and the average water temperatures as upper boundary conditions. A ground surface temperature of -4°C was used; this is slightly warmer than the mean annual air temperature due to the surface offset demonstrated in Table 1. A temperature of -0.1°C was used as the seabed boundary condition; this is the mean annual measured water temperature with interpolated temperatures for the missing 1.5 months of data.

The model was also run in a transient mode (snapshot in Fig. 5B) to compare the model results with the temperatures measured in Borehole 1. In the transient mode, eight simulations were run per day, and each node result was input to the next model run. Here the model was forced with meteorological data from 1 Jan 2006 to 10 September 2007. The meteorological inputs were maximum and minimum daily temperature, maximum and minimum daily humidity, and average wind speed. Latitude and longitude were supplied and the TEMP/W program used an energy balance approach to model the surface energy balance. To simulate the seabed temperature, a time dependent te mperature function was supplied as boundary condition, consisting of the average measured water temperature on 14 day basis. These are seen as crosses in the lower part of Figure 3.

No attempts were made to simulate the tidal fluctuation and its affect on the ground temperatures.

The model was run on two profile sections of different lengths and depths to both obtain detailed information on the near surface conditions, and impressions of the larger-scale ground temperatures in the coastal zone. The profiles were 92 m and 260 m long respectively and simplify a profile across the moraine and into Vallunden crossing Borehole 1.

Model results

Figure 5A shows a steady-state simulation for the immediate shore area. A high horizontal thermal gradient is seen in a narrow zone just below the shoreline. Since the mean annual water temperature is slightly below zero (-0.1°C), permafrost is modeled to be present in a thin layer below the seabed.

Figure 5B shows a snapshot plot from the transient model run from 7 April 2007. The sharp decrease of near surface temperatures reflects the winter freezing on land. A -1 °C isotherm has formed close below the seabed reflecting that the water temperatures approach -2°C during winter.

Figure 5C is a model run of the larger and deeper section but with the boundary conditions as those of Figure 5A. The pattern is similar as the one in Figure 5A but suggests that at depth, the presence of the sea will affect the ground thermal conditions more than 100 m from the shore, and similarly, that the cold temperatures from land will affect the sub-seabed temperatures at a similar distance offshore.

Figure 6 compares the measured and modeled temperatures in Borehole 1 for 7 April 2007. The discrepancy of model temperatures near the surface and towards the bottom is quite small, whereas the modeled temperature is up to 1.4°C wrong in the middle of the borehole. This and other snapshots throughout the year show that, while the general pattern is simulated reasonably well, there are discrepancies. These are often larger than those shown in Figure 6. However, the reasonable agreement of the modeled to the measured temperatures gives us some confidence in the general modeling results.

Discussion

The pronounced sill, Akseløya, restricts warm coastal water from entering Van Mijenfjorden and probably makes this fjord colder than other western Spitsbergen fjords. Sea ice cover is longer-lasting and more stable here. Therefore, this fjord is a primary candidate for possible subsea permafrost in western Spitsbergen fjords.

The modeling results of the subsea permafrost extend presented here should be seen as a minimum scenario. This is because the water temperatures were measured in a shallow, high-current strait, where the fjord water is strongly mixed with warmer fresh water during the summer. July temperature measurements from two deep basins in Van Mijenfjorden (Gulliksen et al. 1985) of -1.53°C and -1.27°C, respectively, indicate that water temperature in the deeper parts of the fjord remains below 0°C all year.

Permafrost, as defined solely on the basis of temperature, may not necessarily indicate cryotic subsea conditions. Sea water freezes at temperatures slightly above -2°C but capillarity and adsorption—in particular in fine-grained sediments—can further reduce the freezing point (Williams & Smith 1989). Thus, depending on the sediment properties, the seabed may well have permafrost by definition but still remain unfrozen. If the seabed consists of saline marine deposits, they will not be cryotic, even if thermally defined permafrost exists.

The 1300 A.D. surge of Paulabreen deposited lateral moraines in a rim around the inner parts of the fjord. A new detailed bathymetric survey indicates that glacial deposits also occupy the seabed here (Ottesen et al., in prep.). A seabed consisting of terrestrial sediments of glacial origin and with fresh rather than saline porewater could actually be frozen, but this hypothesis has not yet been tested.

The Crednermorenen moraine contains large amounts of buried glacier ice. It is possible that the unusual cold water conditions in Van Mijenfjorden are influencing the preservation potential of the ice-core in this moraine.

Conclusions

The permafrost temperatures measured in three boreholes in the ice-cored Crednermorenen moraine were studied for a period of a year. The surface temperatures in all holes were higher than the corresponding air temperature. The highest surface temperature was measured in Borehole 1 that normally has a snow cover of 20 cm while the two other boreholes are nearly snow free during winter. Most likely the warmer surface temperature in Borehole 1 is due to a surface offset (Smith & Riseborough 1996) caused by the insulating effect of snow.

Increasing temperatures were observed from the surface down through the active layer to the top of the permafrost in two of the boreholes. This is opposite to what would be expected if higher thermal conductivity of frozen ground compared to unfrozen ground causes an active layer (or thermal) offset. So this offset appears not to be important here; probably the ground is too dry.

Borehole 1 is located six m from the shore and is significantly warmer than two other boreholes both about 150 m away from the shoreline. To investigate the effect of the proximity to the sea, the finite element program TEMP/W was used to model the ground temperatures at the shore and below the seabed in both a steady-state and transient mode. Meteorological data and water temperature measurements were used to force the model.

The program manages reasonably well to simulate the ground temperatures in the near-shore borehole. The simulations indicate that permafrost, as defined solely on temperature, is present in a thin layer beneath the seabed of Van Mijenfjorden. Whether it is frozen or unfrozen will depend on the material properties.

At depth, the warming effect of the sea on the ground temperatures is modeled to penetrate more than 100 m inland and the cooling effect of land is affecting the seabed at an equal distance. The temperatures closer to the surface, however, are primarily locally controlled.

Acknowledgments

Many thanks to Store Norske Spitsbergen Kulkompani for funding the drilling and instrumentation of the boreholes and for providing logistical support when collecting data. LNSS, local contractor, preformed the drilling. Jomar Finseth, NTNU, supervised the drilling, sediment sampling, and laboratory work. John Inge Karlsen, logistics at UNIS, dived twice in muddy waters to emplace and recover the tide gauge that also recorded the water temperatures. The manuscript was improved by comments of an anonymous reviewer.

Thermal Deformation of Frozen Soils

G.P. Kuzmin
Melnikov Permafrost Institute, SB RAS, Yakutsk, Russia
V.N. Panin
Melnikov Permafrost Institute, SB RAS, Yakutsk, Russia

Abstract

A relationship between temperature deformations of frozen soil and physical characteristics that change with increasing or decreasing temperature has been derived. This relationship is based on the assumption that the volumetric expansion of the soil is equal to the sum of the volume changes of its components. The gaseous component is assumed to change in volume due to both thermal deformation of the gas and elastic deformation caused by a change in thermal stresses in the soil. This assumption is confirmed by the results of experiments.

Keywords: gaseous constituent; phase change; soil components, temperature deformation.

Introduction

Frost cracking of frozen soils subject to sub-freezing temperature fluctuations is a common phenomenon in permafrost regions. It is responsible for the formation of widely occurring polygonal features and affects various types of engineering structures (Ershov 2002).

Prediction of frost cracking in frozen ground requires knowledge of the thermal expansion coefficients, along with temperature data, and the soil thermal and mechanical properties (Grechishchev 1972).

The purpose of this paper is to derive an equation for obtaining the thermal deformation coefficients for frozen soils instead of time-consuming experimental determinations.

Thermal deformation of frozen soils, which generally consist of solid mineral particles, ice, water, and gases, determine the processes of the cryogenic rebound and formation and development of frost cracks.

Temperature change causes all frozen soil components to change volume in conditions of free or finite deformation. The most significant soil volumetric changes happen as a result of the water phase change, accompanied with the volume change accounting some 9% (Votyakov 1975). However frost penetration is accompanied with frost heave only if there is sufficient water-saturation (Votyakov 1975). When the water content is less than the plastic limit, freezing clay soils compress. When the water content is more than this limit, expansion develops during the freezing, and compression develops after freezing. Thus, the final deformation can be either positive or negative depending on initial in-situ water content.

No data is available on the influence of the soil gaseous constituent that reaches more than 10% in volume (Brodskaya 1962) on temperature deformations of frozen soils. Internal structural transformations of soil at freezing can not but influence the elastic deformations of gaseous constituent.

The Dependence of Temperature Deformations on Physical Characteristics of Frozen Soils

The resulting volumetric change of the frozen soil with temperature is not the direct sum of thermal deformations of its components (Ershov 2002). However, the internal structural transformations in the soil caused by changes in its temperature should have an effect on elastic deformations of the gaseous component. Therefore, the increment of volume change of the frozen soil at a change of temperature from t_1 to t_2 can be written as the sum of its components volume increments

$$\Delta V = \Delta V_d + \Delta V_W + \Delta V_i + \Delta Va \tag{1}$$

where ΔV_d, ΔV_W, ΔV_i, and ΔV_a are the increment of volume of soil skeleton, water, ice, and gaseous constituent, respectively.

Volumes of frozen soil components can be expressed through the physical characteristics and the whole soil volume.

$$V_d = \frac{\rho_d}{\rho_S} V \tag{2}$$

$$V_W = \frac{w_W \rho_d}{\rho_W} V \tag{3}$$

$$V_i = \frac{\left(w - w_W\right)\rho_d}{\rho_i} V \tag{4}$$

where ρ_d, ρ_S, ρ_W, and ρ_i are densities of the soil, mineral particles, water, and ice accordingly; w and w_W are the total water content and unfrozen water content.

Equation (1) in view of Equations (2)–(4) can be given as:

$$V_2 - V_1 = \left(\frac{\rho_{d,2}}{\rho_{S,2}} V_2 - \frac{\rho_{d,1}}{\rho_{S,1}} V_1 \right) + \left(\frac{w_{W,2}\rho_{d,2}}{\rho_{W,2}} V_2 - \frac{w_{W,1}\rho_{d,1}}{\rho_{W,1}} V_1 \right) + \left(\frac{w - w_{W,2}}{\rho_{i,2}} \rho_{d,2} V_2 - \frac{w - w_{W,1}}{\rho_{i,1}} \rho_{d,1} V_1 \right) + (V_{a,2} - V_{a,1}) \tag{5}$$

Characteristics for t_2 can be expressed through the corresponding parameters for t_1 in Equation (5).

The soil volume at t_2 can be presented as:

$$V_2 = (1 + \beta \Delta t) V_1 \tag{6}$$

where β=coefficient of volumetric temperature deformation; $\Delta t = t_2 - t_1$.

At temperature change the soil skeleton weight remains unchanged, hence:

$$\rho_{d,1} V_1 = \rho_{d,2} V_2. \tag{7}$$

The volume change of the closed-form gaseous constituent of frozen soils is the result of both its temperature deformations and action of temperature induced stress. Hence

$$\rho_{a,2} V_{a,2} = \rho_{a,1} V_{a,1} k \tag{8}$$

where ρ_a is soil gaseous constituent density; k is the coefficient considering the gases elastic deformations under the action of soil temperature stress.

The frozen soil components density for t_2 can be expressed through corresponding components for t_1

$$\rho_{S,2} = \frac{\rho_{S,1}}{1 + \beta_S \Delta t} \tag{9}$$

$$\rho_{W,2} = \frac{\rho_{W,1}}{1 + \beta_W \Delta t} \tag{10}$$

$$\rho_{a,2} = \frac{\rho_{a,1}}{1 + \beta_a \Delta t} \tag{11}$$

$$\rho_{i,2} = \frac{\rho_{i,1}}{1 + \beta_i \Delta t} \tag{12}$$

The coefficient of volumetric temperature deformation for frozen soils is related to the linear coefficient of deformation as

$$\beta = 3\alpha \tag{13}$$

In view of Equations (6)–(13) we find formula of coefficient of linear soil temperature deformation from Equation (5).

$$\alpha = -\frac{1}{3\Delta t} \left\{ \begin{array}{l} \rho_{d,1} \left[\begin{array}{l} \dfrac{3\alpha_S \Delta t}{\rho_{S,1}} + \dfrac{w_{W,2}(1 + 3\alpha_W \Delta t) - w_{W,1}}{\rho_{W,1}} + \\ \dfrac{(w - w_{W,2})(1 + 3\alpha_i \Delta t) - (w - w_{W,1})}{\rho_{i,1}} \end{array} \right] + \\ \dfrac{V_{a,1}}{V_1} \left[(1 + 3\alpha_a \Delta t) k - 1 \right] \end{array} \right\} \tag{14}$$

In Equation (14) gaseous constituent abundance in the soil $V_{a,1}/V_1$ can be evaluated as follows. We present the total soil volume as the sum of volumes of its components.

$$V = V_d + V_W + V_i + V_a \tag{15}$$

Having substituted in Equation (15) formulas of volumes of components Equations (2)–(4), we get

$$\frac{V_{a,1}}{V} = 1 - \rho_{d,1} \left(\frac{1}{\rho_{S,1}} + \frac{w_{W,1}}{\rho_{W,1}} + \frac{w - w_{W,1}}{\rho_{i,1}} \right). \tag{16}$$

Then the temperature deformation coefficient Equation (14) in view of Equation (16) is:

$$\alpha = \frac{1}{3\Delta t} \left\{ \begin{array}{l} \rho_{d,1} \left[\begin{array}{l} \dfrac{3\alpha_S \Delta t}{\rho_{S,1}} + \dfrac{w_{W,2}(1 + 3\alpha_W \Delta t) - w_{W,1}}{\rho_{W,1}} + \\ \dfrac{(w - w_{W,2})(1 + 3\alpha_i \Delta t) - (w - w_{W,1})}{\rho_{i,1}} \end{array} \right] + \\ \left[1 - \rho_{d,1} \left(\dfrac{1}{\rho_{S,1}} + \dfrac{w_{W,1}}{\rho_{W,1}} + \dfrac{w - w_{W,1}}{\rho_{i,1}} \right) \right] * \\ \left[(1 + 3\alpha_a \Delta t) k - 1 \right] \end{array} \right\} \tag{17}$$

Results, Analysis, and Summary

The coefficient k is unknown in Equation (17) and can be determined from experimental data. To this end, the thermal deformation coefficients were determined experimentally for artificially prepared frozen samples of loam and sandy loam, at two moisture contents, and sand, at one moisture content (Table 1). To prevent water drainage, the samples were insulated with a polyethylene film. After rapid freezing at low temperatures (20 C–30 C below zero), they were placed in a chamber with temperature t_1= -17°C, and maintained until

Table 1. The soil characteristics and results of definitions of coefficients and *k*.

Type of soil	ρ_d, g/cm^3	ρ_S, g/cm^3	w, fraction	$\alpha \cdot 10^6$, gr^{-1}	$w_{W,1}$ fraction	$w_{W,2}$ fraction	k
Loam	1.524	2.7	0.25	417	0.083	0.068	0.834
Loam	1.301	2.7	0.35	465	0.083	0.068	0.832
Sand loam	1.918	2.65	0.13	113	0.048	0.031	0.707
Sand loam	1.320	2.65	0.34	143	0.048	0.031	0.830
Sand	1.698	2.65	0.19	71	0.016	0.009	0.836

stabilization. Then, the samples were moved to a chamber with temperature t_2= -4.1 C, and the changes in length were observed until the cessation of deformation. The changes in length of the samples were measured using a dial gage with an accuracy of 0.01 mm.

The temperature deformation coefficient was calculated by the formula

$$\alpha = \frac{\Delta l}{l_1 \Delta t} \tag{18}$$

where $\Delta l = l_2 - l_1$; l_1 and l_2 are initial and final lengths of the sample; $\Delta t = t_2 - t_1$.

The *k* values were calculated by Equation (17) using the experimentally determined α values. Herewith the following values were introduced: α_S=10•x 10^{-6}gr.$^{-1}$; α_W=17.4•x 10^{-6} gr.$^{-1}$; α_i=50•x 10^{-6} gr.$^{-1}$; α_a=1217•x 10^{-6} gr.$^{-1}$. The unfrozen water content at t_1 and t_2 for all types of tested soils were taken from Votyakov (1975).

Experimental values of the coefficient of the temperature deformation, the deformations of samples received after stabilization, rather exceed the one-daily values, given in the paper by Votyakov (1975). The changes in the internal structure of the frozen soils with increasing thermal stresses caused elastic compression of the gaseous component, as is indicated by the values *k*<1.

Conclusion

1. The dependence of the frozen soils temperature deformation coefficient on its physical characteristics, where the gaseous constituent elastic deformations come into account, has been received.
2. The elastic compression of the jammed gaseous constituent occurs when the cooling of frozen soils in the range of water change phase.
3. The *k* values, obviously, depend on conditions of the frozen soil cooling.

Channel Realignment Using Natural Channel Design Principles

Alexandre Lai
Alyeska Pipeline Service Company, Fairbanks, Alaska, USA
Marc N. Gaboury
LGL Limited environmental research associates, Nanaimo, British Columbia, Canada

Abstract

The Trans-Alaska Pipeline crosses Hess Creek on a 180 foot steel plate girder bridge. Thermal and hydraulic erosion altered the stream pattern with formation of a meander bend upstream of the bridge, leading to misalignment of the stream with the bridge abutments. To meet diverse stakeholder needs, an innovative approach to river engineering was implemented. Instead of a traditional riprap revetment, redirectional flow vanes were installed along an 800 foot meander bend. The vanes manipulate flow direction upstream of the bend, nudging the stream to a shallower curvature prior to entering the bridge opening. This new alignment improved conveyance through the bridge, created an active floodplain between eroding bank and the active channel, and over time will reestablish a functional riparian zone. Besides ecological benefits of a functioning floodplain, the riparian zone creates a buffer that insulates the ice-rich stream bank from further thermal and hydraulic erosion.

Keywords: erosion; floodplain; meander; realignment; stream; vanes.

Introduction

Hess Creek is located 85 miles north of Fairbanks, Alaska at Dalton Highway milepost 24 and is approximately 32 miles south of the Yukon River. The Trans-Alaska Pipeline crosses Hess Creek at pipeline milepost 375 on its 800 mile journey from the Beaufort Sea at Deadhorse, Alaska, to the port of Valdez. At the pipeline crossing, the creek corridor is 130 ft wide, and the pipeline is supported by a 180 ft single span steel plate girder bridge. The drainage basin is 508 mi^2 and the bankfull discharge is 3375 ft^3/s (cfs), based on a flood frequency analysis for gauged station USGS 15457800 on Hess Creek near Livengood, Alaska (1970–86; 662 mi^2). The area has discontinuous permafrost, and a typical floodplain soil profile consists of an organic layer, followed by silts, and alluvial gravels and sands down to bedrock.

At the time of construction in 1976, the pipeline crossing was in a stable reach of the creek with well-vegetated banks and no signs of bank erosion. A decade later, bank erosion upstream of the pipeline bridge was observed, and remedial action was taken to protect the north bridge abutment. But thermal and hydraulic erosion continued upstream of the bridge abutment and accelerated in the early years of 2000, most likely due to wildfires in the area. Continued erosion resulted in formation of a meander bend upstream of the bridge that previously was a relatively straight reach at the time of construction. This resulted in a misalignment of the bridge with the upstream and downstream reaches of the creek that could outflank the bridge abutment in a major flood event (Fig. 1). To meet the various stakeholder needs, such as protection of critical infrastructure, habitat preservation, and protection of an ecologically delicate region, an innovative approach to river engineering was used.

Figure 1. Hess Creek looking downstream, spring 2005 breakup. Hydraulic and thermal erosion of right bank resulting in misalignment with pipeline bridge.

Design Concept

A riprap revetment is typically used to halt streambank erosion (Alyeska Pipeline Service Company 1973). However, unless a new bank and floodplain are built, rip-rapping the existing bank will lock in a radius of curvature for the meander bend that will continue to be misaligned with the pipeline bridge opening. Instead of a traditional riprap treatment of the streambank, a series of flow deflector vanes were installed in Hess Creek to readjust the existing stream alignment into a smooth curvature with the bridge orientation. The vane design was based on an approach applied by the Rural Water Commission of Victoria in Australia (Standing Committee on Rivers and Catchments 1991). The design relied on a visual estimation of the critical line of attack (i.e., notional straight lines of maximum stream velocity that align the riverward tip of the upstream vane to the base of the next consecutive vane downstream to ensure the eroding bank is not attacked directly during floods) on

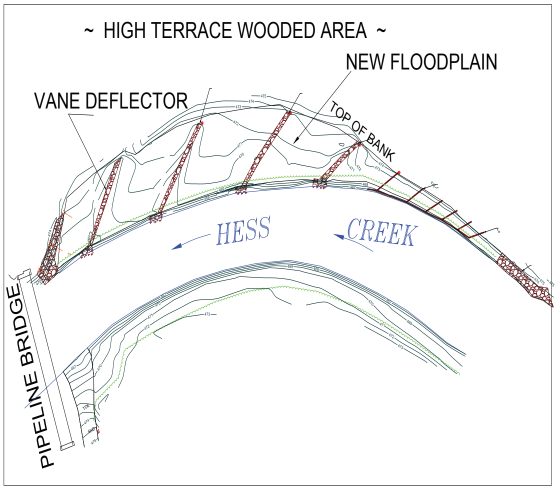

Figure 2. Plan view of 10 deflector vanes, new floodplain, and alignment of meander bend.

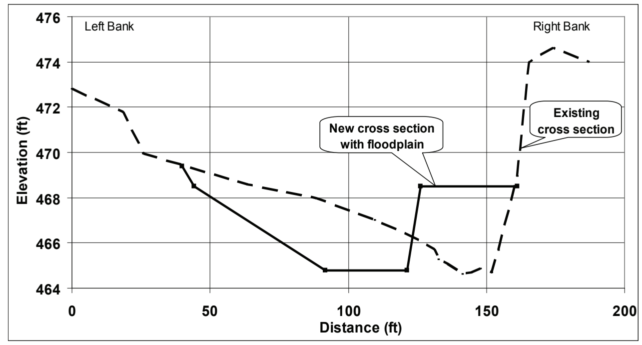

Figure 3. New cross section superimposed over existing eroding bank. A floodplain on the right bank was created from realignment of the meander bend.

Figure 4. Hess Creek upstream of pipeline bridge. Willows were planted along the bank and on the newly created floodplain.

the outside streambank of the meander during flood stage. Detailed planimetric drawings, based on topographic surveys, and aerial photographs were used to estimate the critical line of attack and to position, through an iterative process, the location of the deflector vanes (Fig. 2). The guidelines followed during the design stage were that: (1) the radius of curvature for the eroding meander bend would be realigned with the bridge orientation, (2) the new channel design width and meander radius would mimic stable channel and meander radii upstream and downstream of the project site, (3) each deflector vane would be spaced so the flow passing around and downstream from the riverward end of the vane intersected the next vane and not the eroding bank, and (4) vanes would be angled approximately 10° downstream of the perpendicular to the estimated critical line of attack.

Prior to construction of the deflector vanes, the channel was realigned laterally towards the south (left bank looking downstream), gradually from 0 ft at the upstream end to 40 ft at the downstream end, just before the bridge abutments (Fig. 3).

Based on reference reach surveys upstream and downstream of the work site, the bankfull channel width of the new channel was set at 82 ft. The channel realignment was about 800 ft long and gravel excavated from the point bar was used to build a floodplain terrace along the right bank in space created by the channel realignment. To provide a stable transition from the new floodplain to the existing terrace on the north banks, a 3H:1V slope was shaped.

After the new floodplain footprint was established, 10 riprap directional flow vanes, 10–98 ft long and up to 6 ft wide and 6 ft deep, were installed orienting downstream along the 800 ft meander bend. The vanes manipulated flow direction, nudging the stream into a shallower curvature prior to entering the pipeline bridge opening. The vanes were constructed of riprap, ranging in diameter from 1–4 ft. Spacing and length of the vanes increased from upstream to downstream in the meander bend. Vane spacing and length were dependent on the estimated critical line of attack and the existing and proposed radius of curvatures for the meander bend. A riprap-armored guidebank was constructed along a 50 ft section at the upstream end of the meander to prevent flood flows from outflanking the vanes located downstream. The tops of the vanes were generally level with bankfull elevation along much of their length, with a gradual slope at the landward end to the top of the shallow streambank. Height of the vanes was approximately 4 ft above the new channel thalweg (defined as the deepest point in a given cross-section). The vane was keyed into the streambed and bank about 3 ft with riprap. About 650 yd^3 of riprap were used to build the vanes, and an additional 100 yd^3 were used to reinforce the existing guidebank on the north bank. To enhance instream cover for fish, logs were buried into the floodplain between the downstream vanes. The logs extended instream about 12 ft and were submerged at low-water level.

Once the vanes were completed, willow cuttings were installed along the riverward edge of the new right bank. In addition, the floodplain was vegetated with live stakes and willow transplants the following summer (2006) (Fig. 4).

Post-Construction Monitoring

Although additional time is needed to properly assess the success of the design concept, initial results based on two full years of monitoring, since their installation in the fall of 2005, are encouraging. No additional bank erosion has occurred, and the active floodplain is slowly becoming vegetated with natural riparian species. Deflector vanes have effectively nudged the thalweg away from the eroding terrace. Cross section surveys confirm that the thalweg is along the tip of the vanes as can be seen from Figure 5, where the main current is away from the right bank and flowing in the middle of the flooded channel during breakup.

Continuous riprap treatments typically halt bank erosion entirely, while discontinuous measures like deflector vanes or bank barbs deflect flows with discreet instead of continuous hardpoints. Therefore, some limited adjustments between structures after construction are expected until a stable "scalloped" bank line is formed (McCullah & Gray 2005).

A scalloped bank line developed in between the constructed deflector vanes on the newly constructed floodplain in Hess Creek (Fig. 6). This occurred after the first snowmelt flood following construction, but has remained stable since 2006. These scallops are a result of flow separation due to expansion of flow lines downstream of the rock deflector vanes. The expansion zones are beneficial to the aquatic ecosystem because they provide back eddies, hydraulic complexity, refuge and resting areas for fish.

The low profile deflector vanes provide flood capacity during peak flows when the floodplain is overtopped relieving stresses along the bank and the vane structures. These floodplain overflows result in deposition of seeds and woody material, which over time will hopefully result in a healthy riparian zone.

Figure 5. Post-construction spring breakup 2006, as compared with Figure 1. Overbank flow completely submerged floodplain and deflector vanes. No bank erosion, and main flow current is along the tip of deflection vanes, away from the right bank (note location of white "bubble line").

Figure 6. Looking upstream from the bridge, September 2007, showing scallops between deflector vanes and woody material that accumulated along the bank and floodplain.

Conclusion

The deflector vanes provided bank protection by realigning the channel thalweg away from the eroding streambank and by providing a riprap key tie-in of the vane to the streambank. The former measure provided stability along the toe of the bank, and the latter safeguarded against outflanking of the vane structures during extreme floods. The new alignment improved conveyance through the bridge, created an active floodplain between the eroding bank and the active channel, and will reestablish over the long term a stable streambank and functional riparian zone. By adopting a channel width and meander radius based on channel morphology in undisturbed natural reaches in Hess Creek, it is expected that the stability of the channel and constructed works will be maintained under the range of existing hydrological conditions. Incorporating these natural channel characteristics in the meander realignment will also help to create and maintain some of the key physical components of a healthy aquatic ecosystem. These key components could include, for example, deep residual pool depth along the bend to provide high-quality holding pools for fish, sorting and distribution of substrates to obtain suitable sizes and quantities of spawning gravels, and over-stream deciduous vegetation and recruitment of woody debris from the new floodplain to provide cover for rearing fish. In addition to the ecological benefits of a functioning floodplain, the constructed works also created a buffer to insulate the exposed ice-rich streambank from further thermal and hydraulic erosion. There is also a direct economic benefit to this design approach, because only one third of the rock quantity typically used in a traditional riprap revetment was needed to build the structures.

Acknowledgments

Many individuals provided invaluable input to the design of this project, among them are, Wim Veldman, P.E., Philip Hoffman, P.E., and Habitat Biologist Kenneth Wilson. Their diligent review and suggestions contributed to improvement of the overall design and satisfying stakeholder needs.

Abstract

The potential of space-borne synthetic aperture radar interferometry (InSAR) to estimate both magnitude and spatial pattern of slope motion in a periglacial environment has been evaluated over a large area of the western Swiss Alps, using data from the ERS-1 and ERS-2 satellites. About 280 active rock glaciers with different classes of velocities have been identified on the analyzed interferograms. The velocities range from a few centimeters per year to several meters per year. These data were validated by some differential GPS measurements and compared to numerous field observations. The resulting classification permits a better description of the full range of rock glaciers velocities and dynamics. Therefore, ERS InSAR reveals itself to be an efficient remote sensing technique, not only for inventorying active rock glaciers over a wide area, but also for estimating and categorizing rock glacier displacement velocities.

Keywords: InSAR; permafrost creep; rock glacier activity; Swiss Alps.

Introduction

The study of rock glacier dynamics constitutes one of the major topics in alpine periglacial research (e.g., Haeberli et al. 2006). The abundant literature related to the creeping of ice-rich permafrost attests the great diversity of rock glacier velocities, from a few centimeters per year for the slowest ones to more than 5 m per year for the fastest ones (e.g.. Roer 2005). Recent studies in the European Alps have evidenced (1) the great inter-annual variation of rock glacier velocities (Delaloye et al. 2008a), (2) an acceleration since the 1980s (Kääb et al. 2007), and (3) the partial or complete destabilization of some rock glaciers (e.g., Delaloye et al. 2008b, Roer et al. 2008). For these reasons, it appears that the usual classification—active, inactive, relict—does not permit the whole range of rock glacier velocities and dynamics to be described accurately. Therefore, a more precise classification of rock glacier velocities would be desirable.

Space-borne Synthetic Aperture Radar Interferometry (InSAR) is a well-established technique for mapping centimeter temporal changes in surface topography (Bamler & Hartl 1998, Rosen et al. 2000, Strozzi et al. 2001). In mountain areas above the tree line, it is possible to detect mass movements mostly during the snow-free period (Rott et al. 1999, Delaloye et al. 2007a). In particular, several studies have demonstrated the efficiency of InSAR for estimating rock glacier displacements (e.g., Kenyi & Kaufmann 2003, Strozzi et al. 2004, Kääb et al. 2005, Kaufmann et al. 2007). In the framework of the ESA (European Space Agency) SLAM (Service for Landslide Monitoring) project and with the support of the Swiss Federal Office for the Environment, the potential of InSAR to inventory mass wasting in the alpine periglacial belt has been tested. Both magnitude and spatial pattern of slope instabilities have been evaluated over a large area of the western Swiss Alps (50 x 30 km) (Fig. 1), using data of the European Remote Sensing satellites ERS-1 and ERS-2 dating from 1995 to 2000.

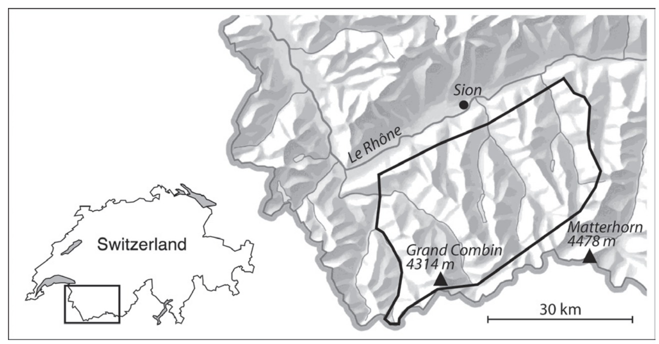

Figure 1. Area investigated.

This paper focuses on the various rates of rock glacier activity, which can be evaluated by ERS InSAR. After presenting the method and the dataset, the paper proposes a classification of rock glaciers, according to their typical ERS InSAR signals and morphological characteristics. Special attention was put on destabilization signs, which indicate a change in rock glacier dynamics.

Methods and Datasets

For this study, a total of 34 interferograms computed from ERS SAR images acquired at C-band (wavelength: 5.6 cm) between 1995 and 2000, with baselines shorter than 100-150 m, were used. Time lapse ranges between 1 day and 1085 days (in fact multiples of 35 days ± 1 day). The topographic reference was determined from an external digital elevation model with a spatial resolution of 25 m and an estimated vertical accuracy of 3 m (DHM25 © 2003 swisstopo). The InSAR products were also computed at 25 m spatial resolution. A change of the InSAR phase of one cycle is related to a movement of half the wavelength (2.8 cm) in the satellite line-of-sight direction, which is inclined at ~23° from the nadir and, in the western Swiss Alps, oriented toward the east +~12° for ascending orbits and toward the west -~12° for descending orbits. Thus, phase signals (i.e., change in the InSAR phase) detected on 1-day lag, 35-day lag, and 1-year lag interferograms can be interpreted as three orders of velocities, that is, respectively, centimeters per day, per month, and per year.

Important limiting factors of InSAR in mountainous terrain arise from temporal decorrelation, the satellite viewing geometry, and inhomogeneities in the tropospheric path delay. Atmospheric perturbations may cause phase changes related to the altitude. Among the other disruptive parameters, the wet snow, typically, can strongly reduce the reliability of an interferogram. This problem is especially present when working in alpine periglacial areas. In the Alps, above 2500 m a.s.l., the snow-free period is reduced to a few months, between July and early October. In addition, summer snowfalls are not uncommon at these altitudes, which can make many acquisitions unusable. On the other hand, cold snow is almost transparent to a radar wave. Thus, if the snow cover does not evolve, which may be possible only for few days, rapid movements can be identified in winter (Strozzi et al. 2004). Another limitation is the vegetation, which disturbs the radar backscatter and prevents any analysis in forest areas. Rock walls appear also strongly decorrelated, because of topographic effects. Finally, it is not possible to identify creeping landforms smaller than at least 2 x 2 grid cells (i.e., 50 x 50 m).

In order to identify the various rates of activity of active rock glaciers, different steps were followed:

- Evaluation of the reliability of the different interferograms. In particular, it was necessary to select the images for which the signal was not perturbed by the snow cover (both from the previous winter and from recent snowfalls). As a result, several interferograms could not be used in this study. The eight most reliable interferograms are listed in Table 1.
- Identification and delimitation of areas showing signals of potential slope motion by analysing the selected interferograms with various time scales and with different zoom levels.
- Determination of the corresponding geomorphological process (or landform) by orthophoto analysis or field observations.
- When available, comparing the InSAR estimated velocities to differential GPS data or airborne photogrammetric analysis.

Table 1. Dates of the best suited ERS SAR interferograms.

Dates	Direction	Days
11-12 March 1997	asc./desc.	1
29-30 July 1997	asc./desc.	1
3 Sept. - 8 Oct. 1997	descending	35
29 July - 3 Sept. 1997	ascending	35
18 Sept. 1996 - 30 July 1997	descending	315
8 Oct. 1997 - 23 Sept. 1998	descending	350
15 July 1998 - 8 Sept. 1999	descending	420
7 Oct. 1997 - 14 July 1998	ascending	279

InSAR-Detected Velocities

About 600 polygons corresponding to spatially limited slope movements were identified throughout the whole investigated area. Among these polygons, about 280 were attributed to "active" rock glaciers. The other ones correspond to landslides, solifluction, push moraines, or debris-covered glaciers.

For four rock glaciers of the inventory, an obvious phase signal is detected on 1-day lag interferograms. Figure 2 illustrates the data for the Tsaté-Moiry rock glacier. The summer interferogram displays a very clear signal all along the rock glacier (Fig. 2a). On the winter interferogram (Fig. 2b), the signal is a little less marked, which may indicate slower winter velocities. These data mean that the motion is in the cm range per day, which corresponds to more than 3 m a^{-1}. Terrestrial measurements with differential GPS carried out on the rock glacier revealed velocities even up to 7 m a^{-1} between 2006 and 2007. Similar InSAR signals were observed on the Petit Vélan rock glacier, where seasonal velocities up to 2 cm per day were measured in summer 2005 and 2007 (Delaloye et al. 2008b).

Some rock glaciers display a low 1-day phase signal, whereas the 1-month signal is decorrelated, that is larger than 1-phase cycle (2.8 cm). This is, for example, the case for the Tsarmine rock glacier (Fig. 3). In Figure 3a, a low signal can be detected on the 1-day summer interferogram (arrow), even if it is close to the noise level. The corresponding velocity can be estimated to a few millimeters per day, that is 1-2 m a^{-1}, which is confirmed by differential GPS measurements carried out since 2004 (see also Lambiel 2006). On the 1-month interferogram, the decorrelation is widespread over the landform (Fig. 3b).

Rock glaciers with velocities corresponding to the two previous categories constitute 5% maximum of the sample. On most of the InSAR-identified rock glaciers, a signal can only be detected with a 1-month interval. These rock glaciers can appear widely decorrelated, as it is the case for the Becs-de-Bosson rock glacier (Fig. 4) (Perruchoud & Delaloye 2007). This corresponds to minimum velocities of 20-30 cm a^{-1}. Another example is the Milon east rock glacier (Fig. 5a).

On numerous rock glaciers, the signal is hardly detectable at a 35-day lag, but is evident at a 1-year interval. The Milon west rock glacier is a nice example of this type (Fig. 5). Whereas only a very low signal occurs on the

1-month interferogram, the signal is evident on the 1-year interferogram. However, it remains rather correlated on the major part of the landform, which indicates a surface velocity of 2-3 cm a^{-1}.

Finally, rock glaciers showing only a low 1-year ERS InSAR signal or no signal at all creep with velocities slower than the phase cycle, i.e., 2.8 cm a^{-1}.

Interpretation

The presented examples show the strength of InSAR for distinguishing the large range of active rock glaciers velocities. Table 2 summarizes the ERS InSAR-detected velocities and the corresponding classification which can be proposed. The frequency of destabilization indices for each category, which attests a change in the rock glacier dynamics, is also reported in the table.

Very high velocity

Phase signals observed on 1-day lag interferograms allowed movements in the order of a centimeter per day, which means several meters per year, to be identified. This magnitude of velocities, which can be qualified of *very high*, has rarely been mentioned hitherto. However, recent studies have reported the existence of other unusually rapid rock glaciers (e.g., Roer et al. 2008). Landslide-like features, like well-developed scars and crevasses, are often observed on these landforms (Fig. 2c), which indicates a strong destabilization and a complete change in the rock glacier dynamics.

High velocity

Rock glaciers showing a low 1-day and a decorrelated 1-month ERS InSAR signal move with a speed of 1-2 m a^{-1}. Such velocities are in the upper range of the typical rock glacier velocities. These landforms may creep with such velocities because of a large amount of ice, relatively warm temperature, or steep slope, but some of them display indices of a recent acceleration. Among these indices, the thinning of the upper part and associated thickening of the lower part is frequently observed, as it is the case for the Tsarmine rock glacier (Fig. 3c). On such landforms, destabilization signs, like scars and crevasses, are frequent, but are often not as pronounced and obvious as for rock glaciers of the previous category.

Medium velocity

Rock glaciers only detected with a 1-month interval and for which the signal is decorrelated correspond to the classical active rock glaciers. Velocities are comprised between 20 cm a^{-1} and about 1 m a^{-1}. Indices of destabilization are occasionally observed. They may result from strong activity periods, as for the Mont Gelé B rock glacier, which moved with velocities of 120 cm a^{-1} between 2003 and 2004, whereas the velocities measured since 2000 are normally comprised between 20 to 60 cm a^{-1} (Lambiel 2006, Delaloye et al. 2008a).

Low velocity

Rock glaciers showing a correlated or a low signal on 35-day interferograms and a decorrelated signal on 1-year interferograms are active, but the deformation rate is only a few cm a^{-1} (max. 0.2 m a^{-1}). A cold permafrost temperature, low ice content or low inclined slope generally explain these moderate velocities. Even if they are rare, destabilization indices occur in some cases, as for example on Les Lués Rares rock glacier (Fig. 6). On this landform, which is located below the regional lower limit of permafrost (front at 2320 m a.s.l), numerous indices, such as subsidence features, blocks densely covered with lichens and bushes on the front should indicate a very low activity. However, fresh scars in the front underline the current instability of the rock glacier (Fig. 6c), which is confirmed by the obvious and coherent signal visible on the 35-day lag interferogram, indicating velocities of about 10-20 cm a^{-1} (Fig. 6a). Both these velocities and the limit of the moving area are confirmed by GPS measurements. About ten rock glaciers of the inventory display such characteristics. They all show evidences of a former inactivity or at least a very low activity (like vegetation growth and abundance of lichens), but display some recent destabilization indices.

Very low velocity

The rock glaciers which are only detected on 1-year lag interferograms correspond to the classical *inactive* landforms. Their velocity is in the cm range per year.

Discussion

The inventory of creeping frozen debris bodies over a wide area is rarely exhaustive and the delimitation of the landforms can be highly subjective, whatever the method used. This is particularly the case with InSAR, as a potential signal may be due to other causes than a change in topography (atmospheric perturbations, vegetation, snow cover, etc.). Thus, the successfulness of such a study depends mainly on the availability of reliable interferograms. In this project, the discovery of a few very rapid rock glaciers was possible thanks the availability of very good quality summer and winter 1-day lag interferograms. Likewise, two excellent 35-day interval images, both in the ascending and descending mode, permitted us to delimitate classical active rock glaciers with a good accuracy. On the other hand, 1-year interferograms were not as reliable, but the identification of several low active rock glaciers was nonetheless possible.

In some cases, the signal is very low, such as, for example, the Tsarmine rock glacier on the 1-day interferogram (Fig. 3a) and the Milon west rock on the 35-day interferogram (Fig. 5a). For the Tsarmine rock glacier, the reliability of the signal was confirmed by GPS measurements. In the absence of terrestrial data, only the analysis of several interferograms and a good knowledge of the corresponding geomorphology allow the signal to be interpreted as a movement and not attributed to noise or atmospheric artefacts. However, the presence of a clear signal on a wider time interval,

Table 2. Classification of the rock glaciers according to their surface velocities.

Classical classification	ERS InSAR signal	Estimated surface velocity	Velocity classification	Destabilization
Active	1 day	> 2 m a^{-1}	very high	very frequent
	(1 day)/ 35 days decorrelated	1-2 m a^{-1}	high	Frequent
	35 days	0.2-1 m a^{-1}	medium	Possible
	(35 days correlated) / 1 year	0.03-0.2 m a^{-1}	low	Rare
Inactive	(1 year)	up to a few cm a^{-1}	very low	No
Relict	No	-	-	No

which confirms the activity of the landform, is an absolute prerequisite for attributing the signal to a change in the topography rather to noise.

One limiting factor for using InSAR in the study of rock glacier velocities is the fact that this technique gives an estimation of the movement for a time-delimited period. For this study, most of the interferograms used correspond to the period 1996–1997. Thus, the observed velocities should be valid only for this period. In addition, numerous active rock glaciers are in an acceleration phase since the 1980s (Kääb et al. 2007), and some of them are suffering strong changes in the process regime (Roer et al. 2008). Thus, the phase signal detected on the available interferograms may no longer reflect the current state of activity of the corresponding rock glaciers. However, the comparison of the ERS InSAR-detected signals to velocities measured with differential GPS on 15 landforms since 2004, that is nearly 10 years later, permitted us to validate the InSAR data. Moreover, additional field observations on several tens of rock glaciers allowed us to understand the cause of such and such range of velocities, like, for instance, the observation of destabilization processes, which are clearly connected to the very high velocities observed on some rock glaciers (Roer et al. 2008). Thus, even if the velocities may have changed since the end of the 1990s, it is very probable that most of the rock glaciers are still in the same range of velocities as ten years before.

Conclusion and Perspectives

ERS InSAR has revealed itself to be an efficient remote sensing technique, not only for inventorying active rock glaciers over wide areas, and more generally the creeping landforms of the alpine periglacial belt, but also for estimating and categorizing their displacement velocities. Thus, InSAR constitutes an interesting tool for the study of rock glacier dynamics in the context of a general acceleration of these landforms. However, the detected signal can be sometimes close to the noise level. Thus, reliable interferograms, orthophotos, and a good knowledge of the local geomorphology are necessary to interpret the detected signal correctly.

Further InSAR studies are feasible with the SAR sensors on board of the European Environmental Satellite ENVISAT (C-band, 5.6 cm wavelength, 35 days repeat cycle), the Japanese Advanced Land Observing Satellite ALOS (L-band, 23.6 cm wavelength, 46 days repeat cycle) and the German TerraSAR-X mission (X-band, 3.1 cm wavelength, 11 days repeat cycle), in orbit since 2002, 2006, and 2007, respectively. They should permit recent data on rock glacier velocities throughout wide areas to be obtained. However, no one is able to provide reliable data on rock glaciers with very high velocities anymore (Delaloye et al. 2008b), as did the ERS-1/2 tandem between 1995 and 1999.

Abstract

Changing sea ice conditions and thawing permafrost in the Arctic could lead to dramatic changes in coastal erosion dynamics. To address this issue, the Arctic Coastal Dynamics (ACD) project brought together experts from all circum-Arctic countries around a common project: the ACD classification of Arctic coasts. This paper uses 545 segments from the beta version of the ACD classification to investigate statistical relations between coastal erosion rates on Arctic coasts and ground ice content. Ground ice content and retreat rates are only weakly correlated statistically ($r = 0.48$, relationship statistically significant at $\alpha = 0.01$), but the multifactor nature of coastal erosion in the Arctic shows us that ground ice is a major factor affecting erosion processes. The current study integrates several geographical settings and time scales and is therefore integrative enough to be used as a benchmark for future empirically based models

Keywords: Arctic; coastal erosion; GIS; ground ice.

Introduction

Arctic coasts are among the most vulnerable environments to climate change. Changing sea ice conditions and thawing permafrost could lead to dramatic changes in coastal erosion dynamics. To address this issue, ACD was initiated to provide a comprehensive review of coastal erosion processes at the Arctic scale. This paper uses data from the beta version of the ACD classification to investigate statistical relations between coastal erosion rates on Arctic coasts and ground ice content. Close to 600 segments were used to systematically compare and plot ground ice content and coastal erosion rates. The specific aims of this paper are to document the statistical relation between ground ice and coastal erosion rates and to compare those relations with previously published studies. The statistical relationship extracted from this study will be used as a benchmark for empirical models of coastal erosion.

Background

Arctic coastal erosion

Coastal erosion in the Arctic is different from its counterpart in temperate regions due to the short open-water season (3-4 months) and to the presence of permafrost, and thus of ground ice, in coastal sediment.

Coastal retreat rates are also highly variable both spatially and temporally (Lantuit & Pollard 2008, Rachold et al. 2000, Solomon 2005). Spatial variability is mainly due to changes in the lithology, cryology, and geomorphology of coastal cliffs, including ground ice content.

Ground ice is a unique feature of polar coastal systems. It is present in the subaerial part of the shore profile, but also underneath the water column, as submarine ground ice (Mackay 1972, Rachold et al. 2007). Its presence affects both the response of the shore to thermal-hydrodynamical forcing and the sediment budget of the coast (Are 1988, Dallimore et al. 1996). The presence of ground ice leads to a process termed "thermal abrasion" (Are 1988) which encompasses the combined action of waves and thawing of the permafrost. It has been shown to facilitate erosion (Héquette & Barnes 1990, Kobayashi et al. 1999), through the presence of ice in coastal cliffs, or through the occurrence of large thermokarst features in the coastal zone (Lantuit and Pollard 2005, Lantuit & Pollard 2008, Wolfe et al. 2001). Dallimore et al. (1996) suggested that thaw settlement of ice-rich sediments in the nearshore zone could induce a change in the shoreface profile, hence enhancing wave efficiency during storms.

However, not all Arctic coastlines are characterized by subsea ice-rich permafrost and other explanations must be sought. Héquette and Barnes (1990) attributed those to the occurrence of ice scours and sediment entrainment by sea ice in the offshore zone, which as shown by Forbes and Taylor (1994) can alter significantly the coastal sediment budget. They based their hypothesis on the weak correlation between retreat rates and several factors including ground ice, wave height, and grain size (Fig. 1). This paper attempts at providing an expanded characterization (Arctic-wide) of the statistical relation between ground ice contents and re-evaluating the relation proposed by Héquette and Barnes (1990) for the southern Beaufort Sea by using the ACD classification of Arctic coasts.

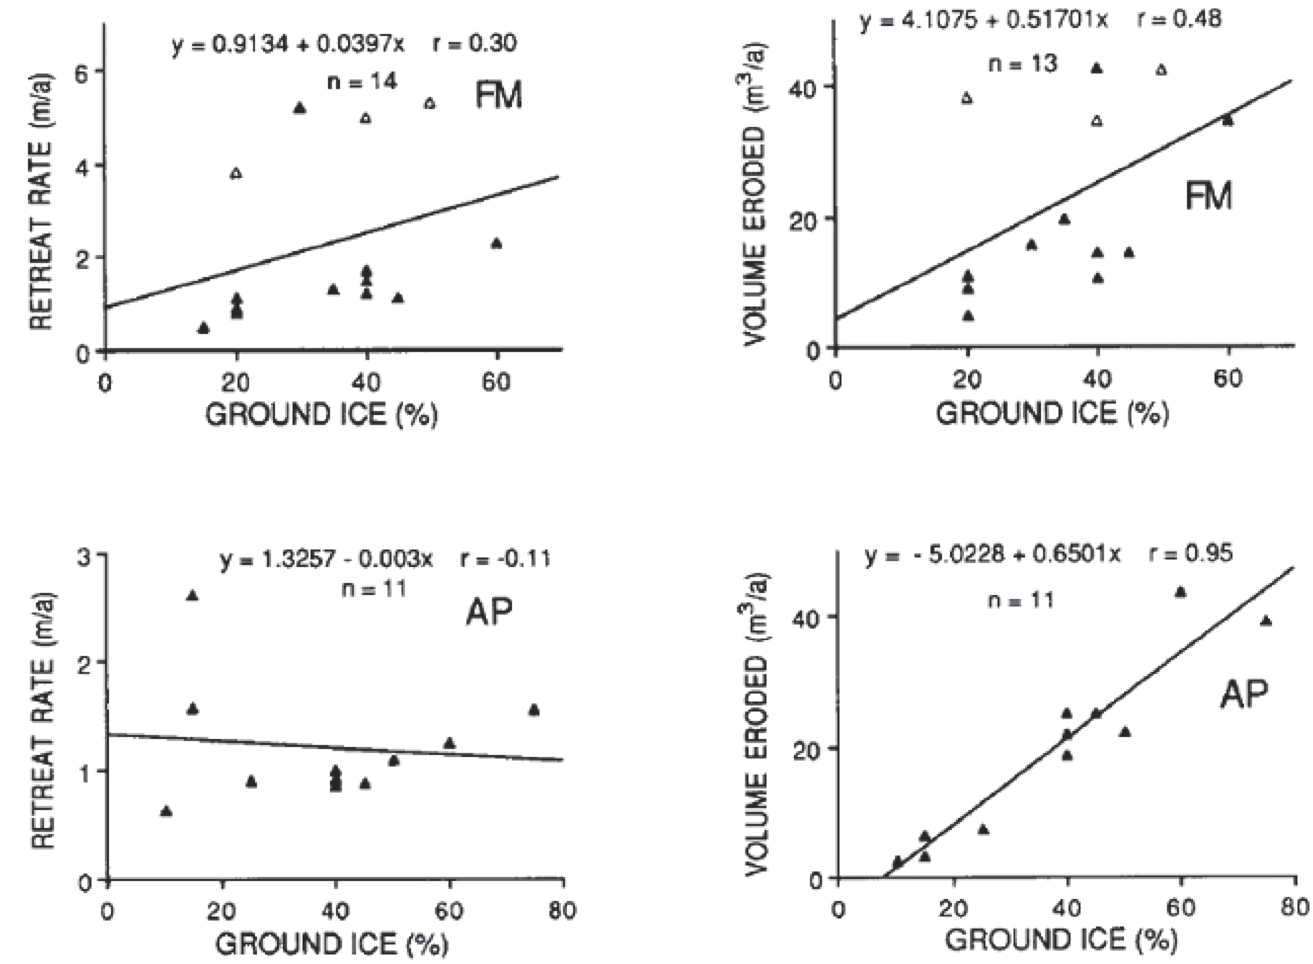

Figure 1. Coastal retreat and erosion as a function of visible ground ice in the bluffs. FM - field measurement sites; AP - aerial photograph sites; open triangles indicate minimum values of retreat rate (after Héquette & Barnes, 1990).

The ACD classification of Arctic coasts

The ACD classification was conceived as a broad enough framework to encompass existing classification schemes while capturing fundamental information for the assessment of climate change impacts and coastal processes. The implementation of the classification was done by so-called “regional experts”, who, based on digital and paper products and personal knowledge provided information which was subsequently gathered into a circum-Arctic coastal database. The classification was primarily geomorphological in nature and considered: (1) the shape or form of the subaerial part of the coastal tract, (2) the marine processes acting upon the coast, (3) the shape or the form of the subaqueous part of the coastal tract and (4) the lithofacies of the materials constituting the coastal zone

The beta version of the classification is made of 1331 segments each characterized by a series of geomorphological quantitative and qualitative variables. The classification is stored as an ISO 19115-compliant personal geodatabase and is therefore mappable in off-the-shelf Geographical Information Systems (GIS) (e.g., Fig. 2).

Methods

The first step of the processing consisted in reducing the dataset to a set of usable segments: Of the 1331 segments available in the beta version of the ACD classification of Arctic coasts, only segments for which ground ice content, coastal erosion rate, and backshore elevation (i.e. cliff height) were conjointly available were retained. The resulting dataset was reduced to 561 segments.

Subsequently, we consolidated the dataset by removing segments for which the presence of permanent sea ice cover in the summer hampered the development of erosion. The objective was to remove segments for which ground ice contents can be medium to high, yet unaffected by erosion due to sea ice presence in the summer. We used the NSIDC 1979-2000 median sea ice edge position and simply excluded segments located within the permanent sea ice zone in the dataset. We chose not to take into account the marked decreases observed in recent years in order to remain consistent with the times at which coastal erosion rates were mostly determined in the ACD classification.

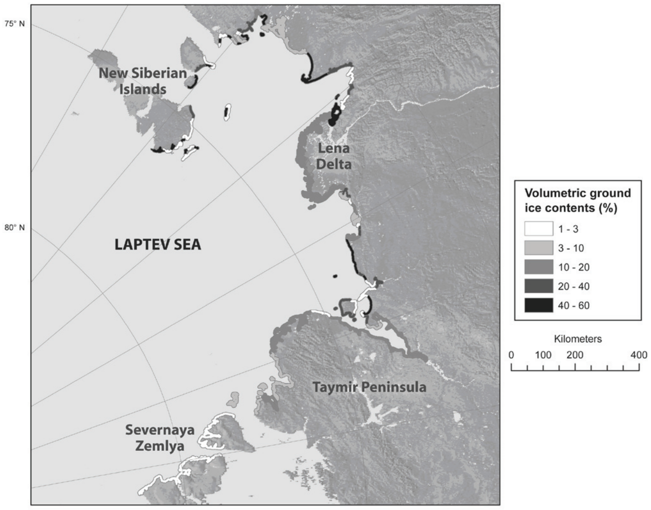

Figure 2. An example of the ACD classification capabilities: Volumetric ground ice contents of shore sediments in the Laptev Sea region (after Lantuit et al. 2008).

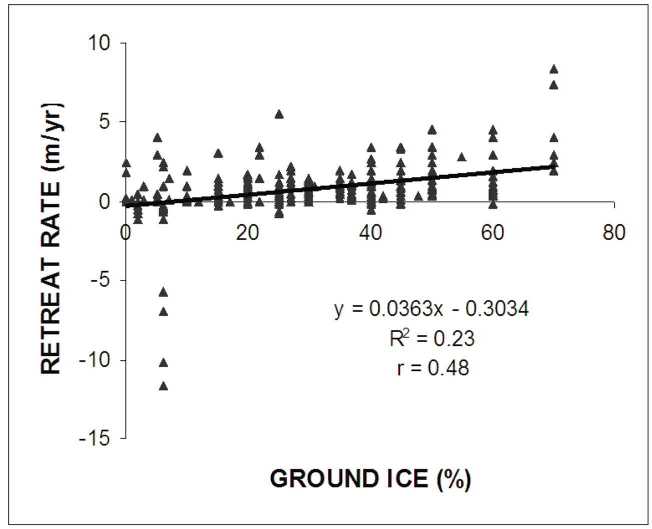

Figure 3. Retreat rate as a function of volumetric ground ice contents.

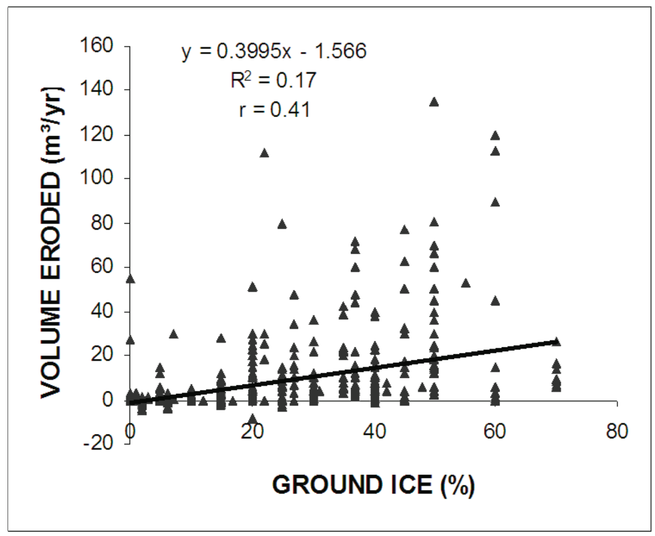

Figure 4. Volume eroded as a function of volumetric ground ice contents.

Using this criterion to consolidate the datasets we brought down the number of segments for analysis to 545. The resulting segments were remarkably ubiquitously distributed along coastal regions of the Arctic and can therefore be considered to be spatially unbiased. The Coast of the Canadian Archipelago was the only section, for which the entire coastline was not retained, due to the presence of sea ice throughout the summer season. At least 50 segments were used for each of the seven other sectors considered in the Analysis (Barents Sea, Kara Sea, Laptev Sea, East Siberian Sea, Chukchi Sea, Beaufort Sea)

We then ran two sets of analysis using retreat rates in m/yr and eroded volumes in m^3/yr (for a 1 m stretch of coastline). Eroded volumes were calculated by combining backshore elevations and retreat rates and constraining artificially the calculation to a 1 km stretch of coastline:

$$V = l \cdot h \cdot CRR \tag{1}$$

where V is the yearly eroded volume, h the backshore elevation, and CRR the annual coastal retreat rate. In our calculation, we normalized all l values to 1 km to facilitate comparison of segments

Results and Discussion

Simple regression analyses

The analysis of the retreat rates versus the percentages of visible ground-ice revealed a relatively weak relationship with a correlation coefficient r = 0.48 (R^2 = 0.23) (Fig. 3). The correlation between volumes eroded and ground ice was weaker (r = 0.41, R^2 = 0.17) (Fig. 4).

Both relations were statistically significant at α=0.01. Though weak, the correlation coefficient relating ground ice contents to retreat rates is considerably greater than the coefficients published by Héquette and Barnes (1990) (Fig. 1). In contrast, the correlation coefficient relating ground ice contents to eroded volumes is lower than the one observed by Héquette and Barnes (1990).

One can logically conclude that coastal erosion in the Arctic is not uniquely related to the presence of ground ice, but that the presence of ground ice significantly influences the process. The data available in the classification doesn't include hydrodynamic forcing and a multi-regression analysis is not currently possible. It should nevertheless be conducted in the future to better assess the statistical weight of ground ice in the thermal abrasion process.

Discussion

The lack of a correct indicator for ground ice in the nearshore zone is a strong deterrent in attempting to establish such relationships. The complex nature of ground ice, including its temperature and cryostructure, makes it difficult to correctly statistically relate ground ice to other variables using volumetric ice contents. One would gain from incorporating heat transfer and temperature properties for instance. For the lack of a better dataset, the relationship established using the ACD classification of Arctic coasts is probably the most detailed attempt at establishing such a relation.

These contradictory results between this paper and Héquette and Barnes (1990) can be explained by the multifaceted interaction of ground ice with coastal processes. Ground ice presence in the nearshore zone influences the course of erosion by modifying the shoreface profile (see above) when it thaws. It also provides the sediments at sea level with a transient strength which lasts until beach sediments are removed during storms and ice-rich sediments are exposed. Most importantly it induces the presence of large thermokarst processes in the subaerial part of the nearshore zone.

Thermokarst processes in the nearshore zone, such as retrogressive thaw slumps, are cyclic and their activity is intimately linked to the removal of sediment by storms. Following periods of large activity, the amount of sediment released by direct melting of ground ice by short-wave radiation influx above water accumulates at the foot of these landforms and progressively impedes the development of new slumps. This lasts until large storms occur and remove the sediment lobes, providing room for a new cycle of activity (Wolfe et al. 2001, Lantuit & Pollard 2008). The timescales at which these processes occur are comprised between 10^1 and 10^2 years (Lantuit & Pollard 2008) and are necessarily larger than the time spans used to calculate erosion rates or eroded volumes. Furthermore, because the cycle is strongly associated with storm activity, it is necessarily local.

This paper hypothesizes that the statistical relations extracted from the ACD classification of Arctic coasts, by their wide geographic distribution integrate this cyclic dimension better than the data from the Beaufort Sea only and should therefore be used in future applications. The two correlation coefficients obtained in this study are much closer to one another than the ones obtained by Héquette and Barnes (1990).

Conclusion

Ground ice content and retreat rates are only weakly correlated statistically, even though the relationship is statistically significant at $\alpha = 0.01$. However, due to the presence of multiple factors acting upon the coast in the Arctic realm, one cannot exclude that ground ice is a major, if not the most important, factor affecting erosion processes. Further studies will be needed to assess the role of each factor in a single integrated framework.

The relation presented in this paper should contribute to parameterization of future empirical models of coastal erosion as the most extensive effort to relate ground ice to retreat rates.

Acknowledgments

The authors wish to thank F. Steenhuisen, from the Arctic Centre, Groningen, The Netherlands and the members of the ACD group for their contribution to the beta version of the ACD classification of Arctic coasts. This paper is a contribution to the Fourth International Polar Year (IPY), 2007-2008.

The Kind and Distribution of Mid-Latitude Periglacial Features and Alpine Permafrost in Eurasia

Frank Lehmkuhl
Department of Geography, RWTH Aachen University, Templergraben 55, D-52056 Aachen, Germany

Abstract

The distribution of different periglacial landforms in various mid-latitude mountains of Eurasia is described. Alpine discontinuous and continuous permafrost is present in all these mountains, but in the humid mountains, this zone is very small due to the lower elevation of the glacier snowline (or ELA). In the more continental regions of Asia, this zone is much broader due to high elevation of the ELA. In these areas cryoplanation terraces, patterned ground, and rock glaciers occur in relative low elevations and are also widespread within the forest ecotone. On the other hand, solifluction features occur in higher regions due to arid conditions and especially the lack of soil humidity during the freeze-thaw cycles. In the Verkhoyansk Mountains further north in latitude, even in the mountain foreland and in the boreal forest of the Lean-Aldan Basin, periglacial features are widespread on continuous permafrost.

Keywords: Central Asia; European Alps; mid-latitude; periglacial features; permafrost.

Introduction

This paper presents a comprehensive review study concerning the kind and distribution of periglacial phenomena of mid-latitude mountains of Eurasia. New results are from continental Asia, in particular the mountain areas of Western Mongolia, the Russian Altai, and the Verkhoyansk Mountains (Fig. 1). The distribution of different periglacial landforms in these mountains is compared to the European and Japanese Alps. A first overview concerning mid-latitude periglacial landforms is given by Höllermann (1985); an overview for the high Asian mountains is given by Matsuoka (2003).

Periglacial Landforms in Mountain Areas

Concerning periglacial phenomena in mountain environments, especially small-scale periglacial or cryogenic landforms, are studied in the literature (e.g., Washburn 1979). Active solifluction (or gelifluction) generally occurs above the timberline as the forests stabilise and protect the ground. In general, the periglacial zone can divide into two sub-belts: First, the lower periglacial sub-belt, which includes mainly bound or turf-banked solifluction (steps, benches, terraces, lobes), and second, the upper sub-belt. The latter is characterized by unbound (or free) solifluction, blockfields, debris, stone pavements, and patterned ground (Troll 1973, Höllermann 1985). This periglacial zonation is obvious in most mid-latitude mountains above the timberline and provides information on the geoecology of high mountain environments, as the distribution of these landforms depends on several different factors (e.g., topography, geology and substrate, climate, vegetation, and soil water; see Fig. 2). Periglacial phenomena are generally controlled by cold climatic conditions, where the mean annual air temperature (MAAT) as well as the duration and depth of snow cover are low. The modern altitudinal belts of the vegetation, the soils, and the geomorphological processes are controlled by these general climatic conditions, but also by the different radiation on the northern and southern slopes (Höllermann 1985). However, new results from the European Alps show that active soil movements only occur in the upper sub-belt (Veit 2002).

Besides the different small-sized landforms of solifluction rock glaciers are typical landforms of high mountain environments. Two types are distinguished: (1) ice-cemented rock glaciers built up by unconsolidated rock or talus, and (2) morainic deposits. They are generated by the creep of mountain permafrost saturated or supersaturated with ice. Ice-cored rock glaciers consist of glacier ice mantled with a debris cover and originate from dead ice (Ishikawa et al. 2001). Rock glaciers affect unconsolidated but frozen rock fragments, creating characteristic landforms with a tongue or lobate shape and a surficial pattern of furrows and ridges that indicate the internal flow process (Barsch 1996, Fort 2002, Haeberli 2000). In addition, protalus ramparts, and talus slope or talus cone rock glaciers are described in the literature (e.g., Barsch 1996).

It is generally accepted that the distribution of rock glaciers is a good marker of discontinuous mountain permafrost (e.g., Barsch 1996). However, Fort (2002) mentioned that the identification of rock glaciers in the Himalayas is similar to other features such as rockslides and/or debris covered glaciers and, therefore, it is sometimes difficult to distinguish these landforms. Rock glaciers are described in detail especially in the European Alps and in mountain regions of North America (see reference in Barsch 1996). The knowledge of the distribution of rock glaciers in the different mountain systems on Earth is still very incomplete (Barsch 1996). Nevertheless, mountains with a continental climate, and thus the greatest differences between timberline and snowline (up to 1500 m) are more favourable for rock glaciers than those with a difference of less than 500 m (Höllermann 1985, Barsch 1996).

The upper limit of the periglacial belt results from steep high mountain topography or from the extent of perennial snow and ice in the higher altitudes (glacial belt).

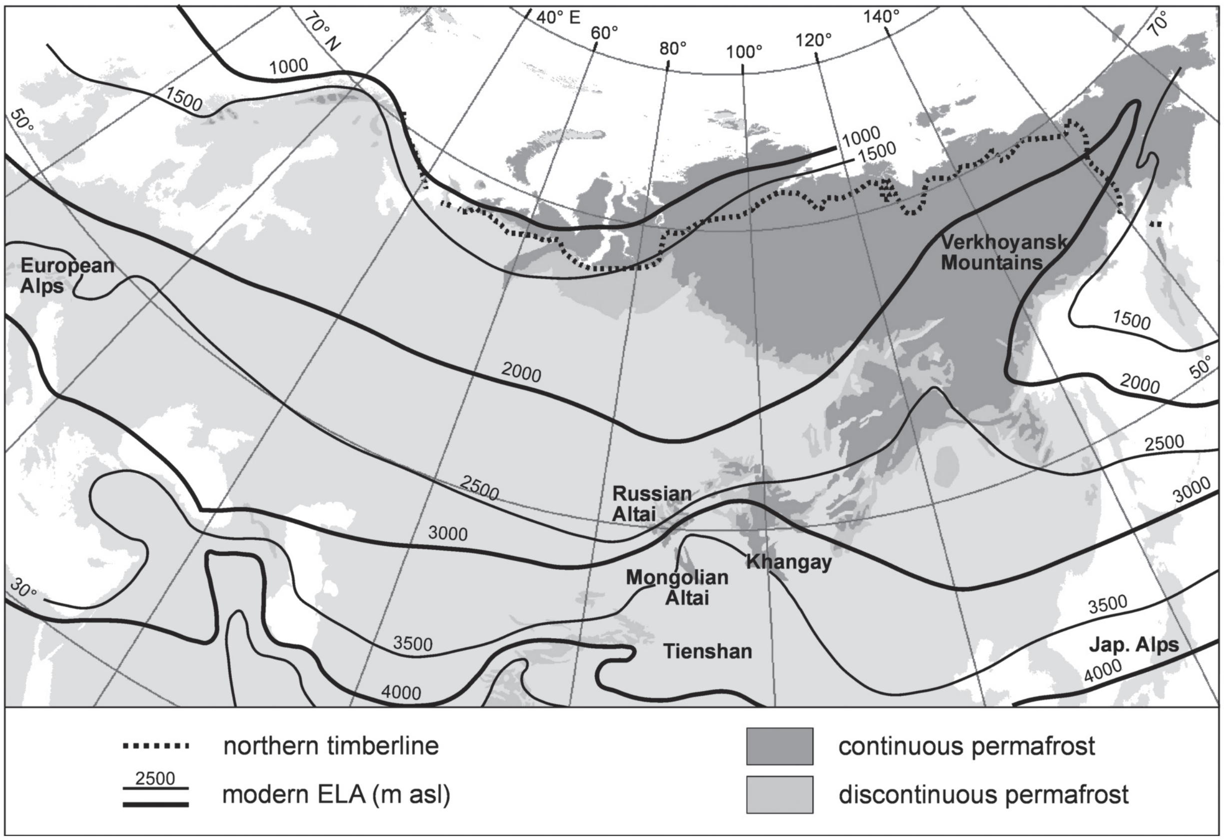

Figure 1. Map of study areas including the distribution of permafrost (modified according to Brown et al. 2001) and the modern ELA (m a.s.l., modified according to Wilhelm 1995).

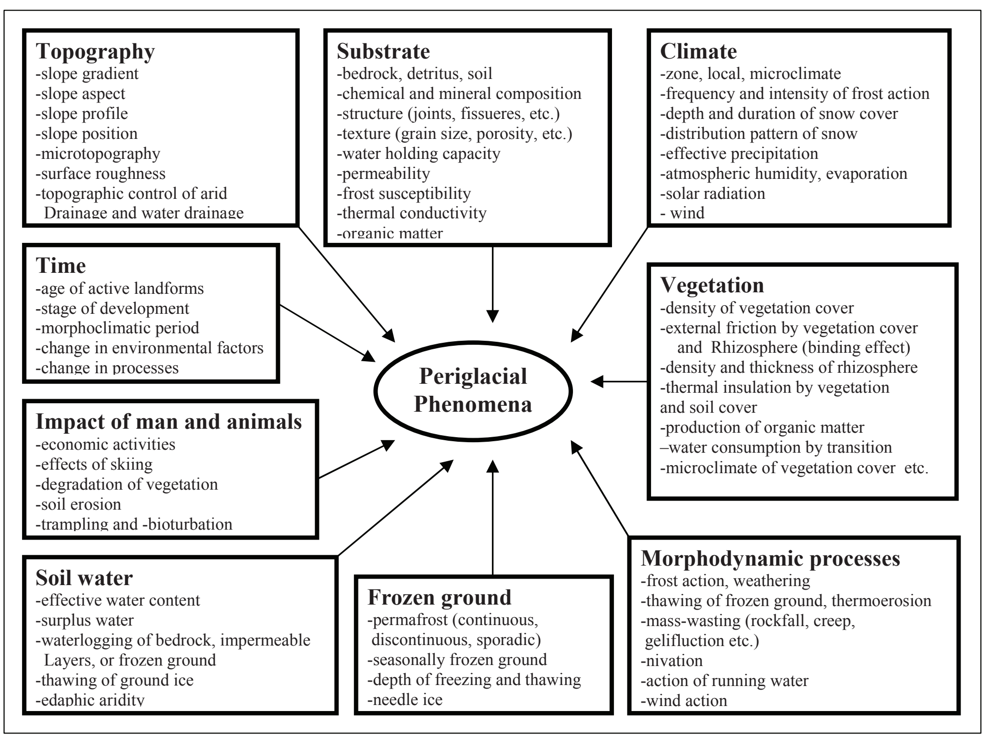

Figure 2. Main factors for the development and distribution of periglacial phenomena. Modified according to Höllermann (1985).

Results

In the following, the distribution of periglacial phenomena, such as lower limit of solifluction and rock glaciers, are described for the different mountain areas. The details for the lower limit of different periglacial and glacial features are given in Fig. 5 and Table 1.

European Alps

In the European Alps there are several studies regarding the periglacial phenomena. Veit (2002) summarized the current state of research for the European Alps. The periglacial phenomena can be divided in the humid European Alps into two sub belts: the lower limit of bound or turf-banked solifluction (occurs roughly above the timberline, Fig. 3) and the zone of unbound solifluction, dominated by blockfields, patterned ground, and bare bedrock. Active rock glaciers and other indicators of discontinuous permafrost are assumed to be generally in the upper periglacial sub-belt of the European Alps and of similar mountains. Active solifluction (or gelifluction) generally occurs above the timberline (see above). However, studies concerning the processes show that active movements occurs only in the upper part of the periglacial sub-belt (unbound solifluction); the turf-banked solifluction are fossil landforms (Jaesche 1999, Veit 2002).

Figure 3. Solifluction lobe (bound or turf-banked solifluction) in the Grossglockner region, European Alps, Elevation: 2200 m a.s.l.

Figure 4. Rock glacier in the Khangay Mountains, Mongolia. Granite bedrock on the eastern slope of the Otgon Tenger. Elevation: about 3000 m a.s.l.

In this paper the results from own field work from two mountain areas with the central part of the European Alps are described (Lehmkuhl 1989). These are the southernmost glaciated areas in the western part of the Alps (Pelvoux Mountains, France, 45°N/6°30′E) and the easternmost glaciated part of the Alps (Hohe Tauern, Austria, 47°N/13°E). Both regions are situated in the central part of the Alps, having more continental climatic conditions much more suitable for rock glaciers than the more humid margin ranges of the Alps (Barsch 1986, Höllermann 1985). The mean monthly air temperature in 2000 m a.s.l. varies between -4°C in January and +12°C in July (MAAT around 0°C). Annual precipitation ranges between 900 mm in valleys and >2000 mm in the mountains.

Rock glaciers occur in 2400 to 2500 m a.s.l., turf-banked solifluction in 2350 and 2200 m a.s.l. and unbound solifluction in 2750 and 2500 m a.s.l. (see Table 1 and Fig. 5).

Tianshan and Russian Altai

There are only a few studies regarding periglacial features in the Russian Altai. Schröder et al. (1996) and Fickert (1998) summarized in a north-south transect the distribution of periglacial phenomena. Their results concerning Tienshan (Sailijskij-Alatau, 42°N/77°E) and the results from own observations from the central part Russian Altai (Katun Ridge, 50°N/86°E) are given in Figure 5 and Table 1. The latter region is characterized by continental conditions with mainly summer precipitation and low winter temperatures resulting in the distribution of rock glaciers down to elevations of about 1600 m a.s.l. These low elevation rock glaciers occur in the forest belt indicating the high amplitude of temperatures with winter temperatures below -20°C and relative high summer precipitation. The precipitation values above 1000 mm/a are similar to those of the central European Alps. Further references see Marchenko et al. (2007).

Table 1. Elevations (m a.s.l.) of snowline (ELA), timberline and selected lower limits of rock glaciers and solifluction (for the Alps: unbound solifluction in parentheses) from selected mid-latitude mountains between 40 and 50°N.

	Western European Alps	Eastern European Alps	Tienshan	Russian Altai	Mongolian Altai	Khangay	Verkhoyansk
Modern snowline (ELA)	3000	2900	3700-3900	2900-3000	3500	>3800	2500
Timberline	2300	2050	2900 (N)	2200-2400	2600–2700 (N)	2600 (N)	1100
Late Pleistocene ELA	ca. 2100	ca. 2000	2700?	1800-2200	2900–3000	2700-2900	1200
Pleistocene ELA-depression	ca. 1200	ca. 1100	1000?	800–1200	600	1000-1200	1300
Diff. Timberline-ELA	700	750	800	700	800–900	>1200	1400
Rock glaciers	2400	2500	2900	1600	2600	3200	--
Solifluction	2350 (2750)	2200 (2500)	2600	2200	2700	2900	800

Mongolian Altai and Khangay

Due to the low winter temperatures and the small amount of snow, frost weathering occurs in the mountains of Mongolia down to the basins below 900 m a.s.l. Other periglacial phenomena, such as solifluction, palsas, and earth hummocks are related to soil moisture, and therefore occur in higher elevations or exceptional geoecological sites with a higher water supply; for example, on north-facing slopes below larch forest spots. However, the distribution of rock glaciers in the continental climate conditions of western Mongolia is determinate on low temperatures, and mainly on the occurrence of granite and metamorphic rocks (Fig. 4). The detailed observations concerning the distribution of periglacial landforms and processes are based on several joint field expeditions and studies of the processes (Lehmkuhl 1999). Detailed investigations from the Mongolian Altai and Khangay are presented, for example, by Klimek & Starkel (1980), Pekala & Repelewska-Pekalowa (1993), Lombroinchen (1998), Lehmkuhl & Klinge (2000), Klinge (2001), Lehmkuhl et al. (2003) and Sharkhuu (2003). Further references can be found therein.

Hourly measurements of the soil temperatures of different depths at distinct geoecological sites in elevations between 1775 and 2760 m a.s.l. were carried out in two measuring cycles (Lehmkuhl & Klinge 2000). The main difference in the intensity of periglacial processes in the basins and mountains areas, respectively, can be seen in the freeze-thaw cycles in springtime. In this time the precipitation in the mountains is still snowfall, and moisture can infiltrate into the soils. Due to higher temperatures the precipitation (mainly rain) in the basins evaporates and rapid drying out of the soils occurs. Therefore, the main controlling factor for the cryogenic and especially solifluction processes in the mountains is the amount of precipitation during springtime. The freeze-thaw cycles during the relatively dry autumn season are a subordinated factor for the periglacial activity. At sites with low radiation, as caused for example, through shading effects in relief, the freeze-thaw cycles displace towards the summer with more precipitation. Therefore, periglacial processes on low-radiation sites are laced to the strength of the summer precipitation. On the other hand, the frequent freeze-thaw cycles at sites with high radiation drop towards the dry winter season, and therefore, the periglacial activity is low at such sites. Accumulation of snow (e.g., in nivation hollows) and/or the occurrence of frozen ground could guarantee sufficient soil humidity apart from the distribution of precipitation during the highest freeze-thaw cycles in the spring and autumn seasons and determines cryogenic processes and periglacial forms (e.g., earth hummocks, patterned grounds). This local influence can be reinforced by effects of radiation. In the larch forests at northern slopes, a cooler local climate with reduced transpiration in the summer allows the preservation of frozen ground and/or permafrost.

The details presented for this paper (Table 1) are based on two mountains ranges: (1) the Turgen-Kharkhiraa Mountains (49°30′N/91°E) as the northernmost part of the Mongolian Altai and (2) the Angarkhoy Mountains (47°N/101°E) as the central part of the Khangay. Mean monthly air temperature varies between -20°C in January and +20°C in July. The MAAT is, for example, about -4°C in the basin of the Uvs Nuur. Annual precipitation ranges between 200 mm in the basins and up to >400 mm in the mountain ranges. Solifluction and rock glaciers occur in elevations above 2600 m. Initial observations from other parts of the Mongolian Altai and the western Russian Altai show that such landforms can be found in almost every mountain system which comprise granite or other metamorphic rocks.

Verkhoyansk Mountains

The Verkhoyansk Mountains are much further north in latitude, and the climate is extremely continental. Mean monthly air temperature varies between -40°C in January and +20°C in July. Annual precipitation ranges between 220 mm in the lowlands around Yakutsk and up to 700 mm on the western flank of the Verkhoyansk Mountains. The observations presented in this paper focused on the central part of the Verkhoyansk Mountain range (64–65°N, 126–130°E) and based on fieldwork and remote sensing analysis (Stauch 2006, Stauch et al. 2007). Permafrost features such as pingos and thermokarst depressions and lakes (alases) are widespread on continuous permafrost even in the mountain foreland and in the boreal forest of the Lean-Aldan Basin. However, solifluction, nivation, and cryoplanation terraces can be found in elevations above 800 m a.s.l. only. No rock glaciers can be found in this study area.

Japanese Alps

Studies concerning mountain permafrost in Japan are summarised in Ishikawa et al. (2003). Mountain permafrost seems to be restricted mainly to north-facing slopes above 3000 m a.s.l. and in some rock glaciers. Matsuoka (2003) presents some more details concerning other periglacial features.

The details presented for this paper (Table 1) based also on own observations and discussions during an excursion led by Y. Ono in 2001 in the central Japanese Alps. MAAT in 2600 m a.s.l. is about 0°C, mean temperature in January and July were estimated to be -11.3 and +12.6°C, respectively. Annual precipitation is rather high (no data published) and northwestly wind across the Japan Sea provides a large amount of snow on the northern and eastern ranges in winter, the Pacific part of the mountains is much drier (Ishikawa et al. 2003).

Solifluction and rock glaciers occur in elevations above 2600 m a.s.l.; there are no modern glaciers in this part of the Japanese Alps.

Conclusion

As stated above, the distribution of various periglacial landforms depends on several different factors (e.g., climate, topography, geology and substrate, vegetation, and soil water; see Fig. 2). Periglacial phenomena are generally controlled by cold climatic conditions, where the mean annual air temperature is below 0°C and the duration and depth of snow cover are low.

The distribution of the periglacial belt in Eurasia at 40 to 50°N is given in the schematic profile in Fig. 6. All altitudinal lines are drawn relatively to the timberline as base level. Alpine discontinuous and continuous permafrost is present in all these mountains, but in the humid this zone is very small due to the lower elevation of the snowline (or recent equilibrium line of glaciers = ELA). In the more continental regions of Asia, like the Altai Mountains, this zone is much broader due to high elevation of the ELA. In addition, cryoplanation terraces, patterned ground, and rock glaciers occur in relative low elevations and are also widespread within the forest ecotone (Table 1).

The Verkhoyansk Mountains are further north in latitude and much drier. In this region, even the mountain foreland and in the boreal forest, permafrost activity and pingos are widespread. However, periglacial features, especially solifluction, occur only in mountain ranges above 800 m a.s.l. There are no active rock glaciers, as the humidity is not sufficient. These results fit recent observations in 2007 in the Gobi Altai, a mountain range within the driest part

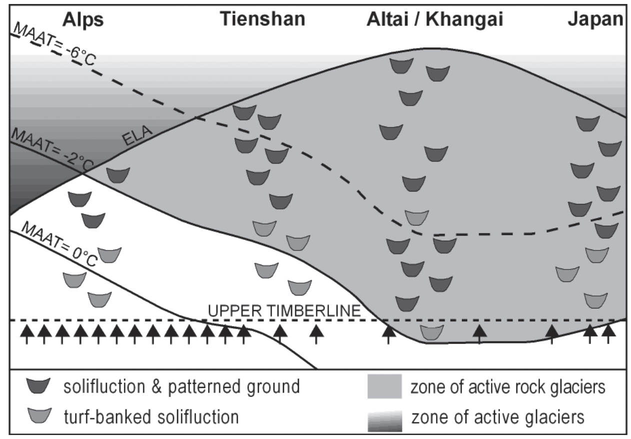

Figure 6. Schematic profile of the periglacial belt in Eurasia at 40 –50°N. All altitudinal lines are drawn relatively to the timberline as base level. Modified according to Höllermann (1985).

of Mongolia, where a few rock glaciers occur only in the highest and more humid parts of the Ikh Bogd Mountain above 3500 m a.s.l. (44°57′N, 100°18′E).

The Japanese Alps are more humid, and especially the thick winter snow cover reduced periglacial activity and permafrost distribution, including rock glaciers, toward a small zone in the highest mountain areas.

These results show that periglacial phenomena occur in the continental part of Asia even in the forest zone. Especially solifluction, but also rock glaciers, are determined through existence of soil humidity during the freeze-thaw cycles. Therefore the distribution of these features in the continental areas of Asia is smaller than in the humid European and Japanese Alps and, for example, restricted to northern slopes or higher elevations. Observations and soil temperature measurements in the Altai Mountains show that active rock glaciers and discontinuous permafrost occur in lower elevations than solifluction features. Thus, solifluction landforms in continental Asia depend more on moisture supply than rock glaciers. However, towards the arid regions of Central Asia, the lower limit of solifluction landforms, glaciers, and the lower timberline are rising in general; whereas the distribution of rock glaciers is even lower than in the humid parts of Europe and Pacific parts of Asia including Japan.

The modern ELA has the lowest position in the humid European Alps. The most significant difference between the timberline and the modern ELA occurs in the Khangay and Verkhoyansk Mountains. (Fig. 5, Table 1). The smallest amount of Pleistocene ELA-depression is in the arid regions of the Altai. However, the distribution of glaciers is related to temperature and moisture supply. The generalised contour lines of the modern ELA in Figure 1 show the influence of the humid mountains of the Altai and the dry part of eastern Siberia on the elevation of the snowline. As the northern timberline is related to summer temperatures and the humidity is even sufficient in the continual parts of Asia, this line shows a west–east latitudinal trend.

Acknowledgments

The fieldwork in Asia was funded by the Deutsche Forschungsgemeinschaft (DFG, LE 730/2-1,2; 7-1; 10-1,2). For help during fieldwork and several discussions, the author would like to thank especially Dr. O. Batkhishig, Mongolian Academy of Sciences, and Dr. N. Lachinski from the Siberian Botanical Garden, Russian Academy of Sciences, and the other Mongolian and Russian colleagues and co-workers. In addition, I would like to thank G. Stauch (Aachen) for discussions.

Abstract

Observations on Yugorsky Peninsula since 1998 cover periods with changing climatic controls of coastal processes. Coastal dynamics are connected to the activation of thermal denudation, the most widespread process in the area with tabular ground ice enclosed in geological sequences. Thermodenudation comprises cryogenic landslides, slumps, and earth flows resulting from tabular ground ice thaw. Thermoabrasion is a less common mechanism of coastal retreat in the study area. The dominating mechanism allows subdivision of coasts into thermodenudation, thermoabrasion, and mixed types. Coast types are time-dependent, and alternation of types depends on climate fluctuations. For the bluffs with tabular ground ice exposures, the increase of sediment yield onto the beach is determined on the one hand, by a relative amount of tabular ice in a section, and on the other, by increase in the thaw index. Activation of thermoabrasion depends on sea ice coverage along with wind speed and direction. Activation of thermoerosion results from heavy winter precipitation followed by a bursting spring.

Keywords: climatic controls; coastal dynamics; earth flows; thermoabrasion; thermodenudation; thermoerosion.

Introduction

Observations on Yugorsky Peninsula since 1998 cover the basic climatic controls of various coastal processes in the study area (Kizyakov et al. 2006): periods with changing summer temperature, ice coverage of the Kara Sea, amount of summer and winter precipitation, wind speed and direction, and wave action.

Coastal dynamics result from the activation of thermal denudation, the most widespread process in the area with tabular ground ice enclosed in geological sequences. The importance of the massive (tabular) ground ice occurrence as a major factor in coastal retreat is recognized in the literature (Lantuit & Pollard 2003, Solomon 2003, Lantuit et al. 2005, Kizyakov et al. 2006). Thermal denudation comprises cryogenic landslide/slump/earth flow processes, resulting from tabular ground ice thaw and removal of meltwater and waste material onto the beach and into the sea by gravitation (Leibman & Kizyakov 2007). Depending on climate fluctuations, coastal dynamics result from alternating or coinciding cryogenic landslide/slump/earth flow, thermoabrasion, and thermoerosion mechanisms. According to the dominating mechanism, coasts are subdivided into thermodenudation, thermoabrasion and mixed types (Sovershaev 1992, Kizyakov et al. 2003). Coasts are affected by nivation, earth falls, and aeolian processes as well, though they play subordinate roles.

Thermodenudation assumes special features in the tabular ground ice areas. These features are the formation of specific thermodenudation landforms such as thermocirques and thermoterraces, resulting from the tabular ground ice thaw and slope mass waste. The rate of coastal retreat at the backwalls of these forms is much higher than the coastal retreat rate at the adjacent portions of the coastal bluffs (Kizyakov et al. 2006).

This paper deals with coastal dynamics at the Yugorsky Peninsula coast. Field observations and monitoring reveal the main mechanisms which determine coastal types and destruction rates.

Study Area, Terms, and Methods

The study area, Yugorsky Peninsula at the southern coast of the Kara Sea (Fig. 1), is located on the Pai-Khoi Mountain range piedmont, a relief of rolling hills being affected by thermokarst and various slope and coastal processes. According to the records of the Amderma weather station, mean annual (summer) temperature for the period of observation ranged from -5.8 to -7.7°C (5.0–6.7°C); summer wind speed may exceed 20 m/sec, mainly in a southwestern direction; and the perennial average of annual/summer precipitation is rather low: 314/148 mm.

The area is characterized by continuous permafrost

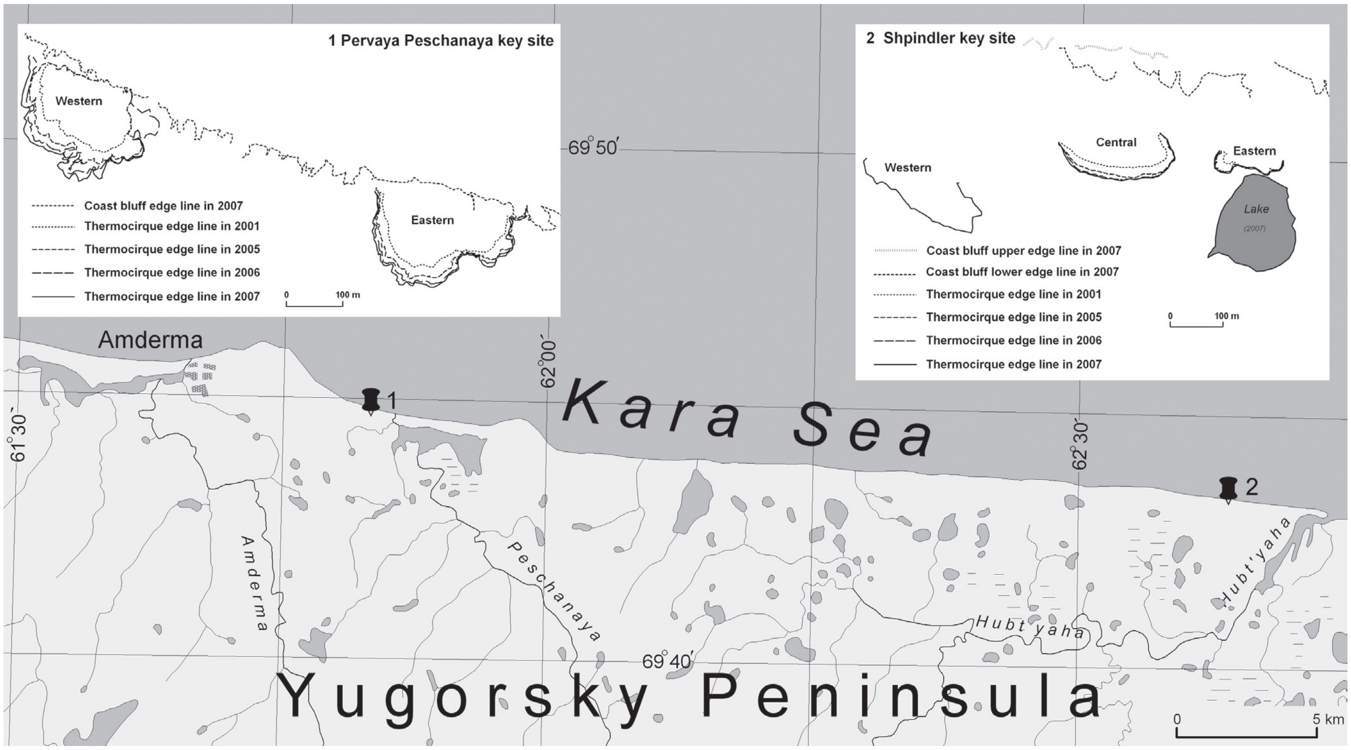

Figure 1. Yugorsky Peninsula. Pervaya Peschanaya (1, left inset map), and Shpindler (2, right inset map) key sites. Thermocirque configuration as well as annual coastlines are shown on inset maps.

distribution with ground temperature as low as -5°C, up to 400 m thickness, with an active-layer depth maximum exceeding 1.5 m, with average around 1 m, and widespread tabular ground ice in layers of 3–12 m thick enclosed in sandy-clayey deposits of glacial (?), marine, fluvial, Aeolian, and slope-wash genesis (Manley et al. 2001, Leibman et al. 2003). Two key sites are under study: Shpindler site is located west of the Hubt'Yakha River at the easternmost end of the coastal zone under study. The westernmost end is Pervaya Peschanaya site, west of the Pervaya Peschanaya River. At both key sites several thermocirques are mapped, four of which are monitored: the western and eastern thermocirques of Pervaya Peschanaya site, and the eastern and central thermocirques of Shpindler site (Fig. 1, inset maps). The coastal zone between these two key sites was described and the thermocirque/bluff edge position measured during a foot and boat trip along the coast.

The methods applied were as follows: A network of transects perpendicular to the edge of most actively retreating thermocirques and flat coastal bluffs was established. Repeated accurate tacheometric surveys were used to create a digital model of thermocirque relief at several time slices so that coastal dynamics were characterized not only in one dimension as a shoreline retreat, but also in two and three dimensions, as area and volume losses. The area loss allows better determination of the average retreat for an edge of complicated configuration, while volumetric loss allows calculation of the volume of material transported onto the beach during the period between two survey dates (Kizyakov et al. 2006).

Retreat measurements were performed in July and August. To better understand climate controls, retreat rates and thaw index were calculated for the entire period between measurements and thus include the warm period of the preceding and following year, not of a calendar warm period.

A tacheometric survey was implemented in 2001, 2003, 2005, and 2006. In the intermediate years, a GPS survey was used to measure the shoreline position and to extend transects farther inland after stakes closer to the edge were lost through the retreat. GPS is of less accuracy compared to tacheometry, but it is still within 1 m, due to repeated measurements in a closed loop.

In Russian literature, different terms are used for coastal and lateral thermoerosion, which make coastal mechanisms easier to understand; in this paper we will use the term *thermoabrasion* for coastal thermoerosion which is the formation of wave-cut niches followed by earth falls resulting in coastal bluff retreat. The term *thermoerosion* will be used to indicate only lateral thermoerosion (linear or ravine thermoerosion produced by running water/mud flows).

A substantial portion of the coast is represented by thermocirques and thermoterraces. Mechanisms of their formation are revealed by A. Kizyakov as depending on the localization of the initial thaw. Thermocirques are formed when the tabular ground ice body gets exposed by thermodenudation inland, and waste material is transported to the shore by local streams. While thermoterraces are formed by ice exposures directly on the bluff planes facing the sea; retrogressive thaw slumps and earth flows deliver waste material directly onto the beach (Fig. 2).

Thermodenudation landforms at the coasts are step-

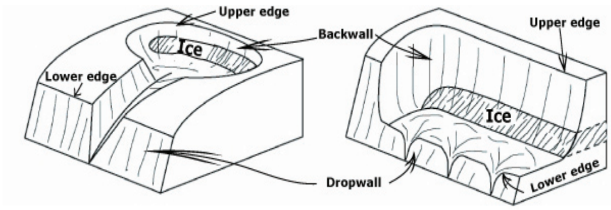

Figure 2. Thermocirque (left) and thermoterrace (right) landforms.

shaped with two retreating planes and respective edges: a thermocirque/thermoterrace backwall (retreating "upper" edge) and a dropwall to the beach (retreating "lower" edge) (Fig. 2).

Results

Table 1 shows the retreat rate in relation to air temperature fluctuations. As instrumental measurements of coastal retreat were performed in mid-summer, long before the coastal processes "winter sleep," we applied a special procedure to make interannual data comparable: thaw index is calculated as a sum of positive temperatures of the preceding year, starting immediately after the date of measurement, plus a sum of positive temperatures of the next year up to the date of measurement. If a period between measurements was more than a year, both total sum and annual average are calculated. The length of the period with positive temperatures is highly variable and depends, along with climate fluctuations, on field logistics. For this reason, we are using a diurnal "thaw index" as a measure of air temperature impact on retreat rate.

Calculations indicate that maximum retreat rate depends directly on degree-days. Each period of measurements is characterized by about 0.8–0.9 cm of retreat per one degree-day of summer temperature.

According to our observations, in 1998–2005, the lower edge retreat was minimal. A boat trip along the coastline did not show any niches or failures, except for several thermocirques. This was most likely related to rather high sea ice coverage till late summer in 1998–1999, and moderate wind speed in 1998–2005. A summer 2003 trip indicated an increase in the number and size of thermocirques and thermoterraces, mainly due to a warm summer (Kizyakov et al. 2003, 2004). But climatic events of spring–summer 2006 changed the rate of the process, especially in the dropwall along the entire 43 km of shoreline observed. That year was marked by extreme wind speed with direction toward the coast, with northern winds prevailing in frequency and speed (Leibman et al. 2006).

In 2007, winter was snowier and spring was cooler than usual. Snow patches covered a significant portion of coastal bluffs preventing wave action. At the same time, snow patches provided active thermoerosion by meltwater. This was made possible by a bursting spring with June–July diurnal temperature some days as high as 24°C. That high temperature stayed only for a few days; the rest of the days the air temperature was below 10°C, thus most snow patches were preserved, but meltwater was abundant. Thermoerosion activated retrogressive thaw slumps and earth flows with mud streams running over snow patches directly onto the beach. Thus processes of coastal destruction proceeded by the alternation of thermodenudation in 2000–2005, thermoabrasion in 2006, and joint thermoerosion and thermodenudation in 2007.

Table 2 presents the average annual retreat at all 4 key thermocirques for various periods of measurement.

Analysis of Table 2 indicates that the maximum annual retreat rate of the backwall was observed in 2005–2006 when the thaw index was maximum. Thermocirques at Pervaya Peschanaya site show a higher retreat rate compared to Shpindler site. Though the thaw index reduces in 2006–2007, retreat at Pervaya Peschanaya site is rather essential (almost 4 m average). Extremes of 2005–2006 were not only due to the high summer temperature (see Table 1, thaw index per day), but also because of strong wave uprush (Leibman et al. 2006). The lower edge started retreating fast, niches were formed, earth falls occurred, and ice exposures appeared at formerly stable slopes (Fig. 3).

Table 1. Shpindler monitoring key site, Yugorsky Peninsula, Russia. Central thermocirque backwall retreat in relation to thaw index.

Period	Average* backwall retreat, m	Days between measurement	Warm period**	Thaw index total/ diurnal degree-days
16.09.2001 10.08.2002	1.6	328	77	398.4/5.2
11.08.2002 22.08.2003	4.2	377	122	755.2/6.2
23.08.2003 05.08.2005	7.65 (3.83)	714	252	1401.9/5.6
06.08.2005 28.07.2006	3.74	358	120	839.3/7
29.07.2006 15.07.2007	1.25	353	93	502.4/5.4

*Calculated as average from retreat measured along the fixed transects, in parentheses annual value if period exceeds 1 year.
**Calculated for the period between measurements including preceding and following year's warm period.

Table 2. Retreat rate of the thermocirque's upper edge at key sites "Shpindler" and "Pervaya Peschanaya," Yugorsky Peninsula in 2001–2007.

Thermocirque	Average linear retreat, m*		
	2001–2005/annual		2006–2007
Shpindler, Central	14/3.5	4	1.25
Shpindler, Eastern	4/1	1	0.48
Pervaya Peschanaya, Eastern	14/3.5	5	3.00
Pervaya Peschanaya, Western	18/4.5	10	3.83

*Calculated as retreat area divided by a bluff edge length in 2001

Figure 4. Snow patches in 2007 protect coastal bluffs from thermoabrasion at Yugorsky Peninsula, Kara Sea coast.

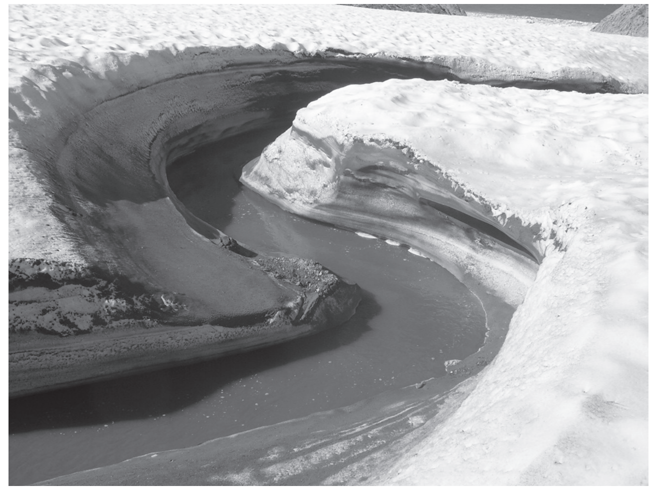

Figure 5. Snow patches filling coastal thermocirque bottoms in 2007 cut through by the meltwater streams bearing and transporting sediment load towards the beach at Yugorsky Peninsula, Kara Sea coast.

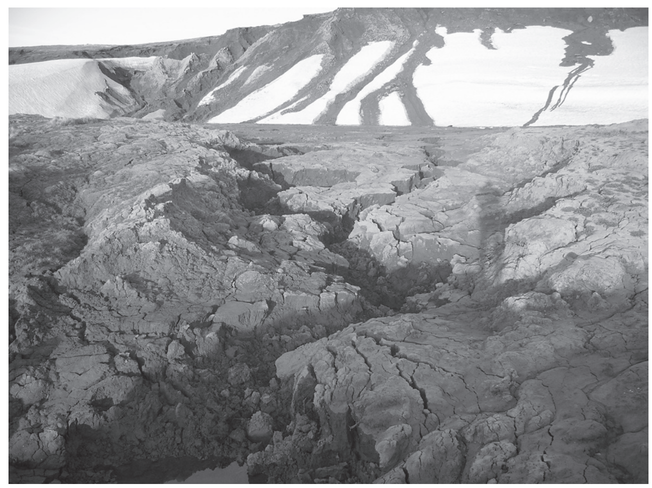

Figure 6. Snow patches in 2007 provide domination of mudflows and thermoerosion in destruction of coastal bluffs at Yugorsky Peninsula, Kara Sea coast.

Summer of 2007 was very different compared to 2001–2006. Snow patches covered most of the coastal bluffs (about 50% of the shoreline) protecting them from thermoabrasion (Fig. 4).

The high retreat rate at Pervaya Peschanaya in summer 2006–2007 is explained by both extreme wave action of fall 2006 and the increased effect of thermoerosion through the meltwater from snow patches in spring 2007 (Fig. 5). Also, nivation promotes retrogressive thaw slump/earth flow activity. Earth flows cut the surface of snow patches (Fig. 6) or run over the snow surface onto the beach. Thus, in 2007 landslides/slumps/earth flows and thermoerosion canals, promoted by snowmelt and nivation, dominate in coastal destruction mechanisms. Calculations show that a 2-week snowmelt period due to thermoerosion, transports as much sediment downslope as earth flow/slump activity during the entire warm period of any previous year.

While thermoerosion provides more intensive sediment transport compared to earth flows and retrogressive thaw slumps, thermoabrasion is quite a sparse and sporadic process at Yugorsky coast, though with an extensive mass waste due to earth falls (Fig. 7).

The rates of coastal retreat for thermocirque edges may be 2–5 times higher than thermoabrasion retreat rates. Sediment transport through a narrow (10–30 m) exit from thermocirque onto a beach is equal to the sediment yield from 500–1000 m portion of a flat-bluff coast (Kizyakov et al. 2006).

Discussion

Observations in the key area with tabular ground ice occurrence show results close to those obtained in the Canadian Arctic by Lantuit & Pollard (2003), Lantuit et al. (2005), and Solomon (2003): tabular ground ice through thermodenudation (retrogressive thaw slumps) essentially increases the rate of coastal retreat, not only in the area of their direct occurrence, as in our study, but in the nearest vicinity (Lantuit & Pollard 2003).

The long-term retreat rate calculated from analysis of remote-sensing data at the Yugorsky coast (Kizyakov et al.

2006) was close to that obtained for various arctic areas and is around 1 m/yr for the period 1948–2001. Rather similar areas of the Canadian Arctic, as mentioned above, show a retreat rate of 1.03 m/yr in 1970–2000 (Lantuit et al. 2005). Though records averaged for a long period (53 years for Yugorsky Peninsula after Kizyakov et al. 2006, and 30 years after Lantuit et al. 2005) show a relatively low retreat rate, annual data at the coasts with tabular ground ice and respective retrogressive thaw slumps (thermal denudation in Russian terminology) display much higher rates. The highest rates are not directly connected to immediate climate warming. Lewkowizc (1987) reported retreat rates for slumpy slopes on Banks Island at 8.6–11.4 m/yr in average with a maximum 15.5 m/yr in 1983–1984. Lantuit & Pollard (2003) noted that the retreat rate was much higher in 2000–2001 (average 7.6 m) and even higher in 2001–2004 (9.6 m/yr).

These data correlate with our observations of increased retreat rates in the 2000s (up to 10 m/yr average, Table 2), exceeding a 55-year average by an order of magnitude. An order of magnitude difference between perennial average retreat rate and seasonal rates at the years of process activation shows that coastal retreat is of a cyclic character, and after several years of thermodenudation activity (12–15 years as in Lewkowicz 1987), a period of recession follows, compensating high rates of coastal destruction on the long-term scale.

High retreat rates result from tabular ground ice representing an essential part of the geological section. At Yugorsky Peninsula this part may be as high as 30–35% of the section as at the Central thermocirque of Shpindler site (Leibman et al. 2003).

As retreat rates appear to depend essentially on the tabular ground ice amount, it is critical to subdivide coastal types based on the existing exposures. At the coast under study, there are one or two ice layers depending on the marine terrace origin, age, and height. At the high terraces (35 to 45 m above sea level) two ice layers are exposed, the upper being 8–12 m thick at depths 15–25 m from the hilltop surface.

The lower ice layer dips westward, with the lower limit from 5–10 m above sea level at the Shpindler key site, and to below sea level at the Pervaya Peschanaya key site. The lower ice layer is found at practically all the terraces, both low and high ones. Flat coastal bluffs separating areas with tabular ground ice exposures may contain ground ice as well, only well insulated by thick scree deposits separating the ice surface from seasonal thaw even in warm years. But of course it should be taken into consideration that these areas are potential resources for activation of coastal destruction in a case of considerable climate warming. One more way to trigger the ice thaw is active thermoabrasion at the now stable flat bluffs.

A two-layer ice distribution pattern produces a specific shape of the coastal profile. The sea-facing macro-slope may consist of several steps with hanging thermocirque/thermoterrace bottoms formed by the thawed upper ice layer, and lower steps based on the toe of the lower ice layer. Only in the case of ice occurrence below sea level, as at Pervaya Peschanaya key site no steps are formed, but rather a thermokarst depression (Leibman et al. 2003, Leibman & Kizyakov 2007).

Figure 7. Intensive mass waste due to thermoabrasion (frozen-block falls) at Yugorsky Peninsula, Kara Sea coast.

Upper thermocirque/thermoterrace edges are located at a distance (several dozen to several hundred meters away) from the shoreline, they are not interacting with the sea. Even low terraces with thermocirques formed due to lower ice layer thaw are not affected by wave action and develop only due to air temperature and precipitation.

An overview of the flat coastal bluffs, thermocirques/thermoterraces, and thermoabrasion coasts during 7 years at the key sites, as well as observations during a long-shore trip showed the following: There were 2 periods of active coastal destruction. The summers of 2000 and 2001 were noted for re-activation of thermodenudation and exposure of tabular ground ice at the eastern (2000) and western (2001) thermocirques of Pervaya Peschanaya key site.

The summer of 2006 changed the whole coastal type structure. Most of the stable dry slopes, as well as dropwalls of thermodenudation slopes, turned into thermoabrasion coastal types with niches, frozen block falls, and cracks at the bluff edges, which prepared continuous failures for the remaining summer months of 2006. In 2007 about 50% of the coasts turned into the thermodenudation-thermoerosion type, thermoabrasion being almost entirely suppressed because wave action was prevented by abundant sea ice and snow patches armoring the dropwalls.

Thus, a combination of coasts of various types at any given time slice constitute the Yugorsky coasts. Coasts are represented by flat to convex bluffs, retreating parallel to themselves due to slow gravitation processes (scree and slopewash) or thermoabrasion (formation of niches followed by earth falls), combined with stepped, concave coasts with thermocirques/thermoterraces and ravines developing due to thermodenudation and thermoerosion. Material transported to the beach is evacuated, depending on the wave activity, in a few days under a strong wind and open sea conditions, to a few weeks if none of the above occur.

After a year of active thermoabrasion in 2006, the lower tabular ice layer was exposed, and this started thermodenudation at the dropwall, which continued in 2007 beneath the snow patches when the melt season started.

The basic conditions for proceeding activation are: (1) presence of rather thick ice layers; and (2) removal of the material delivered from the bluff onto the beach. For the bluffs with tabular ground exposures, the increase of material yield to the beach is determined on the one hand, by a relative amount of tabular ice in a section, and on the other hand, by an increase in summer air temperature, surface-thaw rate, summer atmospheric precipitation, speed and sediment load of eroding flows, and accordingly, amount of sediment and distance of its transportation.

The dual role belongs to winter precipitation. Plentiful snow preserves slopes from thaw. However, the snow contributes to thermodenudation through the nivation process, and provides excessive meltwater flow, increasing sediment yield to the bluff toe, at the same time speeding up the sediment removal from the beach.

Air temperature acts dually as well. High summer temperature prolongs the ice-free period, and along with the intensive wind enhances wave action, promoting both thermoabrasion and removal of sediment. If the summer temperature rise is not accompanied by significant atmospheric precipitation, then sediment yield and removal are slowed down by landslide bodies in the transition zone.

The activity of cryogenic processes unequivocally amplifies only at increase of the thickness and proportion of tabular ground ice.

Conclusions

A coastal dynamics study at the Yugorsky Peninsula coast (Kara Sea) was performed in 2001–2007. Tabular ground ice in the geological sections is responsible for the essential role of thermodenudation in the coastal destruction. Two commonly subdivided types of coasts: thermoerosion and thermodenudation cannot be applied in a study devoted to time-related patterns. Any portion of the coastline in a short-term dynamic under the climate fluctuations cannot only be transformed from stable into actively retreating, but also into a different type or into a mixed type existing within one time slice. Years with a wave uprush increase the proportion of coastal bluffs with the thermoabrasion mechanism dominating. Mixed type occurs when the "upper" edge is retreating according to thermodenudation pattern, while the "lower" edge is destructed by thermoabrasion.

From climatic controls, the main forcing factor for the rate of coastal retreat is summer air temperature (thaw index). The dominating mechanism for the time-dependent coastal destruction (dynamic type of coasts) is determined by different climatic parameters such as wave uprush caused by low sea ice coverage and strong landward winds, intensive winter precipitation resulting in numerous snow patches, which in the conditions of a bursting spring cause domination of thermoerosion and earth flows.

Gully-Polygon Interactions and Stratigraphy on Earth and Mars: Comparison of Cold-Desert, Near-Surface, Fluvial, and Periglacial Processes

Abstract

We examine the distribution and structure of composite-wedge polygons in the South Fork region of Wright Valley, Antarctica, in order to document the manner in which patterned ground contributes to the flow of water in cold desert gully systems. These gully-polygon systems are comparable to terrains observed in high-resolution images of the martian surface. We find that thermal contraction crack polygons contribute to the generation, transport, and storage of water in the Wright Valley gully systems. Further, we evaluate the formation sequence of gully-polygon systems. Similar relationships between gully alcoves, channels, and fans, and patterned ground on Mars suggest that many martian gullies formed on patterned surfaces, cross-cutting a continuous permafrost layer. Therefore, these gullies may result from the melting of atmospherically derived ice under appropriate microclimate conditions.

Keywords: Antarctica; Dry Valleys; gullies; Mars; microclimates; polygons.

Introduction

Gullies on Mars are a class of young features, initially interpreted to have formed by the surficial flow of rapidly released groundwater (Malin & Edgett 2000, 2001), and which may still be active (Malin et al. 2006). Although numerous alternative formation mechanisms have been proposed, however, many workers conclude that an aqueous phase is involved in gully erosion, making gullies features of great astrobiological interest (Malin et al. 2001, SR-SAG 2006). Recent terrestrial analog fieldwork in the Antarctic Dry Valleys (ADV) of Southern Victoria Land, Antarctica, has reported on the primacy of top-down melting of snow as a source for water flowing through the active layer and hyporheic zone of terrestrial gullies (Dickson et al. 2007, Head et al. 2007a, Levy et al. 2007, Morgan et al. 2007).

Although the role of ice wedge polygons in the development of Arctic fluvial systems has been addressed (e.g., Lachenbruch 1962, Fortier et al. 2007), the effects of patterned ground on cold desert fluvial systems have not been broadly discussed, despite the observation of gullies in periglacial terrains on Earth and Mars (e.g., Bridges & Lackner 2006, Levy et al. 2008). Physical models constraining the deposition and behavior of ice-rich soils under present Mars surface conditions suggest that ice deposition and melting can occur on pole-facing slopes at high latitudes under suitable microclimate conditions (Hecht 2002) and that ice-rich soils can undergo thermal contraction cracking, generating patterned ground (Mellon 1997). We present the results of ADV gully-polygon interaction studies, outlining the use of polygons as for determining the stratigraphic sequence of gullied landscape evolution. This analysis provides a baseline for interpreting relationships between gullies and polygons observed in 70 HiRISE images of the martian surface. Analysis indicates that thermal contraction crack polygons play a similar role in the accumulation and transport of gully materials on both Earth and Mars, and that some gullies form or evolve in the continuous presence of actively expanding thermal contraction crack polygons.

ADV Analog Studies

The South Fork of Wright Valley, Antarctica is located at 77°33′36″S, 161°17′24″E in the Intermediate Mixed Zone of the ADV (Marchant & Head 2007) (Figure 1). Gullies, composed of a broad alcove, a sinuous channel, and a distal fan (e.g., Malin & Edgett 2000) are common on the southern wall of the valley (elevation spanning: ~300–1000 m) (Levy et al. 2007). Continuous permafrost is present in the South Fork region beneath a dry active layer 20–45 cm deep (McGinnis & Jensen 1971). Composite-wedge polygons are common on the unconsolidated colluvium surfaces of Wright Valley and show a wide variety of sub-forms. Climatically, the South Fork study area is a cold, hyper-arid desert, with mean annual temperatures of -20°C (Ragotzkie & Likens 1964).

Gully-polygon processes

Monitoring of polygonally patterned ground covering all components of the South Fork gully systems (alcoves, channels, and fans), suggests that polygons modulate the accumulation, transport, and storage of meltwater in the Antarctic gully systems.

Previous work has shown that windblown snow accumulated in gully channels and alcoves is the primary source of meltwater for ADV gullies (Dickson et al. 2007,

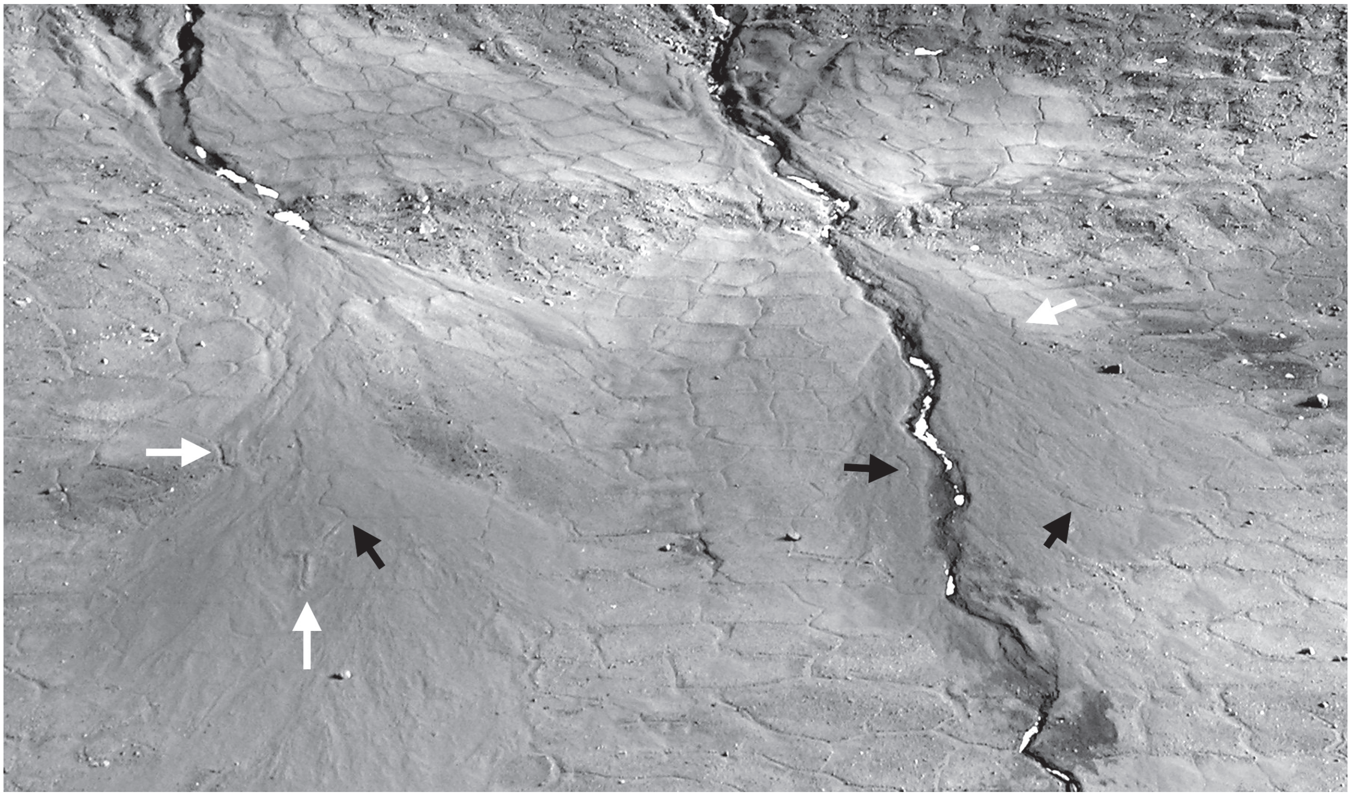

Figure 1. Gullies in the South Fork region of Wright Valley, ADV. Polygons are ~16 m wide. White arrows indicate embayment of patterned surfaces by fan deposits; black arrows indicate dissection of fans by thermal contraction crack polygons.

Levy et al. 2007, Morgan et al 2007, Head et al. 2007a). Windblown snow also accumulates in polygon troughs (~5–30 cm deep) in the South Fork study site, and ablates by melting and sublimation over the course of the austral summer (Levy et al. 2008). Polygon troughs intersecting a gully channel were measured, and the maximum volume of trapped snow was calculated to be comparable to or exceed the volume of windblown snowbanks calculated to be stored in the gully channel (~135 m^3). Where polygon trough snowbank melt-water can be transported into the channel, it becomes available to augment gully flow.

Water transport within South Fork gullies is enhanced by changes to ice-cement-table topography produced by polygon trough evolution. In some sediment excavations, liquid water is observed to flow along the base of the ice-cement table, through the active layer overlying depressed polygon troughs (the surficially depressed region above the polygon wedge). The ice-cement table depth and gradient are locally steepened by the development of polygon troughs, resulting in the concentration of meltwater derived from the melting and infiltration of overlying snow banks (Levy et al. 2008). Where water sources are large enough to initiate overland, channelized flow (i.e., gully channels), polygons directly contribute to gully water transport. At locations where gully channels intersect down-slope-oriented polygon troughs, the troughs are "annexed," as surface flow is transferred into the polygon troughs (Fig. 1). Annexed polygon troughs are generally wider, and more sinuous than adjacent non-annexed polygon troughs.

Water storage in the South Fork gullies is influenced by the presence of polygons in the distal hyporheic zone (Levy et al. 2007, 2008). Colluvium darkening in the distal hyporheic zone results from darkening of clay and silt-rich polygon interiors due to enhanced water content (~5% water by mass) (Levy et al. 2008). In contrast, pebble-rich polygon-wedge materials are bright and considerably drier (0.3–0.5% water by mass) than average colluvium surfaces in the South Fork study area (1.1–1.3% water by mass) (Levy et al. 2008). The concentration of wet, fine-grained colluvium in distal hyporheic zone polygon interiors and coarse, dry colluvium in distal hyporheic zone polygon troughs suggests that localized freeze-thaw processing is sorting grains within gully-terminal composite-wedge polygons, modulating spatial water distribution within the distal hyporheic zone.

Gully-polygon stratigraphic relationships

Relationships between polygon troughs and gully channels in Wright Valley indicate cross-cutting of pre-existing polygons by the gully channel. Polygon troughs intersect gully channels at oblique and near-orthogonal angles, and polygon wedge material is exposed on both sides of the gully channel. Some polygons are cut twice by the same gully channel (on up-slope and down-slope margins). Further, annexed polygon troughs could only develop if polygons preceded the presence of the gully channel. Taken together, these observations suggest that South Fork region gully channels were incised into previously extant polygons.

Contacts between gully fan surfaces and inter-gully,

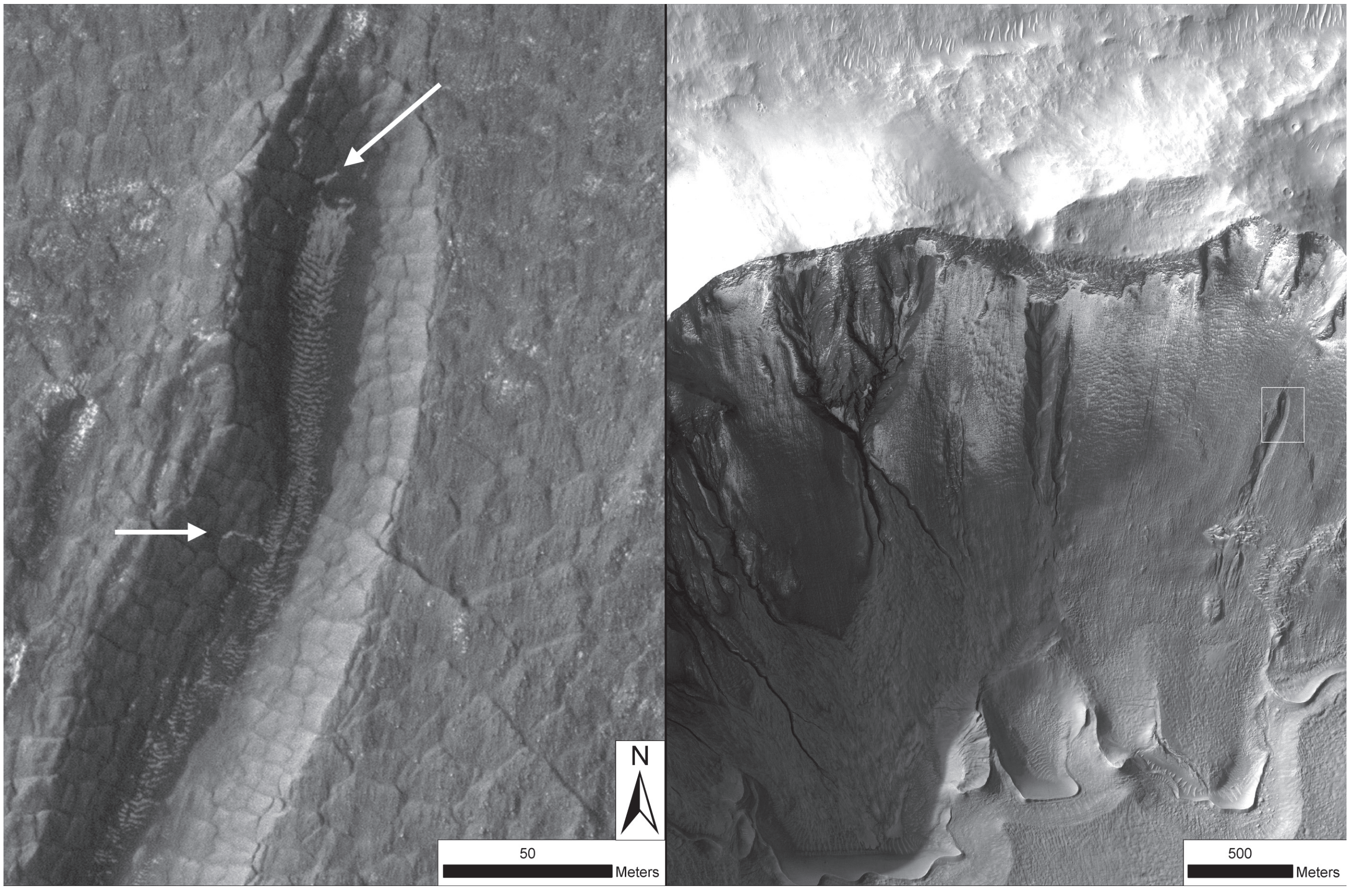

Figure 2. Left: Gully alcove surface with patterned ground. Arrows indicate frost preferentially present in polygon troughs during southern hemisphere winter. Right: Crater interior with gully-polygon suite. Area shown at left is boxed. Both images are from PSP_001882_1410. Illumination from left.

polygonally-patterned colluvium deposits can be used to trace the formation sequence of gully fans (Fig. 1). Local topographic high areas of patterned colluvium, including raised polygon shoulders, are embayed by gully fan deposits. Fan deposition is also blocked in places by the presence of a deep polygon trough (Fig. 1). Fan deposits are dissected by fine thermal contraction cracks which form a polygonal network continuous with the polygon network on the inter-fan surfaces. Taken together, these observations suggest that South Fork region gully fans formed in the presence of polygonally patterned ground, and that the expansion of thermal contraction cracks has kept pace with the aggradation of the gully fans, implying the continued presence of near-surface ice-cemented sediment during the entire process of gully channel and fan formation and evolution.

Gully-Polygon Interactions on Mars

Polygonally patterned ground is a ubiquitous surface feature of high-latitude terrains on Mars (Mangold 2005). Thermal contraction cracking is expected in ice-cemented regolith polewards of ~30° (Mellon 1997), and features interpreted as thermal contraction crack polygons are mapped to within ~10° of the martian poles (Mangold 2005); higher latitudes are dominated by polar cap processes.

A survey of high-resolution (30 cm per pixel) images of the martian surface between 30°–80° latitude was conducted, comprising 537 HiRISE camera images from the primary science phase of the HiRISE mission. Gullies are present in 118 of the images, and occur in conjunction with polygons in 70 of the images: primarily in the southern hemisphere (on account of higher topographic roughness). In both hemispheres, gully-polygon suites commonly occur within multi-kilometer impact craters. Northern hemisphere gullies have little aspect preference at the scale of MOLA gridded altimetry data (~460 m per pixel), while southern hemisphere gullies have a strong pole-facing preference, consistent with the extensive survey results of Dickson et al. (2007). Gullies forming in association with polygonally patterned ground show an equally strong pole-facing preference in the southern hemisphere (58%), and little aspect bias in the northern hemisphere.

Three gully-polygon suites were selected for initial stratigraphic and process analysis. Physical characteristics for the three sites are summarized in Table 1.

Mars gully-polygon process

Morphological analysis of HiRISE images shows relationships between martian polygonally patterned ground and gullies analogous to those observed in Antarctica.

Polygons in and around the alcoves of two gullies (Figs. 2, 3) are outlined by bright deposits which have accumulated preferentially in polygon troughs (either through direct deposition of frost, after Hecht 2002, or wind-capture of ice or particulates, after Morgan et al., 2007): a process analogous to the accumulation of windblown snow in Antarctic polygon troughs. Polygon-modified transport of gully materials on Mars is evidenced by the presence of sinuous, sub-linear, bright features interpreted to be analogous to annexed polygon troughs (Fig. 4). High-albedo material with a similar texture and brightness to the primary gully fan deposits is present in polygon troughs which extend down-slope of the gully fans. The polygon troughs filled by the material are wider than adjacent troughs, have less angular intersections between polygon trough segments, and are more sinuous along the lengths of the trough segments than neighboring troughs. Taken together, we interpret these features as evidence of preferential transport of gully-fan-forming material through these polygon troughs, and erosion of pre-existing polygon troughs during gully fan formation. Preferential storage of gully-related fluids within polygons is not directly observed in HiRISE images. Sorting of polygon-forming sediments by freeze-thaw/sublimation processes may be occurring below martian gullies, however, this process is not visible at 30 cm pixel scales. Alternatively, little grain-size dependent partitioning of water within polygons in martian gully distal hyporheic zones may be occurring on account of the precarious metastability of water at the martian surface (e.g., Hecht 2002).

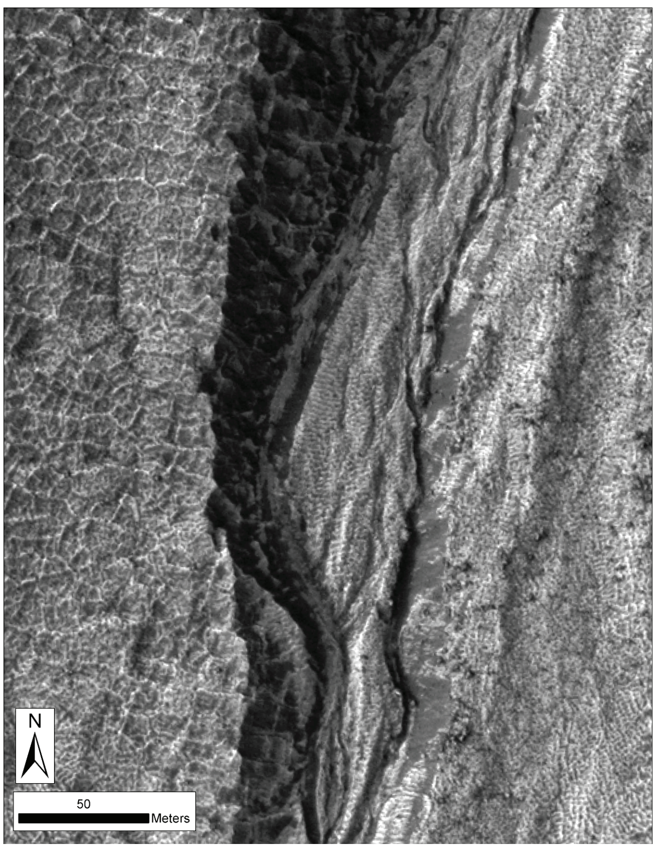

Figure 3. Portion of PSP_002368_1410 showing frost preferentially present in gully-alcove polygon troughs.

No evidence of any gully-polygon interaction is observable within gullies on equator-facing slopes, even those present within the same craters as gully-polygon suites on pole-facing slopes (Fig. 5). When present, equator-facing gullies appear to be extensively softened by sublimation and deflated by aeolian modification.

Mars gully-polygons stratigraphic relationships

As on Earth, polygons present in gullied terrains can be used to determine the formation sequence of landscape elements. A continuous network of polygonally patterned ground is commonly present across gully alcoves and inter-gully surfaces (Fig. 2). This relationship suggests that formation of polygonally patterned ground has continued through the period of gully alcove incision, making these polygons the youngest elements within the gully polygon system (in contrast to previous observations by Malin & Edgett, 2000, suggesting gullies exclusively overlie polygons). Contacts between gully fans and polygons (Fig. 4) show blocking of fan expansion by polygon troughs, annexation of polygon troughs (and filling with fan-like sediments), and incision of gully fans by polygons. Polygons present within gully fans 1) have narrower trough widths than polygons on inter-gully walls, 2) have subdued topographic relief, and 3) have interiors surfaced by gully fan material. Taken together, these observations suggest that these gully fans formed in the presence of polygonally patterned ground, overprinted the previously extant polygons, and were incised by continuously expanding thermal contraction crack polygons during fan emplacement.

Conclusions

Polygonally patterned ground in the South Fork of Wright Valley was analyzed as a component of a near-surface hydrological system in which channelized, subaerial water flow occurs under cold desert conditions. Patterned ground

was found to play a significant role in the accumulation, transport, and storage of atmospherically-derived gully meltwater. Gully-polygon stratigraphic relationships indicate that patterned ground formation preceded gully formation and continued throughout gully evolution. This suggests the continuing presence of climate conditions permitting the expansion of composite-wedge polygons. Further, these results suggest the continuous presence of an impermeable ice-cemented sediment permafrost layer during the entire course of gully evolution.

Analysis of 537 HiRISE images in the 30°–80° latitude range revealed 70 gullies on the martian surface interacting with polygonally patterned ground. Our analysis indicates that patterned ground on Mars plays an analogous role in the accumulation and transport of martian gully materials to those observed on Earth. Further, stratigraphic relationships between gullies and polygons on Mars indicate that some gullies have formed in the presence of continuously expanding thermal contraction crack polygons. In some gullies, thermal contraction cracks are the youngest stratigraphic element in the gully system. The processes of frost-trapping by polygon troughs, polygon trough annexation, polygon overprinting by gully fans, and dissection of gully fans by thermal contraction crack polygons, have all been observed in martian gullies, suggesting that some martian gullies have formed and evolved on surface units underlain by a continuous layer of shallow permafrost during the most recent period of gully activity. No evidence of catastrophic water release was observed. Polygon-gully interactions and fresh-looking gully structures were found to form preferentially on pole-facing slopes in the presence of shaded alcoves. Taken together these lines of evidence suggest an atmospheric origin for some gully volatiles, consistent with the model of gully activity observed in the Antarctic Dry Valleys.

Abstract

Ccritical embankment heights were computed for warm permafrost regions in the eastern Tibetan Plateau using geographical and geological conditions. The resulting modeled results agree well with the data collected on the Qinghai-Xizang Highway over the past 30 years. At first, for concrete and gravel road surfaces, the thermally-stable critical heights of embankments were estimated to be 2.50 m for concrete surfaces and 2.00 m for gravel surfaces, using regression analysis. When the heights of embankments are higher than the critical heights, the degrading permafrost table will gradually stabilize after construction. However there is no critical height of embankments for the asphalt pavement road in warm permafrost regions according to our models.

Keywords: degrading permafrost table; embankment stability; highway engineering; mathematical models; pavements; permafrost; thermal analysis.

Introduction

When the natural ground surface is changed by roadway embankment construction, the thermal balance of the permafrost is also altered. Thermal equilibrium will not be reached for many years. As a result, the permafrost table under the roadbed is also degraded. As thermal balance is achieved, the permafrost table may rise or lower depending on roadway thickness and surface. For example, after construction of the Qinghai-Xizang Highway, the permafrost temperature under the roadbed increased, and the permafrost table was lowered. The roadway was paved with asphalt, which absorbs heat resulting in higher surface temperatures. Thaw settlement of the embankment occurred, destroying the road (Li & Wu 1997). Consequently, it is very important to understand the thermal stability of embankments after construction in permafrost regions, especially warm permafrost regions where the mean annual ground temperature is higher than or equal to -1.0°C. This corresponds to a mean annual air temperature of -3.5°C or higher.

The Qinghai-Sichuang Highway crosses the eastern part of the Qinghai-Xizang Plateau, China. The highway crosses about 300 km of mostly warm permafrost. The thickness of the permafrost has been degrading in this region since the 1960s (Zhu 1995, Li 1996).

We analyzed the thermal stability of embankments on permafrost in an effort to predict the temperature of the permafrost with different road surfaces and estimate critical heights.

Methods and Conditions

Mathematical model

Since Harlan (1973) presented the first model for coupled heat and mass transfer in freezing soils, his strategy has been referred to and further developed by many other researchers (Guyman & Luthin 1974, Outcalt 1977, Taylor & Luthin 1978, Jame & Norum 1976, Nixon 1975, Li & Wu 1996). These authors applied two partial differential equations, using temperature and water (ice) content or water pressure to describe the transient heat and water flows in freezing soils. The two equations are coupled through the relationship between unfrozen water content and temperature. If vapor transfer and heat convection are omitted, the application of the laws of heat balance to saturated or unsaturated soil and the mass conservation of water in soil pores result in the following two equations:

$$\frac{\partial}{\partial x}(\lambda_x \frac{\partial T}{\partial x}) + \frac{\partial}{\partial y}(\lambda_y \frac{\partial T}{\partial y}) = C\rho \frac{\partial T}{\partial t} - L\rho_i \frac{\partial \theta_i}{\partial t} \tag{1}$$

$$\frac{\partial}{\partial x}(K_x \frac{\partial \psi}{\partial x}) + \frac{\partial}{\partial y}(K_y \frac{\partial \psi}{\partial y}) = \frac{\partial \theta_u}{\partial t} + \frac{\rho_i}{\rho_w}\frac{\partial \theta_i}{\partial t} \tag{2}$$

where ρ_w, ρ, and ρ_i are the densities of water, soil, and ice, respectively; t, x, and y denote the time and two space coordinates; θ_i and θ_u are the volumetric fractions of the ice content and the unfrozen water content; $\lambda x(\lambda y)$ and $Kx(Ky)$ are the thermal and the hydraulic conductivities in the x and y directions; T is the temperature; C is the specific heat; L is

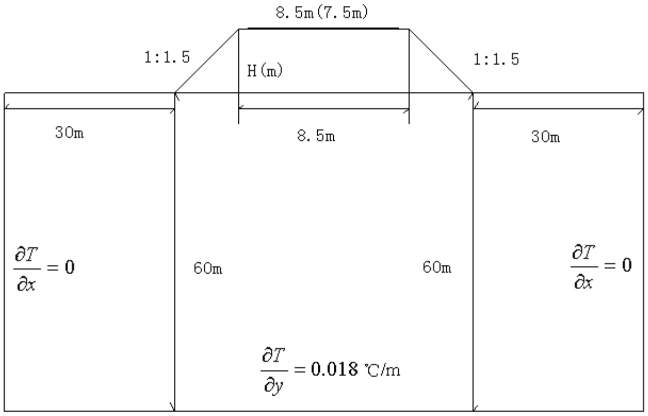

Figure 1. The profile of embankment for calculations.

the latent heat; ψ is the total potential of water in soil; $\psi=\varphi+Z$, where φ and Z denote the volumetric potential of water in the soil and the gravitational potential, respectively.
In general, Z can be omitted and therefore $\psi=\phi$.

According to the characteristic relationship, $\theta_u=f(T)$ between the unfrozen water content θ_u and the temperature T, we obtain the following differential relationship:

$$\frac{\partial\theta_u}{\partial t}=\frac{\partial\theta_u}{\partial T}\frac{\partial T}{\partial t} \tag{2a}$$

Substituting this differential relationship into Equation (2) and reducing Equation (1), we can derive:

$$\begin{gathered}(C\rho+L\rho_w\frac{\partial\theta_u}{\partial T})\frac{\partial T}{\partial t}=\\ \frac{\partial}{\partial x}(\lambda_x\frac{\partial T}{\partial x})+\frac{\partial}{\partial y}(\lambda_y\frac{\partial T}{\partial y})+L\rho_w\left[\frac{\partial}{\partial x}(\mathrm{K}_x\frac{\partial\psi}{\partial x})+\frac{\partial}{\partial y}(\mathrm{K}_y\frac{\partial\psi}{\partial y})\right]\end{gathered} \tag{3}$$

Equations (2) and (3) can be solved when given the function ψ and the characteristic relationship between the unfrozen water content and temperature. The temperature is determined empirically. From these equations, we can develop several models.

Taylor (1976, 1978) investigated the volumetric potential of unfrozen water in frozen soil. He showed the volumetric potential could be determined using the characteristic relationship between the unfrozen water content and temperature, similar to the volumetric potential of unfrozen soil, when the action of ice in the frozen soil is omitted. The characteristic relationship of moisture for unfrozen soil is suitable for frozen soil.

By introducing the new differential relationship:

$$\frac{\partial\psi}{\partial T}=\frac{\partial\psi}{\partial\theta_u}\frac{\partial\theta_u}{\partial T} \tag{3a}$$

and using the terms of the differential water capacity $c=\partial\theta/\partial\psi$ and the soil-water diffusivity $D=\mathrm{K}/c$, we reduce Equation (3) to:

$$C(T)\frac{\partial T}{\partial t}=\frac{\partial}{\partial x}(\beta_x(T)\frac{\partial T}{\partial x})+\frac{\partial}{\partial y}(\beta_y(T)\frac{\partial T}{\partial y}) \tag{4}$$

where:

$$C(T)=C\rho+L\rho_w\frac{\partial\theta_u}{\partial T}$$

$$\beta_x(T)=\lambda_x+L\rho_w D_x\frac{\partial\theta_u}{\partial T}$$

$$\beta_y(T)=\lambda_y+L\rho_w D_y\frac{\partial\theta_u}{\partial T}$$

$$D_x=\frac{\mathrm{K}_x}{\frac{\partial\theta_u}{\partial\psi}},D_y=\frac{\mathrm{K}_y}{\frac{\partial\theta_u}{\partial\psi}}$$

Since the characteristic relationship between the unfrozen water content and the temperature can be determined by testing, the set nonlinear Equations (2) and (4) can be solved. The implicit finite difference method was used to derive the results reported in this paper.

Boundary and initial condition

The input for the derived equations is established in part by Chinese standards and in part based on experience. According to the Chinese standards for designing and building national highways, road surface width is 8.5 m, and shoulder width is 0.5 m. The height of embankment varies. The side-slope is 1:1.5. Finally, the bottom boundary is located at 60 m depth. Based on drilling records, the temperature and the heat flux at the bottom of the permafrost were found to be constant on the Eastern Tibetan Plateau (Li et al. 1998). The ground temperature gradient at the lower boundary was estimated to be 0.018°C per meter. The lateral boundary (30 m from the slope corner) is situated so far from the road that the temperature gradient is regarded as 0.0°C/m horizontally (see Fig. 1).

The initial ground temperature field under the road was obtained from a borehole. The ground temperature without embankment was simulated using the boundary conditions noted until stable temperature field under the natural ground surface was established. This initial temperature profile was used to estimate the transient temperature field after road construction. The initial temperature in the embankment was assumed to be -1.0°C. The mean annual temperature of the embankment slope is 0.5°C lower than the upper boundary temperature of road surface, because that is often influenced by traffic.

Using meteorological information from Hua Shixia Valley and Ma Duo County in the Eastern Tibetan Plateau (Yu 1993), and by regression analysis of the sine function, we can reduce the upper boundary temperature of road surface to the following sine function:

$$T=T_s+G(t)+12.2\sin\left(\frac{2\pi}{8640}t+\frac{4\pi}{3}\right)$$

Here, T_s is the mean annual temperature at the ground surface; t is the time in hours of the annual cycle after the construction of embankment, respectively ranging from 0 to 8640 hours; $G(t)$ is the mean annual climate warming rate; here $G(t)=0$.

The mean annual air temperature in the warm permafrost regions was taken as -3.5°C. Ground temperature in the eastern part of the Qinghai-Xizang Plateau, T_s is -1.0°C for natural ground, +3.0°C for an asphalt surface, +1.5 for a concrete surface and +1.0°C for a gravel road surface (Wu 1988). The natural permafrost table is about 2.00–2.20 m in the Hua Shixia Valley, a continuous permafrost region.

The hydrogeological conditions and heat parameters are as follows:

1. 0.00–2.00 m, organic clayey soil, water content 40.0%, dry density 0.9 g/cm3, heat capacities of unfrozen and frozen soils 1.17 J/cm^3·°C and 1.34 J/cm^3·°C and thermal conductivities of that 13.97 J/cm·h·°C and 16.72 J/cm·h·°C, respectively.
2. 2.00–3.30 m, clayey soil, water content 178.5%, dry density 0.36 g/cm^3, heat capacities of unfrozen and frozen soils 1.03 J/cm^3·°C and 0.89 J/cm^3·°C, and thermal conductivities of that 26.36 J/cm·h·°C and 77.40 J/cm·h·°C, respectively.
3. 3.30–7.60 m, gravel, water content 24.5%, dry density 1.52 g/cm^3, heat capacities of unfrozen and frozen soils 2.82 J/cm^3·°C and 2.23 J/cm^3·°C, and the thermal conductivities of that 40.59 J/cm·h·°C and 56.90 J/cm·h·°C, respectively.
4. Below 7.60 m, mantle rock, water content 4.0%, heat capacity of soil 2.29 J/cm^3·°C, thermal conductivity of soil 97.20 J/cm·h·°C.
5. Fill materials of embankment contain clayey soil with coarse-grained gravel; water content 8.0%–10.0%, dry density 2.0 g/cm^3. The capacities and conductivities of unfrozen and frozen soils were taken as those in 3.30–7.60 m deep gravel soil.

The relationships between unfrozen water content, temperature, total moisture, and thermal properties are taken from experimental research on moisture transfer in frozen soil (Xu & Deng 1991).

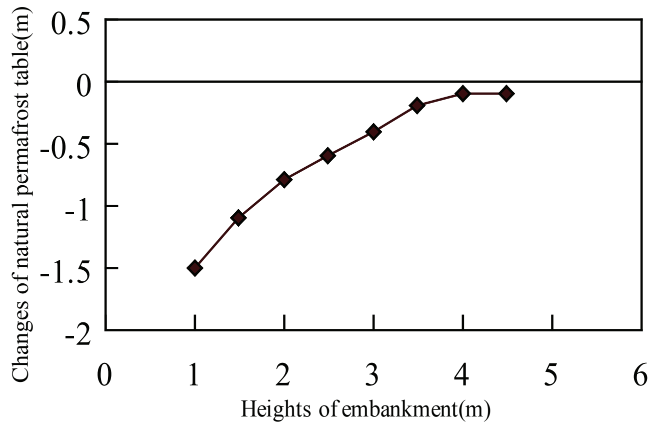

Figure 2a. Relation between height of embankment and the changes of natural permafrost tables under roadbed (asphalt).

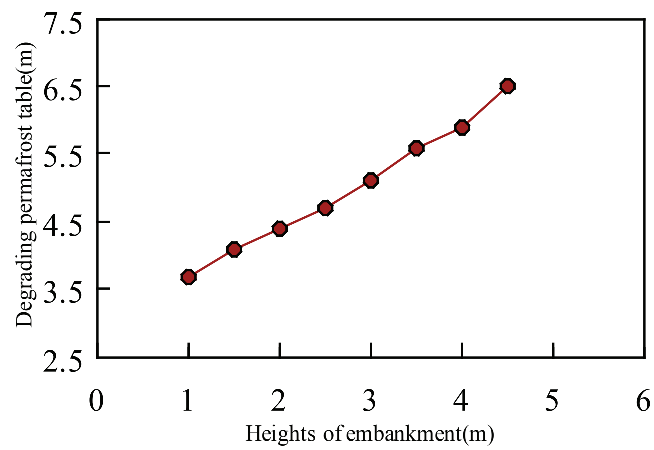

Figure 2b. Relation between height of embankment and the degrading permafrost table of embankment (asphalt).

Results and Discussion

Because traffic is increasing, replacing the existing gravel surface with pavement is necessary. To keep the road surface smooth, the fill stability must be maintained. In order to prevent thaw settlement, the permafrost table under the roadbed must be maintained and not lowered. Frost heaving of the active layer above the permafrost must be controlled to less than 1%. The calculations in this paper use the two principles as guidelines. Using the different types of road surface and embankment heights, changes in the level of the permafrost table as a function of time are analyzed. Using the results, the critical design heights of the embankment for a 30-year period after construction are determined using linear regression analysis between heights of embankment and changes of the natural permafrost table.

The analysis is summarized in Figures 2–6. Figures 2a–4a show for asphalt, concrete, and gravel road surface the relation between the height of embankment and the changes of the level of the natural permafrost table under the middle sections of road in the 30 years after construction on the high-temperature permafrost sections. On the other hand, Figures 2b–4b show the relation between the height of embankment and the degrading permafrost table (changed permafrost table under the roadbed) under the middle sections of the road; that is, the critical design heights have a relationship with the age of the road after construction. Figures 5 and 6 show the zero degree isothermal curves under the roadbed with asphalt pavement at the embankment height of 4.0 m and 3.5 m in 30 years.

From Figure 3 to Figure 4, for concrete and gravel surface embankments, when the embankment height is lower than 3.0 m, it can be seen that there is an almost linear relation between the height of embankment and change in the natural permafrost table and degrading permafrost table under the road in the thirtieth year after construction. This is in agreement with that for low-temperature permafrost regions (Li et al. 1998); therefore, from a linear regression analysis, the heat-stable critical heights of embankment for concrete and gravel roads are figured out as 2.50 m and 2.00 m in the thirtieth year after construction.

From Figure 2, however, for the asphalt pavement road, the above-mentioned relation is nonlinear. After 10 years the permafrost table under the roadbed is always lower than the natural permafrost table. As shown in Figures 5 and 6, when the height of embankment is higher than 3.5 m for an asphalt

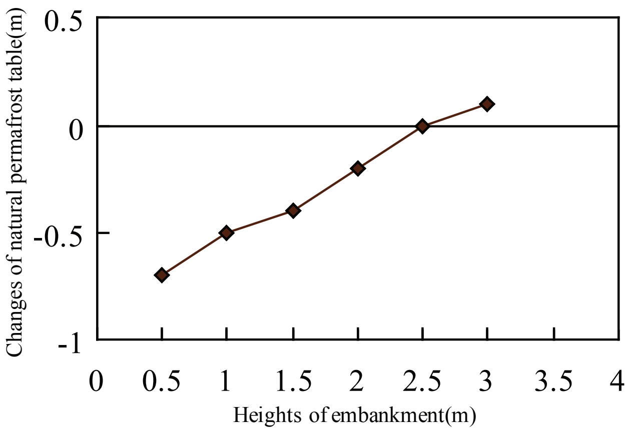

Figure 3a. Relation between height of embankment and the change of natural permafrost tables under roadbed (concrete).

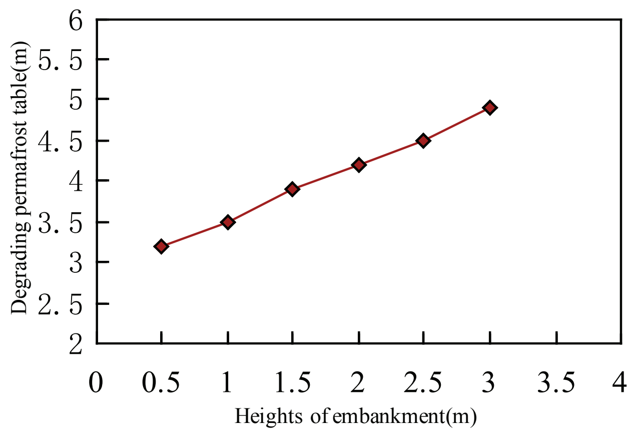

Figure 3b. Relation between height of embankment and the degrading permafrost table of embankment (concrete).

road, there will be a residual thaw zone (an upper thawed course) (Huang 1983) above the degrading permafrost table in the embankment more than 10 years after construction. Again, the predicted permafrost table is lower than the natural permafrost table under the road from that point forward. Consequently, the degrading permafrost table under the roadbed was always lower than the natural permafrost table under the roadbed after 10 years following construction or in the thirtieth year; we cannot get any critical height for asphalt pavement, as we did for concrete-surface and gravel-surface roads. Because of the existence of the upper thawed course (an unfrozen area in the embankment above the degrading permafrost table), the frost deformation of the embankment, therefore, would be largely increased making it impossible to maintain smoothness specifications. In other words, it is not desirable to build an asphalt-pavement road in the warm permafrost regions of the Tibetan Plateau.

For concrete and gravel surface roads, there is no upper thawed course (an unfrozen area in the embankment above the degrading permafrost table) in the embankment for embankment heights less than 3.0 m; that is, there are critical heights of embankment. These are in correspondence with the observed results on high-temperature permafrost regions in the Qinghai-Xizang Highway during the 30 years or more of the last century (Wu et al. 1988).

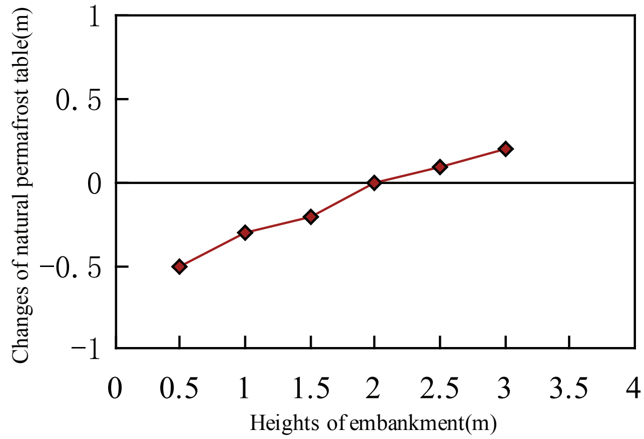

Figure 4a. Relation between height of embankment and the changes of natural permafrost tables under roadbed (gravel).

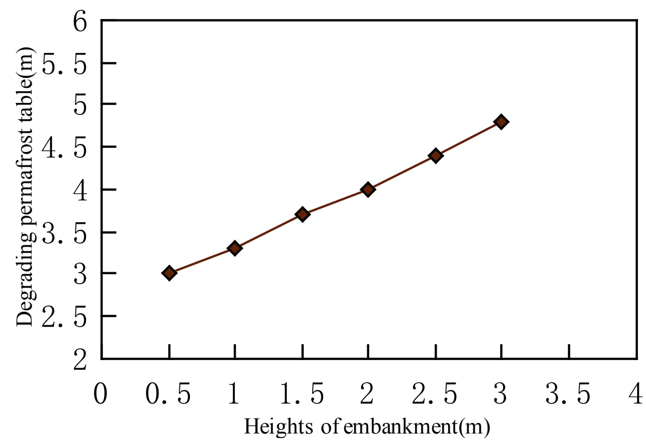

Figure 4b. Relation between height of embankment and the degrading permafrost table of embankment (gravel).

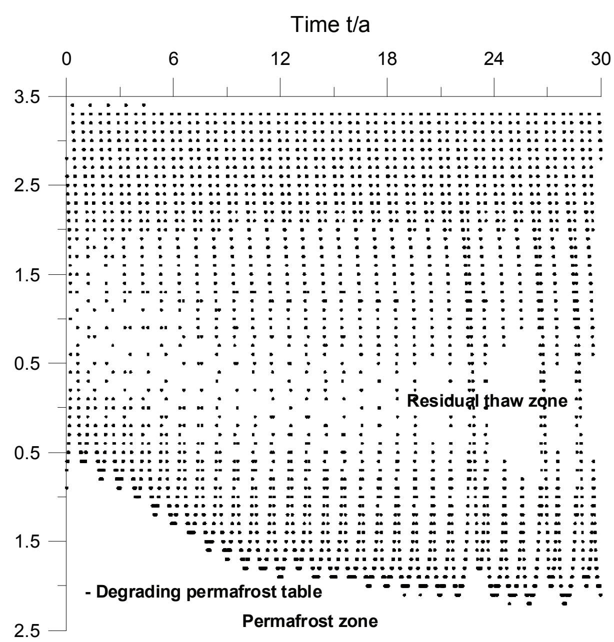

Figure 5. The zero degree isothermal curves under the roadbed at the embankment height of 3.5 m in 30 years (asphalt).

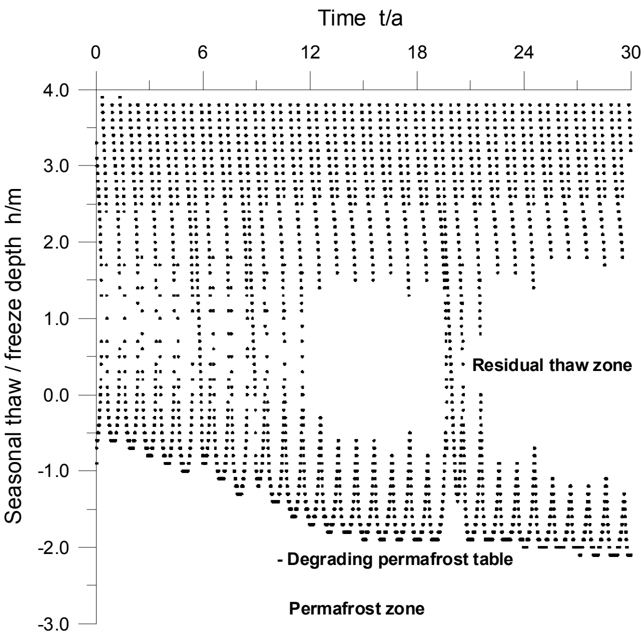

Figure 6. The zero degree isothermal curves under the roadbed at the embankment height of 4.0 m in 30 years (asphalt).

Conclusions

1. It is important to predict permafrost change under the road with running time after construction. The applied numerical model provides the ability to predict and estimate critical heights of embankment in cold regions.

2. The heat-stable critical heights of embankment on the high-temperature permafrost regions in the Eastern Tibetan Plateau are 2.50 m and 2.00 m for a 30-year analysis period after construction for concrete and gravel road surfaces, respectively.

3. According to the principle of protecting the permafrost, it is not desirable to build an asphalt pavement road in the area; that is, there is no critical height of embankments for the asphalt pavement road in high-temperature permafrost regions in this area.
