These proceedings of the Ninth International Conference on Permafrost (NICOP) extend the documented legacy of permafrost related research begun in 1963 when the first International Conference was held in West Lafayette, Indiana, USA. NICOP also marks the 25th anniversary of the Fourth International Conference on Permafrost that was convened in Fairbanks in July 1983. It is imperative that we continue this international and long-ranging dialogue of cooperation on permafrost, particularly during a period of overall global warming. At no time in the past has our overall interest level in permafrost been greater. The number of papers published in these proceedings substantiates this interest. In addition to climate change, development in regions of permafrost is contributing additional stress to this thermally sensitive environment. This recent increased growth is often associated with resource development such as oil and gas, and various mineral resources.

The papers presented in these proceedings are diverse in both time and space; they cover results from field and laboratory studies, remote sensing, analyses and modeling – or some combination of these. Both scientific and engineering aspects of various permafrost issues are presented, and are often intertwined with each other. We hope these proceedings provide one more positive step in our understanding of the permafrost environment that intrigues us as scientists and engineers.

Volume 2

Preface

Since the first International Permafrost Conference convened in 1963, we have sustained an international scientific and engineering collaborative effort until we now are immersed in this, the Ninth International Conference on Permafrost (NICOP). Considerable change has occurred over the past 45 years, resulting in heightened interest in the permafrost environment and understanding of its many aspects. Participation by engineers and scientists in advancing our knowledge of permafrost as a thermally impacted medium has continued to grow in the wake of both resource development and climate change.

The University of Alaska Fairbanks (America's Arctic University) is an excellent choice for the location of this conference. Permafrost is ubiquitous in Interior Alaska, and it influences many aspects of our society. Our local field trips are arranged around some of the most interesting phenomena here in the zone of discontinuous permafrost, including the world famous Permafrost Tunnel, the Trans Alaska Oil Pipeline, evidence of anthropogenic impacts on permafrost, and thermokarsting of warm permafrost. Fairbanks is also a good starting point for trips to other parts of Alaska, including the North Slope, Seward Peninsula, Denali National Park (Mount McKinley), and many other adventures. We have also taken this opportunity to offer courses related to the permafrost environment for high school and elementary teachers, advanced graduate students, and working professionals.

The University of Alaska Fairbanks hosted the Fourth International Conference on Permafrost in 1983. It was at this meeting that the International Permafrost Association (IPA) was formally established. IPA members are truly pleased with the strong international flavor of this year's conference, with approximately 30 countries participating. IPA's uninterrupted activities over the past 25 years are partially responsible for this concerted effort to expand our understanding of the permafrost environment, both spatially and temporally. It is also, however, abundantly clear that much of our current interest in this environment is driven by climate change.

Currently, many aspects of permafrost research are receiving considerable attention. These include carbon release into the atmosphere, discharge from catchments dominated with permafrost, the role of gas hydrates in cold environments, degrading permafrost and thermokarsting, infrastructure design in a changing environment, and the overarching issue of climate change on this thermally sensitive environment. It is essential that our scientific and engineering communities help our societies adapt to living and working on warming permafrost. Permafrost degradation will affect all aspects of life in the high latitudes and high elevations. We must anticipate the changes in ecology, hydrology, and infrastructure construction that will accompany degradation of permafrost with a warming climate. That is the challenge facing permafrost scientists and engineers. It is our hope that by sharing our knowledge and understanding, we may better serve our nations and people.

Enjoy the conference. We hope you will go home with increased knowledge and an invigorated appetite for expanding our understanding of the environment we call "permafrost."

—Douglas L. Kane
Water and Environmental Research Center, Institute of Northern Engineering
—Larry D. Hinzman
International Arctic Research Center

Acknowledgments

We, the organizers of the Ninth International Conference on Permafrost (NICOP), cannot sufficiently express our gratitude to those who have made NICOP both possible and successful. There are those who contributed financially by keeping the cost of the registration low, supporting young investigators, helping defer the cost of the proceedings, and sustaining many other behind-the-scenes activities. There are those who served on the numerous committees associated with this conference at the local, national, and international levels; we hope they found this exercise to be professionally rewarding. Finally, there are those who served as associate editors and reviewers of the more than 400 papers submitted. This conference is advertised as an International Conference; to be truly successful, much work must be done to overcome language barriers. While not always finding success in bringing a paper to publication, the associate editors and reviewers performed in a very commendable manner. Thank you all for your help.

Abstract

Disturbance from off-road vehicle operations was measured to determine damage to the soil and the vegetation. A 20-ton Stryker vehicle was used for maneuver impact tests on various terrains at a training land in Alaska during winter and spring. The trafficking consisted of both single and multiple passes for straight and turning maneuvers. The wintertime maneuver test was conducted on frozen terrain with 10 cm of snow cover. The initial disturbance to the soil and vegetation was observed to be minimal during the winter maneuver test, which showed limited vegetative shearing or soil disturbance in the vehicle tracks. The initial disturbances during the spring maneuver tests were observed to be minimal on shallow thawed terrain and significant in some areas with deep thaw depth, high moisture content, and sparse vegetation cover. The locations where the initial survey points were taken were revisited during the growing season to measure the recovery. The recovery was measured almost every year for up to four years in some locations to examine and assess the rebounding of the vegetation and healing of the ruts. Soil erosion from flooding and soil slumping were observed on ruts or tracks during the first recovery visit. The results showed significant vegetation rebound after three years. Recovery rates varied significantly depending on the terrain, ground and soil conditions, and initial impact severity.

Keywords: permafrost; rutting; seasonal terrain; thawing condition; vegetation recovery; vehicle disturbance.

Introduction

A 20-ton Stryker was newly introduced to U.S. Army Alaska (USARAK) training lands to train and support the Stryker Brigade Combat Team (SBCT3) (Shoop et al. 2004). Vegetation recovery rates on non-seasonal terrain have been examined after being disturbed by military vehicles (Howard et al. 2007). However, disturbance information from this type of vehicle was limited and unknown on Alaska training lands, especially since USARAK used light vehicles prior to SBCT. The initial question was how much impact could be expected from the Stryker vehicle. Secondly, what are the expected recovery rates from various types of disturbance? These questions were important for the training land managers for planning, suitability, and rehabilitation management. Maneuver impact tests using a 20-ton Stryker vehicle were conducted in March and May of 2003. The tests were conducted at one location during winter with frozen ground and snow cover and at three locations during the spring breakup when soil strength was at its annual minimum immediately following the melting of seasonal frost. This study was an attempt to quantify the initial disturbance generated by 20-ton Stryker vehicle (Affleck et al. 2004, Affleck 2005). The test in March 2003 was conducted on a permafrost terrain, while the tests in May 2003 were conducted on a permafrost area and on two sites with seasonal frost.

Prior to this study, there had been few studies conducted on the long- and short-term effects of off-road vehicle traffic on arctic tundra and subarctic alpine tundra soils (Abele et al. 1984, Walker et al. 1977, 1987, Sparrow et al. 1978, Slaughter et al. 1990). These studies concluded that poorly drained soils underlain by permafrost are often most heavily damaged, and soil bulk densities were higher on traffic areas than on the undisturbed areas. In addition, their findings included that the disturbances were based on many factors, including vehicle type, acceleration, turning radius, speed, time of summer, number of passes, slope, and vegetation. However, these off-road vehicles are mainly used for recreational and transportation purposes in Alaska, are lighter in weight (less than 10,000 kg), and have lower contact pressures than the Stryker vehicle.

Approach

The maneuver impact tests were composed of spiral and multi-pass tests. For the spiral test, the vehicle performed turning maneuvers by traversing from a large radius to a small radius to examine the disturbance generated when the vehicle is turning. The multi-pass tests were composed of lanes with 1, 4, 8, and 13 passes. The maneuver impact tests were conducted at three locations in May 2003 during spring and in one location in March 2003 during winter.

Test Vehicle

The Stryker vehicle used during the test was an infantry carrier vehicle (ICV) with no additional armor; it weighed approximately 18,000 kg (40,000 lbs) when loaded. The vehicle configurations listed for the Stryker are based on one of its variants (Table 1). The eight-wheel-drive Stryker is a combat vehicle and consists of four axles with 44.3 cm (17.43 in.) of ground clearance (Fig. 1). Although the vehicle has the capacity to run under cross-country tire inflation, it was operated using on-road tire pressures of 550 kPa (80 psi) on all eight tires.

A Global Positioning System (GPS) unit was mounted on the Stryker vehicle to track its position. The GPS unit recorded the position data of the test at 1-s intervals. The GPS data were used to determine vehicle speed and turning radius.

The terrain disturbance measurement categories included an imprint, a scrape, or a combination of both, and a pile (Ayers et al. 2000, Haugen 2002, Haugen et al. 2002, Affleck 2005). An imprint is where soil and vegetation are compressed in the vehicle track. A scrape is where the soil and vegetation have been stripped away from the vehicle track. A pile disturbance is where soil and vegetation have been displaced from the vehicle track and piled on the side(s). The impact severity was characterized by the amount of vegetation disturbed and removed, and the amount of bare soil exposed along the track.

Test locations and conditions

The test sites are described in detail by Affleck (2005) and Affleck et al. (2004). The sites include Arkansas Range, Eddy Drop Zone, and Texas Range. The test conditions during the trafficking to quantify terrain disturbance are briefly described in Table 2. There was only one test site during winter season on limited snow cover.

Initial disturbance

The initial disturbance to soil and vegetation along the vehicle tracks in the maneuver test area was measured in August 2003. The guidelines were established using impact severity and its corresponding disturbed width using guidelines (Ayers et al. 2000, Haugen 2002, Haugen et al. 2002). Although the initial survey was conducted a few months after the maneuver tracking, changes in vegetation in terms of recovery were considered minimal or almost zero. The initial disturbances from the Stryker maneuver tests were thoroughly described by Affleck (2005) and Affleck et al. (2004).

Recovery measurements

Recovery surveys were conducted in May 2004, August 2006, and June 2007. Guidelines used to measure the recovery of the soil and vegetation were established using impact severity and its corresponding disturbed width, based on work by Ayers et al. (2000), Haugen (2002), and Haugen et al. (2002), and modified for seasonal and permafrost areas as listed in Table 3.

Percent recovery and recovery rate

An overall assessment is quantified based on percent recovery and recovery rate. Percent recovery is measured in terms of the soil and vegetation rebound for each monitoring

Table 1. Stryker vehicle mobility parameters.

Width, cm (in.)	265.4 (104.5)
Length, cm (in.)	693 (273)
Weight, kg (lb)	17,745 (39,120)
Contact pressure, kPa (psi)	193 (27.94)

Table 2. Test site locations, terrain description, and conditions during tracking.

Test Sites		Arkansas Range (AR)		Eddy Drop Zone (EDZ)		Texas Range (TR)
Terrain description		Flat, seasonal		Flat, seasonal		Gently sloping permafrost
Vegetation		Grass and short bushes		Sphagnum moss, sedge, tall grass and thick bushes	Tall grass, bare ground	Sphagnum moss, sedge
Soil type		Silty sand (SM)		Silty sand (SM) with thick organic layer in dense vegetative areas		Peat, organics
Test section conditions		Wet	Dry	Dense vegetation	Sparse vegetation	Ice-rich, high water content
Spring thaw	Avg. water content (%)	49.3	33.9	94.5	36.2	315.7
	Avg. thaw depth (cm)	28.8	23.4	14.5	44.5	7.6
Winter	Snow depth (cm)	—	—	—	—	10.0

Table 3. Modified recovery impact severity guidelines for seasonal terrain.

Impact Severity (%)	*Guidelines*
0	No visible disturbance as compared to surrounding vegetation/area; **no depression of vehicle track or rutting**
100	Slight leaning of vegetation; vegetation may be leaning in the direction of the vehicle track instead of standing straight compared to surrounding vegetation; **minimal compression of vegetation and organic mat and depression of vehicle track or rutting still exist [≤ 7.6 cm (3 in.)] but vegetation cover** similar or same in size as surrounding vegetation; vehicle track only slightly visible
200	Leaning of vegetation, likely in the direction of vehicle tracking compared to surrounding vegetation; **depression of vehicle track or rutting still exists but vegetation cover** similar in size to surrounding vegetation; visibility of tracks; little to no disturbance of soil visible
40	Depression of vehicle track **narrowing and more shallow due to soil slumping, movement, or erosion**; bare soil visible; over one third of the vegetation not present compared to surrounding; vegetation growing in track not as fully grown or as large as surrounding vegetation **or other vegetation types growing along the tracks** (e.g., moss); if rocky soil, some rock visible in bare soil; **organic matter accumulating in tracks**
600	About one third of the area with growing vegetation; vegetation smaller than surrounding vegetation **or sign of other vegetation types growing along the tracks** (e.g., moss, dominant or invasive vegetation); significant amount of bare soil still exposed; if rocky soil, rocks visible on soil surface; depression of track visible; sign of **soil slumping, movement, or erosion in tracks**
800	Few vegetative species growing on vehicle path; vegetation present is much smaller and less developed than surrounding vegetation; depression of track visible; if in a rocky soil, increasing amount of rocks visible in track
100	Track is bare soil with no vegetation growing; depression of track visible; if in a rocky soil, rocks highly visible in track

time with respect to the initial disturbance at the same location. The equation used to calculate percent recovery for each monitoring time (or measurement date) is

$$\%\text{Recovery}_t = \left(\frac{IS_i - IS_t}{IS_i}\right)100 \qquad (1)$$

where IS_i is the impact severity during initial time and IS_t is the impact severity at the time of interest.

Recovery rate can be obtained by plotting the percent recovery with the time.

Results

Permafrost terrain

The disturbance from the Stryker vehicle during the winter test at Texas Range (TR) was generally in the imprint category in which the snow and vegetation were compressed by the tires, showing bare ground in some areas along the tracks (Fig. 2a). The initial impact severity values were mostly near 10%, with vegetation being flattened and with broken stems or branches as shown in Figure 2b. Because the ground was frozen during the test (and had sufficient bearing capacity), the ground showed no rutting or depression. Tracks were still visible after a year (Fig. 2c). However, it was fully recovered after 3.42 years, when tracks were very hard to find (Fig. 2d).

Because the thaw depth was minimal during the test, the initial impact severity during the spring test at Texas Range was mainly compression of the vegetation and organic layer down to the frozen layer, where some vegetation had been sheared off the track at a few locations due to the vehicle turning.

Seasonal terrain

The initial impact severity (IS_i) during the spring test at Arkansas Range and Eddy DZ varied tremendously depending on the soil condition and vegetation cover. In the wet section at Arkansas Range and the sparse vegetation areas at Eddy DZ, the IS_i was up to 100%, resulting in complete removal of the vegetation and displacement of soil with significant ruts along the tracks (Fig. 3a). Soil slumping occurred during the following spring thaw, and possibly soil settlement from water ponding in the area made the soil fill in the tracks as shown in Figure 3b. At Arkansas Range, soil slumping on the ruts' side walls occurred, possibly due to freezing and thawing effects. Both the soil erosion and slumping processes made the ruts more shallow and narrow over time. In addition, organics (dead leaves) accumulated on the tracks. Over time, other vegetation types were observed growing in the tracks (e.g., moss, dominant or invasive vegetation), as seen in Figure 3c, for example, and adjacent vegetation sprawled into the tracks. In dense vegetative areas and dry soil locations at both Arkansas Range and Eddy DZ, the initial disturbance ranged from minimal compression of vegetation and organic mat to slight vegetation removal, to deep ruts with some shearing of plant at roots and some bare soil exposed.

Recovery

The disturbances were grouped based on the initial impact severity. IS_i >50% was considered to be high initial impact, while IS_i <50% was defined as low initial impact. The percent recovery values were obtained using Equation 1, and then an average value was taken from both inner and outer tracks and for each measurement date.

The percent recovery varied significantly depending on the terrain, ground and soil conditions, and initial impact severity (Fig. 4).

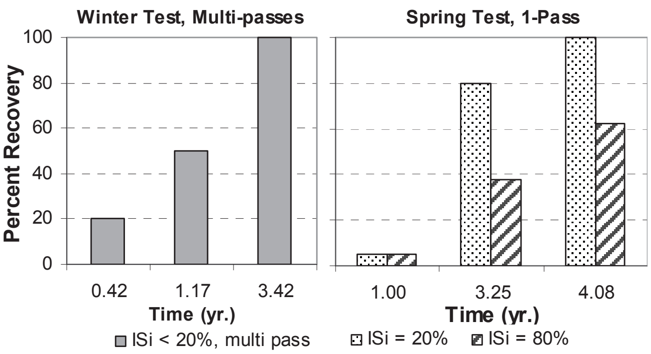
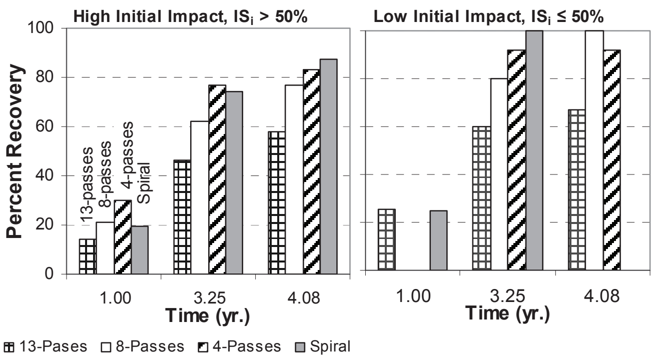
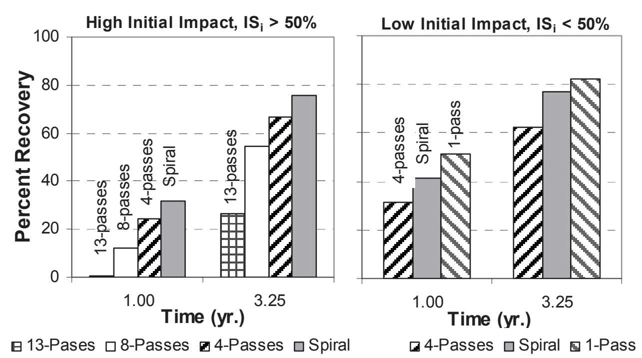
Figure 3. Left track disturbance and recovery on a track at Eddy DZ after 13 passes.



(a) Texas Range, permafrost terrain.



(b) Spring test disturbance at Arkansas Range.



(c) Spring test disturbance at Eddy DZ, seasonal terrain.

Figure 4. Recovery rates at various locations from disturbance during winter and spring tests.

At the permafrost site (Texas Range), the recovery from the disturbance during the winter test produced a correlation with a rapid recovery of 100% after 3.42 year (Fig. 4a, left chart). On the other hand, the recovery for the spring test depended on the severity of the initial disturbance (Fig. 4a, right chart). 100% and 60% of recovery were found after 4 years for disturbances with initial impact severity of 20% and 80%, respectively.

Considerable differences in recovery rates were found at Arkansas Range and Eddy DZ from the disturbance generated by the Stryker vehicle during the spring tests (Figs. 4b & 4c). The percent recovery was higher and at a higher rate when the initial impact was less, but it also depended on the number of passes (Fig. 4b). For example, for initial high impact (severity of greater than 50%) after 4 years, approximately 58% and 87% recovery had occurred for the 13 passes and the spiral (single pass), respectively. However, with low initial impact (severity of less than 50%), the recovery rates were approximately 66% and 100% for the 13 passes after 4 years and for the spiral after 3.25 years, respectively.

Only up to 3.25 years of monitoring were conducted at Eddy DZ. The percent recovery was very limited for the 13-pass tracks, with zero recovery after the first year and only 26% after 3.25 years. During trafficking, the 13-pass tracks had less vegetation with bare ground compared to the rest of area at Eddy DZ. Overall, the recovery seemed to increase with a decreasing number of passes for initial impact severities greater than 50% (Fig. 4c, left chart). The recovery was a bit higher for low initial impact (severity less than 50%, Fig. 4c, right chart), and these tracks were in the dense vegetation area.

Summary and Conclusion

The initial disturbance from a Stryker vehicle at various sites and terrain conditions was assessed. Vegetation and surface recovery were monitored for up to 4 years in some sites. Percent recovery was quantified based on the impact severity for each measurement date with respect to the initial impact severity. Findings about the recovery can be summarized with the following:

1) The percent recovery and recovery rates varied significantly depending initial disturbance, which is a function of the terrain, ground and soil conditions and maneuver types (number of passes, tracks on turns and straight).

2) Recovery was rapid when the initial disturbance was low during winter with a snow cover on permafrost.

3) A higher rate of recovery was observed on areas with low initial disturbance of less that 50% impact severity.

4) There was very slow recovery after multi-pass trafficking and turns when the trafficking was on sparse vegetation, wet soils, and higher thaw depth areas.

5) The initial disturbance decreases and recovery rates increase with decreasing number of passes.

6) Overall the recovery from the vehicle impact of the Stryker vehicle is very promising as long as the tracks are allowed to heal over time.

Acknowledgments

Funding for the study was provided by the U.S. Army Garrison Alaska Directorate of Public Works and from AT42 High-Performance Ground Platform and Terrain Mechanics Modeling. The authors thank Jerry Reagan of the Cold Region Testing Center and his crew for conducting the Stryker maneuver tests at Donnelly Training Area. Technical support from U.S. Army Alaska staff, including Gary Larsen, Kevin Gardner, and Michael Davis; U.S. Army Alaska, Donnelly Training Area Range Control; and Sarah Brobst was greatly appreciated. We gratefully acknowledge Paul Ayers and Katie Simmons of the University of Tennessee for their technical support. The authors gratefully acknowledge the support provided by ERDC-CRREL staff, including Paul Richmond, Christopher Berini, Garrett Quillia, Maj. Douglas Anderson, the late Judy Strange, and Thomas Douglas.

Abstract

The Barrow Environmental Observatory (BEO) is bounded to the east by the 10.7 km long Elson Lagoon shoreline of the Beaufort Sea. Rates of erosion along the 2 to 4 m high, ice and organic rich permafrost bluffs have been monitored annually at 14 transects since 2002 as part of the Arctic Coastal Dynamics (ACD) program. Continuous, ground-based Differential Global Positioning System (DPGS) surveys were conducted along the entire length of the BEO coastline in 2003, 2006, and 2007. The mean erosion rate during the four-year period was 2.3 m per year. A comparison of fall and summer erosion rates calculated from repeat DGPS surveys indicate similar amounts of erosion during fall 2006 (between August 2006 and June 2007, 8120 m^2) and summer 2007 (between June and August 2007, 7934 m^2). The total area lost to erosion during the four-year period was 9.8 hectares (average 2.5 ha/yr), which is almost twice the rate (1.3 ha/yr) calculated for the period 1979–2000 by previous studies

Keywords: ACD; bathymetry; coastal erosion; DGPS; ground ice; permafrost.

Introduction

Erosion of ice-rich, permafrost coastlines in the Arctic is limited to periods of ice-free seas. The duration and extent of seasonal ice-free seas in the Arctic is increasing (Serreze et al. 2007, Stroeve et al. 2007) and it is predicted that this in combination with increased storminess could increase rates of erosion experienced along arctic coastlines (Atkinson 2005). Increased rates of coastal erosion can impact communities, affect industry, and alter ecosystem structure and function in coastal terrestrial and marine ecosystems. Evidence supporting increased rates of erosion in the Arctic remain relatively scant and until recently the relationship between seasonal and interannual variations in erosion and storminess has been poorly studied. This study, linked to the Arctic Coastal Dynamics (ACD) program, documents the seasonal and interannual variations in coastal erosion along the Elson Lagoon coastline of the Barrow Environmental Observatory (BEO) situated on the Beaufort Sea coast of northern Alaska.

The Elson Lagoon shoreline is an ideal location to observe changing shoreline conditions. Coastal erosion research along this coastline dates back to 1948, is associated with the ACD program, and is situated on the BEO, a 7466 research preserve set aside by local land owners for research. Because of the availability of historical quantitative erosion data, there is potential in creating predictive models for shorelines with similar characteristics. Observing rapid change in high latitude shorelines creates urgency for these models to be developed. Until recently, observations have relied on measurements from sequential, high resolution imagery and repeat line-transect measurements made perpendicular to the coastline. Our additional results reported here are based on repeat, ground-based Differential Global Positioning System (DPGS) surveys that were conducted along the 10.7 kilometer length of the BEO coastline in August of 2003, 2006, and 2007. A similar survey was also conducted in June 2007 to begin to ascertain seasonal variations in the coastal erosion. This paper provides an update from on-going field studies, initial results presented at the eighth international permafrost conference in Zurich (Brown et al. 2003), and observations reported in the proceedings of the Arctic Coastal Dynamics workshops held in 2003 in St. Petersburg and in 2004 in Montreal (Serbin et al. 2004, Francis-Chythlook 2004, 2005, Francis-Chythlook & Brown 2005). Several papers report on regional erosion rates along the Chukchi Sea coast (Sturtevant et al 2005), the entire Beaufort Sea coast (Jorgenson & Brown 2005) and for a section of the Beaufort Sea coastline to the east that is directly exposed to the ocean (Mars & Houseknecht 2007).

The objectives of this continuing ACD project are to improve our understanding of rates and causes of coastal erosion and to assess their contributions to offshore sediment and carbon budgets and the impacts on living resources (Rachold 2004). Like many ACD-affiliated projects, this project also serves as a training ground for a new generation of young researchers and contributes to the International Polar Year and its legacy. Data from this project has been incorporated into the interactive and freely available Barrow Area Information Database-Internet Map Server (www.baidims.org) (Graves et al. 2004).

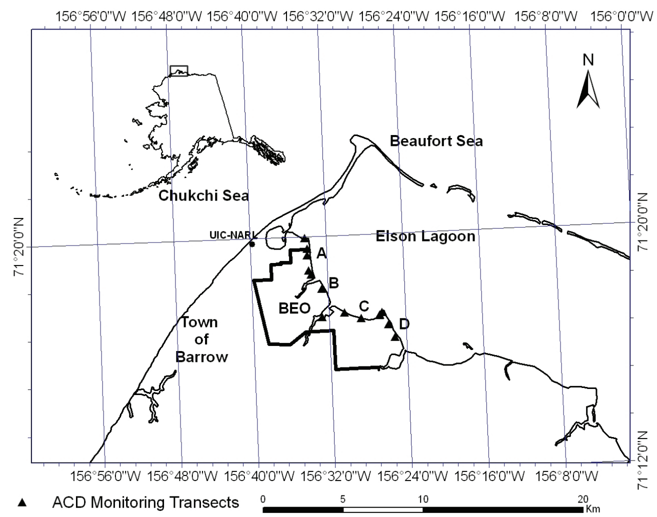

Figure 1. Location of the ACD observatory and key sites on the Elson Lagoon coastline of the BEO near Barrow, Alaska.

Study Area

The Barrow Environmental Observatory (BEO) is bounded on the east by the 10.7 kilometer-long Elson Lagoon shoreline (71°19'53", 156°34'4", Fig. 1). Elevations range from sea level to 4.4 m along this coastal stretch. Terrain is composed of ice wedge polygons, shallow elliptically shaped lakes, drained lake basins, and small ponds (Brown et. al 1980). The area is mainly composed of moist and wet tundra with acidic soils. The ACD observatory on the BEO coastline is divided into four segments with sections A, B, and D facing eastward and section C facing predominantly north. Water depth in Elson Lagoon ranges from 0.5 m to 3.5 m. The lagoon is bounded to the northeast by a series of low elevation barrier islands. Shallow but submerged bars lie at the mouth of most creeks draining from the BEO to Elson Lagoon and a submerged shoal extends northwest from Tekegakrok Point, which marks the junction between Sections C and D of the coastal observatory. Fourteen permanent ACD transect sites are oriented perpendicular to the coastline along the Elson Lagoon coast.

Methods

Field data collection utilized a Trimble NetRS GPS receiver with a Zephyr Geodetic antenna as a fixed Geodetic GPS base station located at the Barrow Arctic Science Consortium (BASC). This base station provides differential correction of data files at 1 second intervals as well as real time correction to field rover GPS units within approximately five kilometers and in line of sight of site of the Trimble HPB450 radio transmitter that is connected to the base station . The base station was upgraded in 2005 from a Trimble GPS 5800, which was used during the 2003 coastal survey described below. The rover system used for 2007 surveys included a Trimble R7 with internal radio that communicated with the base station radio transmitter for real time DGPS correction and a TSC2 survey controller that logged field data. Field surveys in 2003 and 2006 utilized a Trimble 5700 receiver, Zephyr antenna, and a Trimble TSC1 controller. All DGPS equipment was provided by UNAVCO (www.unavco.org) to the local science logistics provider (BASC).

Figure 2. Segment C facing east.

A total of four surveys of the 10.7 kilometer ACD BEO observatory were conducted. These included August 2003, 2006, and 2007 and June 2007. During each survey, field personnel walked along the top of the coastal bluff edge. The initial surveys for the 2003 season were conducted by Serbin et al (2003). In subsequent years surveys were conducted by the lead author of this paper following previously documented survey methodology documented in Serbin et al. (2003). For field surveys, the rover receiver was installed in a standard Trimble backpack configuration with the GPS antenna mounted on the bluff side of the backpack. After antenna height was corrected for the height of the field observer, this configuration allowed for the location of the horizontal and vertical position of the coastal bluff edge to be documented (Fig. 2).

Two survey methods were used. Real Time Kinematic (RTK) surveys were conducted whenever possible. This required a radio link to the base station. RTK surveys allow for instant DGPS processing and the acquisition of centimeter-accuracy horizontal and vertical location data. The second method utilized a Post-Processed Kinematic (PPK) survey style, which did not require a radio link, but instead relied on an unobstructed On-The-Fly (OTF) initialization period and post-survey differential correction with GPS data logged at the base station to provide field survey data with centimeter accuracy. For both survey types, the rover receiver was set to log data at a high resolution of one-second intervals to more accurately delineate the generally irregular coastal bluff edge. Repeat surveys using these vertically and horizontally centimeter-accurate field methods provide a means to accurately monitor the geospatial dynamics of the coastal bluff edge as it changes with coastal erosion.

DGPS survey data was downloaded from the controller and imported into Trimble Geomatic Office Software version 1.63 (TGO). Data was exported in text files suitable for ingestion by ESRI's ArcGIS (Workstation 9.2) Geographic Information System (GIS) software. Data from PPK surveys were processed by downloading base station files that were utilized for differentially correcting data collected by the

rover GPS unit using standard DGPS correction procedures. Processed data were exported as for that of the RTK surveys.

Processed DGPS survey data were imported to ArcGIS as X, Y point data and saved to a point shapefile. Erroneous points that resulted from poor GPS signal when field personnel traversed small coastal gullies were deleted. Using the polyline conversion tool in the ArcGIS extension AlaskaPak Version 2.0 for ArcGIS 9.2, point shapefiles were converted to polyline shapefiles. For each survey, the length of the coastline was computed for each of the four monitoring segments using the attribute data field calculator tool associated with the ArcGIS polyline tool (Table 1). Using the polyline shapefiles as a determinant location of the coastal bluff at each survey time, polygon shapefiles were created to establish the area of coastline lost to erosion for each monitoring segment for the following survey periods: August 2003 to August 2007, August 2003 to August 2006, August 2003 to June 2007, and June to August 2007. The area of each polygon shapefile was computed using the calculate area command from ArcGIS Toolbox. Rates of erosion were calculated for the following five periods by subtracting the total area of a preceding survey period from that of the most recent survey period: August 2003 to August 2007, August 2003 to August 2006, August 2006 to August 2007, August 2006 to June 2007, and June 2007 to August 2007. To enhance inter-comparison of erosion rates between segments of different lengths and different sampling periods, results were normalized by the length of the coastal segment at the earliest survey associated with a given survey period and reduced to a year-long time frame for survey periods spanning the 2003 to 2006 and 2007 periods (Table 4).

The establishment of the 14 coastal erosion monitoring transects (Fig. 1) oriented perpendicular to the coastline has been previously described by Brown et al. (2003). Since 2002, the distance from fixed markers along these linear transects to the coastal bluff and thaw depths have been measured. In 2003, 2006, and 2007, these measurements were made on the same day as the August DGPS surveys. While these survey methods do not permit the geospatial elucidation permissible from the repeat DGPS surveys, they are easy to perform, are part of the long-term ACD monitoring protocol, and are an excellent measurement to cross-check the accuracy of the DGPS surveys.

Results

Table 1 details the length of each coastal segment at each survey time. Section lengths were longest for Segments A and B in 2003 and Segments C and D in 2006. Lengths of the coastal bluff were shortest for Segments A, B, and C in June 2007 and for Segment D in 2003. Segment length is determined by the irregularity of the coastal bluff during each survey time period.

The calculated rates of total loss to erosion are given in Table 2. Overall, 9.8 hectares of tundra were lost to erosion between August 2003 and August 2007. Higher erosion rates were documented for Segments C and D in summer 2007 than in the Fall of 2006. Erosion loss was greatest in Segment D followed by Segments C, A, and B.

Mean annual erosion for all segments except Segment B was greater between 2003 to 2006 than between 2006 and August 2007 (Tables 3, 4). Erosion rates calculated for Segment B were greater between August 2006 and 2007 than during the period 2003 to 2006. Rates of erosion were greater in the Fall of 2006 for Segments A and B than in summer of 2007. As previously reported, Segment D had the highest rate of erosion when normalized by length of

coastline (Table 4). This rate is over three times the rate of loss recorded for the other segments during the period August 2003 and August 2007.

Annual rates of coastal retreat recorded using DGPS methods (Table 4) are similar to those measured using line-transect methods (Table 5).

Discussion

Similar to other studies focused on coastal erosion along Elson Lagoon (Brown et al. 2003, Serbin et al. 2004), this study documents substantial spatial and temporal variability in the rates of erosion. Within the 2003–2007 study period no segment monitored maintained a consistent temporal trend in the rate of erosion measured. Nonetheless, the DGPS study reported above has identified rates of erosion that are comparable to those that have used linear transect methods (Table 5) and GIS interpolation (Brown et al. 2003, Francis-Chythlook & Brown 2005, Serbin et al. 2004). Figure 3 illustrates a section of segment D on 2002 Quickbird panchromatic satellite image (Manley et al. 2005). The location of the coastline identified by DGPS surveys in 2003, 2006, and August 2007 are labeled. Relatively small scale sub decimeter-scale variability in the degree of coastal retreat between sampling periods can be observed. It appears that the variability in the rate of coastal erosion documented in this and other local studies is strongly related to this spatiotemporal heterogeneity.

Seasonally, erosion can begin as soon as the coastal bluffs thaw and Elson Lagoon becomes partially ice-free. This generally occurs around July 11th (Craig George unpublished data). Erosion ceases as bluffs freeze and the lagoon becomes ice covered, which has occurred around the 8th of October since 1988 (Craig George unpublished data). The process of shoreline retreat is enhanced by the undercutting of the coastal bluffs (thermo-erosion notches or niches) and removal by wave action of the slumped and thawed materials that can otherwise protect the coast from additional retreat (Walker 1991). Diurnal tidal movements are not considered to influence erosion in the Barrow area because they approximate only 0.3 m (Beal 1968, Mathews 1970). Brown et al. (2003) suggest the frequency, intensity, and duration of storms, and high water events affect seasonal to multi-decadal rates of retreat, whereas local spatial differences in erosion are generally attributed to the spatial variations in bluff elevation, ice and organic contents of exposed sediments, water depth, and wave fetch (Brown et al. 2003).

To better understand factors controlling the spatiotemporal variability in the patterns of coastal erosion along the Elson Lagoon coastline, a more thorough analysis of the interplay between the spatiotemporal dynamics of coastal erosion and other physical and climatic factors needs to be considered. These include the density of polygons and ice wedges, differences in land cover types, soil characteristics, and the elevation of the eroding coastline. The orientation of the coastline, offshore bathymetry, and the timing of freezing and thawing of the bluff, degree of storminess within a given sampling period are also important. These considerations fall beyond the scope of the current work, which is focused on updating the ACD time series for this section of coastline, but will be explored in a graduate thesis currently being developed by the lead author of this paper. Variations in seasonal soil thaw depths do not appear to play a role in erosion as regional thaw depths have been relatively consistent during the sample period (Nelson et al. 2008).

The DGPS survey method employed for this study demonstrates a potentially excellent method for further understanding how small-scale processes may control coastal erosion. Compared to line transect methods and GIS analysis, DGPS methods permit a greater consistency of measurement along the coast, provide better documentation of coastal shapes, provide more accurate and detailed products, and permit potentially more accurate volumetric calculations of erosion loss. DGPS surveys also appear to be more cost-effective than the acquisition and georectification of aerial or satellite imagery for the study area. The acquisition of imagery is costly and can be difficult to obtain due to the cloudy conditions that prevail during the arctic summer period. Nonetheless, DGPS surveys can be time consuming, require advanced training, and need to be performed at a relatively high frequency (at least twice in the summer, snow-free period) in order to best understand how climate and sea-state controls the seasonal and spatial dynamics of erosion. Products obtained from DGPS surveys are also particularly well suited to the development of process models that may help to predict future erosion patterns in the Barrow area and elsewhere along the arctic coastlines.

Conclusion

Erosion rates along the Elson Lagoon coastline of the Barrow Environmental Observatory in northern Alaska, continue to be monitored as key contributions to the Arctic Coastal Dynamics Program, the International Polar Year, and a sustainable Arctic Observing Network. The Differential Global Positioning Systems approach employed provides a high-accuracy method to track coastline changes and to compute area and potentially volumetric losses due to erosion. The rates of coastal erosion documented in this study, like others in the Barrow area, confirm highly variable rates over time and space. Mean annual rates of erosion documented in this study are consistent with earlier reports, which further support the use of DGPS to monitor coastlines. Similar to Brown et al. 2003, who reported erosion rates between 1948–1949 and 1962–1964 we continue to document erosions rates for the Elson Lagoon between 1–3 m/yr. With the application of DGPS, however, we believe we can better determine where the higher erosion rates along this coastline are occurring and explore further questions such as why some areas are more vulnerable than others. We are currently evaluating the USGS Digital Shoreline Analysis System (DSAS) extension tool for ArcGIS to automate and standardize future analysis. Further research is needed to better affirm the primary controls of coastal erosion along this and similar sections of arctic coastline. This paper is a contribution to the International Polar Year (Project 90) by a member (lead author) of the Permafrost Young Researchers Network (PYRN).

Acknowledgments

The land occupied by the Barrow Environmental Observatory is owned by the Ukpeagvik Iñupiat Corporation (UIC) and has been designated for research and long-term observations. The Barrow Arctic Science Consortium (BASC), a non-profit organization dedicated to scientist/community collaboration, was designated by UIC to manage the BEO with support from the U.S. National Science Foundation (NSF). We are grateful to both UIC and BASC for the opportunity to establish and maintain our sites. NSF grants OPP9906692 and OPP0454996 (BAID) provided support. We also express appreciation to several undergraduate and graduate participants who assisted the authors in the field and with GIS support (Shawn Serbin, David Zaks, Eric Hammerbacher, Edith Jaurrieta Amorita Armendariz, Paulo Olivas, Ryan Cody, Rob Wielder, Sandra Villarreal, Santonu Goswami, and G. Walker Johnson). UNAVCO has generously provided DGPS support and training to field parties since 2002. Pore Water and Effective Pressure in the Frozen Fringe During Soil Freezing

Satoshi Akagawa

Abstract

A model pipe (75 mm diameter, 29.5 mm length) is placed in NSF clay. Thin thermocouples attached to pressure gauges and markers monitor temperature. Five pressure gauges are placed along the pipe centerline and below the pipe: three in the vertical/radial direction, and two in the horizontal/hoop direction. As the frost bulb grows, the pipe moves up by 29 mm. Markers move away along the direction of heat flow during the early stage, but move upward with the model pipe once contained within the frost bulb. The pore-water pressure depresses in a temperature range corresponding to that of the frozen fringe. As the pore-water pressure depression reaches 35 kPa, the temperature is lowered by about 0.12°C. The effective pressure in the frozen fringe increases as temperature decreases, with the magnitude in the radial direction twice that in the hoop direction. The decrease of pore-water pressure is considered the driving force for ice lens formation, and the increase of effective pressure is the driving force for soil consolidation in the frozen fringe.

Keywords: effective pressure; frost heave mechanism; frozen fringe; unfrozen pore-water pressure.

Introduction

The subject of frost heave mechanism has been discussed and studied for a long time, yet it still attracts the attentions of scientists in the 21st century. Several models of the frost heave mechanism were proposed in the 1970s and 1980s (Miller 1978, Gilpin 1980, Takagi 1980), but they have not yet been verified empirically. The authors have attempted to verify those frost heave models empirically, and present results of the lab experiment in this paper.

Taber (1929) foresaw pore-water pressure depression in front of the segregating ice lens. Chamberlain and Gow (1978) speculated that the high consolidation of thawed sub-sea permafrost was due to the pore-water pressure depression as the ground became frozen. Gilpin (1980) and Miller (1978) proposed their frost heave models, and mentioned that the pore-water pressure depression in frozen fringe was the driving force sucking the water to the segregating ice lens. Akagawa (1988) observed consolidation in the frozen fringe during frost heaving with X-ray radiography technology and concluded that the consolidation was caused by pore-water pressure depression at the segregating ice lens.

Direct measurement of the pore-water pressure depression in the frozen fringe was first made by Radd and Oertle (1973) but was under closed system frost heave tests. Miyata and Akagawa (1998) tried to measure unfrozen pore-water pressure at the segregating ice lens in open system frost heave tests and concluded that the pore-water pressure depression was one-half of the value given by Generalized-Clausius-Clapeyron-Equation.

Despite intensive efforts taken to reveal the pore-water pressure depression at the segregating ice lens experimentally, none of them have received wide acceptance so far.

In this paper the total pressure and pore-water pressure in soil are presented. The pressure changes were monitored with frost heave tests in a 2D model. The relationship between the pressure measurements and the pressures depression in frozen fringe is discussed.

Experiment

Test apparatus and thermal condition

The experiment was conducted with an insulated soil box as shown in Figure 1 that was placed in a cold room in which temperature was maintained at 1.50 ± 0.5°C.

The box has inner dimensions of 500 mm in height, 500 mm in width, and 300 mm in depth. Two sides, the rear, and the bottom of the container were thermally insulated with Expanded Poly-Styrene. The front was covered with double Plexiglas to provide transparency and thermal insulation. The top side of the box was open to the air.

The experiment was initiated by circulating -10°C coolant as “thermal-shock,” and then the temperature was warmed to and kept at -4°C.

Monitored items and methods

During the experiment total pressure, pore-water pressure, soil deformation, and temperature of the model ground were monitored.

The total pressure gauge is 23 mm in diameter and 5 mm

Figure 4. Total pressure gauge calibration.

in thickness, and the pore-water pressure gauge is 15 mm in diameter and 15 mm in thickness, as shown in Figure 2. The capacity of both types of transducers is 100 kPa.

Soil deformation was monitored with markers, which were placed between the front Plexiglas and test soil with a coating of grease to reduce the friction, as shown in Figure 3.

All the total pressure gauges were calibrated with the apparatus shown in Figure 4. One of the typical results obtained is shown in Figure 5. According to the calibration, the linearity of loading and unloading processes is considerably good, but it has hysteresis in loading and unloading.

Because the size of the experiment box was not large enough to utilize common thermocouples, the authors have used thin thermocouples, such as Omega TT-T-36, instead. Thin thermocouples, were attached to the pressure gauges and 20 of the markers as shown in Figures 2 and 3, in order to monitor the gauge and marker temperatures and to ensure the proper distance between the gauges and the cooling model pipe.

The temperature measurement method utilized in the experiment was traditional as shown in the Figure 6. However, the authors have confirmed the absolute accuracy of $\pm$ 0.02°C with this method by traceability.

The gauges and markers, with attached thermocouples, were placed in the model soil as shown in Figure 7.

In the vertical direction, five total pressure gauges were placed. Three of them were for vertical or radial total pressure, and the remaining two were for total pressure in horizontal or hoop direction. At about 12.5 mm below the model pipe, two total pressure gauges for radial and hoop direction and one pore-water pressure gauge were placed.

In the following sections, data obtained with these three groups of gauges are discussed.

Soil used and its preparation

Soil utilized in this experiment is commonly known as NSF clay with mineral composition of Pyrophyllite. This clay has relatively high frost heave susceptibility.

NSF clay powder was first mixed with distilled water with water content 1.5 times its liquid limit. It was then poured into the soil box in layers of 5 cm thick, and finally consolidated by dead weights with 10 kPa pressure. The front views of the

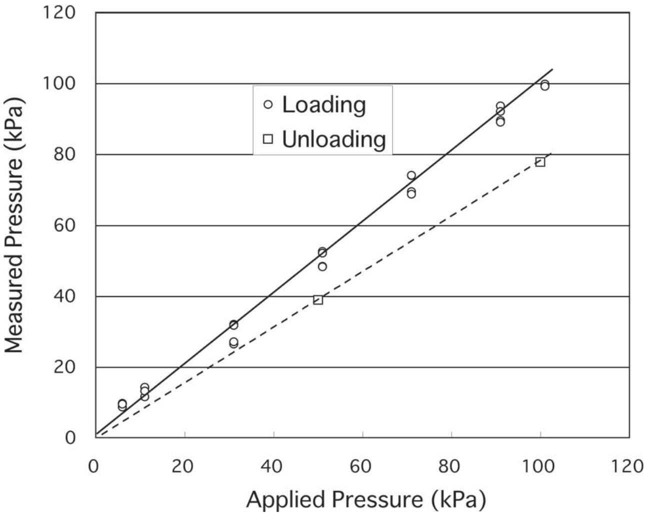

Figure 5. Typical calibration result of the total pressure gauge.

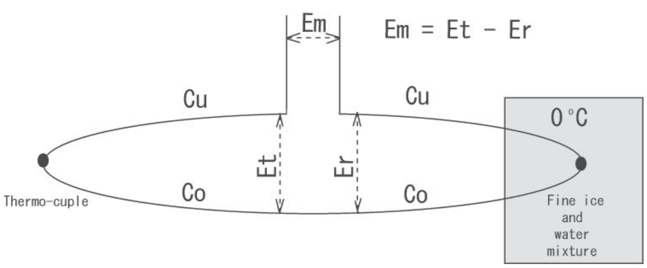

Figure 6. Thermocouple wiring.

soil box right after filling and at the end of consolidation are shown in Figure 8.

The consolidation behavior of NSF clay is shown in Figure 9. According to the e-log *P* relationship, the model soil made of NSF clay is normally consolidated and may cause a considerable amount of consolidation in frozen fringe when it freezes.

Thermal two-dimensionality

Prior to the main experiment the authors conducted a freezing test using agar instead of soil. Through this test we could verify the thermal dimensionality in 2D by checking the shape of the cylindrical frozen agar, which mimics growth of the "frost bulb" by a buried chilled gas pipeline in the arctic regions. As shown in Figure 10, the frost bulb is laterally symmetrical, and the lateral thermal two-dimensionality is presumed satisfied. In addition, the diameter of the frost bulb is almost the same in the middle and the rear end; the two-dimensionality in the pipe direction is considered satisfied for the rear half.

Test Results

Frost bulb growth

The frost bulb growth in elapsed time is shown in Figure 11. As time elapses, the diameter of the frost bulb is getting larger.

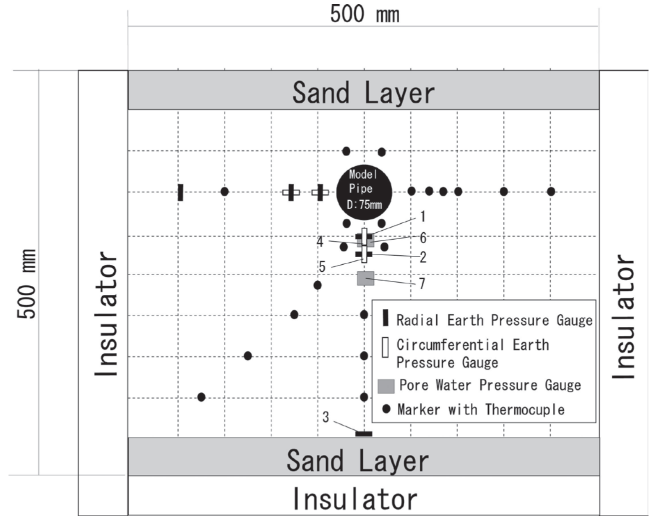

Figure 7. Locations of installed gauges and markers.

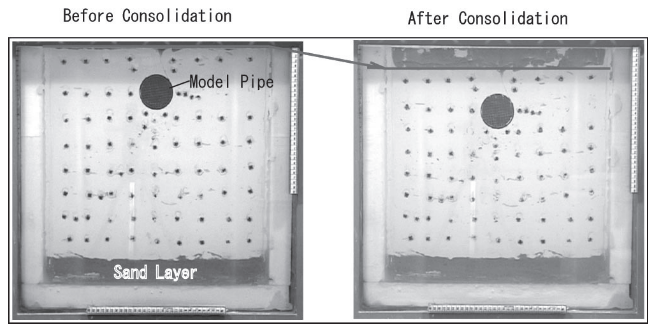

Figure 8. Initial and final condition of pre-consolidation at 10kPa pressure.

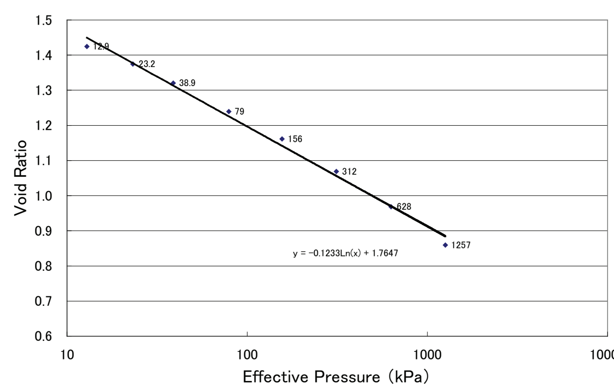

Figure 9. Consolidation behavior of saturated NSF model soil.

Upward movement of model pipe

Analyzing (x, y) coordinates of the markers, which were originally placed at the grid centers with 50 mm spacing on the front Plexiglas, 2D deformations of the model soil were recorded and are shown in Figure 12. As the frost bulb becomes larger, the model pipe is pushed up by 29 mm vertically, as shown in the figure. The movement of the markers during the experiment is also shown in the figure. Before the markers were enclosed by the growing frost bulb, they moved away along the direction of heat flow. However, as the markers were within the frost bulb, they moved upward with the model pipe.

Monitored total and pore-water pressures

Three radial total pressures monitored with gauges Number 1–3, which were placed along the vertical pipe centerline are shown in Figure 13. The most adjacent gauge to the model pipe, Number 1, was captured by the frozen fringe at about 40 hours. This was recognized by its temperature shown in the figure. The frost bulb, however, did not enclose the other two gauges, Numbers 2 and 3, during the experiment. It is clearly shown in the figure that the radial total pressure rapidly increases when its temperature drops slightly below 0°C. It reaches a maximum pressure at about 60 hours, and then starts to decrease as the temperature approaches -0.2°C. Since this temperature range corresponds to that of a frozen fringe, the radial total pressure is presumed to have a sharp increase in frozen fringe and to decline in the much colder frozen portion in axial-symmetric freezing.

Two hoop total pressures, monitored with gauges Numbers 4 and 5, which were arrayed along the vertical pipe centerline, are shown in Figure 14. The frozen fringe captures the gauge next to the model pipe, Number 4, at about 40 hours. Similar to gauge Number 1, this is determined by its temperature at 0°C, as shown in the figure. Gauge Number 5 was not included in the frost bulb during the experiment.

A sharp increase of the hoop total pressure as its temperature dropped below 0°C was not seen in this case. However, a clear increase of the hoop total pressure was recorded after the gauge temperature fell below about -0.2°C, and it continued until the end of the experiment.

According to the data mentioned above, the hoop total pressure did not seem to change in the frozen fringe. Instead, it increased as the temperature dropped in the frozen soil.

Two pore-water pressures monitored with gauges Numbers 6 and 7, which also were placed along the vertical

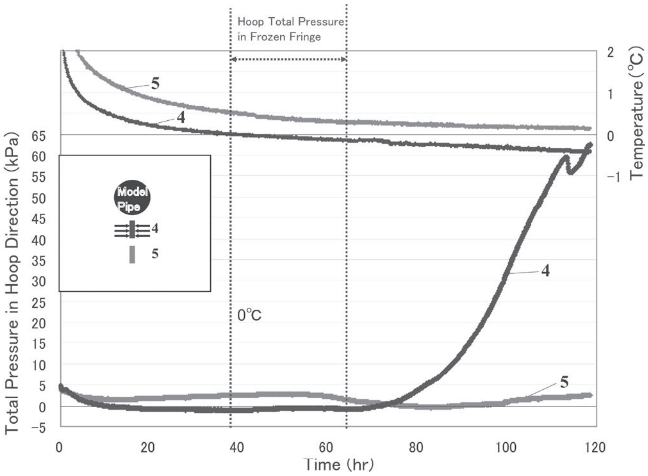

Figure 14. Hoop total pressure below model pipe.

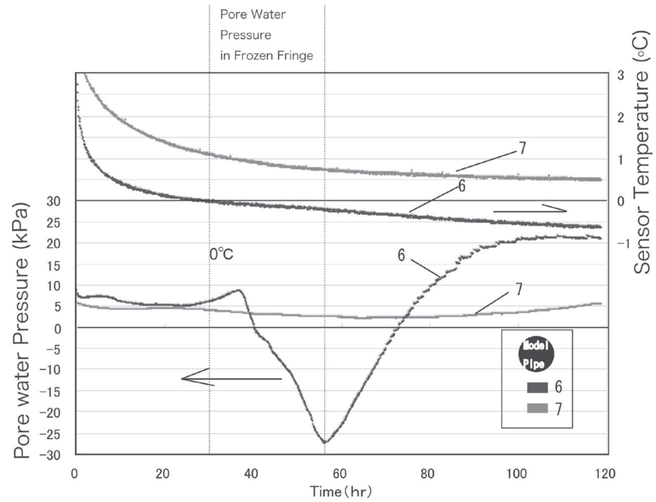

Figure 15. Pore-water pressure below model pipe.

pipe centerline, are shown in Figure 15. The most adjacent gauge to the model pipe, Number 6, was captured by the frozen fringe at about 40 hours. This is recognized by its temperature shown in the figure. Gauge Number 7 was not captured by the frost bulb during the experiment. It is clearly seen in the figure that the pore-water pressure, or unfrozen water pressure, in the frozen fringe sharply decreases when its temperature drops below 0°C and then starts to increase at about -0.2°C.

Discussion

Pore-water pressure in frozen fringe

As is clearly shown in Figure 15, the pore-water pressure depresses in a temperature range corresponding to that of the frozen fringe. Therefore, it infers that the unfrozen water pressure in the frozen fringe decreases as the local soil temperature becomes lower. During the period the unfrozen water pressure depression reached 35 kPa, temperature of the pressure gauge was lowered by about 0.12°C. This relationship between unfrozen water pressure and temperature seems not in good agreement with Generalized-Clausius-Clapeyron-Equation. However, if a certain amount of ice pressure is generated in the frozen fringe, it might likely agree with Generalized-Clausius-Clapeyron–Equation.

Effective pressure in the frozen fringe

The effective pressures in the radial and hoop directions calculated with the measured total soil and pore-water pressures are shown in Figure 16. As is clearly seen in the figure, the effective pressure in the frozen fringe increases as its temperature decreases. However, the magnitude of the effective pressure in the radial direction is about twice of that in the hoop direction.

Another noteworthy trend seen in the figure is that the effective pressure in the hoop direction after 90 hours, which corresponds to a well-frozen soil, continues to increase as time elapses and temperature becomes lower, whereas the effective pressure in the radial direction continues the decreasing trend.

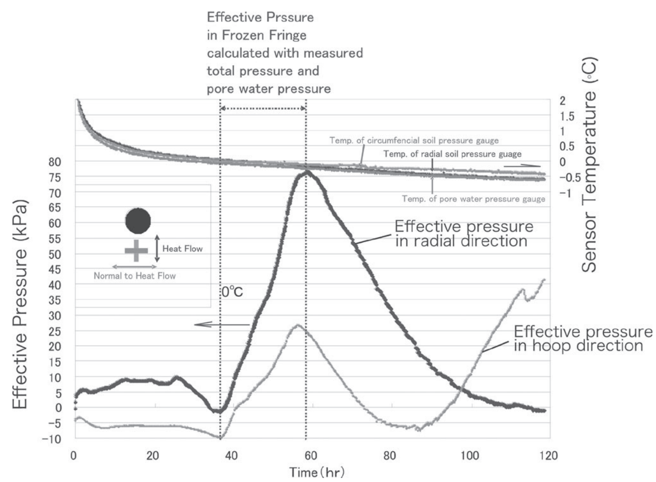

Figure 16. Effective pressures in radial and hoop directions in the frozen fringe.

Conclusions

Total pressure and pore-water pressure were directly measured in freezing soil during the 2D-model chilled gas pipeline experiments.

Because many features, such as frost bulb growth and upward movement of the model pipe, agreed well with the field experiment (Huang et al 2004), the observed pressures seem to be an indication of the real phenomena in freezing ground.

A significant finding from this experiment is that the pore-water pressure gauge has measured a clear pressure depression while it was in the frozen fringe. In addition, the effective pressures in the radial and hoop directions, which were calculated with the total pressure and pore-water pressure, showed steep increases in the frozen fringe.

The decrease of pore-water pressure was considered the driving force for ice lens formation, and the increase of the effective pressure was the driving force for consolidation in the frozen fringe.

Coastal Processes and Their Influence Upon Discharge Characteristics of the Strokdammane Plain, West Spitsbergen, Svalbard

H. Jonas Akerman
Department of Physical Geography and Ecosystems Analysis, Lund University, Sweden

Abstract

Changes in Arctic sea ice conditions have affected conditions ashore along the west coast of Svalbard. Effects upon the discharge characteristics of a drainage basin close to the seashore are discussed. The area studied lies on the strandflat plain, south of Kapp Linné (78°04′N, 13°38′E). The anomalous discharge pattern of the Fyrsjöen Lake catchment area is described. Some years the outlet is blocked by ice-cemented storm ridges, delaying the spring peak flow several weeks and raising the lake level dramatically. Vast areas are flooded, affecting snowmelt, vegetation, and breeding birds of the area. The lake is then tapped during a few days with heavy flow, after which the discharge pattern returns to normal. This process is not unique, but rather common along the west coast of Spitsbergen. The special hydrographic and discharge conditions have an influence on the active layer, the permafrost, the vegetation, and the bird colonies of the area.

Keywords: arctic ecology; arctic sea ice; breeding birds; costal processes; polar hydrology; Svalbard.

Introduction

Sea ice is regarded as a key indicator and vital factor of climate change processes and has received much attention owing to the apparent reduction in coverage in the Arctic Sea (Parkinson et al. 1999, IPCC 2001, ACIA 2004). Since the potential impacts of these changes on climate, ecosystems, and lithosphere processes are great, sea ice is an important variable in any study of Arctic environmental change. The reduction in sea ice over the past several decades varies by region and season (Johannessen et al. 1995, 1999, Serreze et al. 2000, Serreze et al. 2003). The decrease in sea ice extent on the west coast of Svalbard is consistent with the general regional observations (Vinje 1976, 2001a, 2001b), and the periods with ice-free conditions have increased substantially. This has affected the hydrological and ecological environment of the Fyrsjöen catchment, which lies within an area where periglacial studies have been performed 1972–2004 (Åkerman 1980, 1992, 2005). Hydrological effects upon the active layer, river discharge, water balance, and the breeding birds also were monitored as a subproject.

A special focus has been directed toward changes in extreme runoff and floods that are likely to affect the depth of the active layer and the stability of the permafrost. This may lead to thermokarst processes and alter biological production and biodiversity within catchments near the coast. The status of ponds and wetlands, for which water levels are critical, determines whether these wetlands will become sources or sinks of CO_2 and CH_4.

Investigation Area

The investigation area is situated on the southern shore of the westernmost part of Isfjorden, central Spitsbergen (Fig. 1). The central west coast of Spitsbergen lies on the periphery of the extreme arctic zone. The moderating influence of the North Atlantic Ocean reduces temperature extremes and

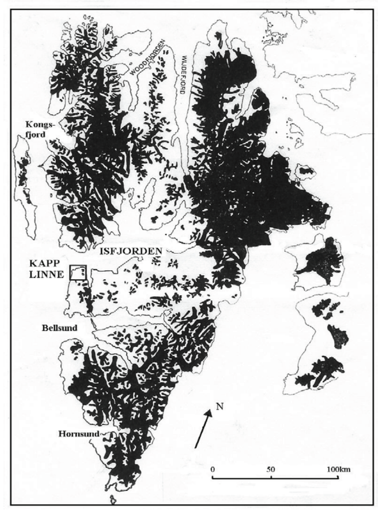

Figure 1. Svalbard and Spitsbergen with its glacial cover in black. The investigation area is indicated by a square

also brings more precipitation than is experienced at similar latitudes (Førland et al. 1997, Humlum 2002, Humlum et al. 2003).

The position on the border between maritime arctic and more continental arctic conditions explains the very great local climatic variations in Spitsbergen (Førland et al. 1997, Humlum et al. 2003). This is important for the interpretation of geomorphological and hydrological processes in an area with very few weather stations. The investigation area, however, offers the advantage of a permanent weather station situated not more than 6 km from the most distant monitoring site. The basic meteorological and climatological data have been obtained from this station.

The MAAT in the study area is -4.6°C, as measured at Isfjord Radio Station for the period 1935–1976 (Steffensen 1969, 1982, Førland et al. 1997 (Table 1). The estimated value for the normal period 1961–90 is -5.1°C (Førland et al 1997). The mean annual precipitation is 435 mm for the post-war period 1951–1975 (Steffensen 1982), and 443 mm during the full official record period (1935–1976), with a data gap during the war 1941–46. The estimated value for the normal period 1961–90 is 480 mm (Førland et al. 1997).

The official weather station was terminated in summer 1976, but an automatic station was established in 1996. After the termination of the official station in 1976, the author continued measurements of metrological and hydrological data within the study and catchment area. The records are covering the period up to 2003 with only minor gaps in the air temperature measurements. Unfortunately, there are long gaps in the measurements of precipitation. The annual course of air temperature and precipitation for Isfjord Radio are given as monthly means in Table 1 (c.f. also Akerman 1980, pp. 14-45, and Steffensen 1969, 1982, Førland et al 1997, Akerman 2005).

Objectives

The main objectives of this study are:

- To describe some of the hydrographical characteristics of the Fyrsjöen Lake catchment area.
- To give a simple description of the water balance of the catchment area.
- Describe how the blocking storm ridges are affecting the discharge pattern and the flooding of the catchment area.
- Illustrate how the flooding has affected the active layer in a small bog within the catchment.
- Investigate how the years of flooding have affected the breeding birds within the catchment.

Methods

Meteorological data have been obtained from the weather station at the nearby Kapp Linné station (Isfjord Radio). Additional precipitation data have been collected within the catchment during intensive study periods by the use of standard pluviometers and collectors. Winter precipitation and the effect of drifting snow (import to the catchment) have been studied through detailed snow surveys in late winters. The discharge in the outlet river needed different techniques during the violent peak flow and gentle normal flow. Water level has been measured with a fixed level gauge plus a recording level gauge put on the only rock outcrop along the short river. Propeller-type current meters applied in a simple traverse cableway have measured water speed during medium and peak flow. At lower flows, the water speed had to be measured with floats.

The highly variable cross-sectional area has been mapped every year or upon demand after "dam break flow" events (Pritchard & Hogg 2002). The dam break flow has here also been named "flush flow" in accordance with the terminology used for quick initial discharge in urban catchments. (Bertrand et al. 2002). Measurements started the first week of June and ended the first week of September. Hardly any flow was missed in May, but some years, flow in September has been missed.

Table 1. Official monthly and annual air temperature (°C) and precipitation (mm) (1935–1975) for Isfjord Radio. Data from Norsk Meteorlogisk Institutt, Oslo, Norway (Steffensen 1982).

Month	Temp °C	Precipitation (mm)
Jan	-10.7	37
Feb	-11.5	34
March	-12.2	34
April	-9.3	24
May	-3.3	25
June	+1.7	28
July	+4.7	38
August	+4.3	53
September	+1.1	47
October	-3.2	44
November	-6.8	40
December	-8.9	39
Annual	-4.6	443

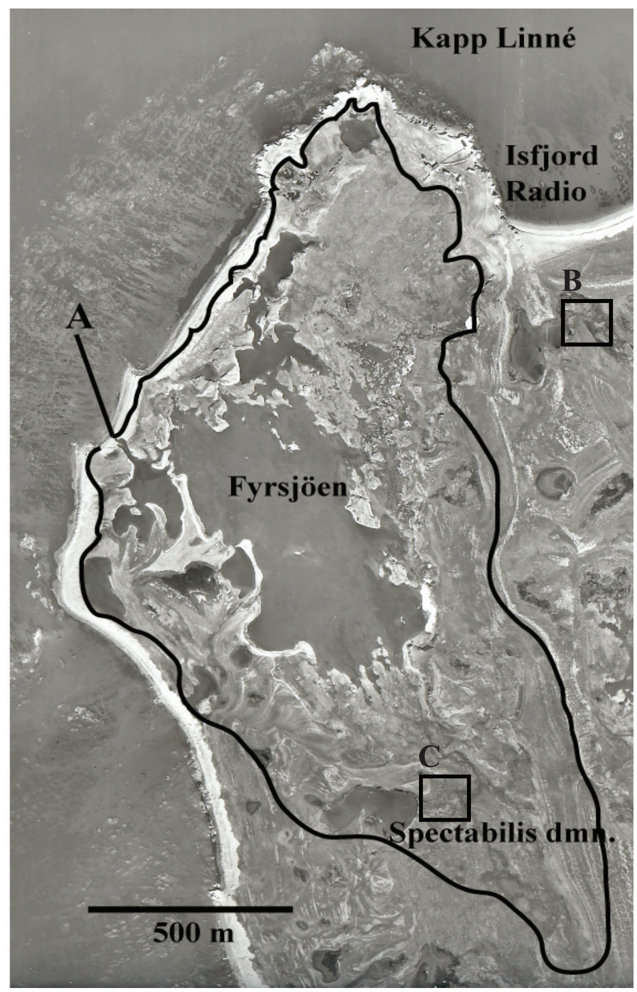

Figure 2. The Fyrsjöen catchment area. *A* indicates the short outlet river through the storm ridges; *B* shows the IPA active layer monitoring site AL3; and *C* is the active layer monitoring site next to the "Spectabilis" pond. (Aerial photograph; Norwegian Polar Institute, No. S69 2431, August 19, 1969.)

The active layer measurements followed the IPA methodology, but here only within a 20 x 40 m area (Brown et al. 2000). Readings were taken the last week of August. The nearest IPA standard site is 1.5 km away.

The breeding success and failure is based upon a nest inventory within the catchment prior to flooding events. This inventory has only been performed along the easily accessible bogs and shores and not upon the islands of the Fyrsjöen Lake. The post-flooding inventory was based upon the position of nests plotted on the 1:7000 topographical map in relation to the maximum water level (Akerman 1980). This makes the result of this part of the investigation relative only, but for the species studied it makes only a minor difference to the result.

Observations

Discharge and water balance

The annual course of flow in the catchment follows a characteristic pattern. In a normal year, the flow in June starts gradually along with the onset of the snowmelt. The catchment has no connection with higher levels (the water divide is 12–14 m. a. s. l.), nor has it connection with any glacier. The June part of the annual discharge is, as a mean, 16.1% (Figs. 3, 4), while July has 64.6%, August 19.2%, and September, only 0.01%. During flooding years, the dam breaks through, and flow normally does not start until July, giving July 77.7%, August 21.9%, and September 0.4% of the annual discharge. The low amounts in September are mainly explained by the fact that the catchment receives no contribution from meltwater from a glacier (cf. Killingtveit et al. 2003). The September precipitation and the active layer discharge flow are quantitatively of little importance. Typical daily discharge graphs are shown in Figure 5.

Despite some clear shortcomings in the measurements and gaps in the background meteorological data, an attempt to illustrate the water balance of the catchment has been performed. A common formula of the common water balance equation can be:

$$P - Q_{river} - Q_{ground} - ET \pm \Delta S = \epsilon \qquad (1)$$

where P is precipitation, Q_{river} is the river discharge, Q_{ground} is the groundwater discharge, ET is the evapotranspiration, ΔS is the storage changes, and ϵ is the error, all expressed in mm water. The error should end up close to 0 if all variables are measured correctly.

In this case the groundwater discharge can be ignored as we, as far as known, have permafrost in the entire catchment. There might be some uncertainties as we are close to the sea and the Lake itself might have some groundwater leakages. There is also a small karst sinkhole within the catchment, but this is, as far as can be judged, of minor quantitative importance.

Regarding evapotranspiration, the figure 80 mm/yr, used by Killingtveit et al. (2003), has been adopted. The storage component S is considered to be constant, as the water level in the lake at the end of the drainage season is down to a

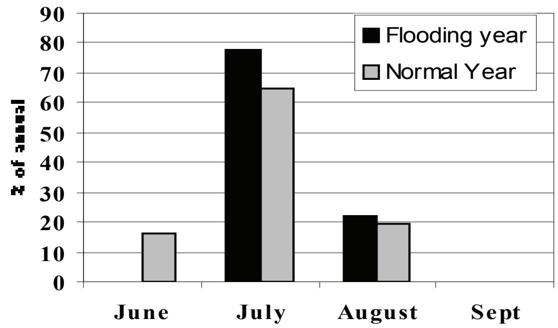

Figure 3. Runoff in the Fyrsjöen Lake catchment per month in % of the total 1974–2001. Note that September might be too low, as measurements some years could not be continued into this month.

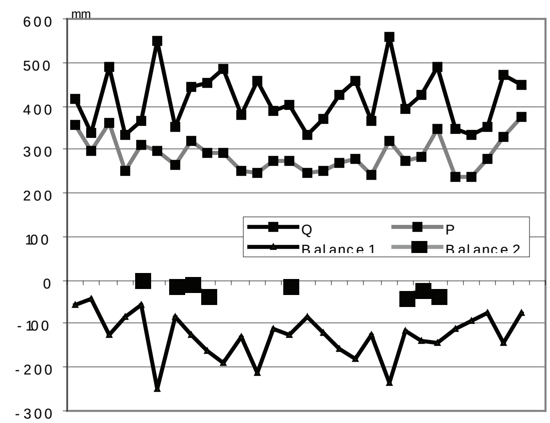

Figure 4. Runoff, precipitation, and hydrological balance for the Fyrsjöen Lake catchment area during the hydrological years (Sept–Aug) 1973/74 to 1999/2000. Q = discharge, P = precipitation-ET, water balance 1 = P–Q, and balance 2 = corrected water balance (considering the snow drift import) in mm during the hydrological years (Sept–Aug) 1974/75 to 1999/2000.

constant level with only marginal variations from year to year. Considering the annual budget, other storage components in this catchment are also of minor importance.

The discharge characteristic of the Fyrsjöen Lake catchment is shown in Figures 4 and 5 and Table 2, in which simple water balance figures are given also. The balance for each and every hydrological year is found negative—on an average -127 mm. The reasons for this lies partly in the precipitation or discharge figures, which may have some errors built in. But there is one factor not considered which became evident during the snow cover surveys within the catchment. Snow cover surveys have been performed in late winter during 8 different years.

The results are given in Figure 4 and Table 2. We find that the catchments contain on an average 100 mm more water equivalents than the winter precipitation measured indicates. The reason for this is the large amount of drifting snow that is accumulated in drifts mainly along the eastern "slopes" of the basin. The shallow basin gets a "precipitation import" through snowdrift mainly from the prevailing easterly winter winds.

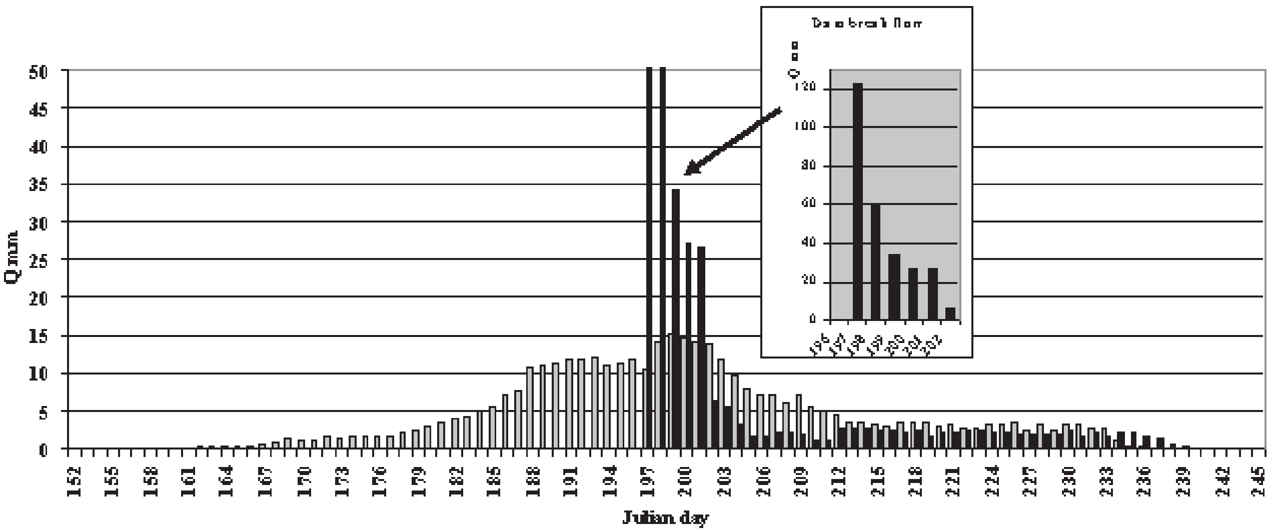

Figure 5. Daily discharge in the Fyrsjöen Lake outlet channel during a "normal" year—in this case 1995 (grey bars)—and a "flooding" year—in this case 1994 (black bars). A "flooding year "is a year with less sea ice and hence unprotected shores along which high blocking storm ridges are formed. Note that the discharge scale for the dam break flow days is different, with up to 120 mm the first day of the "flush."

Storm ridges

The storm ridges that are the cause of the blocked and delayed drainage of Fyrsjöen Lake are built up by the autumn and winter storms. These types of ridges have been observed in the mapping of the Svalbard coasts (Etzelmüller et al. 2003) and are by no means unique. In the coastal geomorphological mapping of Svalbard, they are classified as barriers (Ødegård et al. 1987, Høgvard & Sollid 1988). What is notable is that they now are formed almost every winter as a result of less sea ice along the coast (Fig. 6). Despite that this is indirect observation, they correspond well with the regional sea ice dynamics observed and monitored through RS (e.g., Vinje 1976, 2001, Shapiro et al. 2003).

The barriers vary in height according to the site, but in general they reach between 4 and 6 m above mean seawater level. They are built by coarse beach gravel, sand, and cobbles, typically with a large amount of seaweeds (kelp) mixed in and/or as a cover. In the frozen state, the ridges are like a concrete wall very resistant to melting. During melting, thermokarst features like collapsed thermokarst dolines appear in the surface, and some piping with a low amount of seepage may also occur. This seepage has not been measured, but is of minor importance.

Active layer

The active layer measured in the small bog next to the "Spectabilis dammen" pond follows the same general pattern as the active layer in the IPA bog site some 1.5 km to the north. The small "Spectabilis dammen" bog belongs to one of the bogs and other areas within the catchment that are flooded for years with a blocking storm ridge. The active layer during the investigation period is shown in Figure 7. The two bogs, which apart from size are as similar as can be, show the same general pattern regarding the active layer; that is, a gradual shallower active layer during the period 1972 to the mid-1980s, followed by an equally clear trend of increasing active layer depths. This pattern goes in perfect correspondence with the summer temperature DDT (degree days thaw) that is included in the figure.

However, if we separate the "normal years" and the "flooding years," we find that the "Spectabilis" bog has a deeper active layer (on an average 7 cm deeper) during a flooding year. This clearly indicates the importance of flooding also for the processes in the active layer and the top of the permafrost.

Table 2. Corrected hydrological balance for the Fyrsjöen Lake catchment area based upon snow surveys.

Hy.year	Vinter P mm	Balance mm	Snow in mm	Diff. mm	Corr. Balance
1977/78	267	-55	326	59	4
1979/80	292	-86	368	76	-10
1980/81	261	-123	378	117	-6
1981/82	304	-161	429	125	-36
1986/87	278	-125	391	113	-12
1993/94	298	-119	379	81	-38
1994/95	282	-141	402	120	-21
1995/96	287	-142	397	110	-32

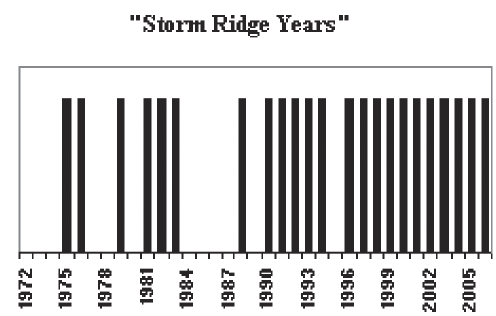

Figure 6. Years with and without larger storm ridges blocking the outlet river from the Fyrsjöen Lake catchment.

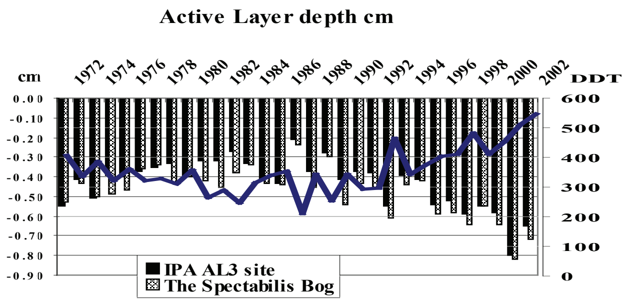

Figure 7. The active layer and the summer climate expressed in DDT (degree days thaw) 1972 to 2002 in the IPA monitoring site AL3 and in the "Spectabilis Bog."

Table 3. Breeding failure during a flooding year (1994) for seven regular breeding species within the Fyrsjöen catchment area.

Species	Nests/Failure	%
Stercorarius parasiticus	1/1	100
Sterna paradisea	26/5	21
Phalaropus fulicarius	6/3	50
Calidris maritima	3/2	66
Somateria molissima	26/5	21
Somateria spectabilis	10/4	40
Gavia stellata	2/2	100

Breeding birds

The breeding birds of the catchment area that have been monitored are shown in Table 3. We find that the Red-throated Diver (*G. stellata*) and the Arctic Skua (*S. parasiticus*) are the species strongest influenced in this case; but the Grey Phalarope (*P. fulicarius*), the less common King Eider (*S. spectabilis*), and the Purple Sandpiper (*C. maritima*) may also locally suffer a loss of 40 to 60% due to the flooding here.

This is, of course, only a very marginal loss considering the total population of these species along the coasts of Svalbard, but considering that this scenario is a trend that prevails, it might be of importance (Fig. 8).

Discussion

Changes in the duration of the open-water season will be critical to the future impacts of coastal and near-coastal processes and environments in the Arctic. An increasing storm frequency and sea level rise are the most well-known possible consequences of climate change, and the fate of sea ice may be equally or more important to natural and human coastal systems (Kerr 2002).

The stability of any coast is a function of the interaction between meteorological and oceanographic forces and the physical properties of coastal materials. The interaction between the atmosphere and the ocean that produces waves and storm surges is mediated by the presence and concentration of sea ice, while coastal materials are either strengthened or destabilized by the presence of permafrost, the abundance of ground ice, and associated temperature regimes (Are 1988; Kobayashi et al., 1999).

Coastal wetlands are likely to move farther inland, and

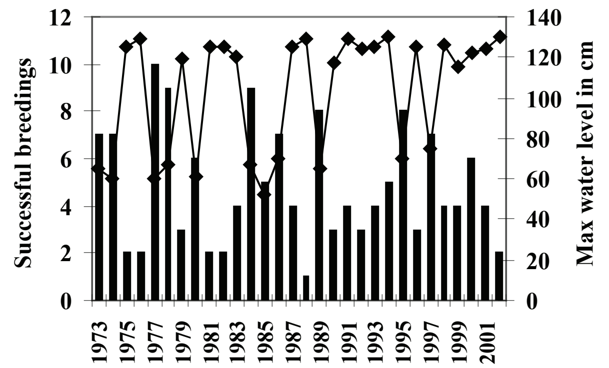

Figure 8. Successfully breeding pairs of King Eider in the Fyrsjöen catchment (bars) compared with the annual maximum water level above mean in cm.

Table 4. Line of observed related "events" from the global scale down to the species level.

A changing climate – a warmer Arctic
Less sea ice
Unprotected shores during winter storms
High ice-cemented storm ridges
Blocked river outlets
Blocked/delayed spring discharges
Anomalous drainage pattern
Flooding of floodplains, lakes, and bogs
Deepening of active layers
Changes in greenhouse gas exchanges
Disturbed plant communities
Breeding failures with birds

coastal flood events will increase. Salinity might increase in coastal marine ecosystems that are now freshened by terrestrial water discharge. If storm surges and coastal flood events increase in frequency and/or intensity, ecosystems in the affected areas are likely to be affected adversely.

This study, which may be summarized in Table 4, is an example of some of these problems.

Abstract

This paper suggests methods of forecasting chemical thawing of frozen soils interacting with cryopegs. We have performed experiments on chemical thawing of frozen soils at negative temperatures and have conducted theoretical research on the interaction between cryopegs and frozen soils. The results of our study are as follows: (1) Peculiarities of cryopeg occurrences across the Yamal Peninsula have been discovered; (2) Five types of cryopeg occurring throughout the Yamal Peninsula have been discovered, and cryopeg classification has been elaborated; (3) Basic patterns of chemical thawing of frozen soils have been identified; thus, experiments have shown the migration of unfrozen water and salt ions from the brine (mineralized water) to the frozen soil; (4) Three models of the most typical cryopeg occurrences across the Yamal Peninsula have been designed, and can be used for engineering purposes; and (5) New methods of forecasting the process of chemical thawing of frozen soils interacting with cryopegs have been suggested and are based on the empiric calculation formula (7) given in this paper.

Keywords: chemical thaw; cryopeg; frozen soil;, highly mineralized groundwater; pile; saline permafrost; saline soil; salt migration; thaw settlement.

Introduction

Yamal Peninsula (Western Siberia, Russia) (Fig.1) is one of the most promising Russian regions currently under intensive development. Primarily this involves exploration of a number of large oil and gas fields.

Modern marine and alluvial-marine deposits in the Pleistocene marine terraces and the deep Pre-Quaternary deposits scattered across Yamal Peninsula are rich in cryopegs.

Cryopegs are highly mineralized (saline) groundwater existing at temperatures below 0°C. Their temperature ranges from -12°C to almost 0°C. A change of temperature entails a change in the degree of cryopeg mineralization, which typically varies from 10 to 150 g/l (promille), but sometimes may be as high as 200 g/l.

Cryopegs pose a significant threat to pile foundations built in the permafrost region. Local thawing of soil adjacent to a brine lens may trigger further thawing of the soil along a pile trestle or a borehole. Such thawing is of chemical nature and occurs at temperatures below 0°C.

This paper deals with the interaction between natural brines (cryopegs) and frozen soil under continental conditions. These are characterized by lower temperatures compared to the subaqueous frost, as well as by certain peculiarities of the structure and composition of the rock mass. This difference can have a considerable effect on the interaction between the brines and the frost.

Cryopeg Distribution and Conditions for their Formation

In practice, civil engineers most commonly have to deal with "near-surface" cryopegs located at shallow depths. Such cryopegs are widely spread on laida (littoral marshy area flooded during the incoming tide and dry during tidal fall) and in the low reaches of rivers exposed to tide and surge, as well as at marine terraces formed by saline soils. However, they rarely occur at temperatures below -4ºC.

The laida and flood plain cryopegs were formed mainly as a result of decrease of temperature and freezing of enclosing deposits. They are located in areas adjacent to river flood plains, on sand spits, and in the rear part of flood plains. On laida the soil strata may be composed of just cooled soil containing cryopegs, of soil freezing only from the surface, or in form of soil frozen throughout the investigation depth interbedded by cooled soil lenses containing cryopegs.

The laida cryopegs feature the highest degree of salinity (up to 150 g/l) and, as a rule, low (up 10 m) water heads (Fig.1).

The flood plain cryopegs are characterized by a lower

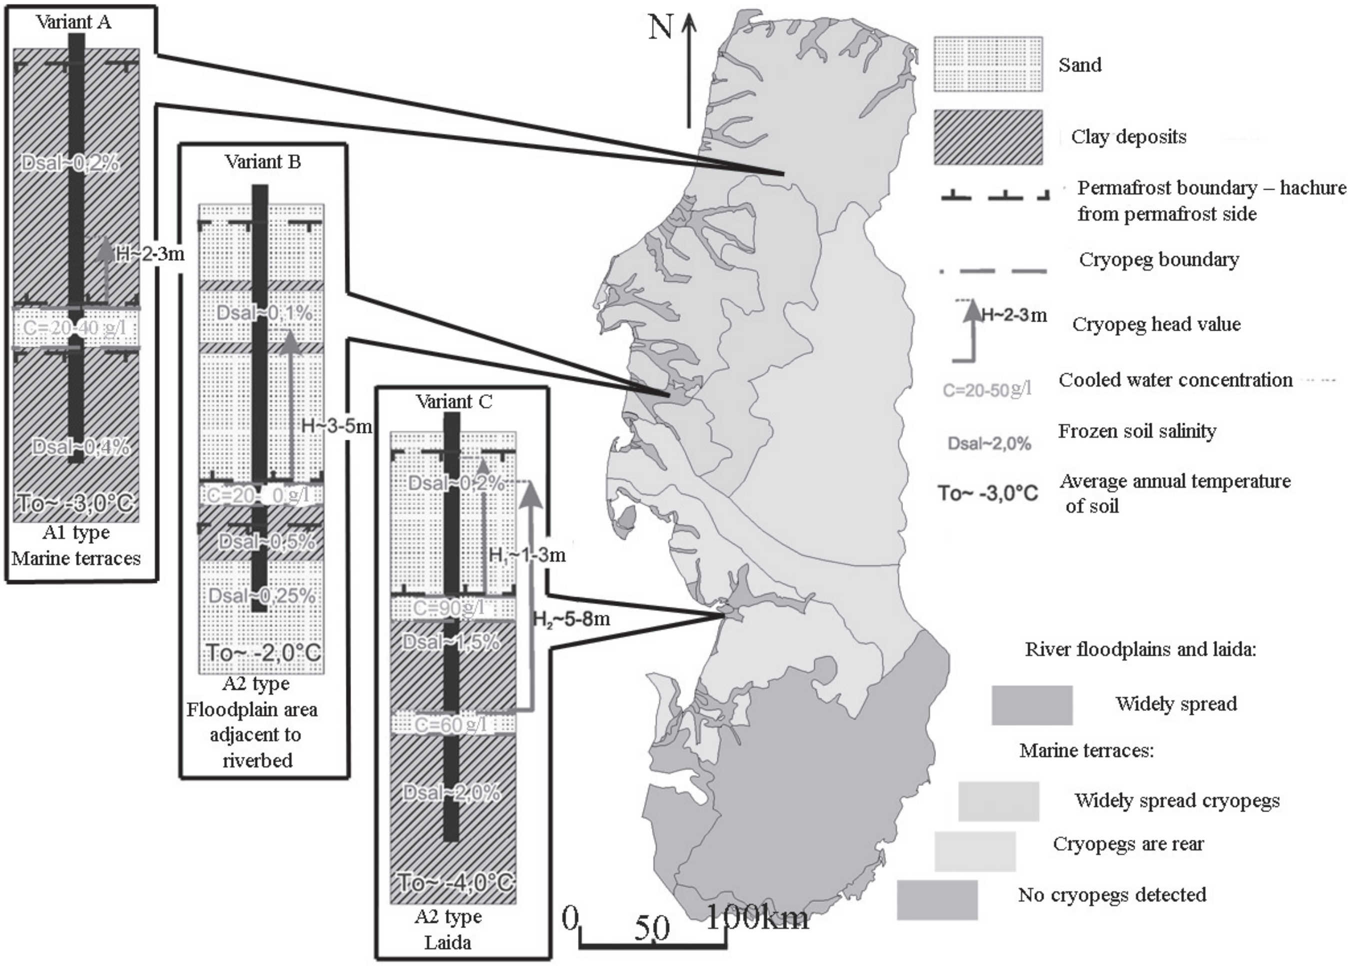

Figure 1. Distribution of cryopegs at Yamal Peninsula.

degree of mineralization (as a rule within 40–70 g/l), but slightly higher water heads. An upper layer of non-saline frozen soil 4–8 m thick is clearly distinguishable in the flood plain deposit profile. In laida this layer is of discontinuous nature and is thinner (2–6 m).

The marine terrace cryopegs occur in the form of relatively thin lenses at various depths and are confined to certain areas featured by enhanced salinity. Within these areas they are confined to local zones with temperatures higher than the background temperature. They are striped on the gently sloping hills, in depressions, on hasyrey (the bottoms of modern and ancient drained lakes), and in areas covered by shrub.

Over the last 40 years a number of researchers have studied cryopegs. As a result of their efforts several systems for classifying cryopegs according to their formation and distribution patterns were proposed and published. The most detailed classifications were proposed by N.V. Ivanova (Ivanova et al. 1992) and one suggested by I.D. Streletskaya (1991). In this paper we take the Streletskaya classification as the basis for our research, but we have modified it slightly to be consistent to the purposes of this study.

This classification is based on the conditions of cryopeg formation. All cryopegs are divided into groups, types, and sub-types (Table 1).

The groups are identified depending on cryopeg position in cryogenic strata (areas of active and passive cryodiagenesis). The cryopeg types are distinguished based on a set of genetic specificities, where the main attribute is the dynamic (period) of change of the cryogenic strata temperature. The sub-types are also identified based on the set of genetic specificities, but the main attribute is the trend (increase or decrease) of the cryogenic strata temperature.

The lenses are up to several meters thick and stretch for 100–300 m. They are featured by hydrostatic and cryogenic heads (10–36 m). The degree of cryopeg salinity is 5–35 g/l; water chemical composition is dominated by sodium chloride. The enclosing ground is represented by various types of sandy-clayey soils (D_{sal} = 0.1-1.0%). The salinity of cryopegs at all levels is 50–80 g/l, and their chemical composition is dominated by sodium chloride.

Cryopeg Impact on Ground Base

Cryopegs occur along the arctic sea coast at depths ranging from several meters to several hundred meters.

Two main factors are decisive in terms of modern distribution of frozen soils and cryopegs with marine-type salinity. The first factor involves sea water percolation through permafrost with the follow-on freezing. The second factor has to do with physical and chemical changes and desalination of the upper layer of permafrost during local warming. The frozen soil thawing and freezing processes are accompanied by salt differentiation between the liquid and solid phases as well as by change of the interstitial solution's concentration. As the interstitial water freezes, a small portion of salt dissolved in it is captured by ice crystals while another portion precipitates and the third portion is squeezed out into the underlying ground. All this enhances mineralization of the residual solution, which, in its turn, facilitates the formation of cryopegs.

In terms of chemical composition, the arctic coast cryopegs are similar to the sea water composition. They have marine-type salinity with the following ion concentration ratio:

$$Cl > SO_4 > HCO_3\ ;$$
$$Na > Mg > Ca.$$

The volume of cryopeg lenses in permafrost varies and depends on conditions under which such lenses are formed. Volume of the brine containing lenses formed in tectonic fractures may be large enough. Small lenses containing non-freezing brine solutions may be formed as a result of sea water percolation through the soft ground. The mechanism of their occurrence is as follows. When soil freezes due to the squeezing of salt out from the phase boundary, an area with low freezing temperature is formed near such a boundary. If the rate of salt diffusion is lower than that of freezing, the conditions favorable for normal crystallization occur below the enhanced salt concentration area. This triggers formation of a new ice sub-layer. Such overcooling of the brine solution caused by enhancement of salt concentration during soil freezing is one of the conditions for formation of a striped structure of frozen soil. In a situation where the brine solution remains unfrozen and the frozen soil enclosing a lens does not thaw, the cryopeg temperature should be the same as that of the enclosing frozen soil. But if the brine solution temperature differs from that of the frozen soil, their contact, depending on the external conditions, should result either in further overcooling of the brine solution with the follow-on freezing, or in thawing of the frozen soil (Gorelik & Kolunin 2002, Grigoryan et al. 1987).

Until now the processes of interaction between frozen soil and saline solutions were under researched. For a long time it was supposed that frozen soils were impenetrable to both water and brine solutions. But in recent years new information has been obtained on the development of the physical-chemical and the mass exchange processes occurring in frozen soils as a result of interaction with the saline solutions (Gorelik & Kolunin 2002, Grigoryan et al. 1987). Recently it was discovered that unfrozen moisture and salt ions migrate from a brine solution into a frozen soil. And here several mechanisms of ion migration are operating: diffusion, convection, and adsorption.

Depending on values and ratio of moisture potential gradient to that of ion concentration, moisture and salt migrate to and from the frozen soil. When brine solution concentration reaches the critical value, the dynamic equilibrium occurs, which leads to termination of the mass exchange process. These critical values of concentration depend on texture, mineral, and chemical composition of the frozen soils, as well as on their temperature. In case of sands interacting with the sodium chloride solution, such critical concentration is not less than 0.1 gram·mol per liter, and for clays it is equal to 5 gram·mol per liter.

The research results show that water and salt migration flows change with time. At the initial stage salt ions migrate and an insignificant amount of moisture is being transferred. Salt ions invading the frozen soil interact with soil mineral particles and with molecules of attached water and ice. Cations interact with the negatively charged surface of mineral particles, while anions interact with the positively charged surface of interstitial ice. In the beginning of the salt transfer process, intensity of anions migration in frozen soil is higher than that of cations. But later on, intensities of migration of anions and cations become almost the same.

Capacity of frozen soil to selectively transfer or hold certain types of ions plays an important role in the salt transport process. Such capacity of frozen soil depends on valence and mass of migrating ions, their hydratability, as well as on a structure of frozen soil pore space. And the structure of pore space of frozen soil, in its turn, depends on temperature and cryogenic morphology of frozen soil.

Mass transfer in frozen soils is possible only if there is a system of continuous water films oriented in the direction of the migration forces. Formation of segregated ice or ice-cement bands results in discontinuity of the active part of pore space participating in the mass transfer processes. This in its turn entails decrease of migration flow rate. This is why structure of pore space plays an important role in the migration processes.

If initial temperatures of soil and brine solution are the same, the phase changes associated with dissolution of interstitial ice contained in frozen soil occur at the interface of soil and brine solution. As a result the temperature of frozen soil will decrease.

In non-saline soils at temperatures below freezing point the relationship between unfrozen water W_w and temperature T is definitely described by the "unfrozen moisture curve." But in the case of saline soils the amount of unfrozen moisture (W_w) depends not just on temperature but also on concentration of interstitial solution. During the phase change process, concentration of interstitial solution changes according to the following formula:

$$C = \frac{C_O \cdot W}{W_w} \qquad (1)$$

where W – total humidity of frozen soil; W_w – content of frozen moisture in frozen soil; Co – initial concentration of interstitial solution. The W_w value can be easily determined from the formula proposed by Aksenov (1980):

$$W_w = 0{,}25 \cdot W_P + (W - 0{,}25 \cdot W_P) \cdot \frac{T_{bf}}{T} \qquad (2)$$

where W_p – humidity at plasticity limit; T_{bf} – temperature at which interstitial solution starts to freeze, determined from the formula:

Table 1. Classification of the North-Western Yamal Cryopegs (according to I.D. Streletskaya with partial modification).

Group	Type (Dynamics of cryogenic formation temperature)	Sub-type (Trend of cryogenic formation temperature)	Geomorphological level	Age and genesis of enclosing deposits	Composition of enclosing deposits and salinity of soils, D_{sal},%	Enclosing soil temperature, °C	Depth and absolute height, m	Head, m	Thickness lens,, m	Mineralization,, g/l

where μ – molecular mass of dissolved salt.

Patterns of Chemical Thawing of Frozen Soil as a Result of Interaction with Cryopegs

We conducted experimental research of a process of interaction between the NaCl solution and a frozen soil. Soil samples were placed into a 5 sm tall cylindrical container being 2 sm in diameter and were kept in a constant-temperature cabinet at a given temperature (below 0°C) during 2–3 days until soil phase changes were completed.

After that, a brine solution with the same temperature was poured on the upper surface of the sample. The soil container was sealed by a lid with a capillary. Soil thawing dynamics was assessed by rate of descent of the solution in the capillary. The side surface of the cylindrical container was covered by thermal insulating material, while the temperature at the container's upper and bottom surfaces was the same as the experiment temperature. By this we simulated one-dimensional interaction between the brine solution and the soil. Similar equipment and procedure of experiments were used by Gaidaenko (1990) and Ostroumov (1990).

Table 2. Constant factors of the formula (7).

	The opened system		The closed system	
	Case of sand	Heavy clay loam	Case of sand	Heavy clay loam
A_1	0,0752	- 0,3062	- 0,0692	– 0,0447
A_2	0,0588	- 1,0633	- 0,2205	0,0008
A_3	1,6036	0,7064	1,8014	1,7719
B_1	- 0,3029	1,9217	0,5746	0,3467
B_2	0,8455	8,0137	2,9339	1,0402
B_3	- 3,3278	2,0932	- 4,8438	- 6,6717

The results of our experiments are as follows. When temperature T = -1.8°C, a contact between frozen sand and brine solution (with concentration of 50 g/l) leads to a situation where chemical thawing of soil occurs during the first 20 hours. After that, interstitial moisture starts to refreeze. If solution concentration is 100 g/l, chemical thawing of soil proceeds continuously. In this case, when temperature T = -1.8°C, refreezing does not occur.

In the case of frozen clay, when temperature T = -1.8°C and brine solution concentration C = 100 g/l, the rate of chemical thawing is twice lower that for frozen sand, while refreezing starts in about 40 hours.

The rate of chemical thawing of frozen soils is influenced by a value of salt diffusion coefficient, which, in its turn, depends on many parameters. Primarily it depends on type of

Table 3. Rate and depth of chemical thawing of frozen soils as a result of interaction with cryopegs.

Cryopeg type and sub-type	Geomorphological level	Composition of enclosing deposits	Salinity, g/l	Enclosing soil temperature T, °C	Heat transfer system	Thawing rate V, sm/day	Thawing depth per 0.5 years h, m	Thawing depth per 1 year h, m
A_1	Marine terrace, flood plain	Clay loam	40	-1.5 < -2.0	Opened “	0.46 0	0.85 0	1,70 0
A_2	Floodplain (area adjacent to riverbed)	Sand	40	-1.5 -2.0 < -2.5	Opened “ “	0.94 0.36 0	1.71 0.66 0	3,42 1,32 0
A_2	Floodplain (hasyrey)	Clay loam	80	< -3.0	Closed	0	0	0
B	All levels	Sand	80	< -3.0	Closed	0	0	0

soil, thickness of water films in soil voids (pores), geometry and relative position of water films and ice crystals. For example, continuous ice beds prevent penetration of salt into soil. The coefficient of salt diffusion in frozen soil is calculated using the following formula:

$$D = W \cdot D_O \tag{4}$$

where D_O is the coefficient of salt diffusion in free water; in case of a NaCl, D_O is approximately 0.04–0.05 sm/h.

The rate of chemical thawing of frozen soil also depends on average density of brine solution-as brine solution density decreases, the duration of chemical thawing of soil increases.

We obtained a simple function that allows for calculating depth of chemical thawing of frozen soil exposed to saline solution:

$$h = h_1 \cdot \sqrt{t} \tag{5}$$

where h is the depth of soil layer thawed during an estimated time t; h_1 is the depth of soil layer thawed during the first day.

Our research demonstrates that when the temperature of brine solution is the same as temperature of frozen soil, the rate of chemical thawing of frozen soil depends on brine solution temperature and concentration in the following manner:

$$f(C,T) = (A_1 \cdot \ln C + B_1) \cdot T^2 + (A_2 \cdot \ln C + B_2) \cdot T + (A_3 \cdot \ln C + B_3) \tag{6}$$

where

$$V = \begin{cases} f(C,T) & at \quad f(C,T) \geq 0, \\ 0 & at \quad f(C,T) < 0; \end{cases} \tag{7}$$

where V is the soil thawing rate (sm/day); C is the brine solution concentration expressed in promille; T is the air temperature expressed in degrees Celsius. The factors A_i and B_i (i = 1, 2, 3) – constant values (experimentally obtained) (see Table 2).

The process of chemical thawing of soil described above will also occur under the foot of a pile driven into a borehole. When a borehole is being drilled, natural pressure of rock formation is released in the area where a pile is driven in.

Practical Examples

Physical and mechanical properties (strength and deformability) of marine deposits scattered along the Arctic coast depend on temperature, salinity, particle-size distribution, and humidity of marine sediments.

Depending on their deformability the Yamal Peninsula soils include hard frozen, plastic frozen, or cooled soils. Plasticity depends on soil type, temperature, and salinity that determine phase composition of interstitial solution and degree of soil cementation by interstitial ice. That is why it is expedient to link boundary of soil state change to phase composition of soil moisture.

Various states of frozen soils (hard frozen, plastic frozen, and cooled soil) also depend on interactions between the ground base and cryopegs. Chemical thawing of frozen soil is triggered by such interactions.

The comprehensive approach to studying distribution and classification of cryopegs, adopted by us, allowed for revealing patterns of cryopegs distribution within ground strata along the western coast of Yamal Peninsula. This makes it possible to assess soil variants as a base for pile foundations.

Let us consider these variants from the viewpoint of the possible load bearing capacity of piles.

Examples are based on typical soil conditions (in accordance with the survey of the Obskaya-Harasaway road (see Fig. 1).

Variant “a” (Fig. 1, variant A). A pile driven into frozen clay, saline soil taps low-pressurized low-mineralized cryopeg lens (C = 20–40 g/l) at a depth of H = 2–3 m. The temperature (T_o) of the saline clay soil of the marine terrace is minus 3°C. As a result, the pile surface is wetted with mineralized water (either fully or partially). Under such conditions the rate of chemical thawing of the soil amounts to zero (Table 3). However, given the above mineralization and temperature, there will be just a film of fresh ice forming in the pile contact area. In general, the bearing capacity of the pile will be largely unaffected. Tables containing construction standards can be used to calculate the bearing capacity.

Thus, if the temperature is minus 3°C and the salinity of clay soil is ~ 0.2%, shearing resistance of the soil adfreezing with the metal pile can be assumed equal to R_{af} = 150 kPa. If the temperature remains unchanged and the salinity amounts to 0.4%, design pressure under the pile butt-end can reach R = 550 kPa, which will ensure the bearing capacity of the pile.

Variant “b” (Fig. 1, variant B). A pile is driven into a frozen ground strata in the laida area adjacent to a riverbed. The upper part of the strata consists of slightly saline sands (D_{sal} = 0.1–0.15%). The bottom part is composed by clayey saline soils (D_{sal}=0.5%). A cryopeg lens penetrated by the pile is featured by high salinity (up to 70g/l). The pile driven into such a borehole is unlikely to have proper load bearing capacity since the rate of chemical thawing is high and equals to 0.36 sm/day (Table 3). Over half a year, chemical thawing along the level (r) can reach 0. 66 m (see Table 3). Bearing capacity of the pile in the lower part across the lateral adfreezing surface of saline (D_{sal} = 0.5%) clay soil is just as small. At a temperature of minus 2°C, R_{af} can amount to 30 kPa. In general, in the upper part of the pile, since soil is not frozen, sand will be thawed due to chemical thawing. In the bottom part of the pile there are plastic frozen soils with weak strength properties. Installation of a pile in such conditions is inexpedient and should be avoided. In such circumstances cooling systems may be used as a last resort.

Variant “c” (Fig. 1, variant C). A pile is driven into cooled soil in the bottom part of the section. The upper layer consisting of frozen sand may be 2–4 m thick. As a result of exposure to highly saline head water, chemical thawing of this layer may occur. The clayey saline soil strata (D_{sal} = 2.0%) may be interbedded by sand containing highly saline head cryopegs. In this situation a construction method based on preliminary thawing of ground strata should be used. The construction standards for thawed ground shall be used for determining strength properties.

Conclusion

Despite insufficient knowledge of the subject under investigation, limited experimental data, and challenges in meeting the set objectives, the research and studies performed by us allow for the first time to reveal basic patterns of change of physical and mechanical properties of frozen soil as a result of their interaction with cryopegs.

Our study comprised a number of experiments on chemical thawing of soils at a temperature ranging between -1.5°C and -6.0°C and with brine concentration ranging between 40 and 80 g/l. The analysis of the results yielded by our experiments enabled us to:

(1) discover basic interaction patterns between frozen soils and mineralized waters at below-zero temperatures;

(2) compile tables and devise formulas for calculating the rates of chemical thawing of frozen soils (see Formula (7), Table 4);

(3) suggest methods of assessing the bearing capacity of piles driven into the rock mass with cryopeg lenses. This allows us to determine whether it is possible to ensure the bearing capacity of pile bases (if there are any cryopegs present), or whether such a possibility is completely ruled out.

Abstract

The Anabar shield is characterized by continuous permafrost. The mean annual temperature of rocks reaches -15ºC, and the zero isotherm position is detected at depth 1000 m. According to the scheme of geocryological zonation, the ice-rich permafrost, underlain by dry permafrost, occurs down to a depth of 200 m; but the hydrogeological studies performed recently on the margins of the shield indicate possible availability of fresh groundwater within its field. Remarkably, this paper for the first time offers the theoretical model of cryopeg formation in crystalline rocks and a new type of permafrost structure. The study suggests that glaciation and marine transgressions have been identified as truly crucial events in the Pleistocene history of the shield. The glacial complexes experienced the processes of seawater-frozen rocks interaction, ground ice melting, and replacement of fresh groundwater with seawater. As a consequence, appropriate conditions were created for ice-rich permafrost and subpermafrost cryopegs to be derived in cryochrons.

Keywords: Anabar shield; brines; cryopegs; glaciation; permafrost; seawater.

Introduction

The Siberian platform is the most ancient and largest geological unit of Eurasia, in which a sustainable portion of rocks have been in a perennially frozen state since Early-Middle Pleistocene. Its northeastern part is occupied by the basement uplift that is the Anabar shield and is characterized by truly complicated natural and geocryological-hydrogeological conditions.

Lack of geocryological and hydrogeological information on the Anabar shield is primarily explained by its remoteness, as well as unavailability of data on deep drilling accomplished within the shield, and targeted survey. Therefore, identification of the main parameters of the Anabar shield permafrost and features of its evolution are key scientific goals. The profound knowledge to be gained will ensure understanding of the general pattern of the continental crust formation on Earth in the Late Cenozoic. The authors of this paper have compiled available data on geological features and the geocryological and hydrogeological settings of the Anabar shield. Paleogeocryological interpretation of these sources of information defined morphological and genetic specifics of the shield permafrost and the major phases of its evolution in the Late Cenozoic, as well as new types of the cryolithozone structure.

Presentation and Discussion of Results

Geology, geomorphology, and climate

The Anabar shield is composed of the Archean metamorphosed rocks of the granulite complex; for example, gneisses and crystalline schists (Fig. 1). They make up some

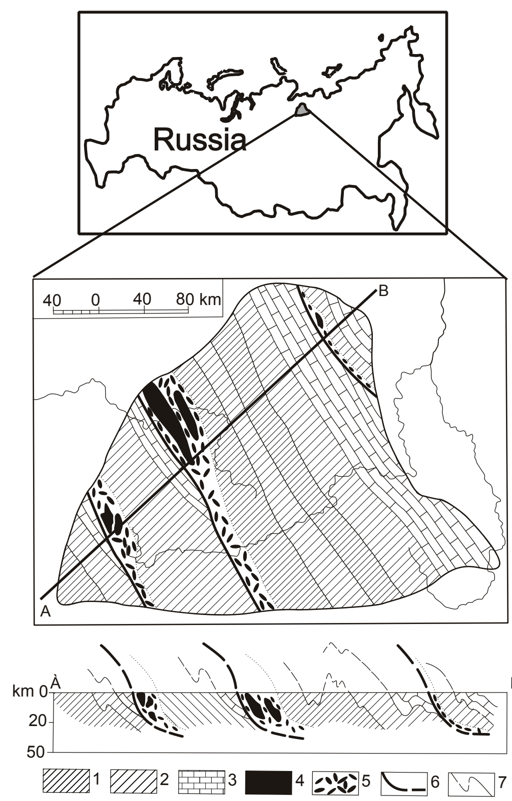

Figure 1. Geological structure of the Anabar shield (Rozen et al. 1986). 1 – Daldyn series, 2 – upper Anabar series, 3 – Khapchan series, 4 – cataclasite, phyllonite and diaphthorite of deep-seated shear zone and diaphthoresis, 5 – faults (mylonite and blastomylonite), 7 – folded structure (shown on section A–B).

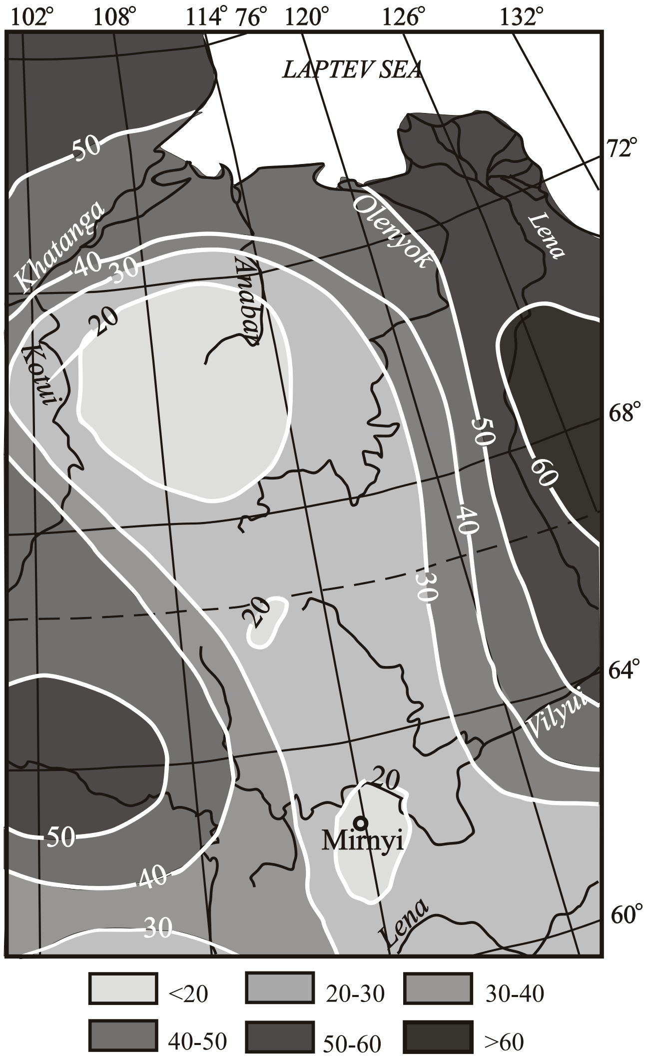

Figure 2. Heat flow values (mW/m^2) in the north of the Siberian platform (*Temperature, cryolithozone*… 1994)

rigid blocks, for instance, the Magan, Daldyn and Khapchan terrains, divided by thick zones of shearing and splitting striking towards the northwest (Rozen et al. 2002).

The Anabar shield is rimmed with a zone of flatly lying Proterozoic (peridotites, amphibolites, and pyroxenites) and Cambrian sedimentary rocks. Quaternary sediments are thin and are not widespread. The ancient magmatic rocks (granites and anorthosites) were formed in the Archean and Proterozoic cycles of volcanism, while young rocks represent Permian-Triassic "Siberian traps" making up thick covers, sills, and dykes. The common units of the Anabar shield structure are large fault dislocations.

The Anabar shield is one of the largest uplifts of the Mid-Siberian plateau. In relief the uplift looks like a deformed flat cupola with massive prominences separated by incised river valleys. A typical structural relief of the plateau was formed over the sedimentary rocks of monoclinal bedding composing the edges of the Anabar uplift. The maximum altitude of the plateau is 900 m in its central and southwestern parts. In the south and northeast, it reaches 600 m; in the southeast, it is 300–350 m; and near the eastern border, it is close to 200 m. The river valleys commonly occur in the zones of tectonic dislocations. They lack such forms of accumulation relief as the first floodplain terrace, river sand bars, spits, and flood lands.

The Anabar shield lies within the Siberian part of the sub-Arctic zone having a sharply continental climate. In the cold period, the climate is much affected by the Asian barometric maximum. The mean annual temperature of air varies from -13 to -15, while the mean minimum of air temperature ranges from -18 to -21°C (Gavrilova 1998). The amplitude of temperature variations reaches 56°C. In time of anticyclone, the air temperature inversion leads to a marked cooling of river valley bottoms. The annual amount of precipitation decreases south to north from 266 to 194 mm/yr. The steady snow cover is formed by early October, and it melts down in late May. On the wind-protected sites, the snow cover is commonly 66–73 cm deep, whereas in the open parts its depth decreases to 46–57 cm. The average value of snow density is 0.16–0.22 g/cm^3.

Geocryology and hydrogeology

The Anabar shield is located in the northern geocryological zone where permafrost is ubiquitous. Knowledge about the thermal status of frozen ground is insufficient and poor, because deep wells applicable for geothermal observations were not drilled. The highest mean annual temperature of rocks (-7…-9 °C) is typical for river valleys, gently sloping shores, and low interfluvial areas overlain with sandy and loam sandy fluvioglacial sediments. On the high, steep slopes and tops of the Anabar plateau, the mean annual temperature of rocks reaches -13…-15°C (Ershov 1989).

Considering geothermal parameters, the Anabar shield is regarded as the region with the coldest crust and the lowest heat flow (Balobaev et al. 1983). The temperature of rocks at depth 500 m amounts to -3…-5, and at depth 1000 m, it raises to -1…+1 °C. The heat flow values vary from 15 to 20 mWt/m^2 (Fig. 2).

It is currently believed that within the Anabar shield the cryolithozone has two layers. In the upper part of the shield and on its slopes, the thickness of permafrost reaches 150–200 m. It is underlain by dry rocks with negative temperature. Groundwater can occur only in the seasonally thawed layer and within closed taliks within river valleys. The total thickness of the cryolithozone is estimated to be over 1000 m (Fotiev 1978, Ershov 1989).

The authors of this paper propose that the sequence of perennially frozen rocks is composed of disconnected blocks and boulders bound by interstitial ice and dispersed material. The ice inclusions basically fill fractures of cleavage, chipping, as well as fractures of slip. The rocks of the Anabar shield inherit fractured and fracture-vein cryogenic structures producing shlierens, nests, and extensive veins. The pattern of fractures and ice-filled cracks essentially changes in massive rocks, and it is defined by the lithological, petrographic, and tectonic factors. In basalts, the net of cracks looks like columnar or pillar jointing (Fig. 3a). In granites and sandstones, the ice-containing cracks produce a system net (Fig. 3b), while in schists this is a wavy net (Fig.

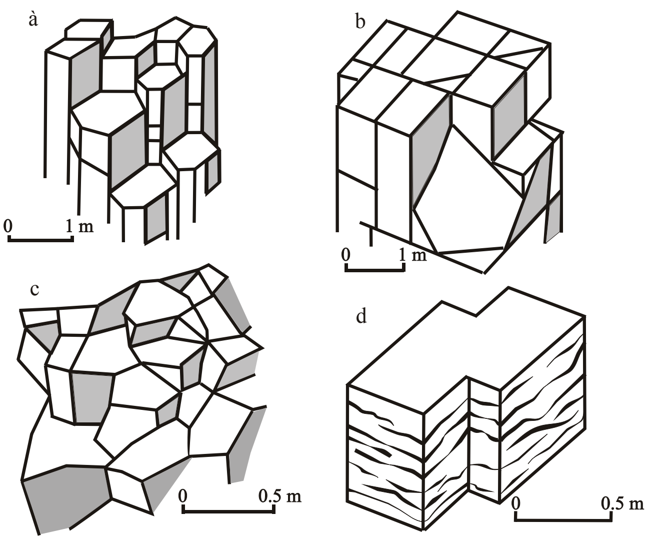

Figure 3. Structures of ice-filled fractures of the Anabar shield: a – polygonal (basalt), b – system (granite), c – chaotic (dolerite), d – wavy (schists).

3d), both occurring on the folds of longitudinal compression and near faults. In the fault zone, next to the ruptures and contact of intrusive rocks the dolerites display a chaotic net of cracks (Fig. 3c). The structure-forming ground ice has cement, infiltration, and sublimation genesis.

Hydrogeological studies performed recently on the margins of the Anabar shield indicate possible availability of fresh groundwater within its inner field (Solopanov & Tolstov 1996). This statement can be exemplified by the Tomtor pluton, hosting the unique deposit of rare-metal ores, located about 180 km east of the shield. The massif is composed of ultrabasic, alkaline, and carbonatite rocks. Geophysical surveys suggest that subpermafrost waters exist within the Anabar shield (Kalinin & Yakupov 1989).

At depths of 170–400 m, the wells penetrated artesian subpermarost waters of chloride-hydrocarbonate sodium composition with salinity of 225–770 mg/L. The head over the aquifer roof was 120–360 m. The well flow rate ranges from 2.4 to 7.0 m^3/day (Solopanov & Tolstov 1996). The geothermal observations in wells indicate that the temperature of rocks at the depth of zero ranges from -6.1 to -8.4°C, which corresponds to calculated estimates of mean annual temperature of rocks of the Anabar shield. The temperatures were measured at the Chair of Geocryology at Moscow State University.

Discussion

The interior of large massifs of crystalline rocks, for example, Baltic, Canadian, and Brazilian shields, contains chloride saline waters and brines of different salinity. Researchers have proposed alternative processes of evaporative concentration of seawaters and dissolution of halogene formations. In recent years, a number of published papers reported formation of chloride brines of the Baltic and Canadian shields due to cryogenic concentration of seawater (Herut et al. 1990, Szilder et al. 1995, Bottomley et al. 1999, Marion et al. 1999, Starinsky & Katz 2003).

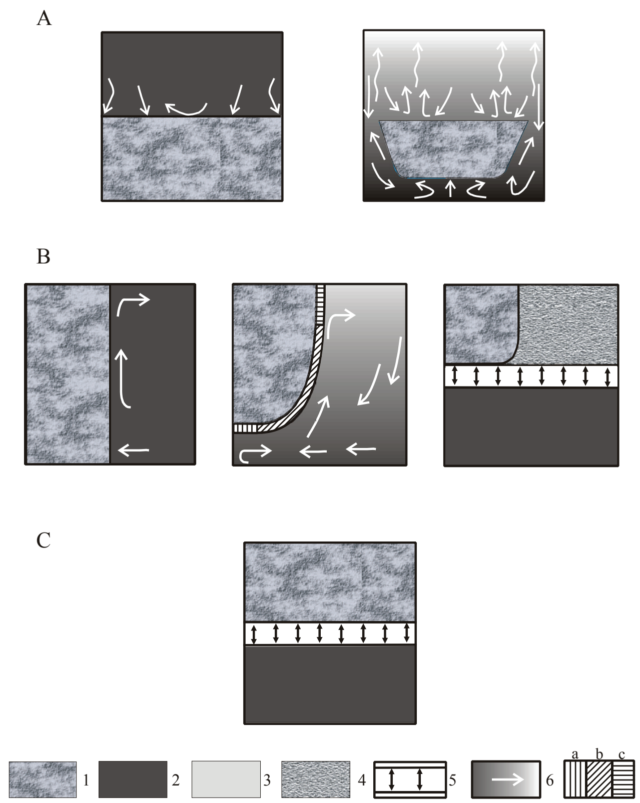

Figure 4. Phase interaction scheme in the brine-ice system (Alexeev 2000): 1 – initial ice, 2 – brine, 3 – diluted solution, 4 – secondary ice, layer of local equilibrium in the system and phase interaction at molecular diffusion, 6 – direction of density convection, 7 – hydrodynamic layer: a) zone of convection beginning and of the most active ice melting, b) zone of decreasing unequilibrium to ice, c) zone of neutral phase contact.

The principally new scenario is proposed as to how cryopegs could possibly be formed in the crystalline rocks of the Anabar shield. The theoretical background of the authors is based on some principal points.

1. Glaciation of the Anabar shield is an important factor of Pleistocene history. It resulted in formation of the thick glacial covers of the Antarctic type, or typical mountain-valley glaciers (Ershov 1990, 1998, Romanovsky 1993). Glaciation left a series of terminal moraines enclosed in each other. The glacier tongues also left moraines behind in the mountain valleys. The glaciers continuously covered the northern part of the Anabar plateau. Deglaciation caused formation of peculiar glacial complexes. They consist of the tongue basin or central depression.

2. The Pleistocene stage of the Anabar shield evolution is responsible for a significant number of marine transgressions, preconditioned by either active tectonic movements or glacial eustatic rises of the ocean level. The sea repeatedly reached the northern margin of the Anabar shield.

3. Marine transgressions proceeded with seawater of different salinity interacting with ice-rich frozen rocks. The phases interacted within the systems: "brine above ice" and "brine in the lateral contact with ice" (Alexeev 2000) (Fig. 4).

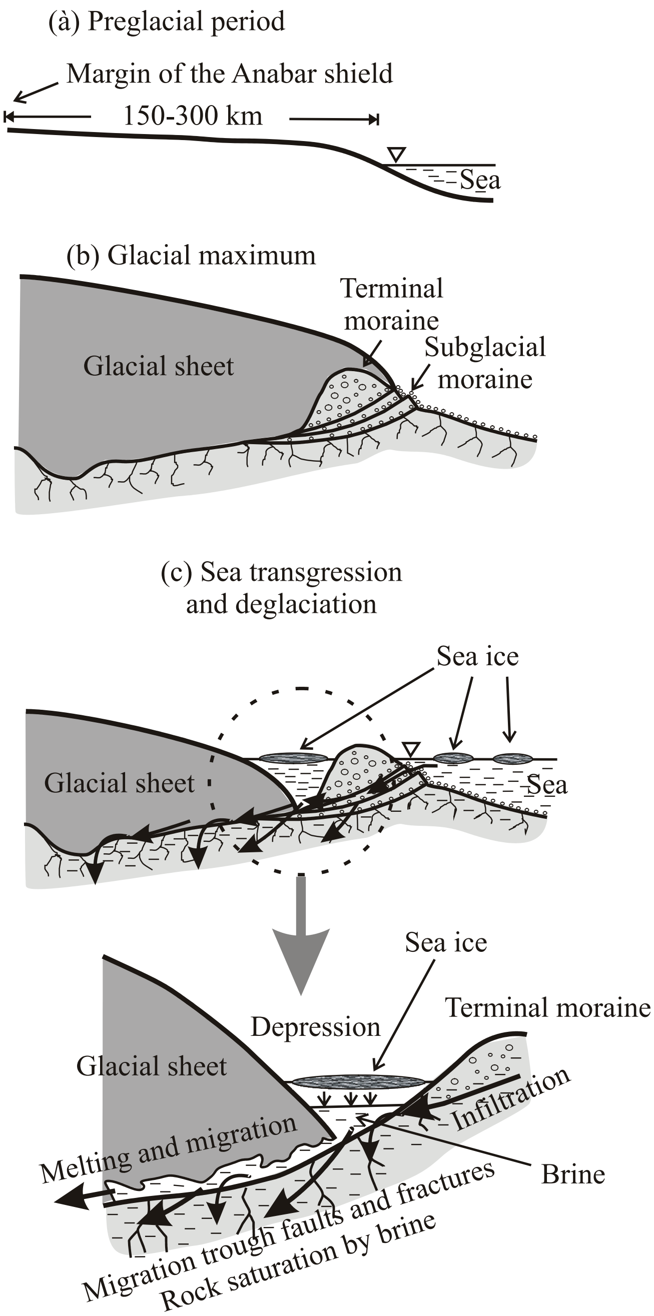

Figure 5. Cryopeg formation in crystalline rocks of the Anabar shield.

With sub-freezing air temperatures, the flooded part of the shelf turned into a peculiar cryogenic basin. Considering its functioning and final salinity, the cryogenic basin is similar to the classic sea evaporitic lagoon. However, the H_2O-solvent was removed due to the ice formation combined with sublimation, and it induced the change of the liquid phase volume and concentration of seawaters. Thus, in the time of glaciation and deglaciation it is suggested that the Anabar shield experienced the following events.

In the preglacial period, the Anabar shield and sea were separated by a narrow zone of intercalating continental and marine sediments extending for 150–300 km (Fig. 5). In time of glaciation, the entire marine material was dragged by a glacier to its termination. While advancing, it displaced a wide and massive terminal moraine forward. The bottom moraine formed in the base of a glacier. It consisted of weathering crust fragments and debris.

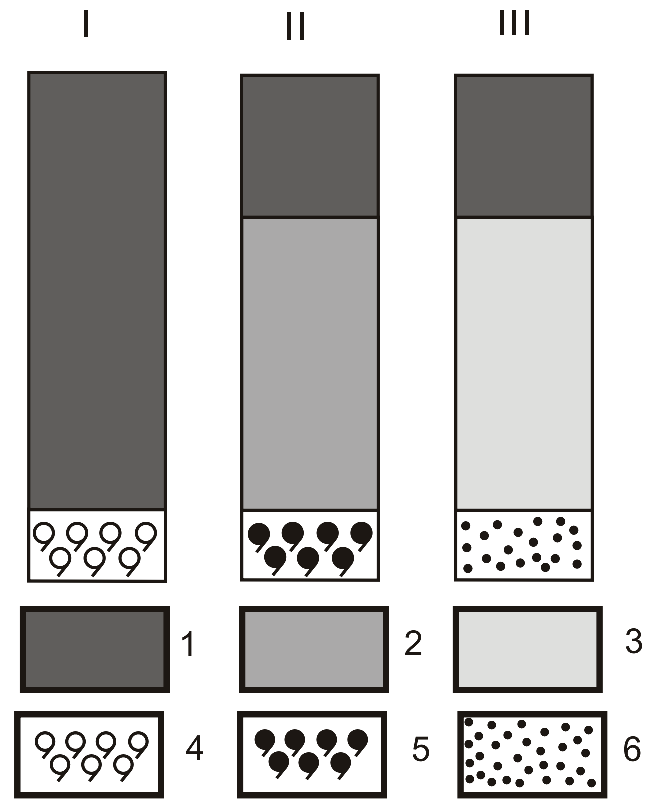

Figure 6. Permafrost structure of the Anabar shield (I and II are new types of permafrost structure, III – commonly accepted type).
1 – ice-rich frozen rocks, 2 – rocks filled by cryopegs, 3 – dry frozen rocks, 4 – rocks filled by subpermafrost fresh water, 5 – rocks filled by saline waters with positive temperature, 6 – dry rocks with positive temperature.

The glacier retreated when the climate turned warm, or if the amount of solid sediment diminished. Due to ice melting, the moraine material piled on the former glacier bed as a moraine line oriented across the valley.

The depression was formed between the glacier and deposited moraine. In the period of transgression, this depression was gradually filled with seawater infiltrating through a moraine either over the planes of scaly overthrusts or over the contact of rocks and lenses of dead ice. Their subsequent cooling was accompanied by ice formation in the near-surface space of depression, concentration, and subsidence of denser brine waters onto the water reservoir bottom. The stronger brines further migrated onto the dislocated bed of the ice shield through steeply dipping fractures of the tectonic zones and exogenous fracturing. If fissures in rocks were filled with ice, it actively melted, and a convective mass transfer took place. The brines also migrated towards the center of the depression along the thawed glacier base. The brines flew out of the depression, and the outflow was made up for new portions of seawater supplied from the moraine line.

During several tens of thousands of years of a transgressive regime, the crystalline rocks could have enclosed a considerable volume of brines. At the next stage of the Anabar shield evolution, the liquid phase in the crystalline rocks was stratified according to the density. This resulted in formation of a peculiar zonation marked by an increase of groundwater salinity at depth. Fresh and saline waters were frozen through, while the brines, when cooled, were transformed into cryopegs. We suggest that this scenario describes how conditions were created for formation of the cryolithozone, which consists of frozen and cryopeg-filled rocks.

Conclusions

Important conclusions have been derived due to the study performed:

1. The glaciation event was an important stage in the Late Cenozoic history of the Anabar shield development. The subsequently occurring deglaciation and transgression of the sea created conditions appropriate for formation in the crystalline rocks of the brines genetically related to seawater, which was infiltrated into crystalline rocks on the glacier/sea border.

2. In the Late Pleistocene cryochrons, the permafrost sequences were derived within the zone of exogenous fracturing. The profound cooling of crystalline rocks brought about cryogenic concentration of groundwater, increase in salinity, and formation of a thick zone of subpermafrost cryopegs.

Therefore, the formerly existing concept that groundwater is lacking within the shield is to be essentially reconsidered. Having considered available data, the proposal is to distinguish two alternatives types of cryolithozone structure with variable ratios of rocks having negative temperature (Fig. 6). The figure displays the relationships between different stages of cryogenic rocks.

When compiling a new map of geocryological conditions in East Siberia the newly recognized types (columns I and II) of cryolithozone, with possible presence of fresh groundwater and brines, should be included.

A First Estimate of Mountain Permafrost Distribution in the Mount Cook Region of New Zealand's Southern Alps

Abstract

The heavily glaciated Mount Cook Region of New Zealand has experienced several recent large rock instabilities, but permafrost conditions related to these events remain unknown. This work presents the first systematic approach for investigating the distribution of mountain permafrost in New Zealand. At this level of the investigation, a first-order estimate is based upon the adaptation of established topo-climatic relationships from the European Alps. In the southeast of the study region, the permafrost estimate gives a reasonable correspondence with mapped rock glacier distribution but the maximum elevation of vegetation growth is situated 200 m beneath the lower limit of estimated permafrost. Extreme climate gradients exist and towards the humid northwest, where rock glaciers are absent and vegetation patterns give an unclear climate signal, large uncertainties remain. Data currently being recorded from a network of rock wall temperature measurements will help remove this uncertainty, and will allow distribution modeling that better accounts for the topographic complexities of this steep alpine region.

Keywords: permafrost distribution; rock instabilities; spatial modeling; Southern Alps; New Zealand.

Introduction

Internationally, mountain permafrost is a well recognized phenomenon in relatively low-angled debris-covered terrain where active rock glaciers produce distinctive landforms that indicate perennially frozen ground beneath. Previous research based upon the identification of active rock glaciers in the Southern Alps of New Zealand has suggested that permafrost probably occurs only sporadically within a very narrow altitudinal zone in the more arid areas of the Alps (Brazier et al. 1998). However, there has been no scientific consideration in New Zealand given to the likely wider distribution of permafrost within bedrock slopes, and in particular, on steep slopes which dominate at higher elevations throughout the Mount Cook Region (MCR). Recent large rock avalanches, including the spectacular summit failure of Mount Cook (McSaveney 2002) have awoken interest in the understanding of permafrost and slope stability interactions in the region. This paper aims to present the first results from permafrost distribution modeling for the MCR, based upon local application and calibration of topo-climatic relationships established in the European Alps. Initial validation of the estimated permafrost distribution is discussed on the basis of a rock glacier inventory and remote sensing-based vegetation mapping, and future research towards improved modeling in this region is introduced.

Background

Studies of permafrost processes in New Zealand are limited (Soons & Price 1990), with only a few detailed studies emerging from the identification and dating of rock glaciers within the Southern Alps. These studies have served to improve the chronology of Holocene glacial activity in the region (McGregor 1967, Birkeland 1982) and offer some insights regarding possible climate sensitivities of rock glaciers (Jeanneret 1975, Kirkbride & Brazier 1995). From the mapping and classification of periglacial landforms in the Ben Ohau Range, Brazier et al. (1998) suggested that permafrost distribution was more limited than would be expected based upon climatic boundaries identified in the European Alps (Haeberli 1985). In the driest, generally low-elevation mountains east of the Southern Alps, rock glaciers are absent and ice-free talus slopes dominate. In the more humid, maritime regions to the west where precipitation exceeds 10000 mm y^{-1}, glacier equilibrium line altitudes (ELAs) are low and temperate mountain glaciers dominate, with no active permafrost landforms evident (Augustinus 2002). Between these two extremes, within a narrow zone where precipitation does not exceed 1500 mm y^{-1} ELAs are higher, glacial ice is limited to debris-covered cirques, and more numerous permafrost landforms are found (Brazier et al. 1998).

Understanding permafrost distribution within complex steep mountain terrain is a relatively new field of scientific research largely stemming from European-based studies in relation to climate warming, permafrost degradation and related slope instability hazards (Gruber & Haeberli 2007). During the past 50 years, several large rock avalanche events have occurred within the MCR (McSaveney 2002), but in the complete absence of data regarding permafrost distribution in the steep terrain of the Southern Alps, the possible role of permafrost weakening within past or future detachment zones is uncertain.

In complex mountain terrain, variations in topography and related permafrost factors such as snow cover result in the necessary use of spatial modeling to achieve any realistic estimate of permafrost distribution (Etzelmüller et al. 2001). A hierarchy of modeling procedures has therefore been developed over recent years (Hoelzle et al. 2001). Readily applied empirical-statistical approaches relate documented permafrost occurrences to easily measured topo-climatic factors such as altitude, slope and aspect, air temperature, and solar radiation (e.g., Imhof 1996) and are particularly well suited for preliminary assessment and planning in relation to geotechnical hazards (Harris et al. 2001). A useful, and essential first step in these studies has been the adaptation of Haeberli's (1975) original topo-climatic key for predicting permafrost occurrence, which provides an immediate impression of likely permafrost distribution, and a basis from which local validation and more advanced modeling can proceed.

Study Region

The MCR is broadly defined here to encompass the 700 km^2 Aoraki Mount Cook National Park, extending west of the Main Divide into the Westland National Park and south to include the Ben Ohau Range (Fig. 1A). The region includes the highest mountains and the most heavily glacierised terrain of New Zealand's Southern Alps. Permanent snow covered peaks are found between 2500 and 3754 m a.s.l., with local relief in the order of 1000–2700 m. Moist westerly airflow perpendicular to the Main Divide, generates very high orographic rainfall amounts and creates an extreme precipitation gradient leeward of the Alps (Griffiths & McSaveney 1983). Glacial retreat since the Little Ice Age maximum has been most rapid during the mid 20th Century, leading to a 25% loss of total ice area in the Southern Alps during this past century, although some highly responsive glaciers have had notable periods of advancement over recent years (Chinn 1996).

Estimating Permafrost Distribution

Based on extensive geophysical and morphological investigations of rock glacier phenomena in the eastern Swiss Alps during the 1970s, Haeberli (1975) developed 'rules of thumb' for predicting permafrost occurrence. Stemming from these rules was the empirical topo-climatic key, incorporating the primary physical factors which influence permafrost distribution, determining both a zone of probable permafrost and the permafrost limit within a transitional zone termed "possible permafrost." These physical factors include significant aspect dependent radiation effects, altitudinal changes in air temperature, and topographically related snow cover variation (Etzelmüller et al. 2001). In relation to snow cover, gentle terrain situated at the foot of steeper slopes where long-lasting avalanche snow may accumulate can maintain cooler ground surface temperatures than steeper slopes of the same aspect. On flat terrain, the local permafrost distribution is determined more by air

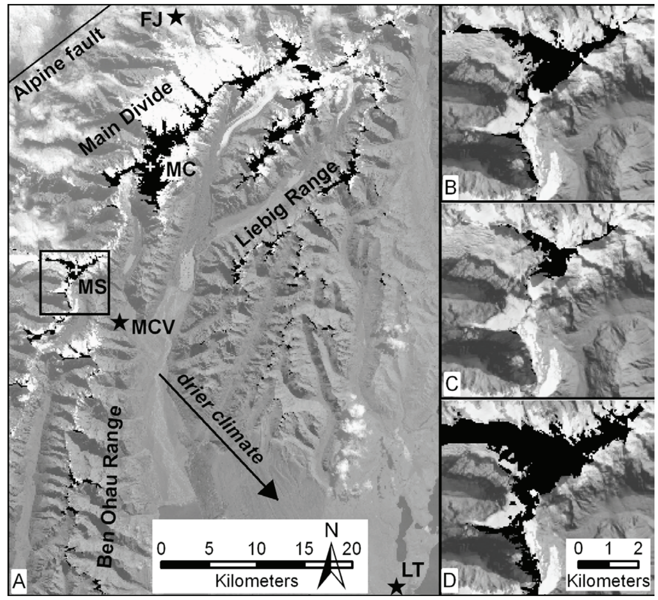

Figure 1. A) GIS-based modeling of possible steep permafrost distribution (black) in the MCR based upon adjustment of the original topo-climatic key (Haeberli 1975) using MAAT calculated from the Franz Josef (FJ), Mount Cook Village (MCV) and Lake Tekapo (LT) climate stations. Also shown are the locations of Mount Cook (MC, 3754 m) and Mount Sefton (MS, 3151 m), B) Closer view of the estimated permafrost terrain around the summit area of Mount Sefton, C) repeated for a 0°C isotherm rise of 200 m, and D) a 0°C isotherm lowering of 200 m. The base image used is an ASTER satellite mosaic from 2007.

temperature and snow cover than by radiation. Calibration of the key to local conditions in the MCR was based upon calculation of mean annual air temperature (MAAT) for the years 1982–2007 and the local 0°C isotherm elevation using daily temperature data from three climate stations located across the region (Fig 1A). For the eight primary slope aspects, the original elevation zones given in the topo-climatic key were either raised or lowered based upon the difference between the local elevation of the 0°C isotherm and the equivalent value from the Swiss Alps where the key was established. Topographic values for all analyses were extracted from the Landcare Research 25 m resolution South Island digital terrain model (DTM).

In an attempt to account for the significant climate gradients associated with the föhn effect which results from initially moist airflow across the Main Divide, the 0°C isotherm was calculated independently using MAAT measured at each of the three climate stations. Hydrological studies in the region have shown that rainfall gradients are approximately parallel to the Main Divide, with maximum rainfall measurements associated with the steepened terrain along the alpine fault (e.g., Griffiths & McSaveney 1983). Because of the effects of decreasing moisture towards the southeast on environmental lapse rates, the following values were used: Franz Josef, 0.005°C m^{-1} (Anderson 2003), Mount Cook Village, 0.0065°C m^{-1} , and Lake Tekapo, 0.0075°C m^{-1}. The latter two rates have not been directly measured, but were inferred from the nearest available

Table 1. Topo-climatic key for the estimation of permafrost distribution in the MCR adapted from Haeberli (1975).

Aspect	Permafrost possible		Permafrost probable	
	Steep slopes	Foot of slopes	Steep slopes	Foot of slopes
S	2280	1980	2480	2430
SE	2330	2180	2480	2580
E	2480	2280	2880	2580
NE	2730	2180	2880	2580
N	2880	2130	2880	2480
NW	2580	2030	2780	2430
W	2380	1980	2480	2330
SW	2230	1930	2280	2280
Flat Areas				
Wind-exposed		2480		2580
Wind-shielded		2530		2880
Variability				
Franz Josef (0.005 °C m^{-1})			270 m higher	
Lake Tekapo (0.0075 °C m^{-1})			190 m lower	

All elevations are given in metres above sea level (m). Values are based upon MAAT at Mount Cook Village (765 m) and an air temperature lapse rate of 0.0065°C m^{-1}. Variability is calculated using MAAT at Franz Josef (155 m) and Lake Tekapo climate stations (762 m) with given lapse rates.

measured locations where precipitation and humidity values are comparable (Brazier et al. 1998). Using a GIS procedure, the 0°C isotherm elevations were then interpolated between the three climate stations in a southeastern direction based upon distance from the alpine fault (Fig 1A). This modeling of 0°C isotherm elevations is a crude simplification, but for the purposes of an initial permafrost estimate, it is able to provide an approximation for the influence of moisture gradients prevailing across this region of the Alps.

Table 1 gives the adjusted permafrost elevation limits based upon the 0°C isotherm elevation of 2114 m calculated at the Mount Cook Village. This establishes a lower limit of permafrost in steep terrain (on slopes >20°) of 2880 m on sunny northern aspects, decreasing to 2230 m on shaded southern aspects. At Franz Josef, where a strong maritime climate prevails, the 0°C isotherm could be positioned up to 270 m higher, with a corresponding rise of the permafrost limits by the same amount, whereas these limits may be 190 m lower towards the drier climate at Lake Tekapo. At the foot of slopes (<20°), permafrost may be possible up to 750 m lower than on corresponding steeper slopes, but is probable at elevations only 400 m lower.

At elevations where possible steep permafrost is predicted along the Main Divide, glacial ice dominates much of the terrain with only limited exposed bedrock around ridge tops, on steep faces and rock outcrops (Fig 1A). In this region of the Alps, the average ELA is around 2000 m, well below the lower boundary of permafrost such that temperate glacial ice dominates, but areas of polythermal ice and associated permafrost interactions are likely within the higher elevation cliff and hanging glaciers (Etzelmüller & Hagen 2005). In the drier southeast, glacial growth is restricted with both talus and bedrock surfaces featuring prominently at elevations within the estimated permafrost terrain.

The accuracy of the selected lapse rates, MAAT, and resulting 0°C isotherm calculations will have a significant influence on the permafrost distribution estimate. This sensitivity is well illustrated for the area of the Main Divide around Mount Sefton (Figs. 1B-D). The current model estimates widespread permafrost surrounding the summit pyramid and along the ridges to the west and northeast. However, a 200 m lowering of the isotherm due to a colder MAAT or greater lapse rate selection would significantly increase the estimated possible permafrost distribution along all surrounding ridgelines and on all slope aspects. Under the scenario of a warmer MAAT or lower selected lapse rate resulting in a 200 m rise of the isotherm, the estimated permafrost terrain becomes mostly limited to the shaded aspects high on the summit area of Mount Sefton. While illustrating the sensitivity of the topo-climatic key to local calibration, this also gives some indication of the effect future climate warming could have on permafrost distribution in the region.

Local Validation Using Rock Glacier Inventory

Active and fossil periglacial landforms have been previously mapped in the Ben Ohau Range using a threefold classification of debris-covered glaciers, cirque-floor lobe forms, and talus rock glaciers (Brazier et al. 1998, Appendix 1). Although the Ben Ohau Range comprises only a small area of the much larger study region, it does contain the only known active permafrost forms in the region, and therefore is able to provide some initial local-scale validation of the permafrost distribution estimate. The original mapped landform data were transferred into a GIS inventory of active and fossil permafrost forms, with some positions and measurements reassessed using high resolution (0.61 m) QuickBird satellite imagery in combination with a DTM. A total of 70 permafrost forms were mapped according to their Rock Glacier Initiation Line Altitude (RGILA) position as measured from the foot of the talus. Active debris-covered glaciers are not necessarily indicative of permafrost conditions, but are included here to further illustrate the distinct landform zonation that occurs along this range (Brazier et al. 1998).

The active permafrost forms predominate on shaded aspects within a narrow 8.2 km north-south zone towards the centre of the Ben Ohau Range where the highest peaks are just above 2400 m (Fig. 2A). The RGILA of all active landforms would therefore be expected to lie mid-way between the permafrost limits estimated at the southern and northern ends of the range, but instead are positioned at altitudes 20 to 180 m lower (Fig. 2B). Permafrost originating at the foot of slopes might account for the preservation of some of these forms at lower elevations, but the possibility that the model estimate is too high within this area of the study region must also be considered. Although data are unavailable for northerly aspects, the aspect-related variability of the model from east through to west appears to match the distribution of active rock glaciers. No fossil permafrost forms are located within

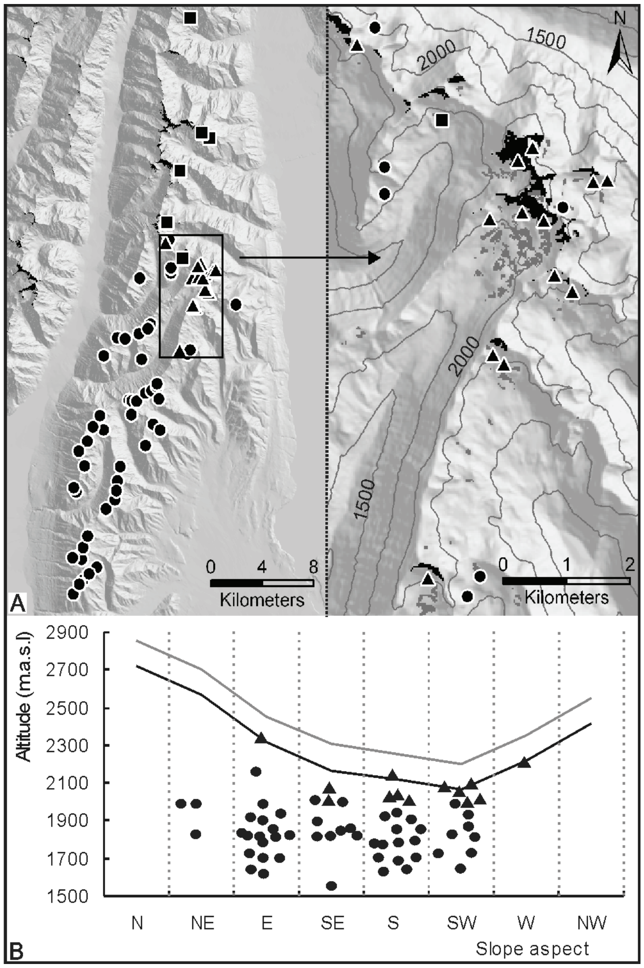

Figure 2. A) Modeled permafrost distribution on steep slopes (black) along the Ben Ohau Range compared with an inventory of active (triangle) and fossil (circle) rock glacier forms, and debris covered glaciers (square). Permafrost modeled at the foot of slopes is also shown (grey), based on slope curvature analyses. B) The spatial distribution of rock glacier forms is compared to steep permafrost lower elevation limits at the northern (grey) and southern (black) ends of the Ben Ohau Range.

the estimated permafrost terrain and most are positioned more than 200 m below the estimated boundary, which is greater than can be expected from 20th Century temperature warming in this region (Salinger 1979). The numerous fossil forms mapped at the southern end of the range are located at much lower altitudes, with surface dating suggesting that many of these forms are periglacial relics from the late Pleistocene (Birkeland 1982). Towards the northern end of the range, increased snowfall combined with topographic effects enables the growth of heavily debris covered cirque glaciers at higher elevations and neither active nor fossil permafrost forms are observed here.

Comparison with Vegetation Mapping

Modern remote sensing-based mapping techniques are able to provide a crude, indirect indication of likely permafrost distribution (Etzelmüller et al. 2001). The presence or absence of alpine vegetation is a particularly well known indicator of

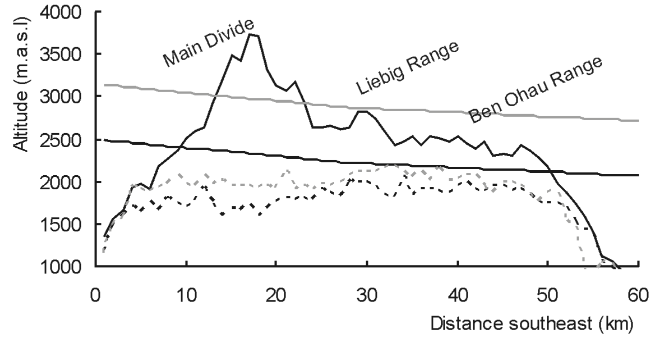

Figure 3. MAV (dashed) and corresponding minimum elevation of estimated permafrost distribution (solid lines) are plotted for steep northern (grey) and southwestern slopes (black) from northwest-southeast across the study region. The topographic profile with main mountain ranges labeled is also provided.

permafrost distribution in mid-latitude mountains (Haeberli 1975), and the inclusion of vegetation abundance mapping from satellite imagery has proven a useful parameter for improved distribution modeling (Gruber & Hoelzle 2001). In the current study, orthorectified 15 m resolution Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) imagery from 2007 was used to create a map of vegetation distribution for the entire study region. To achieve this, the Normalised Difference Vegetation Index (NDVI) was used, which is based upon the contrasting spectral response of healthy vegetation between the red and near infrared (NIR) wavelengths. Combined with a DTM, altitudinal patterns in vegetation distribution were analysed and compared with the estimated permafrost distribution. A comparison is made between the maximum altitude of alpine vegetation growth (MAV) and the estimated lower limit of steep permafrost distribution within every 1 km zone in a northwestern to southeastern direction across the Southern Alps, parallel to the climatic gradient (Fig. 3). To examine the influence of slope aspect on vegetation patterns and any relationship there might be to permafrost distribution patterns, analyses are included for both sunny northern aspects and shaded southwestern aspects. A slope curvature threshold was incorporated to ensure that only pixels with a small change in aspect were included, minimizing the risk of erroneous measurements around sharp terrain features.

In the drier mountains east of the Main Divide, such as the Liebig and Ben Ohau Ranges, the MAV on steep southwestern aspects is positioned at around 2000 m, and is consistently 200 m lower than the estimated lower boundary of possible permafrost for these slopes. Closer towards the Main Divide, this difference increases to over 400 m as the rise in permafrost limits is not matched by any rise in MAV. In fact, the fluctuating MAV decreases closer to the Main Divide possibly as a function of large maritime snowfalls combined with the effects of geomorphic and glacial disturbances. On northern slope aspects the MAV averages 150 m higher than on southwestern aspects, with some greater differences measured nearer to the Main Divide, but never coming close to reflecting the much greater differences that are expected between permafrost limits on these contrasting slope aspects. The lack of any strong MAV pattern across the study region suggests that the usefulness of vegetation as an indicator of likely permafrost distribution is very limited in the Southern Alps of New Zealand. While the presence of vegetation confirms the absence of permafrost, the absence of vegetation offers very little conclusive information as to the distribution of permafrost, particularly nearer towards the Main Divide.

Discussion

Application of topo-climatic relationships established within the Swiss Alps to a more maritime alpine region characterized by extreme climate gradients produces many challenges. MAAT and lapse-rate calibration parameters used here are based on low-elevation climate stations located some distance from the Main Divide, and with the absence of additional data, climate gradients across the highest terrain cannot be modeled with certainty. A current study is suggesting that maximum precipitation might exist very close to, and even leeward to the Main Divide (Kerr et al. 2007), which would likely raise the estimated permafrost limits near to this region. In addition to the effect that climate gradients will have on local MAAT, associated differences in factors such as cloudiness and precipitation will also influence the amount of variation within the topo-climatic key from northern to southern aspects. Heavy snowfall and maritime cloud cover near the Main Divide will influence solar radiation patterns at the ground surface, which largely determine the aspect variation within the key. Therefore, the assumption of uniform variation between slope aspects across the study region must be reconsidered in a more advanced approach to modeling permafrost distribution.

Comparison of modeled permafrost distribution with rock glacier inventories is a well-established approach (e.g., Imhof 1996), but was restricted in the current study by the limited spatial distribution of these landforms. Modern earth imagery such as QuickBird has significantly improved the ability to recognize and map permafrost features, but some subjectivity and potential for error remains in determining active from inactive landforms and defining parameters such as the RGILA. Vegetation patterns in relation to climate gradients and permafrost distribution were explored here on the fundamental basis of being absent or present, but given the ecological diversity that exists across the Southern Alps, more useful patterns might be observed within individual species or by using the NDVI to explore topographic patterns in plant biomass (Gruber & Hoelzle 2001).

Recent large rock failures in the European Alps have suggested that permafrost degradation is a serious concern in relation to climate warming and slope instability (Gruber et al. 2004). In the Southern Alps of New Zealand, the summit collapse of Mount Cook in 1991 detached from a maximum elevation of 3720 m on an eastern exposition (McSaveney 2002). This is well above the estimated lower boundaries of possible permafrost where 20th Century thawing may be expected. However, the large rock buttress involved in the failure extended down to a much lower elevation, and in complex, steep topography, the effects of three-dimensional thermal gradients must also be considered because of contrasting temperatures between colder and much warmer sunny slope expositions of the terrain (Noetzli et al. 2007). Furthermore, bedrock temperatures are complicated by the presence of steep ice bodies because heat exchanges associated with surface melting can induce significant thermal anomalies within the underlying bedrock (Huggel et al. 2008). Of the other large rock avalanche events occurring in the region over the past 50 years, three originated from within the estimated permafrost terrain, while another was initiated from an elevation approximately 140 m below the estimated lower permafrost boundary. In addition, two recent fatal rockfall events near the summits of Mount Cook and Mount Sealy further south, have also originated from within the estimated permafrost terrain.

On the basis of this initial estimate of permafrost distribution and the uncertainties it has raised, a field campaign was initiated during November 2007 measuring the spatial variation of rock surface temperatures on steep bedrock slopes over a 12-month period. Following the methodologies developed by Gruber et al. (2003), 15 miniature temperature data loggers were installed at elevations ranging from 2400 m to 3150 m on various slope aspects both immediately on the Main Divide and on the drier Liebig Range towards the southeast. In addition, a series of high elevation air temperature loggers have been installed across the region to better establish relationships with the low elevation, long term records from the Mount Cook Village climate station. Information regarding the spatial distribution of rock surface temperatures will be used to more accurately model and validate permafrost distribution across the region.

Conclusions

A first-order approach for permafrost distribution mapping in the Mount Cook Region of New Zealand's Southern Alps has been presented. Towards the southeast of the region a drier, more continental climate prevails, and the permafrost estimate gives reasonable correspondence with the limited distribution of active and fossil rock glaciers. Closer towards the Main Divide where conditions are more humid, the lower boundary of permafrost distribution is expected to be significantly higher, but rock glaciers are absent here preventing any potential for local validation. Similarly, modeled vegetation altitudinal limits across the region showed no relationship with the climatic gradients which are expected to influence permafrost distribution. Future modeling will incorporate rock wall temperature data to facilitate permafrost modeling which better accounts for the effects of solar radiation and topographic shading in this complex, steep mountain environment.

Acknowledgments

This paper has benefited significantly from support provided by the Glaciology, Geomorphodynamics & Geochronology Group, Department of Geography, University of Zurich. In particular, Stephan Gruber and Martin Hoelzle are thanked for their suggestions and advice. Fieldwork for this project is funded by the New Zealand Earthquake Commission. We thank Ray Bellringer of the Department of Conservation for his project support. Three anonymous reviewers provided thoughtful suggestions for an improved manuscript.

Abstract

There are several regions on Earth where mean annual temperatures are well below freezing and yet liquid water persists. Such polar regions provide excellent analogues to study the hydrological cycle under conditions that have prevailed in the polar desert environment of Mars. In regions of continuous permafrost, fluxes of energy and water are strongly linked. However, most scientific studies of northern hydrology have been limited to surface process studies focusing on precipitation, snowmelt, evaporation, slope runoff, and stream flow. The springs located at Axel Heiberg Island provide insights into the limits of physical and biological processes associated with groundwater in cold polar deserts. These qualities make them valuable as analogues for groundwater activity on Mars. This paper summarizes the biophysical characteristics of several groups of perennial springs located in a range of settings on Axel Heiberg Island. Included are past and current hydrologic, microbiologic and geomorphic research and climate studies and their application as Mars analogues.

Keywords: astrobiology; groundwater; High Arctic; Mars; perennial springs; permafrost.

Introduction

Groundwater in regions of thick continuous permafrost

Several research groups have reported the occurrence of springs in the High Arctic. Spitsbergen, the largest island in the Svalbard archipelago, resides between 77° and 80°N where permafrost depths are estimated at 100–400 m. Roughly 60% of the island is covered in glaciers and a number of springs occur from Bockfjord in the northernmost part of the island to Sørkapp in the south (Banks et al. 1999, Lauritzen & Bottrell 1994). The Trollosen spring, a thermoglacial karst spring in South Spitsbergen, has a reported discharge rate of about 18 m^3/s of a turbid, 4°C water during the summer. Its flow is thought to originate from moulins on a glacier about 5 km distant. Nearby springs discharge water that is 12–15°C and seem to have a separate hydrothermal source with a subsurface temperature in the deep aquifer of at least 30°C (Lauritzen & Bottrell 1994). The thermal springs at Bockfjord are associated with local volcanic sources and geochemical evidence suggests that temperatures at depth reach between 130–180°C. They form travertine terraces with coatings of biofilms at the surface, and work is presently underway regarding the biological aspects of these springs primarily by the interdisciplinary, international Arctic Mars Analogue Svalbard Expedition (AMASE) team, which is creating a sampling and analysis strategy that could be used for future Mars research (Amundsen et al. 2004, Steele et al. 2004).

Grasby et al. (2003) have reported supraglacial sulfur springs located at 81°019′N, 81°359′W, in Borup Fiord Pass on northern Ellesmere Island in the Canadian high Arctic. Ten spring outlets were observed discharging from the surface of a 200 m thick glacier with active discharges estimated at 1 l/min at some locations and diffuse seeps elsewhere. The origins of the water were not reported, but a large ice-dammed lake located to the north of the spring sites may be a potential source along with basal melting of the glacier. To date, it is not clear if these springs are perennial or are seasonal. The spring outflows are located about 500 m from the terminus of the glacier depositing native sulfur, gypsum, and calcite onto precipitate mounds on top of the ice surface. Grasby et al. (2003) measured outflow temperatures of 1–2°C and reported smelling H_2S in and around the outlets. The water chemistry of the springs is different from local melt water with higher pH and conductivity values than local melt. Light and electron microscopy and culture-independent molecular methods provide evidence of a microbial community associated with the springs. The only other known perennial springs at these high latitudes are those located on Axel Heiberg Island in the Canadian high Arctic. We have identified several groups of perennial springs in a range of settings on Axel Heiberg Island located near the McGill Arctic Research Station (M.A.R.S.); the purpose of this paper is to describe these sites and review the research activities associated with them.

Study Site

Axel Heiberg Island

Axel Heiberg Island (Fig. 1) resides within the Sverdrup Basin, a pericratonic sedimentary trough encompassing roughly 313,000 km^2 and located within the Arctic Archipelago (Pollard et al. 1999). The axis of the basin strikes northeasterly from the Sabine Peninsula on Melville Island to the northwestern region of Ellesmere Island. Axel Heiberg is geologically complex, consisting of folded and faulted sedimentary rocks ranging

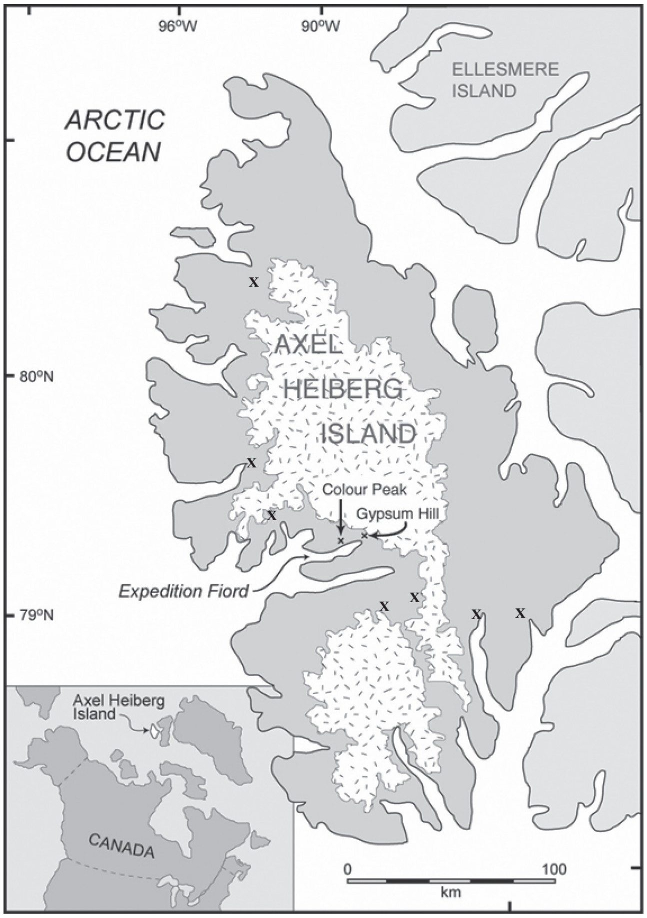

Figure 1. Map of Axel Heiberg Island. The x-marks show approximate locations of perennial springs.

from Triassic to Tertiary in age. Late Paleozoic evaporites locally intrude the overlying sedimentary/clastic rocks in a series of exposed piercement structures that occur mainly in line with the basin axis (Stephenson et al. 1992). The intrusions of the evaporites are typically associated with early Tertiary (Innuitian) orogenic activity and are mapped as Tertiary (Otto Fiord Formation) by Thornsteinsson (1971). However, the emplacement of the anhydrite structures at Expedition Fiord took place during an earlier tectonic phase prior to the mid Cretaceous (Embry & Osadetz 1988, Stephenson et al. 1992). Quaternary stream, deltaic, marine, and glacial sediments cover the valley floors and form raised shorelines.

There is considerable relief near the head of Expedition Fiord with peaks approximately 2000 m a.s.l. that decrease toward the fiord mouth. Breached anticlines produce asymmetrical ridges characterized by steep (70–80°) scarp faces and 25–35° dip slopes. In some locations, piercement structures create more regular and symmetrical hill and mountain features. Weathering of gypsum and anhydrite outcrops has given the diapirs very ragged, serrated profiles. Resistant volcanic sills and dikes have differentially eroded, leading to steep slopes mantled with coarse angular talus.

Glaciers currently cover 30–35% of Axel Heiberg Island, including the Stacie and Müller (McGill) Ice Caps and numerous outlet and valley glaciers. Small ice caps and isolated cirque and valley glaciers are widespread. At Expedition Fiord, the

Table 1c Freezing index

Figure 2. Gypsum Hill Springs, "Little Black Pond."

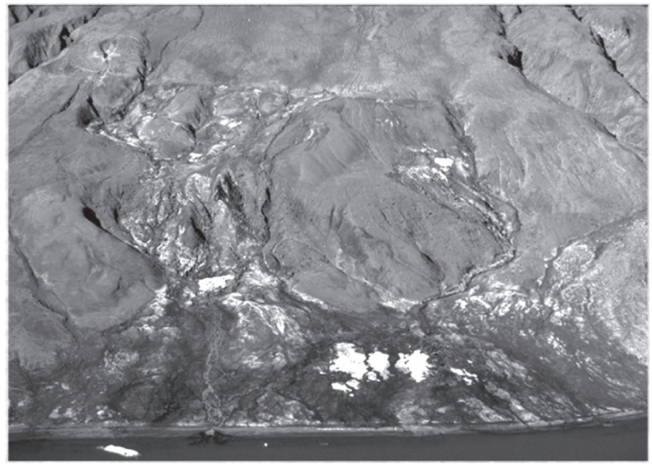

Figure 3. Colour Peak Springs.

White and Thompson glaciers converge roughly 10 km up valley from the head of the fiord, while the terminus of Crusoe glacier lies only a few kilometers west of the Expedition River Valley.

Climate/permafrost

The north and northwest Arctic Archipelago is characterized by polar desert conditions displaying very cold, dry winters and cool summers with maximum precipitation occurring in July. Intermittent climate records for the Expedition Fiord locale are available for the last 47 years, with a more complete record for the last 17 years.

Year-round data from an automatic weather station at Colour Lake (elevation 64 m a.s.l.) has been collected since 1992 indicates a mean annual temperature of -15.5°C with approximately 451 thawing degree-days and 6083 freezing degree-days during an average year (Andersen et al., this study). Tables 1a, 1b, and 1c list the mean average temperatures, thawing, and freezing index (degree-days below and above freezing) for each month during the years 1998–2002.

Permafrost depth has not been measured directly at Expedition Fiord; however, a permafrost thickness of > 400 m was documented in an exploration well at Mokka Fiord on the east side of Axel Heiberg Island, roughly 60 km from Expedition Fiord (Andersen 2004). Other exploration wells in the area reveal that permafrost is generally between 400–600 m thick. Permafrost features include extensive polygonal ice wedge development in unconsolidated fluvial and colluvial deposits at lower elevations.

McGill Arctic Research Station (M.A.R.S.)

The McGill Arctic Research Station is located 8 km inland at Expedition Fiord, Nunavut, on Central Axel Heiberg Island in the Canadian High Arctic (approximately 79º26′N, 90°46′W). Established in 1960 on the shores of Colour Lake, M.A.R.S. is one of the longest-operating seasonal field research facilities in the High Arctic, providing access to glacier, ice cap, and polar desert and tundra environments. Researchers utilizing M.A.R.S. have accumulated the longest continuous mass balance record for any High Arctic glacier (White Glacier). Past and current research conducted at the various springs has been carried out with support of this facility. The geomorphology, climate, chemistry and microbiology of the Gypsum Hill and Colour Peak Springs have been previously described by Pollard et al. (1999), Pollard (2005), Andersen et al. (2002), Heldmann et al. (2005a, b), Omelon et al. (2006) and Perreault et al. (2007), respectively.

Gypsum Hill springs: N79°24.247′, W090°43.968′

The Gypsum Hill spring site (Fig. 2) consists of approximately 40 springs and seeps on the northeast side of Expedition River, discharging along a band nearly 300 m long and 30 m wide between 10–20 m a.s.l. The springs are concentrated at the break in slope where bouldery colluvial materials overlap sandy outwash. The surface around the springs is littered by large boulders from both the till and exposed anhydrite. The area immediately surrounding the springs consists of small mounds separated by shallow gullies. There are outflows occurring in Expedition River; however, thick ice and snow in the winter and high stream flows during the summer have prevented determination of their exact locations. Pollard et al. (1999) estimated the total discharge of the Gypsum Hill Springs to be approximately 10–15 l/s. Spring outflow temperatures range from -0.5°C to 7°C. Major ion chemistry of the spring water is listed in Table 2. Analysis of the dissolved gases and bubbles in the spring water indicates that the source of the water is likely to be a combination of subglacial melt and lake water (Andersen 2004). Two nearby glacially-dammed alpine lakes, Phantom Lake and Astro Lake, provide large reservoirs of water and have basins residing upon gypsum-anhydrite piercement structures. Lake water is transported into the subsurface via permeable strata associated with the piercement structures. The water continues to flow along the subsurface salt strata to the spring sites, accumulating dissolved salts as it flows through this subsurface layer.

The composition of dissolved gases in the springs indicates that only 50% of the water comes from lake water and that the other 50% comes from glacial ice that has melted while isolated from the atmosphere. The dissolved gases in lake water reflect the equilibrium with the atmosphere based on the relative solubility of each gas. In contrast, air trapped in glacial

ice has an atmospheric composition other than for Ne and He. These latter two gases are soluble in ice and would therefore be expected to diffuse through the ice. As an example, the ratio of N_2/Ar in lake water in equilibrium with the atmosphere is 37 while for air it is 84.

Colour Peak springs: N79°22.866', W091°16.270'

The Colour Peak Springs (Fig. 3) are located on the south-facing slope of Colour Peak at an approximate elevation of 100 m a.s.l., emerging from the top of the slope along a line nearly 400 m long. These springs are grouped into three distinct topographically controlled areas with 20 vents discharging directly into Expedition Fiord 300 m down slope. Major ion chemistry of the spring water is listed in Table 2. Interestingly, the springs on Axel Heiberg Island flow all year with little variation in their temperature and are not associated with volcanic activity.

Andersen et al. (2002) show that this can be explained by considering the flow through the subsurface salt layers. The flow enters the subsurface via the permeable strata associated with the salt diapirs that reside beneath the lakes, glaciers, and ice cap. At this depth the groundwater temperature is 0°C. The flow then proceeds below the surface to depths of at least 600 m and is warmed by the local geothermal gradient to temperatures up to 6°C. The flow rate to the surface is rapid enough that the temperature of the emerging groundwater does not change significantly from its initial value at depth.

Perreault et al. (2007) have speculated that sulfur-based metabolism may be the major source of biological energy production in these environments. Surveys of the microbial diversity in the sediments of these springs were conducted by analyzing denaturing gradient gel electrophoresis (DGGE) and clone libraries of 16S rRNA genes amplified with Bacteria and Archaea-specific primers. Dendrogram analysis of the DGGE banding patterns divided the springs into two clusters based on their geographic origin. Bacterial 16S rRNA clone sequences from the Gypsum Hill library (spring GH-4) classified into seven phyla (Actinobacteria, Bacteroidetes, Firmicutes, Gemmatimonadetes, Proteobacteria, Spirochaetes, Verrucomicrobia); δ- and γ-Proteobacteria sequences represented half of the clone library. Sequences related to Proteobacteria (82%), Firmicutes (9%), and Bacteroidetes (6%) constituted 97% of the bacterial clone library from Colour Peak (spring CP-1). Most GH-4 archaeal clone sequences (79%) were related to the Crenarchaeota while half of the CP-1 sequences were related to orders Halobacteriales and Methanosarcinales of the Euryarchaeota. Sequences related to the sulfur-oxidizing bacterium Thiomicrospira psychrophila dominated both GH-4 (19%) and CP-1 (45%) bacterial libraries and 56-76% of the bacterial sequences were from potential sulfur-metabolizing bacteria.

Figure 4. Wolf Diapir Springs.

Skaare Fiord Springs: N78°56.702', W088°17.666'

Sub-glacial discharge has been observed at an alpine glacier near the northeastern end of Skaare Fiord. The flow was discovered by Twin Otter pilots flying over the glacier during April 2002 when air temperatures were still well below freezing. Initial reconnaissance during the summer found an icing that was approximately 0.5km in diameter with red-tinted fine sediments covering the surface. The discharge was flowing from the central area of the icing at a rate of ~250 ml/sec, the water tasting strongly of iron, but not saline.

East Fiord springs: N79°30.109', W093°25.716'

In April 2007 during a wildlife survey, biologists from the Canadian Department of Environment reported to our research team a reddish staining on a glacier in the vicinity of East Fiord. Subsequent exploration of the area by helicopter located a large icing, stained with an iron-rich precipitate forming on and draping over the north edge of the unnamed glacier. Water was observed to be flowing from a series of outlets on top of the glacier about 20 m from the edge.

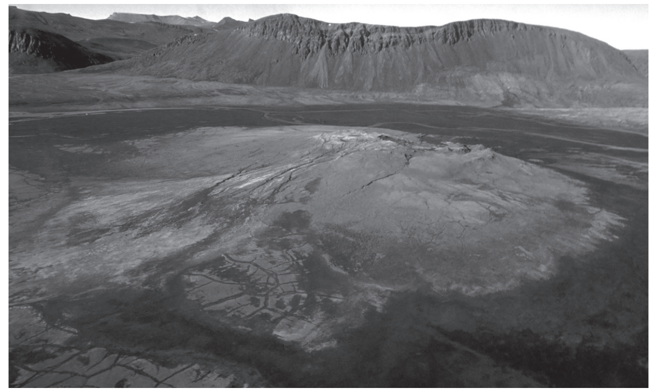

Figure 6. Middle Fiord Pingo with active outflow.

Wolf Diapir springs: N79°04.285', W090°12.755'

The Wolf Diapir site is characterized by a large mound of salt 3m in height and 3m in diameter that forms "fumarole-like" structure (Fig. 4). A saltpan extends about 0.5 km to the west. Water is present as a pool in the central portion of the structure, and during the winter months as temperatures decrease, the water level builds up and flows out and over the top producing a series of small terraces and rim pools on the NNE side of the structure. Increasing air temperatures in the summer allow for the dissolution of the salts (such as hydrohalite), and the spring water breaks through the sides and is released at the base lowering the water level. During July 2004, water flowing beneath and through the side of the structure was saline with a temperature of -3.5°C, pH of 6.4, and ORP of 60.0 (mV, NHE). Hydrogen sulfide was present in and around the discharge site.

Nine km SW of the Wolf Diapir Spring, a saline stream originating from beneath a landslide deposit with a flow rate of a flow of 10–12 L l/ss^{-1} occurs in the vicinity of Junction Diapir, originating on the south side of the dome and bounded by the Steacie Ice Cap. It has not been determined if this flow is perennial.

Stolz Diapir Springs: N79°05.343', W87°02.228'

At Whitsunday Bay a single spring discharges approximately 150 m up the south east side of Stolz Diapir and flows along a deep valley for 200m before it fans onto the Whitsunday River plain (Fig. 5). The position of the outflow moves up and down slope from year to year. Discharge is fairly constant at 40–50 l s^{-1} and the discharge temperature is constant at 1.2°C. Major ion chemistry of the spring water is listed in Table 2. In some years the outflow is marked by a single well-defined vent 40–50 cm in diameter while in others the outflow permeates through a layer of colluvial debris. This hypersaline spring produces a salt tufa deposit up to 5 m thick near the spring outlet and 1m thick near the valley mouth. In winter hydrohalite ($NaCl \cdot 2H_2O$) precipitates form a series of pool and barrage structures that staircase down the outflow channel. Several pools up to 10m wide and 3–5 m deep allow the water to cool in stages as it works its way down the valley with temperatures ranging from -10°C to -17°C in pools near the outlet to the eutectic point of the salts on the floodplain. The hydrohalite deposit merges with a fan-shaped icing that spreads on to the Whitsunday river flood plain. The source of recharge for the spring appears to be snowmelt that flows into and through the dome on the north west side of the diapir. The inflowing water is fresh, low conductivity (58.3 µS/cm) and near neutral pH (6.9). The inflowing water picks up the salts via dissolution of halite, which is present as large deposits at and near the surface of the diapir.

Bunde Fiord Ssprings: N80°22.749', W93°57.584'

Approximately 16 km SSW of Bunde Fiord, a large rectangular icing fills an east-west trending river channel where it dissects the northern edge of an anhydrite diapir abutting the far northwest end of the Mueller Ice Cap. The icing is roughly 200 m by 100 m, 2 m thick, and covered with a thick paste of precipitates and evaporates. The icing forms as a result of perennial flow from a series of small springs that exit the diapir 10–20 m above the base. The discharge is saline and flows into a small stream where it mixes with meltwater from local glacial sources. The stream contains numerous filamentous brown mats consisting of pennate diatoms.

Middle Fiord pingo: N79°43.653', W94°13.794'

At Middle Fiord a small spring flows from the side of a large pingo situated in the middle of a large floodplain 3 km downstream from Middle Fiord Glacier (Fig. 9). The pingo is 110 m in diameter and 20m high and is composed entirely of medium-grained sand and fine gravel. Water discharges at 0.5 to 1.2 l/s and at a temperature of 1.2°C from two or three closely-spaced outlets midway up the west side of the pingo.

Mars

Groundwater and the search for life on Mars

Despite the vast differences between the two planets today, Mars and Earth may have been much more similar early in their histories. If life developed on Mars as it did on early Earth, it may have faced an untimely extinction as the cryosphere of Mars enveloped the entire planet, its atmosphere thinned, and liquid water ceased to exist at the surface; or perhaps it has retreated to subsurface refugia. Nonetheless, even when Mars was wet it was probably cold. Thus the hydrological cycle in the coldest regions on Earth provides the best analog for a Martian hydrology. From studies of springs, rivers, and lakes in the polar regions, quantitative models have been developed that show how liquid water could have persisted on Mars even if mean annual temperatures were below freezing (Lee et al. 2001, Andersen et al. 2002, Heldmann et al. 2005a, b, McKay et al. 2004).

Springs, residual icings, pingos, and massive ground-ice deposits located in the Arctic (and Antarctic) provide opportunities to study microbial ecosystems in extreme polar environments. The ranges in temperature, pH, redox, nutrient availability, and the large seasonal variations in light have undoubtedly shaped the structure and function of the ecosystem as well as impacting the biological record left in the sediments. The planet Mars may have once hosted microbial ecosystems in a physical setting not too dissimilar to the Earth's polar regions. Determining the nature of the early Martian climate, the existence of subsurface water, or whether Mars ever gave rise to life will be aided by studies of terrestrial microbial ecosystems in regions of thick, continuous permafrost.

Abstract

A cut-off wall back dam has been designed for the existing tailings impoundment at the Red Dog Mine, Alaska. The planned cut-off wall, which is about 5,000 ft long and up to 170 ft deep, is located in an area of warm permafrost that consists of colluvium and alluvial materials overlying shale bedrock. The geotechnical program included a total of 41 boreholes on either side of the cut-off wall alignment. Geotechnical considerations included ice-rich and organic materials up to 19 ft thick and establishing design depths for the cut-off wall in frozen shale. These geotechnical issues have been addressed through a stable embankment design and deep excavation technology. Instrumentation and monitoring will be used to monitor the performance of the cut-off wall after construction is completed in the next two years.

Keywords: cut-off wall; dam design; geotechnical investigation; trench cutter.

Introduction

Teck Cominco Alaska Inc. (TCAK) commissioned Golder Associates (Golder) to design a Back Dam to minimize the potential for seepage at the southern end of the tailings impoundment at Red Dog Mine, Alaska. The Back Dam was designed for an elevation of 960 ft with a planned closure elevation of 986 ft.

The Red Dog Mine is located approximately 90 miles north of Kotzebue, Alaska at about 68 degrees latitude. The proposed Back Dam is located at the north end of the Overburden Stockpile, as shown in Figures 1 and 2.

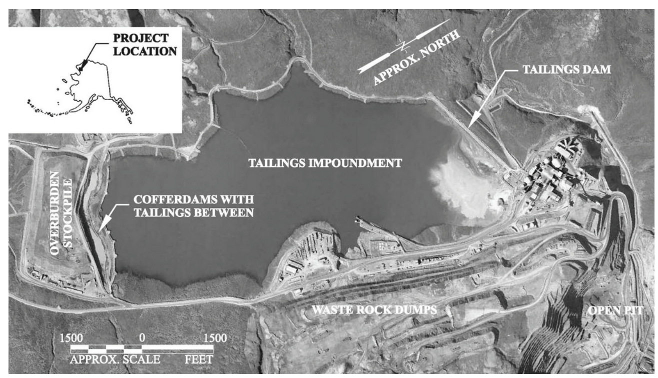

Figure 1: Back Dam location.

Background

Since 2002, the Back Dam design progressed through several stages and several options for reducing the seepage potential were reviewed. The initial design concept included construction of a cofferdam and installing a geomembrane liner on the upstream face of the Overburden Stockpile that would be keyed into silty native soil of relatively low permeability. Subsequently, TCAK constructed two waste rock cofferdams with a layer of geotextile and tailings placed between and a geotechnical investigation was performed by Golder in 2004 to verify the engineering parameters and assumptions used in the design. Based on the 2004 investigation results, ice-rich and organic materials were encountered below the proposed geomembrane liner and highly fractured bedrock was found near the liner key-in elevations.

During revision of the Back Dam design to account for the findings of the 2004 investigation, TCAK requested that the design should incorporate a cut-off to low permeability bedrock to reduce the risk of long-term seepage through the native materials and weathered bedrock. Several cut-off wall options were evaluated such as grouting, deep soil mixing, sheet piles, vibrated beam, a slurry trench, extending the geomembrane liner into a trench, and using a Bauer Cutter Soil Mixer (CSM). The option selected included constructing the cut-off wall with the Bauer CSM through an embankment between the Overburden Stockpile and the cofferdams.

In 2005 and 2006, Golder performed another geotechnical investigation along the southern cofferdam to determine the depth to low permeability bedrock. Ice-rich materials and organics were also encountered during this investigation and the low permeability bedrock was found to be up to about 170 ft below the proposed dam crest elevation of 960 ft.

Following the geotechnical investigation, the Bauer CSM was withdrawn as an option due to its very low production rates through rock and the amount of rock excavation expected. The Bauer CSM was replaced by a Bauer Trench Cutter.

Site Characteristics

Climate

The climate at the Red Dog Mine is characterized by long, cold winters and moderately warm, windy and somewhat rainy summers. The average annual temperature is 24°F (-4°C) with an air freezing index (AFI) of 4731°F-days and an air thawing index (ATI) of 1899°F-days. Total precipitation is generally between 10 to 13 inches per year and the average annual snowfall is 48 inches.

Thermal conditions

In the early 1980s the Red Dog Mine site was the subject of various feasibility and design studies. During this timeframe, approximately 50 thermistor strings were installed in geotechnical boreholes to provide information on the subsurface thermal regime of the area. These early readings are summarized in a monograph produced by the American Society of Civil Engineers (ASCE) (Hammer et al. 1985) that indicated relatively warm permafrost was present at the mine site and that surface water and shallow groundwater greatly influenced the thermal stability of the permafrost soils. Significant thaw bulbs were delineated surrounding streams in the area and the average temperature in a given area was significantly increased by poor drainage conditions and/or exposure to sunlight. In shaded areas with good drainage, temperatures averaged as low as 25°F (-3.9°C). In exposed areas with poor drainage, temperatures averaged as high as 31°F (-0.6°C) in frozen soils and some very poorly drained exposed areas found no permafrost present (to the depths explored).

Between 1995 and 1997, seven thermistor strings were installed within the Overburden Stockpile. Temperature readings from these thermistor strings indicate the permafrost has aggraded into portions of the stockpile and the depth to the top of permafrost varied between about 15 ft to 70 ft below the ground surface (Water Management Consultants 1999).

Thermistor readings were also taken during the 2005/2006 geotechnical investigation that indicated an average thaw depth of 18 ft below the native soil surface and average permafrost temperatures of about 31°F (-0.6°C). The deepest thaw depths were located near historic drainages.

Geology

The Overburden Stockpile site is reported to be generally underlain by a layer of unconsolidated, ice-rich, colluvial deposits, and interbedded Cretaceous age shale with inclusions of dark grey to brown sandstone.

Subsurface conditions

Subsurface conditions have been characterized near the proposed cut-off wall location from the geotechnical investigations performed in 2004 through 2006 that included 15 boreholes near the north face of the Overburden Stockpile and 26 boreholes along the southern cofferdam and near the abutments. The locations of these boreholes are shown in Figure 2 with subsurface profiles shown in Figures 3 and 4. These investigations also included test pits, thermistor string readings, packer tests, and laboratory testing.

- Fill materials were encountered on the haul roads, cofferdam, and Overburden Stockpile. The waste rock fill materials at the haul road and cofferdam generally had a composition of silty gravelly soil with occasional cobbles and boulders. Fill materials at the Overburden Stockpile mainly consist of Kivalina shale that had been stripped from the mining area.
- The native soils are colluvial and alluvial materials comprised of organic soil, ice and ice-rich soil, silty clayey soil and sandy gravelly soil.
    - Ice-rich and organic materials up to 14 ft and 19 ft thick were encountered near the cut-off wall alignment and below the Overburden Stockpile, respectively.
    - The silty clayey soil was loose to compact when thawed, averaged about 6 ft thick and generally thinned out toward the east.
    - The sandy and gravelly soil consists of silty sands to poorly graded sands and gravels that were typically compact to dense when thawed.
- The shale bedrock underlying the colluvial and alluvial materials was typically highly to completely weathered near the contact surface and became fresher with depth. The rock was generally fractured with a rock quality designation (RQD) of less than 20%. Rock strengths varied from weak (R2) to very strong (R5) with estimated uniaxial compressive strengths (UCS) up to 22,010 psi. The majority of bedrock encountered, about 75%, had a UCS less than 7,500 psi.

Design Considerations

Cut-off wall alignment

The cut-off wall alignment was selected to limit the amount of excavation into the Overburden Stockpile and minimize disturbance of the cofferdam. Using an excavation surface derived from the borehole and ground topography data, an alignment for the cut-off wall was developed based on the criteria that included:

- Maintaining the cut-off wall within the center of the constructed embankment to protect the cut-off wall from slope instability issues.
- Using 1H:2V (horizontal to vertical) slopes for the excavation prism starting a distance of 1.5 ft out from the alignment centerline at an elevation of 986 ft. The offset distance was based on a 3 ft cut-off wall width and the slope angle was based on the 2 to 1 stress distribution method, which is an empirical approach based on the assumption that the area over which the load acts increases in a systematic way with depth.

Cut slopes were developed based on natural slope angles with flatter cut slopes expected on the northern side of the alignment within the impoundment area. A limited amount of excavation into the cofferdam was considered tolerable depending on the seepage flows encountered after dewatering.

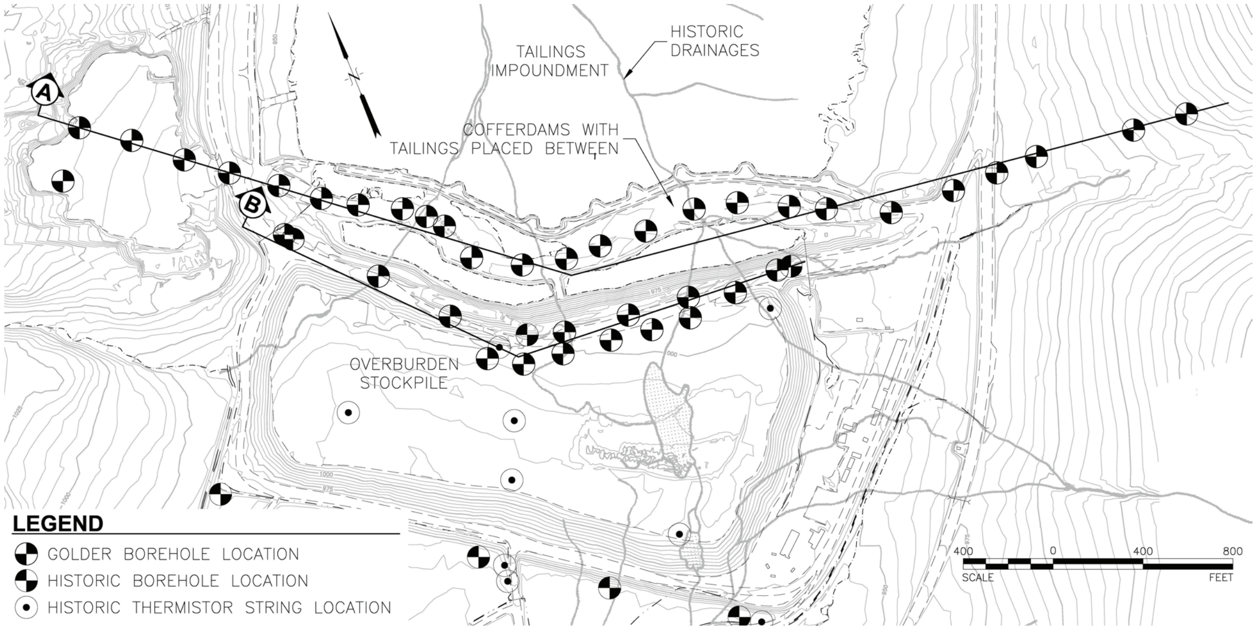

Figure 2. Borehole locations.

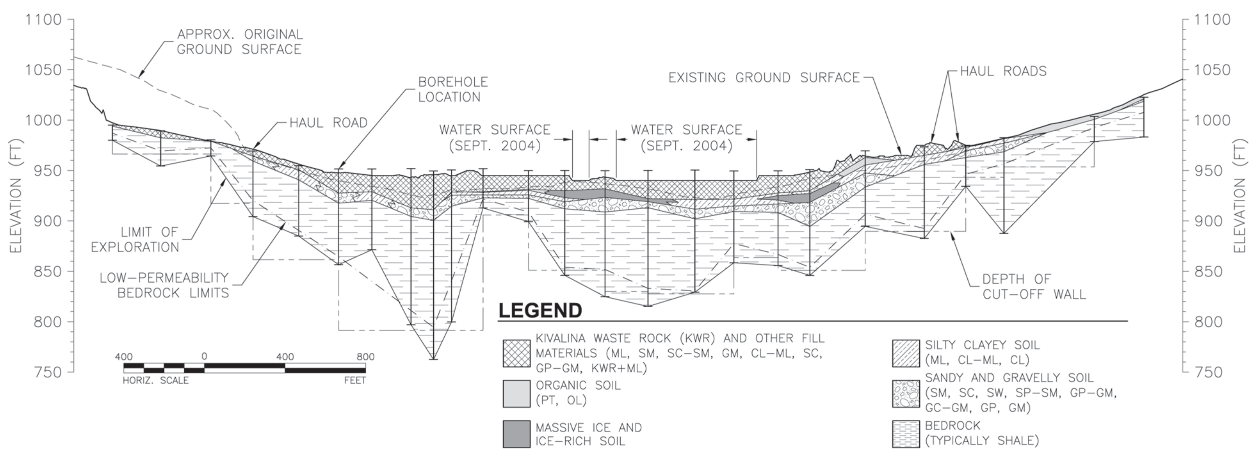

Figure 3. Section A through cofferdam.

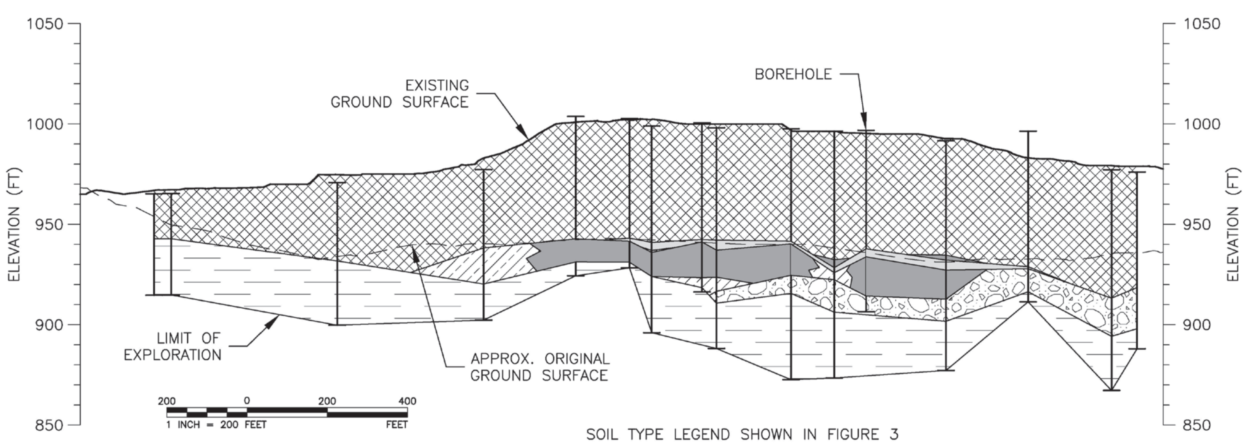

Figure 4. Section B through Overburden Stockpile.

Cut-off wall embankment section

The cut-off wall embankment will consist of a central section composed of select fill produced from screened crushed rock and compacted in controlled lifts to 95% maximum dry density (Modified proctor) to optimize strength and limit impacts from settlement. The select fill width was arbitrarily set at 20 ft for crest elevations of 986 ft and higher with 1H:3V side slopes. This provides a base width equivalent to the estimated deepest fill height (a criterion similar to what is used for impervious core dams) and keeps the select fill within the base excavation limits. The 20 ft width also allows for future raises, if required.

Rockfill, placed in controlled lifts and compacted with a minimum number of passes with a roller, will be used as fill outside of the select fill prism to provide additional stability with 3H:1V side slopes. The rockfill materials will be produced from waste rock from the mining operations or borrowed from other rock quarry areas. Acid producing rock will only be allowed on the upstream side of the cut-off wall. Some maintenance and additional fill placement is expected as the underlying ice-rich materials slowly thaw and consolidate, including some small slope failures and slumping due to as much as 9 ft of differential settlement, especially if the ice thaws quickly. The integrity of the cut-off wall, which is supported by the select fill section, will not be affected as these deformations will occur within the fill materials outside of the select fill section.

The proposed trench cutter and base carrier need a minimum work area of about 30 ft from the centerline of the cut-off wall alignment; therefore, the width of the embankment crest will be about 60 ft to keep the cut-off wall within the center of the embankment. As the cut-off wall construction needs a level work surface, stepped benches are required as the elevation increases at the abutments. In addition, a stepped bench is required at the deepest wall section due to the excavation limits of the proposed trench cutter. These benches were extended in stages to overlap gaps in the cut-off wall.

Cut-off wall panel target depths

The depth to low permeability bedrock, which was defined as having a permeability of 1 x 10^{-6} cm/sec or lower, was established during the 2005/06 geotechnical investigation. Permeability of the bedrock was typically determined using visual methods instead of the planned packer testing due to the frozen state of the rock. The visual criterion for apparent low permeability was one or less tight fractures per foot for a minimum length of three feet. Based on this criterion, the depth to apparent low permeability bedrock is shown in Figure 2. The cut-off wall panels will be keyed 3 ft into the apparent low permeability bedrock.

The deepest panel areas are located near historic drainages. These deeper zones of higher permeability bedrock are believed to be caused by freeze/thaw cycles and other weathering affects. The shallower panels are located outside of these historic drainages and in areas where the bedrock surface was encountered at a higher elevation. Therefore, these higher areas have not been exposed to the same degree of weathering and are less fractured at depth.

Thermal considerations

The cut-off wall is expected to be susceptible to degradation from freeze-thaw cycles; therefore, an insulated section will be installed to keep the frost penetration above the top of the cut-off wall. The insulation must also be wide enough to control frost penetration from the sides.

Due to the warm permafrost temperatures, which are near 31°F, the frozen conditions are not expected to affect the cut-off wall installation.

Instrumentation and monitoring

Instrumentation including thermistor strings, piezometers, and survey monuments will be important to monitor the performance of the seepage reduction structure. Thermistor strings will be installed to monitor degradation or aggradation of the permafrost. Standpipe piezometers will be installed to monitor water levels and seepage potential across the cut-off wall. Surficial survey monuments will be used to monitor settlement. Additional instruments installed within the cut-off wall itself, such as inclinometers and extensiometers to monitor vertical and horizontal movements, are important to monitor the performance of the cut-off wall.

Contingency options

In the event the cut-off wall does not perform as intended, as indicated by an increased head drop across the cut-off wall, some contingency options include jet grouting and permeation grouting. Jet grouting would likely be used for repairing higher than expected seepage in the fill and soils above the bedrock and possibly within the completely to highly weathered bedrock. Permeation grouting would be used to repair the bedrock. Water tests are typically performed prior to permeation grouting to evaluate the permeability of the rock and select the starting mix; therefore, this option would be the most successful under thawed conditions.

After the cut-off wall has been constructed, we expect the permafrost will aggrade into the fill embankment as it did into the Overburden Stockpile. Therefore, these contingency options will be considered following monitoring of the piezometers and thermistors strings.

Engineering Analyses

Engineering analyses performed for the design included seepage modeling, slope stability analyses (for the constructed embankment and cofferdam), hydrology and hydraulic analyses, thermal modeling, settlement, trench stability, and mix design of the cut-off wall materials. The following sections describe the results of the seepage analyses and mix design testing.

Seepage modeling

Potential seepage rates based on the cut-off wall design and future closure options were evaluated using the 2-D finite element program SEEP/W®. Analyses were carried out to evaluate seepage through the deepest section and the average section along the alignment. Some of the variables evaluated included:

- Changing the depth of the cut-off wall at the deepest section from 50 ft below the embankment to a 3 ft key into low permeability bedrock (10^{-6} cm/sec).
- Changing the hydraulic conductivity of the cut-off wall between 10^{-6} cm/sec and 5 x 10^{-7} cm/sec.
- Changing the hydraulic conductivity of the native soils and weathered/fractured bedrock, which were assumed to have the same permeability, between 10^{-3} cm/sec to 10^{-5} cm/sec (worst to best case).
- Changing the closure option from no tailings beach to a 900 ft tailings beach using 300 ft increments.

Results from the seepage modeling included the following:

- Keying the cut-off wall into low permeability bedrock decreased the flux values substantially assuming the worst-case (1 x 10^{-3} cm/sec) for the hydraulic conductivity of the native soils and weathered/fractured bedrock.
- For the best case native soils and weathered/fractured bedrock hydraulic conductivity, there was essentially no difference in flux values if the cut-off wall is installed at least 50 ft below the embankment fill whether it is keyed into the low permeability bedrock or not. Increasing the hydraulic conductivity of the native soils and weathered/fractured bedrock by an order of magnitude (average case of 1 x 10^{-4} cm/sec) about doubled the flux values.
- Assuming the native soils and weathered/fractured bedrock have at least a hydraulic conductivity of 1 x 10^{-4} cm/sec or less, seepage rates will still be relatively low if the cut-off wall terminates above the target depths.
- Adding a tailings beach may reduce the seepage flows up to 50%. A tailings beach that is 600 ft to 900 ft long will reduce seepage flows about 20% more than a tailings beach that is 300 ft long.
- The head drop across the wall could vary from 7 ft to 32 ft. The average head drop across the wall for all cases was 19 ft.
- Under completely thawed conditions, seepage flows should be expected to vary from about 30 gpm to 80 gpm for the entire cut-off wall alignment. Lower seepage values should be anticipated if:
  - The cut-off wall target depths can be achieved during construction;
  - The hydraulic conductivity of the cut-off wall or the low permeability bedrock is less than the design permeability of 1 x 10^{-6} cm/sec; and/or,
  - A tailings beach is constructed.

Mix design

The performance goals for the mix design were developed based on the engineering analyses described above. As settlements and stability are not expected to be a design concern, the minimum mix design compressive strength and deformity was determined qualitatively to be 100 psi and 5% strain, respectively, which should be greater than the surrounding soil. A minimum permeability of 1 x 10^{-6} cm/sec was selected based on the seepage analyses; however, a performance specification was provided based on a flux value of 0.007 gpm/ft width for a head loss of 23 ft and a minimum wall thickness of 2.6 ft to possibly reduce material quantities and save costs. This specification should provide a maximum flow rate of about 40 gpm across the entire cut-off wall.

Mix design testing was performed at Golder's laboratory in Burnaby, British Columbia, Canada using the following available materials:

- Potable water available at site (pH = 7)
- Type I cement meeting ASTM C150
- Bentonite meeting API 13A, Section 9
- ¾-inch minus crushed rock from site, which was passed through LA abrasion devise to simulate cuttings from the Trench Cutter

The mix design results are shown in Table 1. Based on the mix design testing results, Mix Design No. 4, which is 19% water, 10% cement, 3% bentonite, and 68% aggregate, met the performance criteria of 100 psi minimum compressive strength and a maximum permeability of 1 x 10^{-6} cm/sec at a strain of 5%. Additional testing will be performed by the contractor during construction to verify the field mixture continued to meet the performance specifications.

Current Construction Highlights

Excavation and embankment construction

Excavation and embankment construction is being performed by TCAK with construction quality control (CQC) provided by Golder. To date, the embankment has been constructed for about half the alignment and excavation depths have been similar to what was estimated from the design drawings. An example of some of the ice-rich materials encountered during the excavation is shown in Figure 5.

Slope stability was monitored on a daily basis during the embankment construction and slopes were flattened as necessary. Seepage flows through the cofferdam were generally low and easily controlled. However, seepage flows through the Overburden Stockpile were higher than expected and required construction of drainage trenches. A photograph of the constructed embankment is shown in Figure 6. Construction of the embankment is planned for next year with the majority of excavation occurring in the winter.

Cut-off wall construction

The cut-off wall is being constructed by Golder Associates Innovative Applications (GAIA), a wholly owned subsidiary of Golder's Canadian company providing specialized contracting services, with assistance from Bauer Maschinen. About 65 linear ft of cut-off wall has been constructed in 2007 to evaluate the performance of the cutter heads (Fig. 7), the slurry transport systems, and the mix design. Cut-off wall construction is scheduled to continue next year with two 12-hour shifts from May to October. The project is expected to be completed in 2009.

The cut-off wall is constructed by installing a series of primary and secondary panels. Construction begins by installing reinforced concrete guide walls to help support the near surface soils and provide alignment and continuity for the cut-off wall. Slurry is then introduced into the shallow trench between the guide walls and the panel is pre-excavated further to submerge the slurry pump on the trench cutter. Excavation continues with the trench cutter to the design depths. During this excavation, the slurry is recycled through a desander. The working slurry in the excavated column is then replaced with fresh slurry and the panel is completed by backfilling the column with tremied plastic concrete.

Conclusions

Based on the results of geotechnical investigations performed in warm permafrost for a cut-off wall in northwestern Alaska, ice-rich materials up to 19 ft thick were encountered in the overburden materials along the proposed alignment. In lieu of packer testing, which could not be performed in the frozen ground, a visual criterion was also developed to determine cut-off wall target depths in apparent low permeability bedrock. A cut-off wall up to 170 ft deep was required based on the borehole data.

To address the potential settlement issues from the melting ice-rich soils, a stable embankment design was developed that included excavating the ice-rich materials and constructing the central part of the embankment with select engineered fill. The cut-off wall will be constructed using a Bauer Trench Cutter that is capable of excavating into the bedrock to the design target depths. Plastic concrete slurry composed of aggregate, cement and bentonite will be used to backfill the excavation. Instrumentation and monitoring will be used to monitor the performance of the cut-off wall after construction is completed.

Abstract

Based on the results of long-term investigation, this paper outlines the chemistry of groundwater of open and suprapermafrost taliks, occurring beneath the channel and arms, as well as in the low terraces of the Middle Lena River. This paper also illustrates the character of changes in the groundwater chemistry within the vertical profile and along the stretch of channel sediments forming an open talik under the Lena River; how these changes depend on surface water TDS fluctuations during the year-cycle; and specific features of mineral content of underlying bedrock. We have also regarded the impact of permafrost processes and human contamination in change of suprapermafrost talik groundwater chemistry.

Keywords: chemistry; hydrogenous taliks; open river talik; suprapermafrost talik.

Introduction

In Central Yakutia, with prevailing continuous permafrost, the groundwater in taliks is widely distributed under the Lena River channel, under lakes, cut-off meanders, and small rivers. Their chemistry is considerably affected by the geological and structural pattern of the territory, terrain type, geocryologic conditions, and the composition of recharge water.

There has been a thorough investigation of peculiarities of groundwater chemistry origins for taliks in the Middle Lena, where the river passes on from the Prilensky plateau region to the Central Yakutia lowland area. The valley's profile changes correspondingly from a narrow valley with steep rock sides to a vast terraced accumulative valley. The widest terraced part of the river valley situated on the western bank between the Tabaga and Kangalass bedrock fold is known as Tuymaada. It is 6–8 km wide. It includes two terraces and a flood plain which is separated from the main channel by numerous arms and islands. The width of the main channel of the Lena River at the town of Yakutsk is about 3 km. The Lena River flood plain is annually inundated by floodwater, its level above mean water reaching 8–10 m, according to long-term assessment. The flood plain topography is hilly, complicated by numerous narrow, semi-cut-off depressions and arcs. Arcs are made of fine and medium sand of channel facies, its surface covered by flood plain sabulous-loamy sediments 0.5–2.5 m thick. In the upper part of the cross section of semi-cut-off depressions and scourways we can identify a sabulous-loamy layer, up to 5 m thick. The combined thickness of the alluvial sediments, forming the flood plain, reaches 10–15 m.

Alluvial sediments in the Tuymaada region occur in Middle Jurassic rocks, upper layers of which are composed by clayey siltstone interbedded by fissured sandstones. Upstream the river, the thickness of Lower Jurassic terrigenous sediments is gradually diminishing; starting in the town of Pokrovsk the channel alluvium is underlain by carbonates.

The eastern low terraces are separated from the fourth one (Bestyakh) by a bench up to 20 m high. The depth of the river in the middle is 3–5 m, reaching 15–20 m along the fairway.

The spring flood of the river typically brings a rapid and high level rising. The main yield falls in the warm season. The winter period witnesses 9%–11% of the total yield. The river is completely frozen from the first half of November until the second half of May. It is mostly meltwater-recharged (50%), up to 35% rainfall-recharged, and about 15% of the recharge comes from ground water.

In the studied area permafrost covers all the territory, except for the Lena River channel and large lakes which are underlain by open taliks. The thickness of permafrost ranges from 20 to 450 m. The minimal thickness (20–50 m) is identified within low flood plain, under islands, and under some lake taliks. In the first and second fluvial terraces of the eastern bank (opposite Pokrovsk), separated from the channel by wide flood plain, the thickness of permafrost reaches 250–350 m; in the first fluvial terrace of the western bank (Yakutsk and suburbs) it makes 216–270 m, extending northwards up to 475 m (Khatyryk). Seasonal thawing depth depends on the general climate and a number of local factors: lithological composition of soils, their water-saturation, water permeability, shading effect, type of vegetation, the stage of the area in terrain, underlying bedrock temperature, etc. Depending on these factors the thickness of the seasonally thawing layer varies within quite a wide range (from 0.3 to 4.5 m).

The temperature of the permafrost within fluvial terraces is not uniform. The lowest temperatures (from -2.5°C to -4°C) occur in the ground that forms the flood plain, the surface of which is considerably swamped and peated. Within the first and second fluvial terraces the temperature is lower (from -0.9°C to -2.5°C), only in swamped and peated areas in the rear sides of the terraces the temperature falls to -3.6°C.

Research Methods

The existence of taliks in Lena River frozen ground is caused by the warming effect of river-, lake-, and suprapermafrost waters. According to the stage in the terrain, taliks are subdivided into river taliks, occurring in active channel sediments and bedrock immediately under the river, and terrace taliks, formed under flood plain and dead-channel lakes, or in depressions at the floors of arcs, ridges, and terrace slopes.

Initiated in the mid 1950s by the Permafrost Institute long-term investigations on water chemistry of hydrogenous taliks in the middle Lena valley have been continued. The investigations include drilling, water, and ground sampling for chemical analyses, temperature measurements in instrumented boreholes, as well as long-term observations of groundwater level and chemistry in taliks. Data obtained from long-term hydrogeochemical studies of open and suprapermafrost taliks occurring beneath the river channel and arms, as well as in the low and medium terraces in the Middle Lena valley were analyzed. This allowed us to determine variations in groundwater chemistry in relation to the dissolved solids concentration in source surface water in an annual cycle and to the composition of the underlying bedrock. An understanding was gained on the effects of cryogenic processes and anthropogenic contamination on talik water chemistry.

Results and Discussion

Open talik under the Lena River

The Lena River open talik was first tested in 1958 by a Gidroproekt Institute expedition in the Pokrovsk area. The 70–200 m deep drill holes completed on the islands and in the channel penetrated 27 m thick sandy-pebbled sediments and underlying fissured Cambrian limestone. During further investigation the groundwater of the Lena River talik was revealed in the Peschany island opposite Tabaga Point at the interval of 10.4–105.8 m, the water level settled at the depth of 4.37 m from earth surface. Among the water-bearing materials in Peschany island are anisometric quartzo-feldspathic sands, Quaternary gravels, and underlying fissured sands and Lower Jurassic siltstone. In channel sediments where there is no permafrost the water is non-artesian, and in the islands in conditions of active suprapermafrost forming, waters revealed in channel sediments have a slight pressure.

On the projection, the open talik zone contour repeats the contour of the channel zone. Its width ranges from 2.0 to 2.7 km.

Total dissolved solids (TDS) and chemistry of Lena River talik groundwater are not homogeneous judging by alluvial sediments cross section. In upper layers of channel sediments the chemistry of the water varies during the year according to the changes occurring in the composition of recharging surface water.

In winter water TDS reaches 500 mg/l with hydrocarbonate-chloride composition, and during the warm period it reduces down to 70–150 mg/l, when calcium and magnesium hydrocarbonates start prevailing.

In the bottom layers of the river talik alluvial zone the chemistry of water is affected by the mineralogical composition of the underlying bedrock. South from Pokrovsk, where channel sediments overlie Cambrian limestone, the chemistry of the bottom alluvial zone water is dominated by calcium and magnesium hydrocarbonates, and the TDS makes 330–570 mg/l (interval 33–70 m).

Downstream where Cambrian limestone dips below Jurassic sandstone in the basal levels of channel sediments, water, classified by the dominant dissolved ions, is mostly hydrocarbonate and natrium type with a TDS of 350–490 mg/l (Fig. 1).

The temperature in the Lena River channel ranges from 1°C to 4°C. On the old islands the soil is frozen down to 15-60 m deep. In the underlying talik, bedrock water is slightly over-mineralized. Thus, in fissured Cambrian limestone on the island opposing Pokrovsk, water TDS under the permafrost at a depth of 15 m made 500 mg/l, and its composition was hydrocarbonate magnesium-calcium; and on Ponomarev Island, opposing Yakutsk, under 25 m of permafrost, water revealed in Jurassic sandstone had a hydrocarbonate natrium composition, an increased content of chlorides, and TDS of about 1 g/l. Such composition occurs as a result of poor permeability under the permafrost.

The analysis of water chemistry in channel sediments of an open talik under the Middle Lena River (from Bulgunnyakhtakh to Namtsy) showed that there is no mineralized groundwater discharge into the channel from bedrock. The chemistry of the water revealed in the well under 173 m of permafrost in Jurassic sandstone in the western bank flood plain at Tabaga Point according is a bicarbonate-chloride sodium type (hereafter the water type name is given in increasing order of components), and TDS is 1.6 g/l.

Subpermafrost water of Middle Cambrian sediments, revealed in the well on the eastern bank of the Lena River (Krasny Ruchei, southern part of the studied territory) at a depth of 350 m is a bicarbonate-sulfate-chloride sodium type and TDS is 2 m/l.

Tulagino	8.2	115	mg/l	21	7	13	0.4	78	17	18
			meq%	48	26	26		60	17	24

Although this water is high pressure artesian, its discharge to the surface is impeded by aquitard in the overlying zone (Beletsky & Kyrbasov 1972). The drilling of the aquitard consisting of marls interbedded with dolomites and limestone more than 100 m thick was completed starting from the depth of 50–75 m.

Suprapermafrost taliks

The suprapermafrost river talik under the arms of the Lena River was revealed during drilling by *Kommunvodstroi* Institution expeditions in 1932–1934. In 1960–1961 the Yakutsk Geological Board completed 15 drill holes with depths ranging from 12 to 76 m, aimed at estimating groundwater abundance under the Lena River channel near Yakutsk. The wide accumulative flood plain of the Lena River has numerous arms and lakes, flooded in spring. The taliks under them are closed. They are up to 40 m thick. The chemistry of talik water mostly depends on the surface water composition, but the discharges of surface- and suprapermafrost water from terraces also affects it.

Surface water TDS in the Tabaga, Khatass, Yakutsk, Zhatai, and Darkylakh arms situated on the western bank opposite Yakutsk, makes 50–60 mg/l in June, with an ionic composition dominated by calcium hydrocarbonates. At the end of summer it rises up to 170–180 mg/l, and natrium chlorides and sulphates prevail (Table 1). The highest values of water TDS in the river arms (up to 500 mg/l with dominating natrium chlorides) as well as in the main channel, are registered at the end of winter. In the river talik of the Adamovsky arm opposite Yakutsk the composition and mineralization of groundwater in winter (February) varies slightly along its profile; in the upper part (6–9 m deep) TDS makes about 620 mg/l with natrium and magnesium hydrocarbonates dominating, and in deeper layer (at interval of 12–15 m) it is slightly lower (470 mg/l) and has a natrium hydrocarbonate composition.

In the talik under the Darkylakh arm situated downstream, in the upper part of alluvial layer at a depth of 1–9 m, the TDS of the groundwater in April is about 500 mg/l; it has hydrocarbonate-chloride composition, not homogeneous by cations it contains.

The chemistry of water in suprapermafrost taliks under arms of the river which are close to Yakutsk is affected by contaminated suprapermafrost water runoff from urban areas to the alluvium. This is proven by an increased content of chlorine in the talik water and by its increased oxidability of 9.4 mg O_2/dm^3.

Increased accumulation of contaminants in alluvial sediments of river arms usually accompanies low permeability. Thus, for example, while constructing District 202 of Yakutsk, after an inwash of sand on the flood plain surface, TDS in channel sediments increased up to 1–2 g/l with a dominance of natrium chlorides and sulphates, which were being introduced with contaminated suprapermafrost water from the first fluvial terrace and were concentrating at permafrost table.

In the sediments making up the Lena River fluvial terrace suprapermafrost water-bearing taliks underlying minor arms and lakes are widely distributed. In the lower reaches of minor eastern-bank tributaries (Tamma, Lutenka, Menda, Suola) the thickness of river taliks in well-draining sandy-pebbled sediments makes 30–60 m and in some cases extends deeper into underlying bedrock. The maximal water-bearing capability of such arm taliks is indicated under minor arms within the Bestyakh terrace. Even though the channel is not wide (10–20 m) and surface flow is not permanent, here river taliks sustain during the winter as well, due to their increased water drainage and comparatively the high temperature of the permafrost. Thus, for example, water in a talik under the Tamma River dried channel in April (before flood) at a depth of 3–13 m has TDS of 200–300 mg/l. Its type is hydrocarbonate calcium-magnesium.

Increased thickness of river taliks under the Lena's eastern tributaries is indicated in the areas underlain by sandy-pebbled sediments covering fissured bedrock. Thus, in the lower reach of the Menda River the thickness of the aquifer talik reaches 60 m. At August testing the yield made 1.8 l/s, TDS – 200 mg/l, and the chemistry was dominated by calcium hydrocarbonates. The underflows beneath minor eastern tributaries discharge into the Lena River talik. In some cases, icing forms in areas near outlets of such rivers.

Minor western tributaries in Tuymaada Valley

(Shestakovka, Khatynnakh, Markhinka, and Zolotinka) do not have a year-round discharge, therefore during winter small river taliks sustain only in isolated, deep parts of the channels. In one of these river taliks in the lower reach of Markhinka at the end of winter (April) at a depth of 1.5 m, water had TDS of 238 mg/l, hydrocarbonate natrium-magnesium-calcium composition, and a high concentration of organic substances. Shestakovka River taliks occur under the lake-like widening of its channel in the lower reach. Here, TDS in water from the talik, revealed in sands in the interval of 1.0–4.5 m, varies during the year from 510 to 780 mg/l, while TDS in the river is considerably lower (50–95 mg/l). Talik water quality deterioration results from organic matter inflow from the seasonally freezing layer of the catchment area and from overlying stratum in the dried part of the channel.

Suprapermafrost aquifers in the first and second terraces of the Lena River also occur under lakes and cut-off meanders. The groundwater occurrence depth in lake taliks is subject to the depth of lake and in dried frozen parts of the basin corresponds to the thickness of newly formed permafrost. The thickness of taliks under small shallow lakes does not exceed 20 m and at a depth of 2–3 m and a width of 100–200 m it increases up to 30–40 m.

In taliks underlying continuously or periodically discharging lakes water TDS is not higher than 400–700 mg/l. The dissolved ionic type is hydrocarbonate, calcium, magnesium, and sporadically natrium. Under small static lakes no deeper than 1 m, taliks are thin (0.5–1.5 m). Their water TDS is often more than 1 g/l.

The majority of cut-off lakes in low terraces forming a beaded drainage become interconnected during high water. Nevertheless, the connection between their taliks is presently interrupted as a result of permafrost forming between the lakes in dry parts where there are roads.

In lower western terraces of the Lena River where saline lands are widely distributed under drying basins we can often indicate small freezing lake taliks with TDS of 2.5–4 g/l. In relict lake taliks under completely dried basins the TDS in some cases reaches up to 60 g/l, and the ionic composition is dominated by sulphates and chlorides, natrium and magnesium.

Increased salinity of the groundwater in lake taliks within the densely populated part of Tuymaada Valley is affected by human contamination of the territory (Anisimova et al. 2005).

The good quality of water in lakes and their taliks will retain only in case of them being non-stagnant and recharged by meltwater and slightly saline suprapermafrost water. On the western bank such lakes occur at the floor of the alluvial valley slope and on the eastern bank – at the floor of the fourth Bestyakh fluvial terrace. Such are, for instance, lakes to the south of Pavlovsk, where they are recharged not only by precipitation water, but also by intrapermafrost taliks occurring in the Bestyakh terrace. Said taliks discharge either in creek valleys, forming year-round flowing springs or forming submerged crop outs in some low-terrace lakes (Buluus, for instance). This thick intrapermafrost taliks' water is of low TDS and is hydrocarbonate magnesium-calcium and hydrocarbonate natrium type, but it cannot discharge into the Lena River talik due to the impedance of thick layers of low-terrace permafrost.

Conclusions

All stated above demonstrates that there are two crucial factors that affect the quality of water in open and suprapermafrost taliks: permeability rate determined by water circulation, and rechargeability with good quality water. Within the studied area the required properties are indicated only in one Lena River talik upstream from Pokrovsk where channel sediments are underlain by fissured limestone, and in the river taliks under right tributaries of Lena (Menda, Tamma, Lutenga).

In the Tuymaada Valley area, under the arms, yield horizon is confined only by the channel sediments zone. But in the vicinity of Yakutsk, the water chemistry of the river taliks deteriorates as a result of contaminated groundwater runoff of the active layer and suprapermafrost taliks from the urban area.

Abstract

Generally it is accepted that frost heave is a one-dimensional process assuming that the ground conditions are homogeneous and the temperature gradient is one-dimensional. Unfrozen water is attracted to the base of the warmest ice lens for it to grow. Recent laboratory investigations suggest that the growth of ice lenses is more complex. Vertical ice veins form through the frozen fringe in a regular, hexagonal pattern reaching the freezing front. Based on these observations, a new hypothesis for ice lens formation is suggested. As suction builds within the frozen fringe, thin vertical cracks form that do not completely fill with ice, allowing a thin film of water to migrate from the unfrozen zone to the warmest ice lens. The existence of these vertical channels helps explain the measured ice lens growth considering the decreasing hydraulic conductivity in the frozen fringe as voids fill with ice. The tensile strength and the stress state of the soil that governs the crack pattern, therefore, control the ice lens growth and hence frost heave.

Keywords: frost heave; frost susceptibility; ice lens formation; hexagonal cracks.

Introduction

Saturated fine grained soils are known to form horizontal ice lenses when subjected to sub-zero temperatures. These ice lenses change the structure of the soil, generally associated with frost heaving. This change in structure as well as the expansion of these so-called frost-susceptible soils hasve to be taken into consideration when encountering such a soil as a construction or foundation material.

Phenomena associated with frost-susceptible soils have long been recognized by many researchers (e.g., Beskow 1935, Miller 1973, Penner 1959, Penner 1972, Taber 1929, Taber 1930). The basic mechanisms involved in frost heave were identified in the early days based on experimental evidences. Ice lenses form at a certain distance above the freezing front, and water from the unfrozen zone migrates towards the ice lens. Under thermal steady state the warmest ice lens continues to grow as long as water is available. Under transient conditions (penetrating frost front) the ice lens grows until, under some conditions still being debated, a new ice lens starts to form at a location below the initial one. By eliminating the water accessibility or reducing the hydraulic conductivity of the soil, frost heave is significantly reduced. In other words, the water migration towards the ice lens and its amount are the governing factors that contribute to ice lens development and frost heave under thermal steady state.

Based on experimental evidence this paper proposes a new hypothesis on ice lens growth, in particular on how water migrates towards the growing ice lens. The hypothesis assumes that the water migration from the unfrozen zone towards the ice lens is not a simple one-dimensional process. It is further thought that this new hypothesis may explain the phenomenon of frost heave better and may help in better quantifying the frost susceptibility and frost heave potential of freezing ground.

Ideas Behind Frost Heave Theories

Several theories and ideas have been proposed over the years that describe the thermodynamic processes involved in frost heave. Henry (2000) presents a thorough overview of available frost heave concepts. To date two main concepts are widely used to predict frost heave: (1) the segregation potential (SP) concept that was introduced by Konrad & Morgenstern (1980, 1982) and (2) the discrete ice lens theory proposed by Nixon (1991), which is an extension and modification of the rigid ice model by Gilpin (1980) and O'Neill & Miller (1985). Figure 1 shows the idealized frost heave concept generally used. Under a constant thermal gradient, the warm side of the ice lens at a certain time is at a temperature T_1 slightly colder than the temperature at the pore freezing front at the base of the frozen fringe, the partially frozen zone between the warmest ice lens and the freezing front. Water migrates through the unfrozen zone and the frozen fringe towards the warm side of the ice lens. Under saturated condition it can be assumed that the increase in pore water pressure in the unfrozen zone with depth is constant. At the interface between the ice lens and the water, the thermodynamic equilibrium requires that free energy of the ice equals that of the water. By using the Clapeyron equation, the suction at the interface between the ice and the water can be calculated. For example, if the temperature at the bottom of the ice lens is -0.1°C, the suction is -125 kPa

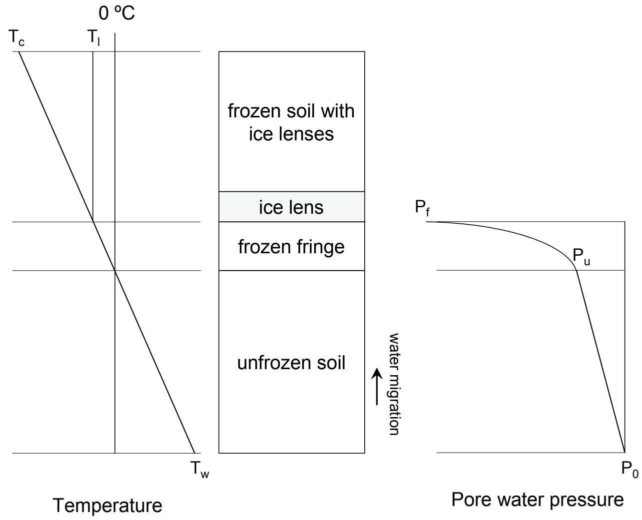

Figure 1. Temperature gradient and pore water pressure distribution und an idealized, one-dimensional ice lens growth scenario after Konrad (1989) and Nixon (1991). Significant suction is noted in the frozen fringe.

and for -0.2°C, the suction is -250 kPa. In order to satisfy the thermodynamic equilibrium, significant suction is required that rapidly decreases within the frozen fringe (Fig. 1).

Experimental Evidence

Recently a series of frost heave tests have beenwere carried out at the University of Alberta using novel visualization techniques. The one-dimensional freezing tests were performed on frost-susceptible Devon silt (Xia 2006). High resolution digital images were further utilized to measure ice lens growth with time under different temperature and stress conditions. Later, particle image velocimetry was applied to measure ice lens growth and soil consolidation during freezing on a microscopic scale (Arenson et al. 2007).

Ice lens structure and growth

The freezing tests clearly demonstrated that ice lens growth is not a simple one-dimensional process, but rather more complex. A snapshot from an early freezing stage (Fig. 2) shows that vertical ice veins precede the formation of the horizontal ice lens. The thin vertical ice vein nearly reaches down to the unfrozen zone through the frozen fringe. Even though the ice veins are not necessarily continuous, they grow more or less vertically on a continuous line. The thin nature of the ice veins makes them difficult to extract using digital image techniques (Fig. 3). However, it can be noted that the thickness of the ice veins does not change much with time in contrast to horizontal ice lenses.

The vertical ice lens structure was also observed when the sample was split at the end of the test (Fig. 4). The vertical ice veins of the frozen segment where well attached to the upper half, whereas a crack pattern was observed in the unfrozen half. The separation of the two halves occurred just below the final horizontal ice lens. In other words one sees on top of the frozen fringe when looking at the unfrozen section

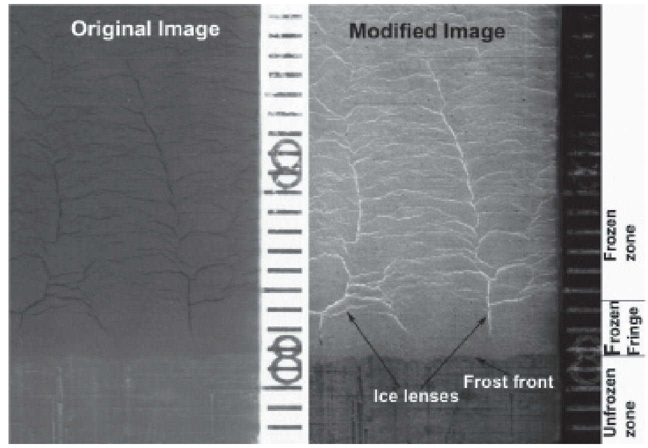

Figure 2. Original and modified image of ice lenses during one-dimensional freezing. The image was taken early during a freezing test at a high cooling rate. Scale in mm (after Xia, 2006).

(e.g., Fig. 4 right). The fact that the unfrozen part could be separated easily from the frozen part with the vertical ice veins attached to the frozen side indicates that there is only a weak bond between the unfrozen soil and the ice within the frozen fringe.

Analysis of the cross section confirms observations that were previously described during observations from the side as the sample froze. A regular pattern of vertical ice veins is formed along the height of the frozen section (Fig. 2). The existence of the vertical ice veins that precede horizontal ice lens formations is not a boundary effect occurring at the outer limit of the circular freezing test. On the contrary, a regular, hexagonal pattern forms throughout the whole cross section. Similar patterns were observed by Mackay (1974, McRoberts & Nixon 1975) for lake and marine clays, glacial tills, and mudflow deposits in permafrost areas of northern Canada. They also provide some theories of the reticulate ice lens growth mainly based on the idea of water being sucked from the clay resulting in suction cracks. Chamberlain and Gow (1979) also presented images of frozen silt that show the reticulate ice structure. They further suggest that there is a direct connection between the vertical ice veins and the vertical hydraulic conductivity of the freezing and frozen soil. However, no evidence or connection is shown between the vertical ice veins and the horizontal ice lenses.

The hexagonal pattern that was observed in the frozen fringe, i.e. the unfrozen side of the sample has a very strong resemblance to drying soils (Fig. 5). The size of the hexagonal elements in the freezing tests further depends on initial conditions, such as consolidation pressure or pore water salinity, and the boundary condition, such as temperature gradient or water availability. Figure 6 shows cross sections from three additional freezing tests. Test #1 (Fig. 4) was consolidated at a vertical pressure of 100 kPa, but frozen at 0 kPa pressure. Tests #4, #5, and #6 in Figure 6, on the other hand, were frozen under the consolidation pressures of 100 kPa, 200 kPa and 400 kPa, respectively. The horizontal ice lens and the frost heave rates decreased with increasing consolidation pressure as expected. In

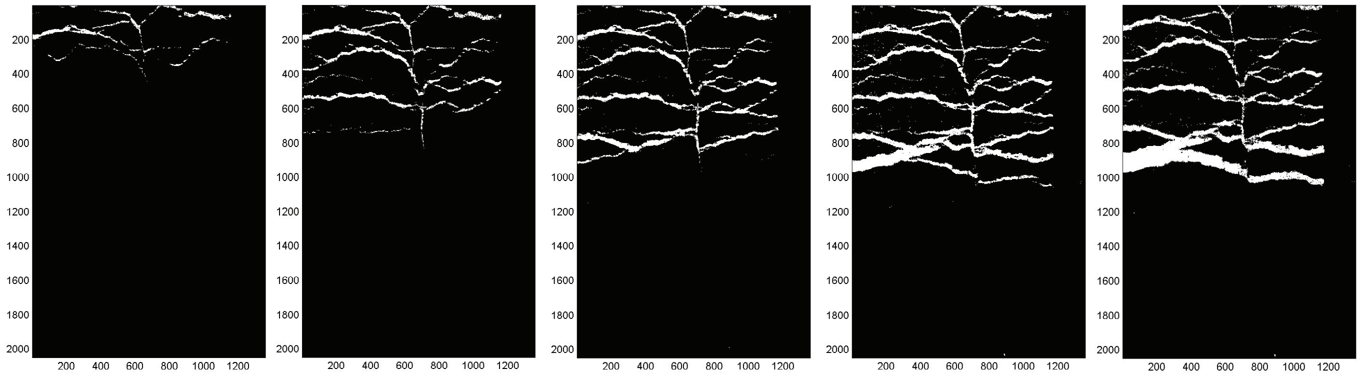

Figure 3. Digitally extracted ice lens structure with time for freezing test. The sequence shows the initiation of the final ice lens (Arenson et al. 2007).

addition, a change in the vertical ice structure can be noted. The size of the hexagonal elements increases with increasing pressure, i.e. the distance between the vertical ice veins increases. This was also visible in the pictures taken from the side of the freezing cell. The change in element size can be quantified by counting the number of full elements within a 50 mm x 50 mm square in the centre of the cross section. Even though the measure is quite rough it shows that with decreasing number of elements, i.e. increasing distance between the vertical ice veins, the final ice lens growth rate decreases. Test #1 and #4 showed similar heave rates of $2.64 \cdot 10^{-6}$ mm/s and Test #5 and #6 displayed values of 1.53 and $1.51 \cdot 10^{-6}$ mm/s, respectively (Xia 2006). The element count gives 18, 17, 11 and 10 hexagonal elements in the centre of the cross section. Even though only four tests are available the trend is convincing.

Hydraulic conductivity and water demand

The one-dimensional ice lens growth hypothesis assumes that all the water at the base of the growing ice lens migrates from the unfrozen soil through the partially frozen soil in the frozen fringe. Experiments on the hydraulic conductivity of partially frozen soils have shown that the permeability decreases rapidly as soon as pore ice forms (Aguirre-Puente and Gruson, 1983; Chamberlain and Gow, 1979; Konrad and Samson, 2000a; Konrad and Samson, 2000b; Williams and Burt, 1974). This reduction is caused by the decrease in void ratio as the pore water freezes and water migration to an ice lens is hindered. Williams and Burt (1974) present data for hydraulic conductivities *k* of silt as a function of temperature that show the rapid decrease in *k* from 10^{-6} m/s at -0.1°C to 10^{-11} m/s at -0.4°C, i.e. 5 orders of magnitude for 0.3°C temperature change. This decrease is not linear. A decrease of four orders of magnitude was actually recorded for the temperature drop from -0.1°C to -0.2°C. Similar trends were obtained by Horoguchi & Miller (1980). They further show a hysteresis effect that depends on whether the silt undergoes freezing or thawing. The hydraulic conductivities of the frozen silt (4-8μ) measured by Horoguchi & Miller (1980) ranged from $2 \cdot 10^{-8}$ m/s (0°C) to 10^{-12} m/s (-0.15°C). The rate of Williams & Burt (1974) are probably affected by the presence of lactose used in their experimental setup, indicating the challenges in measuring the hydraulic conductivity for partially frozen soils.

The authors are not aware of any experimental study that measures the hydraulic conductivity in the frozen fringe. A simple approach is therefore used to estimate the change in hydraulic conductivity *k* within the frozen fringe based on the soil-water characteristic curve (SWCC). Because the freezing process is somewhat similar to the drying process, the SWCC approach was judged to be suitable to estimate this change. The problem of using temperature dependent approximations, such as the temperature dependent permeability function suggested by Gilpin (1980), is that three-dimensional effects are excluded, and vertical flow of water from the unfrozen zone towards the growing ice lens is implied.

The Devon silt used for these investigations has an unfrozen, saturated hydraulic conductivity of $9.9 \cdot 10^{-10}$ m/s at an effective stress of 100 kPa. The moisture content at saturation was 26% with a porosity *n* of 40% (Xia, 2006). The volumetric water content changes in the frozen fringe when suction builds up (Fig. 1). Hence, the hydraulic conductivity changes. The hydraulic conductivity can, for example, be calculated after Fredlund and Xing (1994). The following parameters were utilized to calculate the hydraulic conductivity distribution (Fig. 7):

$a = 1.948$	parameter for Fredlund and Xing (1994)
$n = 2.708$	"
$m = 1.084$	"
$k_{sat} = 9.9 \times 10^{-10}$ m/s	saturated hydr. conductivity
$\theta = 15.6\%$	saturated vol. water content

The water requirement at the final ice lens can be calculated from the ice lens growth rate. For test #1 2.9×10^{-9} m³/s has to migrate from the unfrozen zone through the frozen fringe. Konrad (1994) showed that for temperatures close to 0°, theoretically the suction at an ice lens under atmospheric pressure increases linearly with decreasing temperature at a rate of 1250 kPa/°C. In test #1, a temperature gradient of 0.058°C/mm is applied at thermal steady state. With a frozen fringe thickness of 6 mm, the suction at the ice lens base is estimated to 438 kPa to satisfy the thermodynamic

Figure 4. Hexagonal structure of the vertical ice lenses. The frozen section is on the left, the unfrozen section on the right. The sample diameter is about 100 mm (Xia 2006).

Figure 5. Cracked earth inside the Ubehebe Crater, California (www.tawbaware.com).

equilibrium. In an unfrozen state such suction would reduce the hydraulic conductivity in the Devon silt by more than 70%.

In order to estimate the amount of water flowing through the frozen fringe, an average value had to be determined. The average hydraulic conductivity k_{mv} can be calculated by assuming flow through a series of layers with changing hydraulic permeability and using Equation 1:

$$k_{mv} = \frac{\sum d_i}{\sum \frac{d_i}{k_i}} \tag{1}$$

Where d_i is the layer thickness and k_i the permeability. An exponential decrease in pore water pressure is further assumed in the frozen fringe towards the ice lens with no suction at the freezing front. This is a conservative approach since suction is most likely to penetrate into the unfrozen soil (Seto & Konrad 1994). Under these conditions, k_{mv} = 1.7 x 10^{-16} m/s, and a minimum of 8 x 10^{-18} m/s at the ice lens is determined for the frozen fringe in test #1 (Fig. 8). Utilizing Darcy's law a hydraulic gradient can be estimated. The average hydraulic gradient required in order to attract the necessary amount of water would be 17 x 10^6. This is significantly higher than the hydraulic gradient (~7000) that can be generated over the frozen fringe with a suction of 438 kPa.

Using the suction development at the ice lens and the SWCC may underestimate the hydraulic conductivity of the soil. However, even if the minimum hydraulic conductivity was capped at 1 x 10^{-14} m/s, the gradient would be in the order of 80,000. Such a cap would represent values measured for hydraulic permeability in frozen soils (Williams & Burt 1974).

Even though several assumptions had to be made that need further confirmation, and it may even be possible that the suction generated at the ice lens is capable of attracting enough water towards the ice lens, some concerns remain. If the suction reaches values of approximately 900 kPa it is possible that cavitation occurs under atmospheric conditions, i.e. as it reaches its vapor pressure, the pore fluid vaporizes and forms small bubbles of gas. According to the authors' knowledge no experimental evidence is available that shows the formation of gas bubbles at an ice lens.

New Ice Lens Growth Hypothesis

Based on recent laboratory investigations a new concept behind ice lens growth and frost heave is proposed. In 1979, Chamberlain & Gow (1979) presented similar ideas and experimental evidences. They showed that freezing and thawing caused a reduction in void ratio and an increase in vertical conductivity. The later was attributed to the formation of polygonal shrinkage cracks. However, no definite relationship could be established and the mechanisms observed have not been connected to ice lens formation and growth.

The new idea is based on water flow along vertical ice

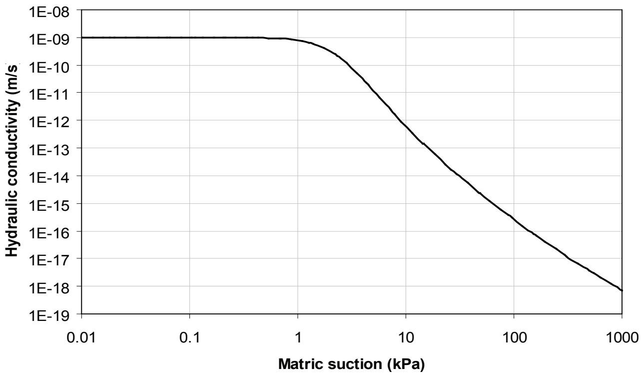

Figure 7. Hydraulic conductivity as a function of suction. Curve determined after Fredlund and Xing (1994).

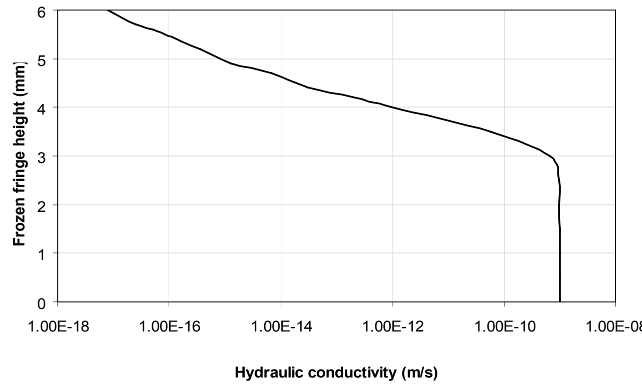

Figure 8. Hydraulic conductivity in the frozen fringe.

veins. As suction builds within the frozen fringe and the unfrozen soil below the freezing front, the soil reaching its tensile strength resulting in thin vertical cracks. These cracks are originally filled with water but will freeze rapidly as the freezing front penetrates. Between the vertical ice vein and the soil, a water film forms. This film is not the same as a water film that would form around a soil particle at thermal steady state, and may only be 60–100 nm thick at 0.1°C.

Instead of a one-dimensional water flow through the frozen fringe, that has a low hydraulic conductivity, water from the unfrozen zone migrates along the vertical ice veins towards the growing horizontal ice lens. By assuming laminar, incompressible, steady flow between two parallel plates (e.g., Streeter and Wylie 1985), a layer of 3 μm and a suction of 100 kPa would be enough to allow the necessary amount of water flow towards the ice lens in test #1. This simple calculation shows that significantly more water can migrate from the unfrozen soil to the growing ice lens along these ice veins at a much lower suction gradient than if it has to migrate through partially frozen pores of the frozen fringe. The thickness of the vertical ice lens did not change with time. It is assumed that no ice accumulation occurs because of the moving water film at the interface between the soil and the ice. Further, there is no major heat loss perpendicular to the ice vein that could lead to horizontal crystal growth. Figure 9 shows a schematic of the flow scheme based on this new concept.

Because water flow along vertical ice lenses controls the amount of water that migrates through the frozen fringe, it is basically the tensile strength of the soil at a certain stress state that governs ice lens growth. In order to attract sufficient water the suction may reach values that would cause tension cracking of the soil below the warmest ice lens. With a higher tensile strength, fewer vertical cracks can form, and therefore a lower number of preferential flow paths are available for water to migrate towards the ice lens. The application of a vertical stress, for example, changes the stress state of the Devon silt resulting in fewer cracks and therefore slower frost heave.

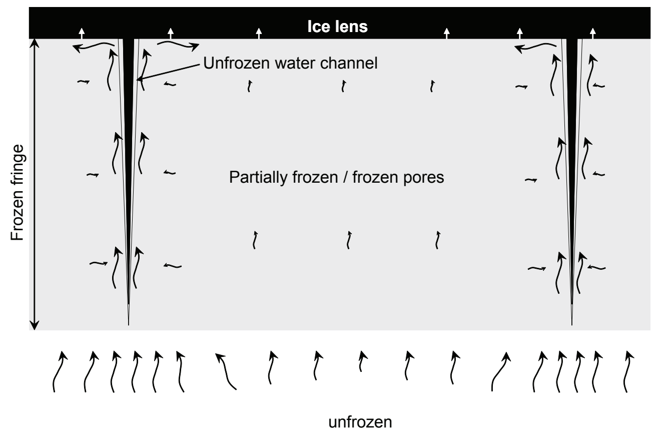

Figure 9. Water migration in freezing soils.

Conclusions

Based on experimental evidence a new hypothesis for a frost heave mechanism is proposed. The existence of vertical channels can explain the measured growth of the horizontal ice lenses considering the consolidation and the decreasing hydraulic conductivity in the frozen fringe. To date it is not clear how these vertical ice veins and water channels form. The tensile strength of the unfrozen soil may be reached as suction occurs. In addition, strain compatibility in the consolidation soil may also trigger the formation of vertical cracks.

However, the stress state and tensile strength of a soil basically govern ice lens growth because they controls the number of vertical cracks and vertical ice lenses that form in the frozen fringe.

A new series of one-dimensional freezing tests is currently being carried out at the University of Alberta Geotechnical Centre to improve our understanding of the hypothesis presented. The relationship between the hexagonal element sizes and frost heave rate will be studied in more detail using different soils as well as saline pore water. Saline pore water is known to change the size and shape of the ice lens pattern as well as the frost heave behavior (Arenson et al. 2006). The goal of this future research is to couple the tensile strength of a soil directly with frost heave potential.

Even though intense research has to be carried out in the future to support these ideas, the authors believe that it is time to move from a one-dimensional frost heave model towards a three-dimensional concept, even for one-dimensional freezing conditions.

Acknowledgments

The authors wish to acknowledge the valuable contributions obtained from three independent reviewers. They would further like to thank Andy Take from Queen's University for his support with the GeoPIV analysis. Tezera Firew Azmatch appreciated the financial support through the NSERC Discovery Grant held by Dr. Sego.

Impact of the August 2000 Storm on the Soil Thermal Regime, Alaska North Slope

David E. Atkinson
International Arctic Research Center, University of Alaska Fairbanks, Fairbanks, Alaska 99775, USA
Larry Hinzman
International Arctic Research Center, University of Alaska Fairbanks, Fairbanks, Alaska 99775, USA

Abstract

The impact of a severe Alaska North Slope storm (August 2000) on the ground thermal regime along a north-south/coastal-inland transect was investigated. Using data gathered by the Water and Engineering Research Center at the University of Alaska Fairbanks, the storm was found to have a strong and widespread effect. Briefly, the storm initiated rapid cooling that was fairly uniformly expressed at all sites, despite their varying distances from the coast. At all of the sites 30 cm ground temperature dropped from 4°C to 1°C which, at the coastal sites, did not return to pre-storm summer levels before the initiation of winter despite two subsequent warm periods.

Keywords: Alaska; arctic storms; coastal; ground thermal regime.

Introduction

Storms in the arctic coastal zones have well-documented impacts on infrastructure and coastal morphometry via waves and storm surges (Rahold et al. 2005); however, the associated impacts on the ground thermal regime are not well documented. Gaining further insight into this issue is especially important in ice-rich regions where the seasonal freeze-thaw cycle is a critical underpinning to many derivative studies. A primary impact of storm passage is a rapid cooling of the entire active layer. This can act to prematurely shorten the thaw season by initiating early fall cooling. Focusing on a particularly severe storm (August 2000) and using a north-south/coastal-interior transect of meteorological and ground temperature data, this issue, one that has received virtually no specific treatment in the literature, is explored in detail.

The North Slope storm of August 10–12, 2000

In August of 2000, a strong storm moved from the north Chukotka coast, across the Chukchi Sea over to Alaska, and eastward along the North Slope coast. The storm strengthened to 996 millibars by August 11, when its center was positioned north of Prudhoe Bay (Fig. 1), and it developed a very strong pressure gradient to the west. The strong pressure gradient generated observed winds of 70 kts (36m/s), which caused the storm to develop heavy sea states that included a moderate surge and high waves. This event caused $7.7 million dollars in infrastructure damages along the North Slope, including the sinking of a barge (Koslow 2000). Unusual for Alaska, this event also caused substantial wind damage in the form of roof failure on many structures in Barrow.

The strength and orientation of the storm circulation (Fig. 2) allowed it to tap into a cold air mass situated over the mid/north Beaufort Sea (Fig. 3) and to draw it over and well south into the north Alaskan landmass. This rapid influx of cold air reduced air temperatures by up to 10°C in coastal areas (Fig. 4), from well above zero in the +6°C to +8°C range to below the freezing point, within a day.

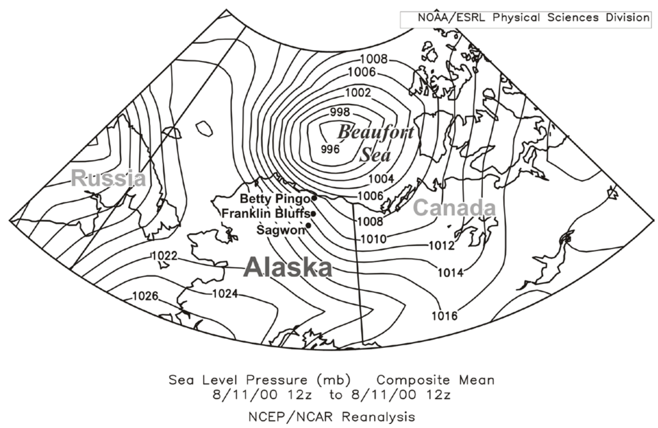

Figure 1. A plot of surface mean sea level pressure showing the August 2000 storm at peak intensity, 0300 AKT on August 11, 2000. The three ground temperature sites from which ground thermal and meteorological data were drawn are indicated. These locations are operated by the Water and Engineering Research Center at the University of Alaska Fairbanks as part of the "Kuparuk River Watershed Studies" project. Note closely-spaced pressure contours to the west of storm center. This flow pattern advected cold air over the North Slope region. (Pressure pattern data from the National Centers for Environmental Prediction/Department of Energy Reanalysis II, plotted at the National Oceanic and Atmospheric Administration's Earth Systems Research Laboratory [NOAA-ESRL]). AKT refers to Alaska Time.

Given its effect on air temperatures, the influx of cold air also likely had an impact on the ground thermal regime. It is the objective of this paper to examine the nature of this response at several locations in the North Slope of Alaska and to assess its possible impact at the seasonal time-frame.

Data and Methods

Meteorological and ground temperature data were obtained from monitoring sites operated as part of the Kuparuk River Watershed project by the Water and Engineering Research Center (WERC) at the University of Alaska Fairbanks (Kane & Hinzman 2000, Kane et al. 2000, Romanovsky

Table 1: The three main locations from which soil temperature profile data were drawn. The abbreviation for each station used in the text is given.

Site	*Sub-sites*	*Distance to coast (Prudhoe Bay)*
Betty Pingo	Upland (BPU)	12 km
	Wetland (BPW)	
Franklin Bluffs (FB)	--	70km
Sagwon (SW)	--	100km

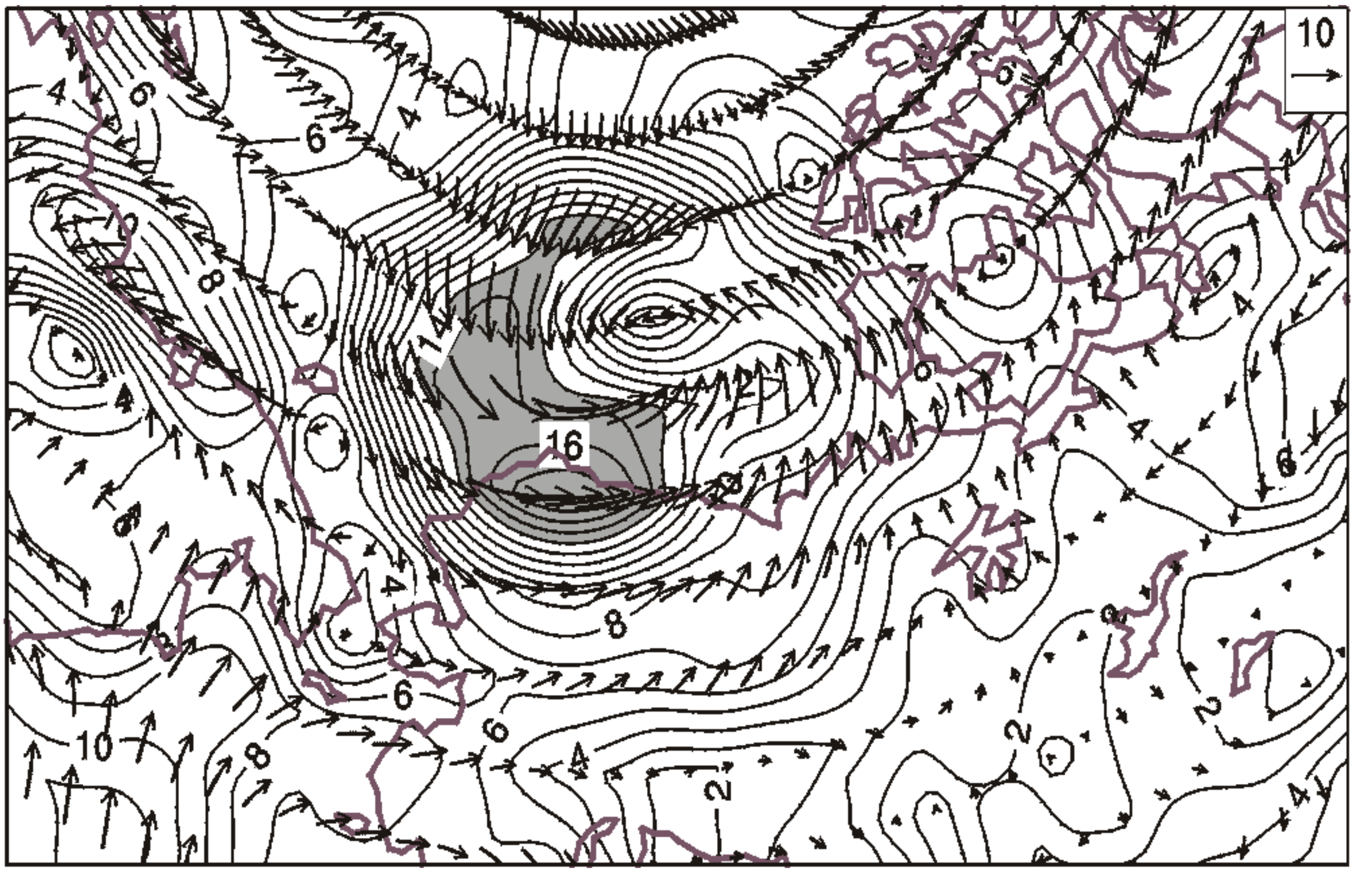

Figure 2. Wind speed isotachs (m/s) and direction vectors at the height of the storm (Aug. 10, 2100AKT). Shaded zone represents wind speeds exceeding 14 m/s.

& Osterkamp 2006). Four data sets were used from three separate locations (Table 1, Fig. 1).

This sampling methodology allowed a north-south transect to be examined with the three locations at successively greater distances from the coast. Storm winds and the strength of an advective temperature change can decrease with distance away from the coast due to a reduction of wind speed, brought about by increased surface roughness, and reduction of air/ground temperature gradient due to a longer exposure of the air mass to the modifying effects of the surface underneath (Wallace & Hobbs 2006, 404). In addition, the two locations at the Betty Pingo site allowed comparisons to be made between a saturated ("Wetland site") and non-saturated ("Upland site") ground. Data are available online at the WERC website (Kane & Hinzman 2000).

Analysis consisted of a direct examination of selected time series and a comparison between sites and between specific elements for the period of time surrounding the storm to determine timing and magnitude of temperature change at different levels. This was performed using a comprehensive plot on which time series from the four stations were laid out side-by-side (Fig. 5). Ground thermal data were recorded hourly at BPU and BPW and once daily at the FB and SW locations. At all locations, meteorological data were recorded once per hour; however, they were subset to once per day at FB and SW for comparison with the ground thermal data.

Results

The ground thermal regime at BPW and BPU responded rapidly to the initiation of cold air advection by the storm winds. The regular daytime cooling that was underway by mid-afternoon, August 10 (all time references are local time) was extended well below the daytime minimum (approximately 6–7°C) at the two sites compared to the preceding days. This coincided with the establishment of

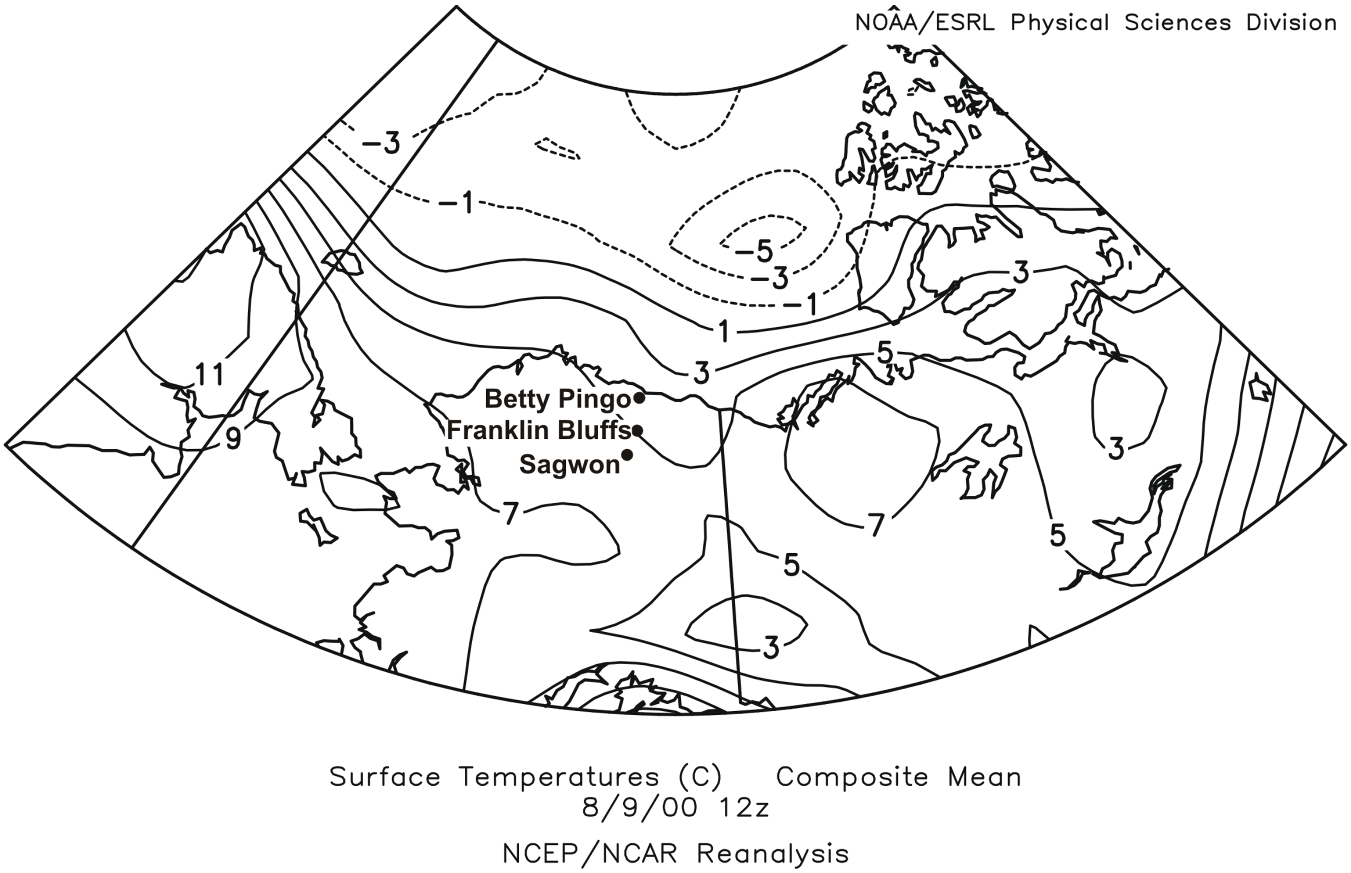

Figure 3: Surface air temperature distribution two days before the storm. Dashed isotherms indicate negative temperatures. Note the cold zone over the north/west Beaufort (circled). Rapid advection of this air mass along the trajectory indicated by the heavy arrow occurred as the storm moved along the north coast.

strong, persistent winds out of the west (Fig. 6 – BPU and BPW). At BPW air temperatures dropped 16°C, to -2°C, within one day and then dropped further the next day. The 5 cm soil depth temperature responded with a drop from ~7°C to 2°C in a 36-hour period. The 30 cm soil depth temperature dropped from 4°C to 2°C, and then further, down to 1°C, over the next few days. Similar patterns were observed at BPU, although at this location the air temperature drop was not as large, which meant the corresponding decrease in ground temperatures occurred slightly later. The main response difference observed between the BP wetland and upland sites was that soil temperatures at the wetland site exhibited a greater sensitivity to the air temperature forcing, especially 30 cm depth, from 5°C to 1°C at the upland site, whereas at the wetland site the 30 cm temperature change was from 4°C to 1.5°C. This is despite the fact that the upland site sensor is positioned slightly deeper, at 35 cm, and not 30cm. It was interesting to note, however, that the temperature drop at the 5 cm depth was greater at the wetland site, from 8°C to 2°C, whereas at the upland site, the 5 cm temperature change was from 7°C to 2°C.

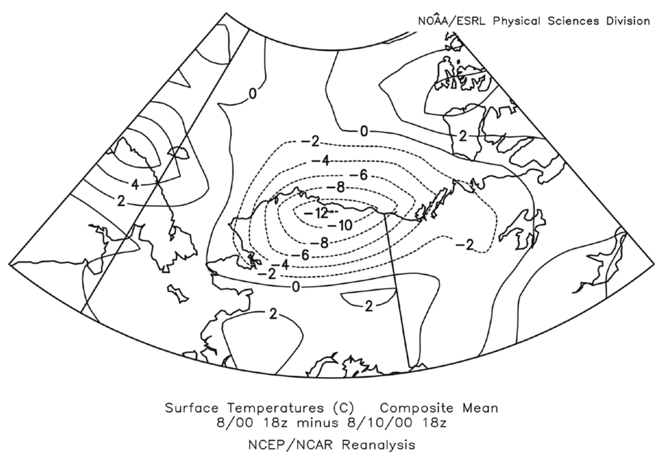

Figure 4. Surface air temperature difference plot, Aug. 11, 0900 AKT minus Aug. 10, 0900 AKT. This indicates the magnitude of temperature change in a 24-hour period over the north Alaska landmass. Dashed lines indicate negative temperature isotherms.

The data availably at FB and SW limited the detail of analysis but the major patterns were apparent. The same pattern of wind speed and direction observed at the BP sites prevailed at FB and SW—a strong peak in wind speeds developed out of the west. Although the two sites started with different air temperatures, at both locations air temperature had dropped to -2°C by the second day, representing decreases of 12°C (FB) and 10°C (SW). At both sites a drop in the 5 cm soil temperatures from 6°C to 2°C (FB) and from 9°C to ~1°C (SW) was observed, and in the 30 cm soil temperatures from 4°C to 1°C was observed.

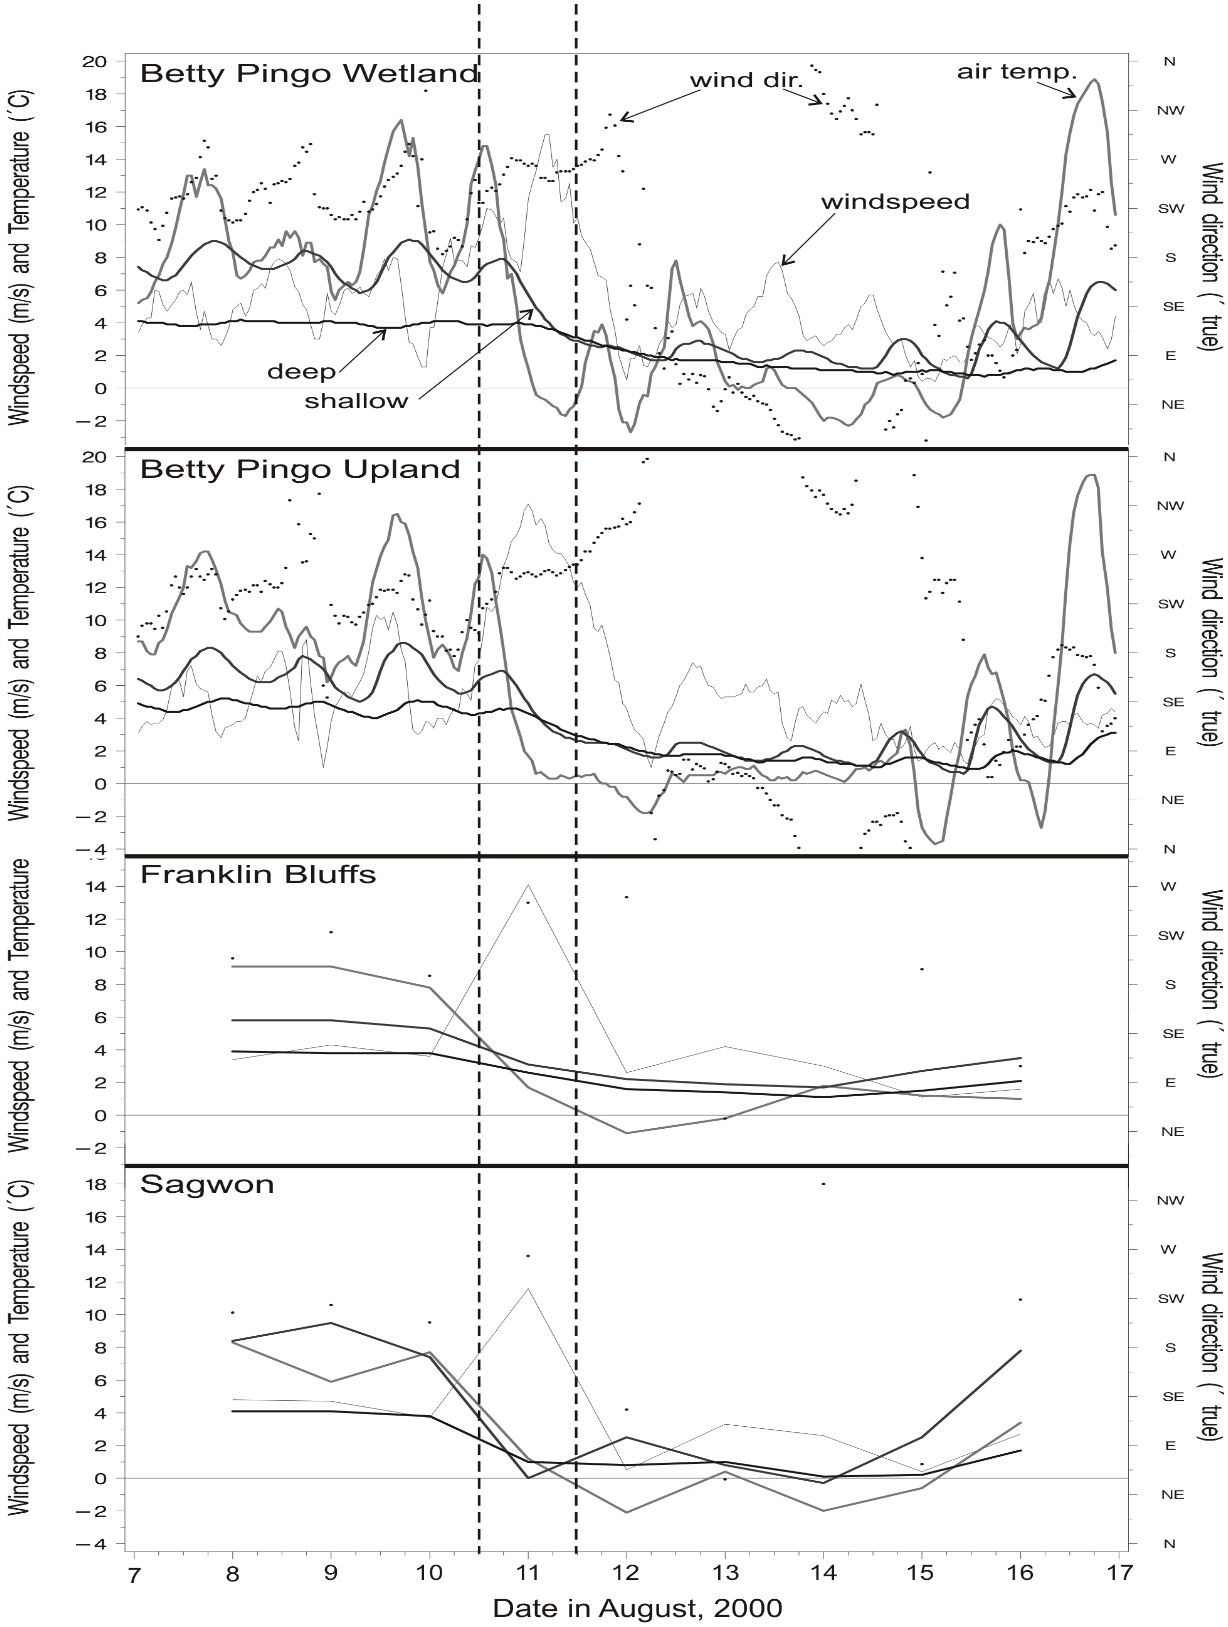

Figure 5. Winds, air temperature, and ground temperatures at the four sites. The following formatting scheme is applied to each plot: the dots represent wind direction observations in degrees true heading (vertical scale on the right), the thin black line represents wind speed (m/s), the thick light grey line represents air temperature (°C), the thick medium grey line represents a "shallow" ground temperature (°C), the thick black line represents a "deep" ground temperature (°C). The distinction "shallow" refers to the 5 cm soil depth at all sites and "deep" refers to 30 cm soil depth at all sites except Betty Upland, where it is 35 cm depth. The two vertical dashed lines represent the core of the storm from 1200 AKT, August 10 to 1200 AKT, August 11, 2007.

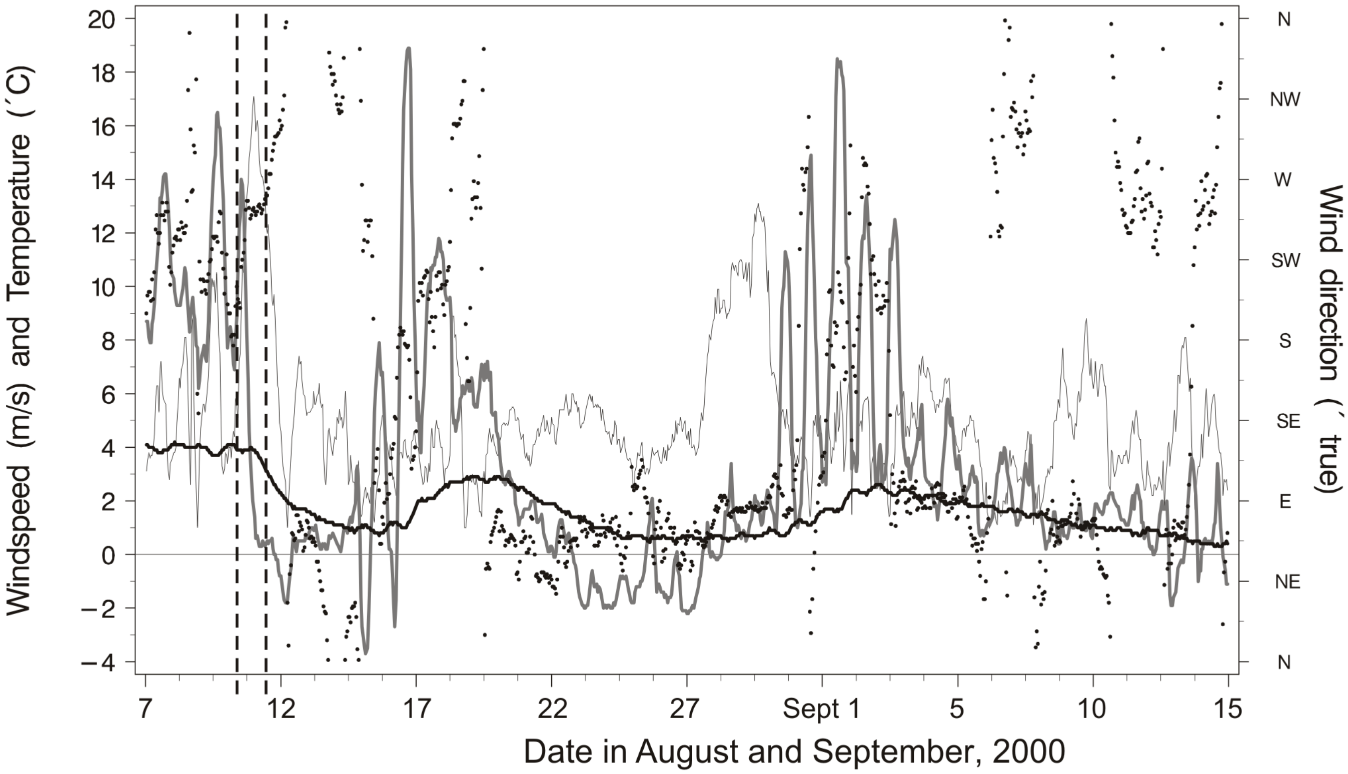

Figure 6. Wind speed and direction, air temperature, and 30 cm ground temperature at Betty Pingo Wetland. Storm time frame is indicated by the vertical dashed lines. Line schema is identical to that used in Figure 5.

Discussion and Conclusions

Examination of the longer-term implications of the storm-induced temperature drop at BPW site shows that, despite two very warm spells (air temperatures >15°C), the temperature at 30 cm does not again reach its summer levels (Fig. 7). This suggests that the influx of cold air from the storm was sufficient to set the stage for winter freeze-up; that is, it may be argued that without the contribution of this storm event, ground freeze-up would have occurred later in the fall. A more frequent occurrence of such storm events, which might accompany conditions of reduced sea-ice cover, could have the paradoxical effect of checking a summer ground thermal warming trend. Cooling did not seem to be quite as prominent at the inland sites (not shown): during the two warm episodes, 30 cm temperatures did warm to return almost to their pre-storm levels, although, as noted below, all sites cooled to a uniform extent.

Overall, the reach of the storm was considerable—marked effects on ground thermal regime were noted 100 km inland at Sagwon site, situated effectively at the foothills of the Brooks Range. Typically when an air mass is advected a long way over a surface, the lowest atmospheric layers begin to take on the temperature and moisture characteristics of the surface. In this case, that means the air mass should warm as it moves inland. However, the lowest air temperature reached during the event (start of August 12) at all four sites—that is, ~-2°C, was essentially the same. The ground thermal response was likewise uniform: at all sites the 30 cm soil temperature dropped to 1°C. This is indicative of the strength and persistence of the wind, that the air was moved so rapidly into the region that it underwent little modification in its lowest layers. Even though the peak wind speeds were progressively lower with increasing distance inland, they were still sufficient to move the advected air rapidly enough. Thus this one event affected soil temperatures to at least 30 cm depth over the bulk of the Alaska North Slope.

It is important to note that this particular event possessed unusual strength, which means it is unlikely that similar events observed on the north coast would be exert an influence as far inland as this event did. This is a question, however, that should be pursued in more detail to better understand the potential of increased summer storm activity on the ground thermal regime of the Alaska North Slope. It is clear that broader consideration of advected air masses and their relative frequency of occurrence over time could be a useful component of ground thermal regime to consider in more detail.

Global Simulation of Permafrost Distribution in the Past, Present, and Future Using the Frost Number Method

Tim Aus der Beek, Ellen Teichert
CESR, Center for Environmental Systems Research, University of Kassel, Germany

Abstract

Currently, about 39 mil km² of the world (including Antarctica) are covered by permafrost. One aim of this modeling experiment is to compare the current global permafrost distribution with its extent in the past and in future projections by integrating the well-known Frost Number method into the global hydrological and water-use model WaterGAP. The Frost Number is related to the zonal arrangement of permafrost and was slightly modified to test its receptivity of different snow parameter formulations. For past extents the Frost Number was averaged for 1901–1930 and set in contrast to present permafrost spreading (1971–2000). The future time slice was computed by averaging permafrost extent for 2071–2100, and was yet again compared with present and past permafrost extents. From the wide variety of climate scenarios, two contrasting IPCC-SRES scenarios, A1B and B1, were chosen. CO_2 and CH_4 feedback loops of melting permafrost were not considered in the model. To account for the specific variability of General Circulation Models (GCMs), two different GCMs were applied for both IPCC-SRES scenarios. Model results imply that the area of global permafrost occurrence decreased by 7% between past and present conditions, and future scenarios project that 30%–45% of the contemporary extent could be diminished by 2100. The application of different snow-parameter formulations yielded only minor changes in the quantification of the Frost Number.

Keywords: climate scenarios; Frost Number; global modeling; permafrost distribution; WaterGAP.

Introduction

The well-known Frost Number has proven its suitability for application to large geographical domains (Anisimov & Nelson 1997), but has never been operated on the global scale. The study presented hereby examines permafrost spreading on the global scale and, contrary to most other modeling efforts, considers three different time periods between 1901 and 2100. Future permafrost zonation is also used to roughly estimate the increase of atmospheric carbon content, released from formerly frozen grounds. The Frost Number method has been applied to several regions, such as the Northern Hemisphere (Anisimov & Nelson 1997), and has proven its suitability for the prediction of permafrost over large geographical domains by comparison with hard data (Anisimov & Nelson 1997). The Frost Number applied in this study relies on freezing and thawing indices based on air temperature (Frauenfeld et al. 2007) instead of modeled soil temperature, as in Stendel & Christensen (2002) or Lawrence & Slater (2005). Therefore, soil water processes and relic permafrost are not considered in the model.

Snow density, which is supposed to be crucial for the computation of snow cover and thus permafrost occurrence, was kept constant in earlier analyses (Anisimov & Nelson 1997). This model experiment also tests the variability of the Frost Number method by employing a snow-density routine. Furthermore, it introduces two different algorithms for the calculation of thermal conductivity of snow.

Methods

WaterGAP and data

To allow for a global application of the Frost Number method, it was incorporated into the hydrology and water-use model WaterGAP 2.1f (Water-Global Assessment and Prognosis), which computes daily water balances for a global 0.5°x0.5° grid with monthly hydrological outputs, such as river runoff and evapotranspiration (Döll et al. 2003). Due to its implemented soil routine, WaterGAP also offers good prerequisites for potential modeling of future active layer permafrost thawing. However, in this study the soil and runoff generation routine has not yet been linked to permafrost modeling.

The input data for past and current climate conditions used in this study consists of the CRU dataset (version TS 2.1, Mitchell & Jones. 2005), which has been compiled and regionalized by the Climate Research Unit (CRU) of the University of East Anglia, Norwich, UK. Air temperature and precipitation for both future scenarios were calculated by two different transient atmospheric General Circulation Models (GCMs) to account for the spatial variability of climate patterns in GCMs. The first GCM projection of air temperature and precipitation applied in WaterGAP is calculated by the Hadley Center Coupled Model (HadCM3), which has been developed at the Hadley Center for Climate Predictions and Observations in Exeter, UK (Gordon et al. 2000). ECHAM5, the second GCM, has been developed by the Max-Planck Institute for Meteorology (MPI) in Hamburg, Germany (Roeckner et al. 2006). Both GCMs have been scaled with the IPCC-SRES (Intergovernmental Panel on Climate Change – Special Report on Emission Scenarios) scenarios A1B and B1 (IPCC 2001). The A1B scenario is driven by very high economical outputs and energy demands, which nearly double today's CO_2 emissions and lead to an air temperature increase of 4.4°C (multi-model global mean) between 2000 and 2100. On the contrary, the B1 scenario projects CO_2 emissions slightly lower than today and an average air temperature increase of 3.1°C (multi-model global mean for 2100), which occurs in combination with a balanced economy and usage of alternative energy systems. CO_2 and CH_4 feedback loops of melting permafrost are not included in the data or model.

The Frost Number

The Frost Number method was developed by Nelson & Outcalt (1983, 1987) to predict and regionalize the presence and absence of permafrost on a large scale by calculation of degree-days of freezing (DDF) and thawing (DDT). The physical derivation and all computational details of the three different Frost Numbers (Air, Surface and Soil) are given in Nelson & Outcalt (1987).

The here-applied *Surface Frost Number* F_+ (equation 1) includes variables from the *Air Frost Number*, such as DDF and DDT, which are estimated from air temperature data for each grid cell. Furthermore, it also considers snow-cover properties at the earth surface, which can have large impacts on the process of soil freezing (Osokin et al. 2001). The *Surface Frost Number* has been applied in this study to analyze permafrost distribution for three different time periods: 1901–1930, 1971–2000, and 2071–2100. For all three time margins, F_+ has been averaged to a single value for each global grid cell to eliminate input inaccuracies caused by annual air temperature variations. The *Surface Frost Number* F_+ can be derived by

$$F_+ = \frac{DDF_+^{1/2}}{DDF_+^{1/2} + DDT^{1/2}} \tag{1}$$

where DDF_+ and DDT_+ are degree days of "surface" freezing and thawing (°C days). Due to this definition, F_+ ranges between 0 and 1, for which Nelson and Outcalt (1987) further derived threshold boundaries for different permafrost types, such as continuous ($F_+ \geq 0.67$), extensive discontinuous ($0.67 > F_+ \geq 0.6$), sporadic discontinuous ($0.6 > F_+ \geq 0.5$) and no permafrost ($F_+ < 0.5$).

We will only explain selected important formulations of the derivation of DDF_+ and DDT_+ to not repeat Nelson & Outcalt (1987). The main feature of F_+ is the integration of the snow cover, which is calculated by

$$\overline{Z}_s = \sin^2 \phi \{ \sum_{i=1}^{k} [(P_i / \rho_r)(k-(i-1))] / k \} \tag{2}$$

where $\overline{Z}_s$ is the average winter snow-cover depth, P_i is water-equivalent precipitation for months i (i = 1, 2, …, k), ρ_r is relative snow density of each cell, and Φ is the cell's latitude. The trigonometric function of equation (2) determines shorter and less pronounced thaws with increasing latitude, whereas the latter term weights snow falling early in the year at higher latitudes, simulating a more realistic snow-cover distribution. A description of the influence of intra-annual variability of snowfall on permafrost occurrence can be found in Zhang et al. (2001).

As snow density was kept constant in earlier applications of the Frost Number, this study explores the effects of applying two different formulations of snow density for the 1971–2000 period. First, snow density is set constant to 100 kg m^{-3} for all cells and F_+ is being calculated. For the second case, snow density ρ_s (in kg m^{-3}) for each cell is computed by

$$\rho_s = 545 * (5 - \overline{T})^{-1.15} + 50 \tag{3}$$

where $\overline{T}$ is the mean winter air temperature in °C. Equation (3) was defined by Meister (1986), who derived this air temperature–fresh snow density relationship by analyzing more than 850 snow-density measurements for three different climate regions. He also showed that, for stations below 1500 m.a.s.l., wind effects are negligible for the computation of snow density. In this study, snow density calculated by equation (3) has been limited to a maximum of 700 kg m^{-3}, which is concordant with the findings of Mellor & Mellor (1988). In general, equation (3) yields slightly higher snow-density values than in well-known functions described by Jordan (1991) and Hedstrom & Pomeroy (1998). Another modification from the original set of formulations provided by Nelson & Outcalt (1987) is the application of two regression functions of snow density and snow thermal conductivity (equations 4 and 5). Both methods have been applied for both versions of snow-density derivation for 1971–2000, resulting in a total of four different global computations of the Surface Frost Number for that period. Here and in previous studies on F_+, thermal conductivity of snow λ_s (in W m^{-1} K^{-1}) has been calculated with the formulation of Van Dusen (Paterson 1994: 205):

$$\lambda_s = 2.1 * 10^{-2} + 4.2 * 10^{-4} \rho_s + 2.2 * 10^{-9} \rho_s^{\ 3} \tag{4}$$

where snow density ρ_s is in kg m^{-3}. The second method of obtaining λ_s is given in Sturm et al. (1997) who found the following regression by the statistical evaluation of nearly 500 snow thermal conductivity measurements:

$$\lambda_s = 0.023 + 0.234 * \rho_s \quad \text{for } \rho_s \leq 0.156 \tag{5}$$

$$\lambda_s = 0.138 - 1.01 * \rho_s + 3.233 * \rho_s^{\ 2} \quad \text{for } \rho_s > 0.156$$

Equation (5) requires ρ_s in g cm^{-3} and yields λ_s in W m^{-1} K^{-1}. The computation of F_+ for all three time slices has been carried out with equations (3) and (5), whereas present conditions were additionally calculated by three combinations of constant ρ_s and equations (3) to (5).

So far, the Surface Frost Number has been applied to Canada (Nelson 1986), Russia, and the Northern Hemisphere (Anisimov & Nelson 1996, 1997). All modeling results were validated by comparison with measured permafrost extents and generally showed good agreements. A sensitivity analysis for the Surface Frost Number in combination with climate change scenarios has been conducted by Anisimov & Nelson (1996).

Results

The modeled global distribution of permafrost for all three time periods is shown in Figure 1. The zonal extent of all

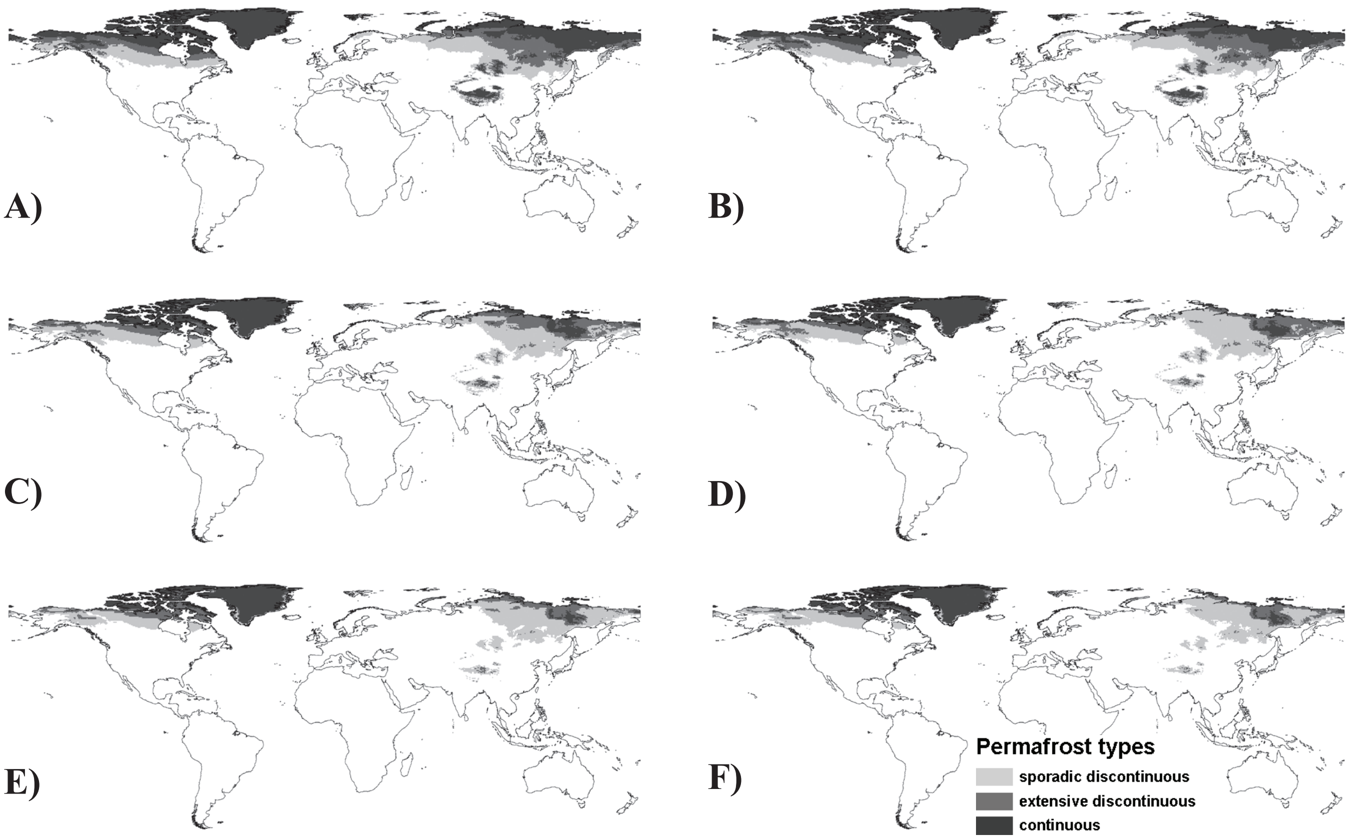

Figure 1. Global permafrost distribution modeling results (Surface Frost Number, using equations (3) and (5)). A): 1901-1930. B): 1971-2000. C): 2071-2100 (B1, HadCM3). D): 2071-2100 (B1, ECHAM5). E): 2071-2100 (A1B, HadCM3). F): 2071-2100 (A1B, ECHAM5).

permafrost calculations is given in Table 1. When comparing past and present conditions (Fig. 1A and 1B), it is noticeable that both, continuous and discontinuous permafrost boundaries, experience a moderate northeast shift. Due to the continental climate of the Eurasian permafrost regions, its degradation is more pronounced than for its North American counterpart. According to Table 1, the time period 1901–1930 featured 13% more continuous and 9% more discontinuous permafrost than today. An explanation for these findings can be derived by the analysis of air temperature data. Data analysis revealed that global average temperature in this modeling experiment increased by 0.5°C between both time periods, whereas the increase for permafrost regions averaged 0.7°C. Rising air temperature is strongly related to CO_2 emissions, which drastically increased since begin of industrialization.

Validation of present permafrost distribution

In order to assess the accuracy of the model results, we compared the Northern Hemisphere permafrost map of Brown et al. (1998) with the calculated present permafrost distribution. This was achieved by scaling the map to the 0.5° grid of WaterGAP. In general, total permafrost occurrence is underestimated by 7% (see Table 2), which could partially be explained by the model's inability to represent relic permafrost. The prediction of continuous and discontinuous permafrost cells is less accurate. However, this could be improved by adjusting the empirical threshold boundaries of the Frost Number. Additionally, we applied the map comparison algorithm *Kappa* (Pontius 2000) to contrast our results with the permafrost map. *Kappa* can vary between -1 and 1, where 1 describes a perfect fit and -1 is equivalent to a negative correlation of both maps. The global comparison yields a *Kappa* value of 0.67, whereas the comparison of the different permafrost zones yields a still acceptable value of 0.5.

A validation of simulated past permafrost distribution is not possible, as no permafrost map of this time period is available. However, as model results for past permafrost occurrence rely on the same climate data source as the validated present results, we can assume the results to be reasonable. In addition, Romanovsky (2005) found increasing permafrost temperatures for the last few decades at a multitude of boreholes. These outcomes support our model results of melting permafrost.

Future projections of permafrost distribution

The comparison of present and future permafrost occurrences (Fig. 1B versus 1C to 1F) can be discussed exemplarily for the HadCM3 climate forcing datasets. The pessimistic IPCC-SRES A1B scenario reveals significant zonal permafrost reductions of about 42% for the HadCM3 dataset (Fig. 1E). Once again, the impacts of climate change are more evident for the Eurasian continent, where continuous and extensive discontinuous permafrost is reduced to patches at the northeastern shoreline. Further, continuous permafrost with mid-continental exposition, such as in Mongolia and China, will be nonexistent. On the other side of the globe, modeled permafrost formations in Canada and Alaska undergo a northbound shift of 500 to 700 km. These findings can again be attributed to global warming. Thus, mean air temperature values of contemporary permafrost areas were compared to scenario temperatures for the same area. This revealed that the temperature increase was 15% (HadCM3) and 23% (ECHAM5) higher than the global average. Generally, the GCM ECHAM5 generates higher average air temperatures than HadCM3, and its combination with the IPCC-SRES A1B scenario yields with 11.6 million km² or -45% the strongest decrease of zonal permafrost arrangements of all four scenarios (see Table 1 and Fig. 1).

On the contrary, the optimistic IPCC-SRES B1 scenario indicates permafrost degradation of about 30% for both GCMs, whereas ECHAM5 again predicts higher losses than HadCM3. Since ECHAM5 triggers higher air temperature, much more continuous and extensive discontinuous permafrost is transformed to sporadic permafrost, which causes an increase of sporadic permafrost for this scenario. The spatial distribution of permafrost shows a less severe but yet significant shift of permafrost boundaries to the northeast. In contrast to the A1B scenario, northern Siberia still features a thick band of extensive discontinuous permafrost.

The conversion from continuous to discontinuous to no permafrost will have large impacts on society and climate. Nelson et al. (2002) describe how the permafrost-thawing processes already apparent cause soil instabilities; for example, by thermokarst, which render streets and buildings in Alaska and Canada useless. As permafrost regions are projected to be diminished by 7.7 to 11.6 million km² (see Table 1) during the next 100 years, the economical infrastructure expenses will rise dramatically for all circum-Arctic countries. In addition, large quantities of carbon are fixed in today's frozen ground which, if set free, can give impetus to feedback loops of an even more rapidly increasing climate. Zimov et al. (2006) state that the atmospheric global carbon budget rose by ~170 gigatons (GT) from preindustrial times to ~730 GT today. They further estimate that currently some 1980 GT are retained in glacier moraines, sediments beneath ice sheets, frozen Siberian loess, and steppe-tundra soils. If permafrost degradation follows the prediction of our analysis, about 600–900 GT of formerly frozen carbon will be released into the atmosphere and enhance already existent global warming until 2100.

The modeling results also suggest that the future rate of permafrost degradation will quadruple compared to today. During the last 70 years, annual global permafrost decline averaged ~23,000 km² per year, whereas the next 100 years will face an average loss of ~95,000 km² per year. In combination with the already described intensified global warming by carbon release from frozen ground, it is likely, that this average rate will rise even higher.

The Southern Hemisphere

Due to the fact that WaterGAP does not include Antarctica, Southern Hemisphere permafrost is very rare. The past time slice displays a total of four model grid cells containing discontinuous permafrost, which are reduced to three cells for contemporary conditions, and to none for all four future scenarios. The location of these cells in Argentina is concordant with the position of mountainous permafrost-

Table 1. Global area occupied by discontinuous and continuous permafrost in million km² (using equations 3 and 5). Values in parenthesis indicate percentage change to modeled 1971–2000 conditions.

	1901 – 1930	1971 - 2000	2071 – 2100 A1B, HadCM3	2071 – 2100 A1B, ECHAM5	2071 – 2100 B1, HadCM3	2071 – 2100 B1, ECHAM5

Table 2. Global area occupied by discontinuous and continuous permafrost in million km² for 1971–2000 and comparison of different snow density ρ_s and thermal conductivity λ_s equations for the calculation of permafrost. Values in parenthesis indicate percentage change relative to permafrost map compiled by Brown et al. (1998). Anisimov & Nelson (1997) used different climate input and modeled Northern Hemisphere permafrost distribution (F_+) for 1961–1990 (using constant ρ_s (300 kg m^{-3}) and equation 4).

	ρ_s: equation (3) λ_s: equation (5)	ρ_s: constant λ_s: equation (5)	ρ_s: equation (3) λ_s: equation (4)	ρ_s: constant λ_s: equation (4)	Anisimov & Nelson (1997)	Permafrost map (Brown et al. 1998)
Sporadic discontinuous	9.4 (-17)	8.9 (-22)	9.7 (-15)	9.1 (-20)	8.1	11.4 (0)
Extensive discontinuous	6.7 (+24)	6.6 (+23)	6.8 (+26)	6.7 (+25)	5.6	5.4 (0)
Continuous	9.4 (-12)	9.7 (-9)	9.6 (-10)	9.9 (-7)	11.7	10.6 (0)
All permafrost regions	25.5 (-7)	25.2 (-8)	26.1 (-5)	25.7 (-6)	25.5	27.4 (0)

monitoring boreholes; for example, *Balcon I* at 32°57’43”S, 69°22’19”W (Trombotta et al. 1997), which are operated by the Global Terrestrial Network for Permafrost (GTNP).

Modification of the surface Frost Number

The aim of this model application was not only to predict global permafrost distribution, but also to test the framework of the Frost Number for the implementation of different formulations for snow density ρ_s and thermal conductivity λ_s. Table 2 compares the influence of these formulations on global permafrost distribution for contemporary conditions. The variation of total permafrost occurrence is rather small and lies within the range of one million km², whereas the combination of equations (3) (ρ_s calculated) and (4) (λ_s according to Van Dusen) yields the largest permafrost extent. Thus, as total permafrost occurrence is generally underestimated by the model, this combination of equations yields the smallest divergence (-5%) to the map of Brown et al. (1998). The lowest extent has been predicted by combining constant ρ_s and equation (5) (λ_s according to Sturm et al. 1997). The integration of equations (3) and (5) in the Frost Number calculations, which have also been used for the scenario estimates, generates mid-range permafrost spreading compared to other combinations. However, with 9.4 million km² of modeled continuous permafrost area, it also provides the smallest zonation of all four combinations.

Thermal conductivity of snow λ_s has been calculated using two different formulations, of which equation (5) generally yields lower values than equation (4) for ρ_s smaller than 345 kg m^{-3}, which holds true for most cells in this analysis. Table 2 shows that all permafrost calculations conducted with equation (5) feature smaller discontinuous and continuous permafrost extents than its counterpart equation (4). When snowfall occurs in the early stages of winter, low λ_s and thick snow layers can cause an insulation of the upper soil layer and thus prevent permafrost occurrence (Zhang et al. 2001). This effect is partially accounted for in equation (2), where snowfall early in the year is weighted higher than late snowfall.

There are two more options of snow-depth modeling, which could be applied for further studies on the Surface Frost Number. First, a physically detailed approach, which considers snow metamorphism and overburden (Jordan 1991). Secondly, if necessary input data are not available, a conceptual approach, as in Pomeroy et al. (1998), who suggest initializing annual snow density with 100 kg m^{-3} and add 25 kg m^{-3} for each month colder than 0°C.

In general, the comparison with results from a similar study conducted by Anisimov & Nelson (1997) shows good agreement for total permafrost extent. However, continuous permafrost is 25% lower, and discontinuous permafrost spreading is 15% higher in the current study. This could be explained by different climate data input, higher constant snow density, and an earlier and colder time period. Thus, in between the climate normal 1961–90 and 1971–2000, air temperature increase caused a transformation from continuous to discontinuous permafrost, which could explain some of the differences between both studies.

Conclusions

This model experiment projects that, due to climate change, increasing air temperatures do have a significant impact on global permafrost distribution and thawing. According to the model results, which esteem from two IPCC-SRES scenarios and two GCMs, future continuous permafrost will suffer the largest zonal reductions, which vary between -53% and -67% compared to today. Discontinuous permafrost faces two different pathways of decay, depending on its type. On the one hand, extensive discontinuous permafrost experiences losses between -35% and -61%. On the other hand, sporadic discontinuous permafrost faces moderate spatial changes between +1% and -13%, which is due to the conversion from continuous and extensive discontinuous to sporadic discontinuous permafrost. These thawing processes can have large impacts on urban infrastructure and can trigger feedback loops of enhanced global warming. The modeling results also show, that permafrost degradation in the next 100 years will progress much faster than during the last 70 years.

In this study, a validation of the Frost Number for present total permafrost occurrence has been carried out successfully. The general underestimation of modeled global permafrost extent can probably be addressed to the existence of relic permafrost which is not considered by the model.

The incorporation of additional snow parameter equations showed little sensitivity to the calculation of the Surface Frost Number.

Although the Surface Frost Number has proven its suitability to display contemporary permafrost distribution to some extent, the interpretation of all modeling results should be regarded with caution. Especially the interaction of transient GCMs, climate change scenarios, climate data-input uncertainties, and empirical model functions can lead to large inaccuracies in the prediction of permafrost occurrence. In this study, the main disadvantage of the Surface Frost Number can be seen in its dependence on climate input solely. Further, snow property calculations, such as modeled snow depth, should be subject to more physical approaches, which also consider snow typical processes, such as snow compaction (e.g., as in Jordan 1991). It is recommended further studies integrate soil properties, relic permafrost, and carbon and methane cycling in the assessment of climate change driven permafrost thawing. Potential candidates for the integration of soil features are formulations such as the Stefan Frost Number (Nelson & Outcalt 1987) or the more detailed Kudryavtsev solution, which is described in Anisimov et al. (2007).

Acknowledgments

We thank our colleagues, especially Florian Wimmer and Frank Voß, at the Center for Environmental Systems Research (CESR) for valuable discussions about the thermal properties of snow. We also gratefully acknowledge the helpful comments by two anonymous reviewers. This work was funded by the German Federal Ministry of Education and Research (FKZ:033762A).

Abstract

This article discusses long-range terrestrial laser scanning (TLS) as a monitoring technique focusing on recent geomorphic changes at the near-terminus zone of the Hinteres Langtalkar rock glacier (46°59′N, 12°47′E). This rock glacier is characterised by extraordinarily high movement rates at its lower part since the mid-1990s. The surface of this collapsing part of the rock glacier is characterised by a very disturbed topography, which causes problems for terrestrial as well as remote sensing monitoring methods. The lack of textural information makes approaches such as optical flow detection in grey-scale images non-applicable at this study area. Long-range TLS is completing the dataset with distance measurements leading to 3D point clouds, which are afterwards converted into accurate 3D models. Analysis of surface kinematics derived from five digital elevation models (DEM) obtained during TLS campaigns between 2001–2006 shows promising results covering this lack of data in unfavourable terrain.

Keywords: Austrian Alps; high-resolution DEM; LIDAR; rock glacier kinematics; terrestrial laser scanning.

Introduction

Surface dynamics of rock glaciers are of increasing interest due to a high relationship to thermal conditions of permafrost areas. A few rock glaciers in the Alpine arc reacted to increasing air temperatures with extraordinarily high movement rates over several years (Roer et al. 2003). Most of them now show decreasing surface velocities (Delaloye et al. 2008). The Hinteres Langtalkar rock glacier changed its behavior most likely in 1994, moving over a prominent bedrock ridge into steeper terrain (Avian et al. 2005). Despite the remoteness of the location, a comprehensive monitoring network has been installed to get a better understanding of present processes, such as a geodetic survey (annually since 1998; Kienast & Kaufmann 2004), monitoring of the near-surface and surface thermal regime (since 2006 within the project ALPCHANGE), terrestrial laser scanning (2x2000, 2x2001, 2004, 2005, 2006, and 2007; cf. Bauer et al. 2003), and digital photogrammetry (1969, 1974, 1983, and 1997; cf. Kaufmann & Ladstädter 2004), providing data of different nature and in different resolutions in time and space. Long-range TLS ought to monitor the lowest part of the rock glacier to gather information about vertical surface changes and 3D movement rates.

Geographical Setting

The cirque-system Hinteres Langtalkar (46°59′N, 12°47′E) is situated in the Schober Mountains within the Hohe Tauern Range (Central Alps, Austria) (Fig. 1). The cirque-system is a hanging valley at the orographic right side of the Gössnitz Valley. The cirque covers an altitudinal range between

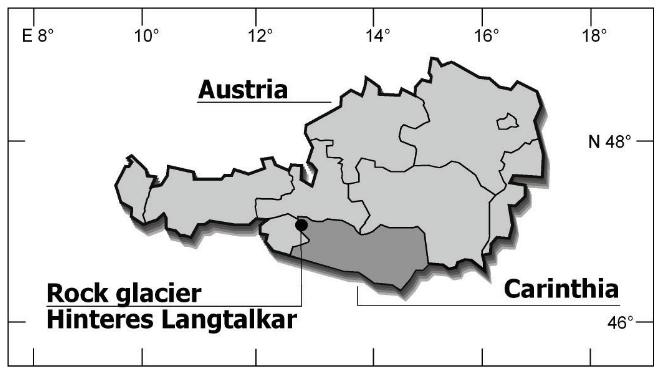

Figure 1. Location of Hinteres Langtalkar within Austria.

2300–3019 m a.s.l. The northwest facing tongue-shaped rock glacier itself covers the entire upper cirque floor with a lower margin at 2455 m a.s.l., root zones beginning in appr. 2700 m a.s.l, and a geometry of 600x300 m (Fig. 2). In general, rock glaciers are numerous in the Schober Mountains due to favorable geological conditions, leading to a total number of 77 intact rock glaciers (*cf.* Lieb 1998). Furthermore, the main range of the Central Alps (10 km to the N) causes pronounced continental climatic characteristics with a mean annual air temperature (MAAT) of 0°C at 2200 m a.s.l. and precipitation of ~1500 mm at 2000 m a.s.l. Glaciation in the Schober Mountains is developed only in some cirques and decreased rapidly during the last decades due to atmospheric warming (Kellerer-Pirklbauer & Kaufmann 2007). Auer et al. (2002) report a rising of the MAAT of 1.6°C since 1886 at the Hoher Sonnblick Meteorological Station (3106 m a.s.l., 15 km E of Hinteres Langtalkar) which is above the global average of 0.74°C (*cf.* IPCC 2007).

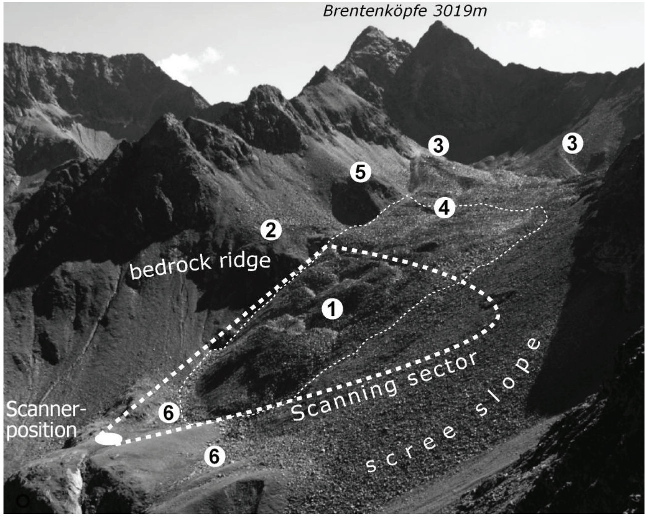

Figure 2. The cirque-system Hinteres Langtalkar including the monitoring configuration. Codes in photograph: (1) Area of intensive rock glacier movement and disintegration, (2) prominent bedrock ridge partly covered by periglacially weathered debris, (3) latero-terminal moraine ridges dating from the Little Ice Age (~1850 AD), (4) crevasses on rock glacier indicating high strain rates, (5) meteorological station and (6) fresh boulders spreading over alpine meadows adjacent to the rock glacier front. The thin dashed line comprises the recently fast-moving part of the rock glacier. Scanner position is in a distance of ~90 m to the rock glacier front (Photograph by Viktor Kaufmann 24.08.2003).

Methods

Laser scanning or LiDAR (Light detection and ranging) data have been used intensively for high mountain applications during the last decade. Examples are monitoring of glacier surface elevation changes by Airborne Laser Scanning/ALS (e.g., Baltsavias et al. 2001, Würländer et al. 2004) or TLS (e.g., Avian et al. 2007), monitoring of periglacial processes using TLS (e.g., Bodin et al. 2008), hazard monitoring by TLS (e.g., Conforti et al. 2005, Rabatel et al. 2007) or snow cover monitoring using TLS (Prokop 2007). Primary resulting digital elevation models (DEM) are used to consider surface elevation variations to quantify, for instance, glacier dynamics. Determination of horizontal flow fields with high-resolution DEMs was presented by e.g., Bucher et al. (2006) with the aid of the software IMCORR, using concepts from aerial image matching (cross correlation in grey-scale images).

The ability of TLS to acquire high-resolution 3D data of surface structures makes this technique an interesting instrument for measuring high mountain environments. The integrated measurement system is capable of describing 3D motion and deformation of rock glacier surface within a few hours measurement. It is a time-of-flight system that measures the elapsed time of the pulse emitted by a photo-diode until it returns to the receiver optics. Maximum range depends on the reflectivity of surface (which is favourable for snow and debris-covered terrain) and atmospheric visibility (best for clear visibility, bad for haze and fog). A measuring range of up to 2000 m allows hazardous sites to be easily measured from a safe distance. Since each single measurement consists of a multitude of laser-pulses, different measurement modes (“first pulse,” “last pulse,” “strongest pulse”) give proper results even during bad weather conditions and on poor surfaces like vegetated, moist, or roughly structured terrain that might otherwise lead to ambiguous measurements. Table 1 gives an overview of technical information concerning the long-range TLS Riegl LPM-2k.

Table 1. Scanner parameters and values of the used instrumentation Riegl LPM-2k Long-range Laser Scanner.

Scanner parameter	Value (range)
Measuring range for:	
- good diffusely reflective targets	up to 2500m
- bad diffusely reflective targets	>800m
Ranging accuracy	+50mm
Positing accuracy	+0.01gon
Measuring time / point	0.25s to 1s
Measuring beam divergence	1.2mrad
Laser wavelength	900nm
Scanning range	
- horizontal	400gon
- vertical	180gon
Laser safety class	3B, EN 60825-1
Power supply	11-18V DC, 10VA
Operation temperature range	-10 to +50°C

The measurement

Information at each individual measurement point includes the distance to the surface, the exact angular positions, the reflectance, and an estimated root mean square error (RMSE) of the distance measurement for reliability check. Measurements with an accuracy of distance better than 5 cm are automatically combined to a measurement grid. In general, several methodological, technical, and logistical problems are to be encountered when establishing an integrated monitoring system in this high alpine environment. These include among others the stability of device control software, the automatic sensor orientation, the high number of measurements, the compensation of weather influences, and the selection of reliable measurements. In addition, it is of particular importance to consider the highly heterogeneous surface in terms of material (rock, vegetation, and humidity in general) and structure. Many years of experience in the field of TLS (beginning in 2000) result in the development of a well-engineered, stable acquisition and analysis system, which in combination with expert field work, copes with all the conditions.

Data processing

The TLS dataset is converted to a DEM, which is a digital raster representation of surface topography. In general, a horizontal reference surface is used. However, topology is often highly varying in terms of inclination; for example, most of the potentially insecure surfaces are characterized by comparable steep fronts. In order to represent the surface data in best resolution, we generalize the DEM to an analytical reference model that best describes the global shape of the observed surface. To raster, a regularly spaced grid is defined on the reference model, and the "height" on every pixel is processed as normal distance to the reference surface. This data structure complies well with practical requirements such as difference measuring, volume change evaluation, and various visualization tasks. Neighbourhood relations of measured data points are directly described in the DEM structure; therefore, operating on DEMs allows quick access to the surface heights in a well-defined geometry. Direct mapping from the sensor spherical system to the DEM cartesian coordinate space would result in a sparse and non-uniform elevation map, especially at great distances. To avoid interpolation artefacts, the Laser Locus Method (Kweon et al. 1992) for DEM (Bauer et al. 1999) generation proves to be a robust tool for data acquisition from flat angles and supports error detection and utilization of additional confidence values provided by the range sensor. Since the DEMs of (temporally) different surface measurements are geo-referenced, simple differences between the DEMs reflect the changes in elevation. In consequence we can derive a full description of change in volume, spatial distribution of shape, or arbitrary profiles on the surface.

Single time-of-flight measurements are automatically combined to a measurement grid that enables the generation of a dense, enhanced DEM of the rock glacier surface. Repeatable sensor orientation is performed using reflective targets fixed on stable surfaces somewhere in the spherical field of view of the sensor. TLS measures the position of a theoretical, stable point on the surface within a given reference system.

Surface motion analysis

The DEM differences primarily only describe the vertical distance of the surface change. In order to understand the complex kinematics of rock glacier deformation – like the highly dynamic lowest part of the Hinteres Langtalkar rock glacier – further knowledge about the 3D surface motion patterns is required. Among others, Kääb et al. (2003) and Kaufmann & Ladstädter (2004) provide solutions to calculate the 3D motion by means of optical flow detection on the grey level images using correlation-based matching. This method is not applicable to the current laser scanning configuration, since similar reflectance conditions cannot be assured (basic requirement for robust matching). Tracking of objects on the surface can still be performed by the high-resolution surficial morphology provided by the DEM (despite the lack of textural information). Only on surfaces, where the structural surface changes are relatively small, state-of-art matching methods (cf. Paar & Almer 1993) obtain dense tracking vectors. In combination with the primarily obtained DEM differences mentioned above, this results in a three-dimensional vector field that describes the kinematic state of the rock glacier surface within the given periods.

Table 2: Periods of data acquisition and quality parameters. Data used for analysis discussed in this study are indicated in bold.

Period	total pts	used pts	PR (1)	OA (2)
07/2000	27048	26381	0.98	0.07
08/2000	**27048**	**26437**	**0.98**	**0.06**
07/2001	27048	26274	0.97	0.02
08/2001	**26910**	**26312**	**0.98**	**0.02**
08/2004	**20424**	**19818**	**0.97**	**0.02**
08/2005	**27048**	**17843**	**0.65**	**0.02**
09 2006	**7836**	**6048**	**0.77**	**0.02**
07/2007	6384	5739	0.90	0.02

(1) PR: point ratio = numbers of points used/total number of points measured. (2) OA: orientation accuracy [m].

Cross check with auxiliary data

To control the significance of the image matching data, cross checking with displacement rates from adjacent parts of the rock glacier were considered. Geodetic survey has been carried out in the middle part of the rock glacier (data kindly provided by V. Kaufmann) with its lower measurement boundary at the disintegrated lower part of the rock glacier. These campaigns provide verification data for the displacement vectors derived from image matching (Tab. 2). Some limitations in interpretation have to be considered due to distances of up to 60 m between scanning area and respective control points.

Results

Quality of data from image matching

To get more information about interpretability, a review of data quality is essential. In 2000–2005 the total number of acquired points is high with 20,000 to 30,000 per campaign. The surface topography of a rock glacier consists of boulders with sizes between a few decimeters up to some metres. This is of crucial importance in the face of a true reproduction of the real surface and subsequently in receiving reasonable results in terms of surface motion patterns. Due to problems with energy supply in 2006 and 2007, the scanning increment had to be reduced during these campaigns, leading to total point numbers below 10,000. This low number is unfavourable for interpolation and obtaining a DEM for an area-wide precise motion analysis. Orientation accuracy is satisfying for all periods with 0.02–0.07 m (Table 2).

Annual displacements from image matching

Results of the rock glacier motion analysis are given in mean annual horizontal displacement rates.

2000–2001: The stepped lowest part differentiates clearly in velocity patterns. The ridges show mean annual displacement rates of 0.78 ma^{-1} (max. 1.38 ma^{-1}) (Fig. 3A; zone 1), 0.95 ma^{-1} (max. 1.73 ma^{-1}) (Fig. 3A; zone 2), 1.38 ma^{-1} (max. 1.64 ma^{-1}) (Fig. 3A; zone 3), and 1.35 ma^{-1} (max. 1.75 ma^{-1}) (Fig. 3A; zone 4). The adjacent scree slope at the orographic left side of the rock glacier shows constant movement rates of 0.02–0.06 ma^{-1} over the entire scanning area.

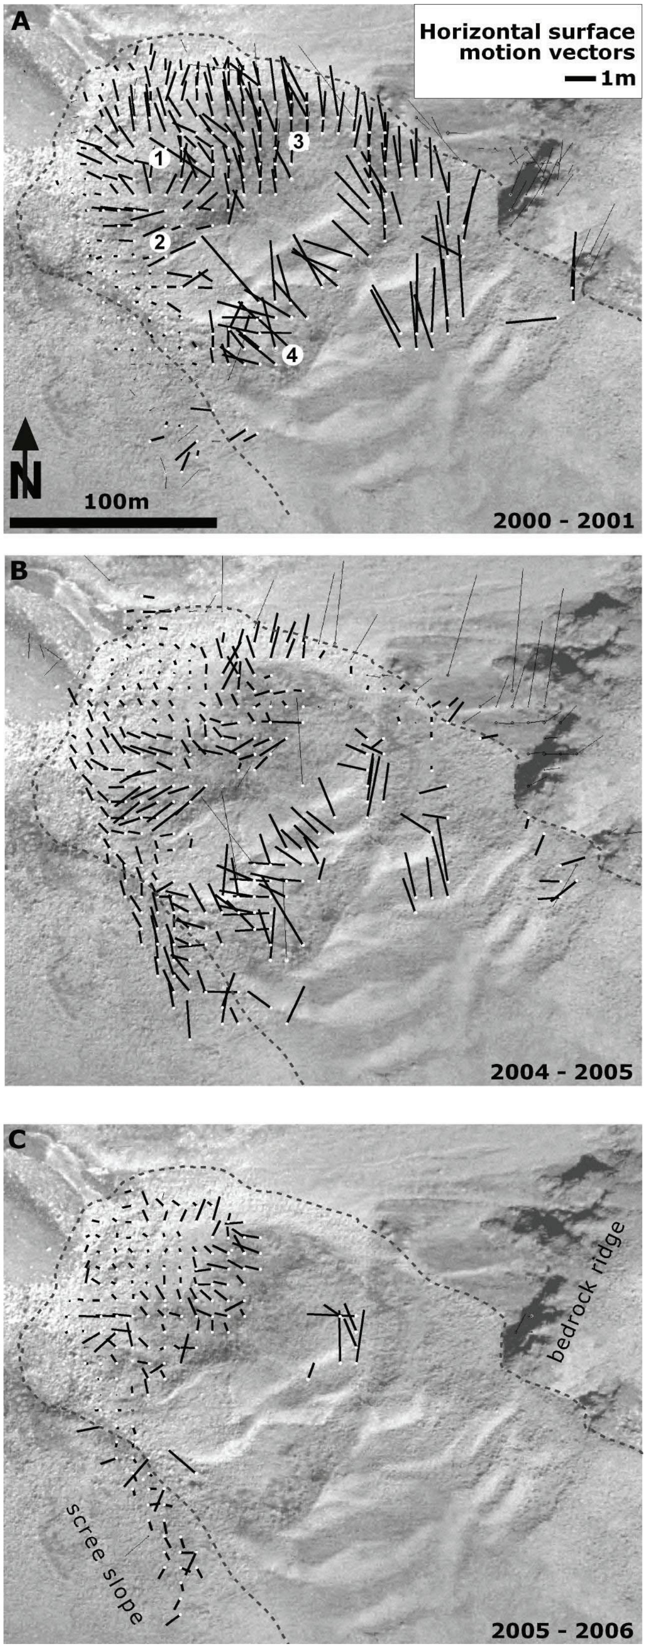

Figure 3. Horizontal displacement rates [ma^{-1}] for three annual periods: (A) 2000/01, (B) 2004/05 and (C) 2005/06. Motion vectors are obtained from DEM differences, DEMs were derived from TLS data. Numbers (1-4) indicate zones of different behaviour in terms of surface velocity; for details refer to text (Orthophotograph ©Nationalpark Hohe Tauern, 1998).

2004–2005: Quality of velocity data from this period tends to be unsatisfying in some areas. Distinct differentiation between obviously moving and akinetic areas at the margin of the rock glacier is not possible. Velocity patterns do not indicate a distinct border between the scree slope and the rock glacier body. Furthermore, displacement rates of 0.35–0.40 ma^{-1} seem to be unreasonable for this particular area. Surface topography on the rock glacier itself can be deduced from flow fields properly, as they show similar patterns as in the other periods.

2005–2006: Flow velocities and patterns are more difficult to interpret, although the ridges are detectable due to higher displacement rates (0.75 ma^{-1}). The main front shows rates around 0.15 ma^{-1}, the left margin is distinguishable towards the non-moving scree slope. Coarse point resolution leading to small spots of areal data does not allow reasonable interpretation of the upper part of the rock glacier tongue (cf. uppermost scanning area in Fig.2).

Direction of annual displacement vectors

Direction of movement at the terminus zone of the rock glacier shows outward movement of displacement vectors as expected. The ongoing development of the imbrication and the distinct shifting of detritus is visible in abrupt changes of the magnitude and direction of velocity vectors (Fig. 3, A-C, 1-4).

Cross checking with results from geodetic survey

Surface displacements derived from geodetic surveys in both periods at least coincide with displacement ranges obtained from TLS image matching (Tab. 3). However, substantial controlling is not possible due to poor data overlap. The main problems are hazardous working conditions for terrestrial monitoring, making geodetic or GPS surveys hardly feasible in the fast-moving sections of this rock glacier (up to 2.38 ma^{-1} in 2003–2004). The steep rock glacier's front surface changes rapidly in shape, texture, and object distribution. This results in unfavorable conditions for analysis of optical data; viewing angles nearly vertical or area-wide changes in surface cause problems in automatic detection).

High values at some areas of the right margin of the rock glacier, the bedrock, and vegetated areas are results due to unfavorable scanning geometry and therefore are not taken into account as the exact rock glacier extent is known from fieldwork.

Discussion and Conclusions

High-resolution DEMs derived from long-range terrestrial laser scanning are a good data basis for monitoring permafrost processes related to geo-hazards. Derivates like surface elevation changes and displacement vectors (in case of the availability of multi-temporal high-resolution DEMs) provide useful information about 3D surface dynamics. However, the quality of dataset s and concepts for calculating morphometric parameters have to be assessed critically. Point density is a crucial factor (cf. Bodin et al. 2008) as is the quality of the measurement itself (high point ratio and total point number). Remoteness (sufficient energy supply) and atmospheric conditions (e.g., air humidity) are crucial limiting factors. The exemplary study of the Hinteres Langtalkar rock glacier demonstrates the importance of independent control data for evaluation, and the problems in acquisition of the latter. High landscape dynamics – frequent shifting of material, block falls – inhibit terrestrial surveys. Methodological problems in automatic data interpretation (e.g., inadequate texture for photogrammetry) complicate remote sensing approaches. The current monitoring configuration lacks additional control targets in the vicinity of the upper rock glacier tongue on the bedrock. Large differences in velocity values of different periods do not allow the interpretation of recent processes precisely at present.

In terms of velocity patterns, topography, and surface modification, some considerations are appropriate. In the lowest section of the rock glacier front, the surface velocity is decreasing to the margin as expected. Flow patterns are detectable in step-like relief which geomorphodynamically results in a distinct surface topography (Figs. 2, 3). High velocities within ridges and sharp limits at the ridge fronts to slower areas support this assumption. The formation of the micro-relief within ridges is also visible in the displacement patterns. Surface velocity patterns also exhibit distinct differences between the main rock glacier body and adjacent permafrost areas at the orographically left side. At the beginning of the steeper part of the lower rock glacier tongue, varying directed vectors in both periods indicate non-laminar movement of that particular part and are therefore interpreted as intense modification and frequent shifting of the disturbed surface.

As this particular rock glacier shows extraordinary surface velocity rates (cf. Avian et al 2005, Roer et al. 2005), upcoming TLS campaigns on the middle and upper section of the rock glacier would enhance knowledge about methodological problems due to the availability of independent data derived from geodetic measurements.

Acknowledgments

These activities were carried out within the framework of the project ALPCHANGE (www.alpchange.at) funded by the Austrian Science Fund (FWF) through project no. FWF P18304-N10. We kindly acknowledge the help of Viktor Kaufmann (Institute of Remote Sensing and Photogrammetry, Graz University of Technology) for providing data from geodetic surveys. We also thank students of the Institute of Geography and Regional Science, University of Graz and the Institute of Remote Sensing, Graz University of Technology, Austria as well as several volunteers of the Nationalpark Hohe Tauern for their support during field campaigns.

Abstract

Shishmaref, Alaska, is located on Sarichef Island in the Chukchi Sea. Sarichef Island is composed of very fine-grained sand permafrost, most likely wind-blown deposits formed as dunes when global sea levels were much lower. With present-day sea levels and changing climatic conditions in the region, these permafrost soils are more susceptible to erosion from wind, wave, and ice forces. In recent years, erosion at Shishmaref has been more pronounced due to the changing climatic conditions in the region. To combat this erosion, several local protection projects have been constructed with varying degrees of success. In an effort to learn more about the thermal conditions of the permafrost at Shishmaref, ERDC-CRREL and the Alaska District installed a series of thermistor strings beneath these revetments. This data will allow us to gain an understanding of the temperature of the permafrost throughout the year and during periods of intense fall storm events.

Keywords: convective cooling; permafrost; Shishmaref.

Introduction

Shishmaref, Alaska is located on Sarichef Island, in the Chukchi Sea, just north of the Seward Peninsula. Shishmaref is 8.5 km from mainland Alaska, 210 km north of Nome, and 170 km southwest of Kotzebue. Shishmaref has a population of approximately 615, most of whom are Inupiat Eskimo. The people of Shishmaref live a traditional subsistence lifestyle.

Sarichef Island is a barrier island 4 km long by 0.7 km wide. The island is one of a string of barrier islands separating the Chukchi Sea from the Alaskan mainland. These islands are composed of very fine-grained sand-permafrost, most likely wind-blown deposits formed as dunes when global sea levels were much lower. With present-day sea levels and changing climatic conditions in the region, these permafrost soils are more susceptible to erosion from wind, wave, and ice forces.

Short period waves from locally generated storms appear to be the most problematic for the island. The shoreline is directly exposed to the southwesterly and northwesterly fetches across the Chukchi Sea and can experience moderately high waves under storm conditions. Such waves are generally in the 1.5 to 2.5 m high range with periods of 4 to 5 seconds based on observations at the bluff. Events with waves as high as 3 m have been estimated from observations during extreme storm conditions. These waves can cause severe erosion when coupled with high storm surge events. Fall storms can cause extreme erosion to the shoreline at Shishmaref. The wave action caused by these storms cuts into the banks and in the spring the banks that were undercut will thaw, drop, and wash away, thus exposing more frozen soils. Figures 1 and 2 illustrate how much damage can occur to the shoreline at Shishmaref due to one storm. Figure 3 illustrates the permafrost degradation seen at Shishmaref.

Figure 1. Shoreline fronting the Teacher's Quarters in July of 2004. Note steps to grass-covered bluff.

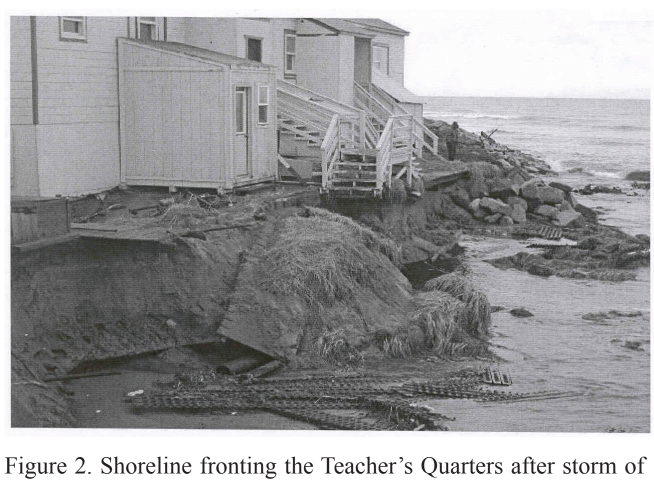

Figure 2. Shoreline fronting the Teacher's Quarters after storm of October of 2004.

Figure 3. Permafrost degradation at Shishmaref, Alaska showing exposed permafrost horizon.

Figure 4. USACE revetment fronting the Teacher's Quarters – summer 2005.

Figure 5. USACE revetment construction fall of 2007.

The frozen horizon can be clearly seen at the base of the bluff. Documented history of storm damage and coastal erosion problems at Shishmaref extends back more than 50 years and includes numerous reports by various consultants and State and Federal agencies, including the Alaska District, U.S. Army Corps of Engineers (USACE).

Erosion Protection

The community has tried many techniques throughout the years to arrest the erosion of their coastline including barrels, gabions, sandbags, and articulated concrete mat (AMC). All of these proved to be only temporary solutions as wave action and high water level events have all but destroyed these structures. Because the shoreline continues to recede, the community has moved houses and other structures back from the shoreline but they are quickly running out of room due to Shishmaref's limited size and soil conditions.

To combat the erosion several local erosion protection projects have been constructed with varying degrees of success. In 2004 the Bureau of Indian Affairs (BIA) constructed approximately 150 m of rock revetment. The Alaska District constructed approximately 70 m of rock revetment in the summer/fall of 2005, with the City of Shishmaref extending this effort by constructing an additional length of rock protection. In a continuing effort to protect the shoreline, the Alaska District will complete another 200 m of rock revetment in the fall of 2007 and summer of 2008. Figures 4 and 5 illustrate these construction efforts. Eventually the community would like to see their entire shoreline protected.

Permafrost Temperature Measurement

In an effort to learn more about the thermal properties of the permafrost at Shishmaref, the U.S. Army Corps of Engineers Engineer Research and Development Center-Cold Regions Research and Engineering Laboratory (ERDC-CRREL) and the Alaska District have installed a series of thermistor strings beneath several of the rock revetments placed at Shishmaref. This data will enhance existing knowledge of the temperature of the permafrost throughout the year at Shishmaref, as well as during intense fall storm events. With a better understanding of the permafrost conditions on Sarichef Island, USACE and other agencies will have more information with which to design stable erosion protection measures.

The Alaska District and CRREL installed the first thermistor string in the summer of 2005, coinciding with the construction of the USACE revetment fronting the school property. Figure 6 illustrates the placement of this thermistor string prior to covering with core rock. In addition, in the summer of 2006 a string of thermistors was placed beneath a gabion revetment built by the City of Shishmaref. Both of these strings were placed beneath the filter fabric prior to the placement of the core rock or the gabion baskets. The gabion revetment has subsequently been covered by the USACE rock revetment in the fall of 2007. In July of 2007 a vertical string, descending approximately 3.3 m was placed near Nayokpuk store and in August of 2007, a string was placed beneath the new USACE revetment along the shore fronting Nayokpuk store. This string was also placed between the filter fabric and the parent soil material.

All of the thermistor strings are connected to and read by Campbell Scientific CR10X data loggers and powered by three deep discharge gel-cell marine batteries. The thermistor strings are constructed from a multi-conductor cable with one of the conductors used as a common leg for the resistance measurement of each precision glass bead thermistor. Each thermistor location is isolated and waterproofed. The multi-conductor cable is protected by an outer conduit. The initial installation at the school property used a reinforced washing machine hose while later cables were protected with non-metallic liqui-tight conduit. Figure 7 shows the approximate location of each string on the island. Also included in this figure is the location of a proposed thermistor string in a relatively undisturbed portion of the shoreline. This string is intended to provide data on soil temperatures where convective cooling is not possible due to the native soil conditions and would be one of the last portions of the shoreline to be protected.

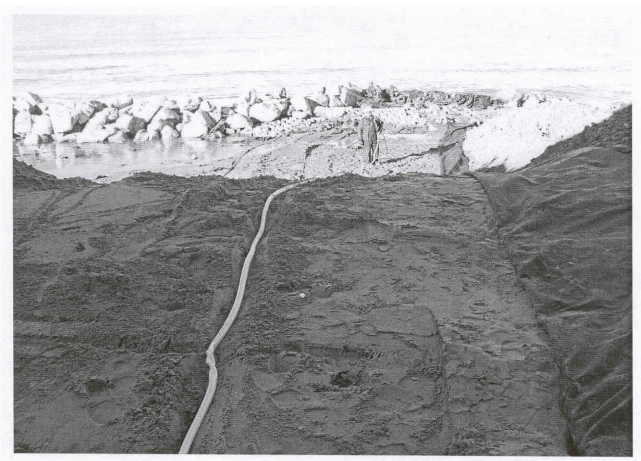

Figure 6. Thermistor string installation in the USACE revetment fronting the Teacher's Quarters.

Potential for convective cooling

There are several pieces of information that the Alaska District and CRREL hope to obtain from the data acquired from these thermistor strings. The first is a better understanding of the thermal interaction between the rock revetment and the natural soil materials at Shishmaref. The hope is to be able to establish where the active layer is generally located at the shoreline. The data will also be used to determine how the permafrost reacts to fall storm events. The data should show whether or not there are thermal fluxes in the soil temperatures during fall storms. Knowing whether or not the soil temperature fluctuates during these fall storms can enable a better understanding of when and what causes the shoreline permafrost to degrade and thus cause erosion.

Data provided by the thermistor strings may also provide knowledge of the link between the temperature of the permafrost and convective cooling. The fact that natural convection can have a large impact on heat transfer in a porous medium is well known (Goering 1995). In order to maintain stable permafrost, it is generally necessary to ensure that the mean annual surface temperature (MAST) is maintained below 0°C (Goering 1998). While the rock and gap sizes are greater than those recommended for efficient convective cooling, it is surmised that after a period of stabilization the revetment will help to maintain the MAST below 0°C, thus thermally stabilizing the permafrost.

Convective cooling is heat transfer by the natural upward flow of air from the relatively warmer object being cooled. Convective cooling techniques have been used with varying

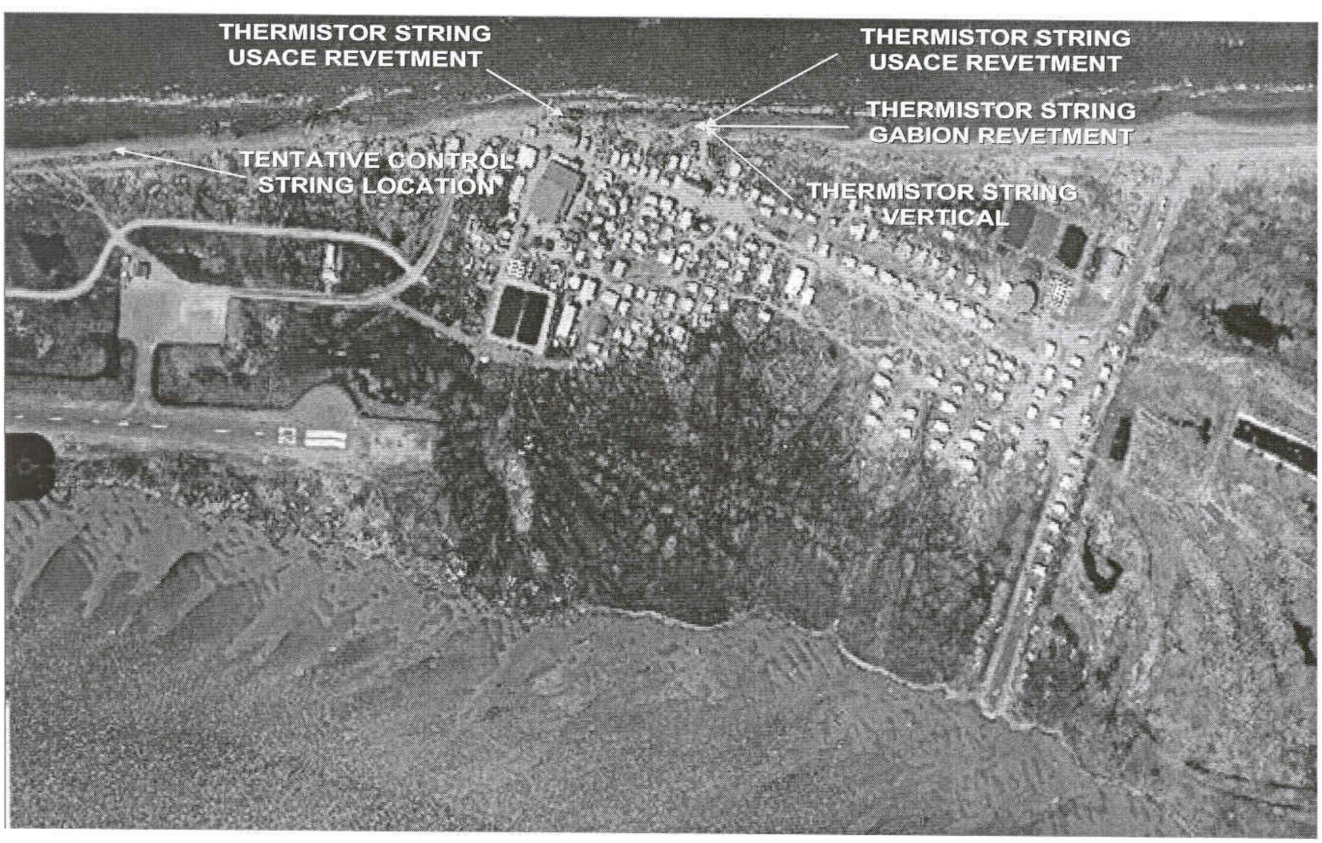

Figure 7. Thermistor string locations at Shishmaref.

degrees of success in road embankments in the Fairbanks, Alaska area. Several studies have previously been conducted on the use of Air Convection Embankments (ACE), which allow for natural convection of the pore air to occur within the embankment during the winter months (Goering 1998). Convection enhances the upward transport of heat out of the embankment during the winter months thus cooling the lower portions of the embankment and underlying foundation soil (Goering 1998). The cooling effect is achieved by maintaining a relatively small temperature difference during the winter compared with the summer. During the winter, colder pore air in the upper potion of the embankment will descend due to its greater density while warm pore air from the embankment base rises. This results in a pattern of convection cells within the embankment.

With the aid of convective cooling, the permafrost table should begin to rise. In order to achieve this cooling effect the embankment must be composed of a rock and gravel matrix, which is railroad ballast sized (0.05 to 0.075 m), poorly graded, and with a very low fines content (Goering 2003). Due to time, materials available, funding constraints, and coastal conditions the USACE revetments do not fully meet the criteria that best enhances convective cooling. It is still uncertain how much heat transfer will occur from the relative impermeable embankment base to the permeable revetment. The revetment that fronts the teacher's quarters at Shishmaref does not have a poorly graded rock/gravel matrix. The core layer in this revetment consists of dredge spoils with a high fines content. What may enhance convective cooling in this revetment is the armor rock layer. The armor layer in this revetment was constructed using selective placement. Selective placement is the careful selection and placement of individual armor stones to achieve a higher degree of interlocking. This 1 meter (approximate) thick layer of tightly knit rock may help to facilitate convection within the revetment. In the revetment fronting Nayokpuk store, once again the gradation of the gravel layer was not ideal to aid in convective cooling. Instead of a poorly graded material, the gravel in this revetment is closer to well-graded gravel. While not poorly graded gravel, the material used in the revetment should be clean enough (marginal amount of fines) to provide ample void space for convection to occur. It is hoped that the effects of convective cooling will be seen on the landward side of the revetment where a gravel layer has been placed to a thickness of 0.70 m. Water infiltration within the revetment during the spring and summer months may decrease the effects of convective cooling within the system. Presently there is not enough information to determine whether these revetments are helping combat permafrost degradation. Within 5 to 6 years enough data will have been collected so that the Alaska District and CRREL can do further analysis and then re-evaluate the effects of convective cooling.

Temperature data

The data gathered from the vertical thermistor string should allow us to confirm the general location of the active layer. It will also show the maximum and minimum annual permafrost temperatures. Preliminary data for the vertical string, and the string beneath the newest USACE revetment

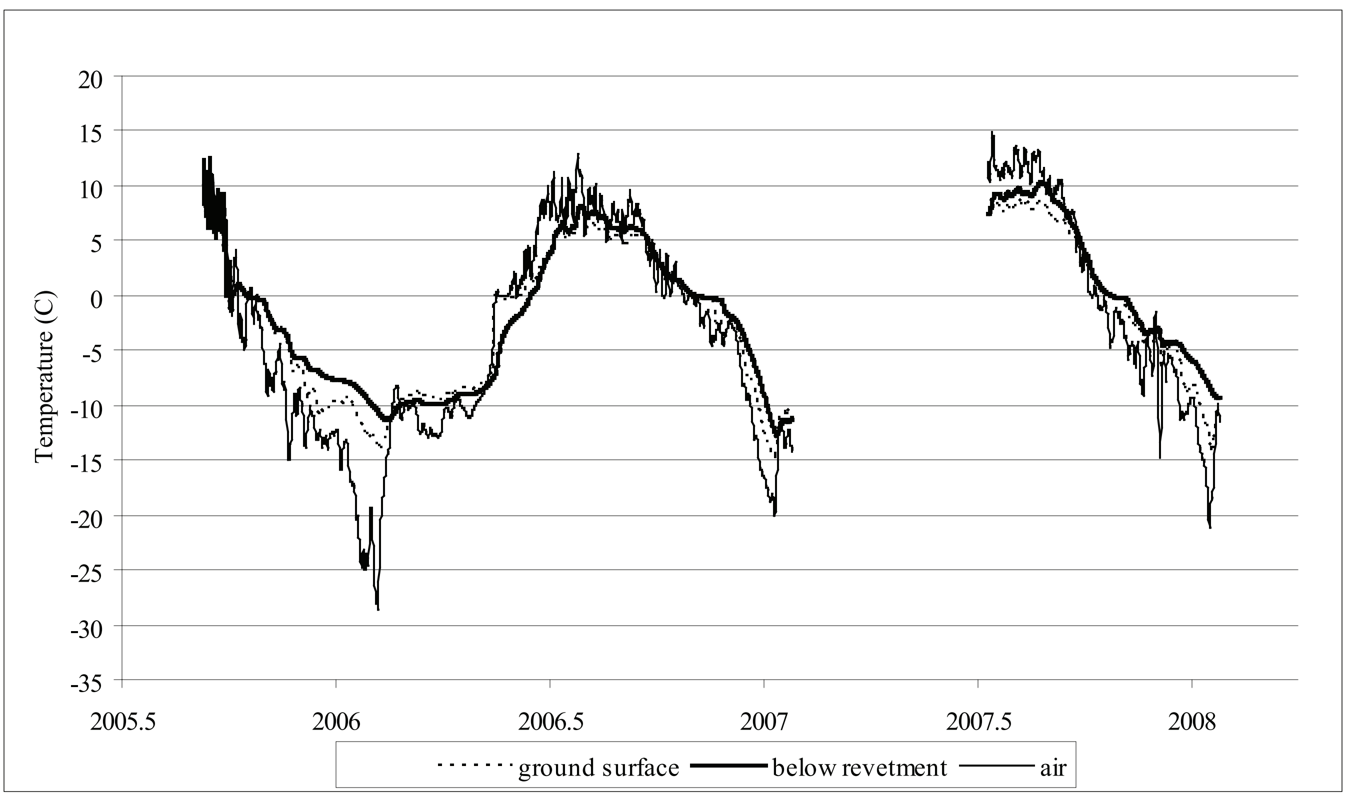

Figure 8. Graph of Temperature vs. Date for the thermistor string placed in the USACE revetment fronting the Teacher's Quarters.

should be available by the time of the presentation of this paper.

Figure 8 shows a graph of the data collected from the thermistor string beneath the USACE revetment fronting the Teacher's Quarters from September 2005 until January 2008. Gaps in data are due to power source difficulties. The data logger was originally placed on a trickle charger to keep the internal battery charged. Due to problems with power source reliability and the desire to keep the system maintenance-free, it was removed from line voltage and placed on the three deep discharge gel-cell marine batteries described above. From the data collected at this point it is apparent that the ground is staying relatively cool. The location of this thermistor string is beneath the filter cloth and just above the native soil. The core rock and armor stone of the shore protection are located vertically above the thermistors. Plotted on Figure 8 are the air temperature from a thermistor located approximately 3 m from the Teacher's Quarters, the ground temperature approximately 0.20 m below the surface, and the temperature beneath the core rock and armor stone. At the time of construction of this revetment, the native soil was contoured to match the final slope of the armor stone which resulted in the native soil, core rock, and armor stone attaining a temperature equivalent to the air temperature. Over the next month, all three temperatures on Figure 8 can be seen to follow the general decline of the air temperature. It can be seen from the period corresponding to the annual cycle of late 2005 to late 2006, the time that the soil temperatures were below 0^{o}C are longer than they were above 0^{o}C. This indicates that the mean annual soil temperature (both beneath the revetment and 0.2 m below the ground surface) is below 0^{o}C, one of the goals of convective cooling. There are some variations noted from year to year for the data presented. The maximum soil temperature beneath the revetment was approximately 8°C in the summer of 2006 and approximately 10°C in the summer of 2007. Similarly, the minimum soil temperature beneath the revetment was approximately -11°C in early 2006, -13°C in early 2007, and was still dropping at -9.6°C in mid-January 2008. This indicates that the base of the revetment is not below the permafrost table but within the active layer. Further data will allow the determination of whether the revetment is acting as an Air Convection Embankment

Summary

ERDC-CRREL and the Alaska District have installed several thermistor strings beneath shore protection projects at Shishmaref, Alaska on Sarichef Island. Data from the strings are beginning to show the variations in the temperature experienced over the annual cycle in the native soil beneath the revetment projects. It is hoped that the grading and selective placement of the armor stone of these revetments causes them to act as an Air Convection Embankment. An additional string placed vertically will supply information about the depth to the permafrost table and the thickness of the active layer.

In the future, along with continual data collection for the 4 strings currently in place a control string of thermistors will be placed at Shishmaref. Due to timing and funding constraints, the control string will be the final thermistor string placed on Sharichef Island. This string will be tentatively placed along the shoreline in the vicinity of the landing strip (as shown in Fig. 7). This area was chosen as a probable location because it will be one of the last areas impacted by revetment construction. Therefore, it should give us the longest period of record for temperatures on the unreveted shoreline. In April of 2008 a Ground Penetrating Radar (GPR) study will be will be conducted by the Alaska District and CRREL to aid in permafrost delineation, including depth to the permafrost table and the thickness of the permafrost layer. When this work is completed the Alaska District and ERDC-CRREL should have a through understanding of permafrost conditions in the vicinity of Shishmaref on Sarichef Island. Knowing the potential stability of the permafrost soils on Sharichef Island will enable the Alaska District and other Federal and State agencies make informed decisions regarding future shore protection and development opportunities.

Abstract

The formation of ice lenses and the water migration during freezing of frost susceptible, fine-grained soils is a dynamic and complex process. Horizontal ice lenses and vertical ice veins form at different spacing, intervals, and growth rates as the pore freezing front penetrates into the ground forming a three dimensional ice lens pattern. One-dimensional step-freezing tests were carried out in a transparent freeze cell with frost susceptible Devon silt to study this effect in detail. Time-lapse photography and particle image velocimetry are used to identify the dynamics of the freezing processes. Three dimensional movements are used to measure the changes in ice lens growth and axial soil strain in-between ice lenses with time. The formation and growth rate of vertical ice veins are studied and local vertical strains are determined. Horizontal soil deformations are also investigated. The detailed strains and ice lens growth rates within freezing soils help in improving formulations for frost heave, strength, and deformation behavior of freezing and frozen soils.

Keywords: frost heave; frost susceptibility; ice lens formation.

Introduction

The formation of ice lenses and the water migration during freezing of frost susceptible, fine-grained soils is a dynamic and complex process. Horizontal ice lenses and vertical ice veins form at different spacing, intervals, and growth rates as the freezing front penetrates into the ground forming a three dimensional ice lens pattern. This pattern and the growth rates of the ice lenses strongly depend on the freezing boundary conditions, such as temperature gradient, cooling rate, or vertical pressures, and the characteristics of the soil, i.e. the grain size distribution, hydraulic conductivity, water availability, and pore water salinity (Konrad & Morgenstern 1982, Konrad 1994, Miller 1973, Penner 1972).

The formation of ice lenses is possible with the presence and migration of unfrozen water at temperatures below its freezing point (Konrad and Morgenstern 1980). It is believed that migration of the free water is induced by a temperature gradient within the soil that induces suction. The suction then drives the movement of free water to the growing ice lens. The flow of water towards the warmest ice lens is assisted by the formation of tension cracks, which increase the vertical hydraulic conductivity of the soil (Chamberlain & Gow 1979).

Freezing tests conducted at the University of Alberta (Xia 2006) have shown that ice lens growth is not a one-dimensional process. Horizontal ice lenses as well as vertical ice veins form as the soil freezes. The vertical ice veins develop a hexagonal crack pattern similar to that observed in drying soils (Arenson et al. in press).

The reticulate ice structure, also observed under natural freezing conditions (Mackay 1974), during freezing deforms the soil horizontally and vertically. When the final ice lens starts to form, part of the soil below the final ice lens consolidates, and part of the soil above the final ice lens heaves. Arenson et al. (2007) measured the vertical deformations in freezing soil and were able to explain the freezing process using these deformation results.

This work was continued, and this paper focuses on the formation of the vertical ice veins and the horizontal soil deformations. Results from the time-lapse photography presented by Xia et al. (2005) are re-analyzed using particle image velocimetery (PIV) to develop a better understanding of the formation and growth of ice structures.

Laboratory Tests

One-dimensional open system (access to water) step-freezing tests were carried out on Devon silt under different boundary conditions. The Devon silt has a liquid limit of 32%, plastic limit of 20%, and specific gravity of 2.65. The samples were frozen from the top downward. Two temperature baths control the temperature conditions at the top and the bottom of the sample to establish one dimensional

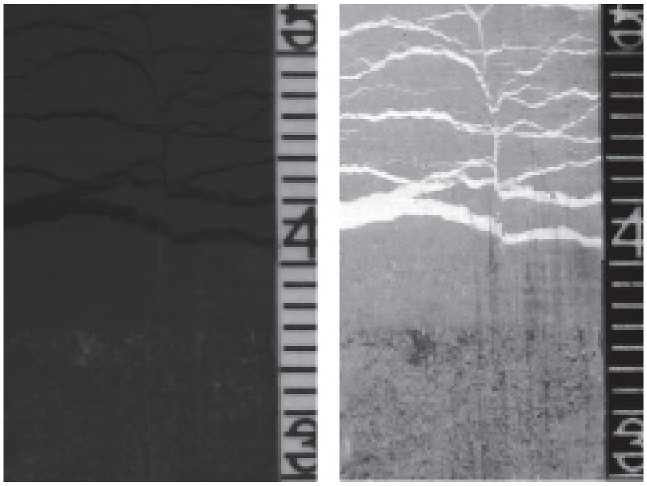

Figure 1. Original picture (left), and visible ice lens structure (right).

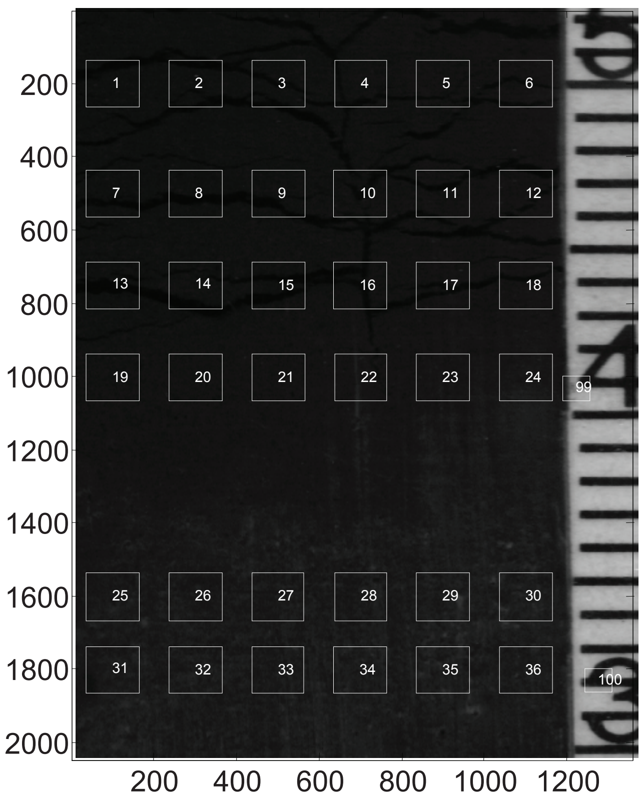

Figure 2. Initial patch locations; the scale is in pixels (1 pixel ~10 μm).

vertical freezing from the top downward.

A fluorescent tracer ($C_{20}H_{12}O_5$), which appears green in unfrozen water but colorless in ice under ultra violet light (Arenson & Sego 2006), was used to determine the frozen and unfrozen zone of the sample during freezing.

Time-lapse photography provided digital photo records to visually observe and document the freezing process. Details of the time-lapse photography technique and of the laboratory freezing tests used herein are presented in Xia et al. (2005) and Xia (2006).

[3] Vertical pressures during freezing

Image Analysis using GeoPIV

The digital images were analyzed using GeoPIV software, a MatLab module which implements particle image velocimetery (PIV) in a manner suited to geotechnical testing. This code has been programmed and successfully used for geotechnical laboratory testing to measure deformations in soils (White et al. 2003). It has also been used to determine the deformations in freezing soils (Arenson et al. 2007).

Figure 1 shows the original image and the corresponding ice lens structure for one of the images.

GeoPIV was used to measure the soil deformation. Geo PIV uses image texture to follow patches over a time series of pictures. A number of patches were defined on the sample and their movement was followed over time (Fig. 2).

Test Results and Image Analysis Results

Three tests from Xia et al. (2005) were analyzed in this paper. These tests were chosen because of their well defined vertical ice veins. The freezing test conditions are shown in Table 1. All the samples were initially consolidated at 100 kPa vertical pressure.

Ice Lens Growth and Deformation

The reticulate ice structures and cross sections of the frozen samples showing the hexagonal ice vein pattern are presented in Arenson et al. (in press). Figures 3 through 10 show various deformation results.

Vertical deformations

In the plots for vertical deformations (Figs. 3, 7) positive values indicate heave and negative values indicate consolidation.

It can be seen from Figure 3 (Test #1) that heaving starts at about 42 hours after the start of the test. By the time heaving has started the consolidation process is nearly complete. This means that heaving and consolidation are not occurring in parallel. Heaving starts almost after consolidation is complete. The heave rate and the consolidation rate are constant.

Figure 3 also indicates that P10 is undergoing heaving, and P22, P24, and P25 are consolidating. Hence, row 2 (containing patches P7–P12) is heaving, and row 4 (containing patches P19–P24) is consolidating. The final ice lens for this test is located between row 2 and row 4. This

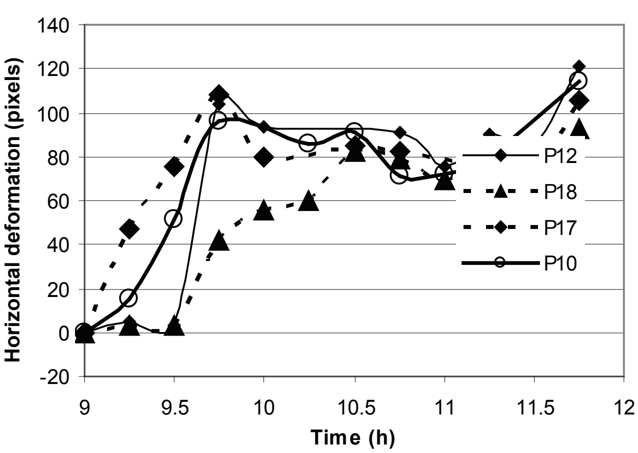

Figure 7. Vertical deformations while the final ice lenses are being formed for Test #8. P3, P4 and P5 are located above the final ice lens. P14 and P17 are located below the final ice lens.

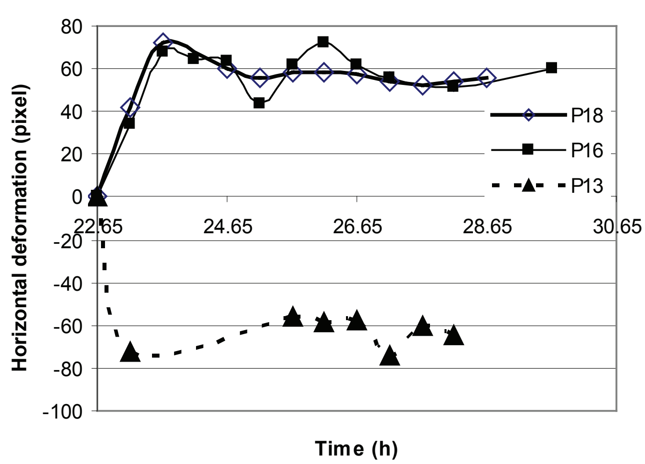

Figure 8. Horizontal deformations while a final vertical ice vein is being formed for Test #8. P13 is located to the left of the vertical ice vein. P16 and P18 are to the right of the vertical ice vein.

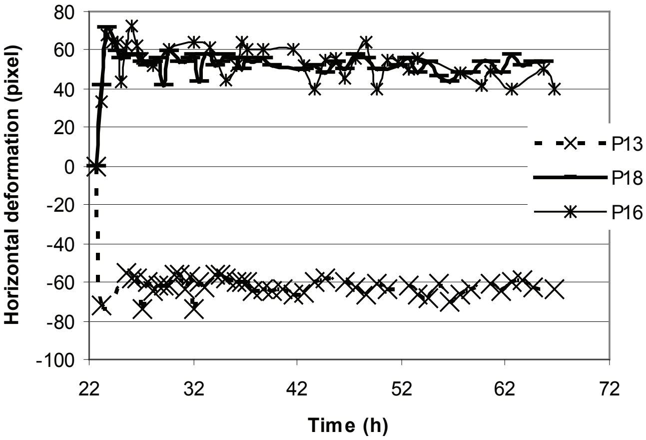

Figure 9. Horizontal deformations while a final horizontal ice lens is being formed for Test #8. P13 is located to the left of the vertical ice vein. P16 and P18 are to the right of the vertical ice vein.

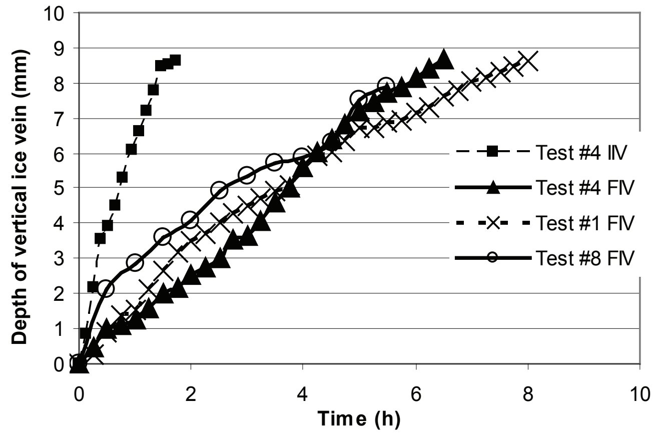

Figure 10. Rate of growth of the vertical ice veins (FIV=Final Ice Vein, IIV=Intermediate Ice Vein).

explains that water is being drawn from the region below the final ice lens. This water is then used to form the final ice lens. As the final ice lens forms, the regions above it start to heave, as observed by the movement of P10. Similar trends have also been observed by tracing other patches in the same test.

In Figure 7, all the patches are consolidating during the first 42 hours. After 42 hours, patches P3 and P4 start heaving, and patches P14 and P17 do not deform anymore. The final ice lens for this test started forming after about 42 hours. This indicates that the development of the final ice lens, hence frost heave, starts after the consolidation is complete. The final ice lens for this test is located between row 2 (containing patches P7–P12) and row 3 (containing patches P13–P18)

Figures 3 and 7 also indicate that the rate of heaving is smaller than the rate of consolidation. It can be concluded that the rate of ice formation is lower than the rate of water extraction from the soils.

Horizontal deformations

In Figure 3, it can be seen that heaving starts around 42 hours after the start of the test. This implies that the final horizontal ice lens starts to form after 42 hours. In Figure 4, it can be noted that the horizontal strains remain constant while the final ice lens is being formed. The same observation can be made in Figures 5, 6, and 8. This implies that the horizontal strains are due to the formation of the tension cracks and not due to the formation of the final horizontal ice lenses. The horizontal strains could therefore be assumed to originate from the formation of the vertical tension cracks, which are a result of the suction created by the temperature gradient. According to the authors, the mechanism of the formation of the vertical ice veins can be described as follows: First, suction is created in the frozen fringe, and tension cracks form; these tension cracks are then filled with water being removed from the soil, and finally, part of the water in the tension cracks freezes to form the vertical ice veins and part of it moves up to form the horizontal ice lenses behind the vertical ice veins. The formation of the tension cracks facilitates the flow of water by increasing the hydraulic conductivity of the soil. It is observed that tension cracks are formed prior to the formation of horizontal ice lenses (Arenson et al. in press).

While the soils are straining horizontally, water is being drawn to form the vertical ice veins and the horizontal ice lenses above their crack tip. Mackay (1974) states, “The vertical and horizontal ice veins are believed to have grown in shrinkage cracks with much of the water being derived from the adjoining clay.”

In most of the tests, the magnitude of the horizontal displacement is between 60 and 80 pixels (approximately 0.6–0.8 mmm). These could indicate that the thickness of the vertical tension cracks formed is almost constant. It can be observed from the digital images that the thickness of the vertical ice veins is the same for almost all the tests.

From Figures 8 and 9, it can be observed that the movements of P13 are in the opposite direction to that of P16 and P18. This is because the patches are located on different sides of the vertical ice vein. P13 is located to the left of the vertical ice vein, and P16 and P18 are located to the right of the vertical ice vein. Hence, their corresponding horizontal displacement is in a different direction but it displaces the same amount, indicating the opening of the vertical crack and the formation of the ice vein.

Rate of growth of vertical ice veins

Tension cracks always formed before the horizontal ice lenses. These tension cracks, which facilitate the flow of unfrozen water, are then filled partly by vertical ice veins.

Figure 10 shows the rate of growth of the vertical ice veins. The final ice veins (FIV) are defined as the vertical ice veins that form immediately before the start of the formation of the final horizontal ice lens. The intermediate ice veins are the vertical ice veins that form before the FIV. The rate of growth of the final vertical ice veins ranges from 1.22 mm/h to 1.57 mm/h. For Test #4, the rate of growth of the intermediate ice vein is 5.78 mm/h. Hence, the rate of growth

Table 2. Depth and growth rate of vertical ice veins.

Test #		Height of vertical ice vein (mm)	Growth rate (mm/h)
1	FIV	8.60	1.22
4	FIV	8.67	1.37
	IIV	8.60	5.78
8	FIV	7.91	1.57

of the IIV is higher than the rate of growth of the FIV.

The height of the vertical ice veins for the tests under consideration is about the same for all tests.

Conclusions

Particle image velocimetry (PIV) was used to measure soil deformations. Patches with a distinct characteristic were followed as the ice lenses formed and grew. The deformations measured were used to explain the freezing process and the resulting ice being formed.

The heaving process and the consolidation process were observed to take place at different times. Heaving followed immediately after consolidation was complete.

The horizontal strains were observed to be a result of the formation of the vertical tension cracks as the freezing front advanced.

The suction produced as a result of the temperature gradient caused tension cracks in the soil. The tension cracks, which increase the vertical permeability of the soil, were then filled with water. A channel formed where water can migrate from the unfrozen zone to the warmest ice lens. Part of the water moved up enhancing the development of a horizontal ice lens above the crack, and part of it froze inside the cracks, leading to the formation of the vertical ice veins.

The vertical tension cracks always formed before the horizontal ice lenses formed. Thus, the formation of the tension cracks, and hence the tensile strength of the soils, play a very important role in the freezing process.

Acknowledgments

The authors would like to thank Dr. Andy Take from Queens University for his support with the GeoPIV analysis. Tezera Firew Azmatch appreciated the funding through the NSERC Discovery Grant held by Dr. Sego.

Evidence of Permafrost Formation Two Million Years Ago in Central Alaska

James E. Beget, Paul Layer, David Stone, Jeffrey Benowitz, Jason Addison
Department of Geology and Geophysics, University of Alaska Fairbanks, Fairbanks, AK, USA

Abstract

Ice wedge casts and thermokarst deposits near the base of loess cliffs at Gold Hill record a previously unrecognized cycle of transient climate cooling and permafrost formation followed by an interval of climate warming and permafrost degradation. The ice wedge casts and thermokarst features occur below the PA tephra (ca. 2.02 myr) and begin above loess recording the Reunion paleomagnetic excursion (ca. 2.14 myr). The dates indicate colder conditions and permafrost formation in central Alaska 2.14–2.02 million years ago and can be correlated with marine isotope stage 77, a time of significant global glaciation and cooling. Warmer conditions during marine isotope stage 76 thawed the permafrost and generated the ice wedge casts and thermokarst sediments preserved at Gold Hill today. Climate and permafrost in Alaska were responding rapidly to global climate forcing by two million years ago.

Keywords: Alaska; climate change; geochronology; loess, permafrost; Quaternary.

Introduction

Loess deposits are common across central Alaska, especially in low-lying areas near the Tanana and Yukon and other glacier-fed rivers. Large areas of ice-rich frozen ground in valley bottoms in central Alaska have formed in loess and reworked eolian silts. River erosion or human disturbance of loess at building, mining, and other construction sites sometimes reveal spectacular views of ice wedges, ice lenses, and other varieties of permafrost.

Pewe (1951) first recognized that the silts that blanket hillslopes and form thick deposits in valley bottoms near Fairbanks and other areas were eolian in origin, and suggested that the ice wedges and other periglacial features found in the loess were produced during the last ice age.

Large areas of valley-filling loess deposits were washed away and destroyed by hydraulic excavation and dredging during 20th century industrial scale gold mining operations near Fairbanks, Ester, Chicken, and other mining areas in central Alaska. When the mining operations stopped, cliffs of loess and other sediments 10–50 m thick were left in some areas. As a result of the gold mining, numerous bones and occasional frozen carcasses of bison, mammoths, and other extinct Pleistocene megafauna were collected from the loess and the alluvial gravels beneath the loess (Guthrie 1990).

The Troy L. Pewe Climatic Change Permafrost Reserve is located along the north side of the Parks Highway beginning about 3 km southwest of the University of Alaska Fairbanks campus. The site preserves the eastern part of an almost continuous vertical bluff of loess almost 5 km long produced by hydraulic mining in the Fairbanks area. The highest cliffs and the oldest deposits of loess occur at the eastern end of the Gold Hill exposure. The original surface of the loess sloped gently downwards to the south, and small "islands" of the original loess valley fill left by the mining operations are preserved on the south side of the Parks Highway.

Pewe (1975a, b) divided the loess at Gold Hill into four main stratigraphic units. A buried horizon containing logs and branches found near the middle of some loess sections was named the Eva Creek Forest Bed, while the upper loess

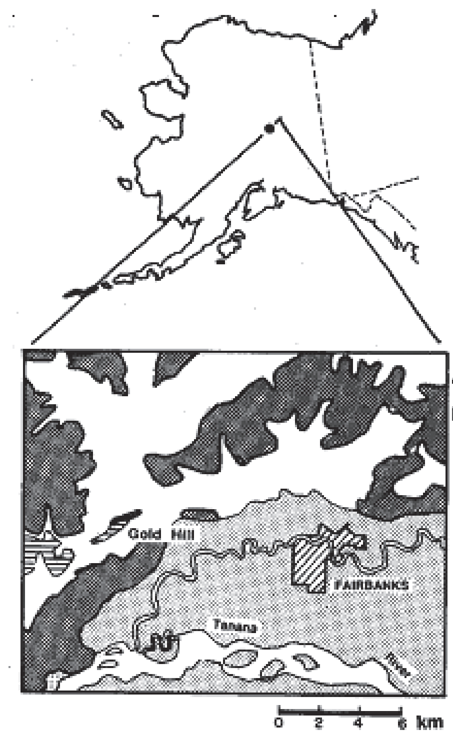

Figure 1. Location of the study site at Gold Hill and simplified Quaternary geology of the Fairbanks area. Light stiple = alluvium, dark stiple = pre-Quaternary bedrock, white = loess deposits, horizontally lined = gravel deposits exposed by mining. Figure modified from Westgate et al. (1990).

was assigned to the Goldstream Formation and the lower loess to the Gold Hill Formation. A basal forest bed occurred in a few sites and was named the Dawson Cut Forest Bed (Pewe 1975b). Pewe also recognized that numerous tephras are preserved in the loess. The base of the entire 30-m-thick loess section was originally estimated to be "Illinoian" in age, i.e., less than 200,000 years old (Pewe 1975a, Pewe & Reger 1989).

The first indication that Alaskan loess deposits might be much older came from the discovery that the loess

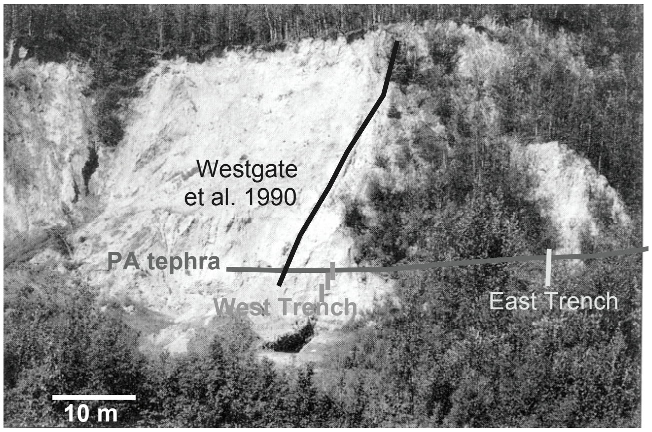

Figure 2. Location of the PA tephra and trenches excavated for stratigraphic and paleomagnetic studies at Gold Hill.

contained numerous paleosols, in addition to the Eva Creek and Bonanza Creek Forest Beds (Beget 1988, 1991). The sequences of multiple paleosols and interstratified loess deposits found at Gold Hill and other sites were interpreted as glacial-interglacial cycles, requiring an age for the loess significantly older than originally inferred by Pewe. These interpretations were supported by geophysical studies that demonstrated that loess deposited in glacial and interglacial periods had different magnetic properties, and that changes in environmental magnetic signals recorded in the loess could be used to produce proxy climate records through loess sections in Alaska that correlated with Milankovitch models of insolation changes and marine isotope records (Beget and Hawkins 1989, Beget et al. 1990, Beget 1996).

Westgate et al. (1990) used tephrochronology and paleomagnetic stratigraphy to determine that the PA tephra found at ca. 21 m depth at Gold Hill was deposited ca. 1.9 million years ago, and loess at the base of the Gold Hill section was as much as 3.1 million years old. Westgate and his co-workers took samples at 10 cm intervals, and found the upper loess was normally magnetized and correlative with the Brunhes paleomagnetic epoch. The lower part of the loess recorded mainly reversed magnetic fields, but in the overall reversely polarized section, there were magnetic reversals back to normal polarity at about 2.5 meters, 3.5 meters, 5.5 meters, and 8.2 meters below the PA tephra layer. The initial transition from normal to the reversely magnetized loess was correlated with the Brunhes-Matuyama boundary, and the two normal epochs below the PA tephra were assigned to the two Reunion subchrons (also known as the Huckleberry Ridge and Reunion events) in the Matuyama Paleomagnetic Chron. More recent work indicates the age of the PA tephra is 2.02 +/- 0.14 Ma (Westgate et al. 2003).

Here we report on the discovery of ice wedge casts, thermokarst features, and interstratified loess and paleosol sequences found below the PA tephra near the base of the Gold Hill section. We also present new paleomagnetic dates for the Gold Hill loess. Our data show that Alaskan loess deposits are surprisingly good recorders of short-lived geologic events, including transient shifts in climate and fluctuations in the earth's magnetic field. Paleoclimatic records from loess deposits are an important source of information about events in terrestrial areas of Alaska.

Field and Laboratory Methods

The PA tephra layer is located 11 m from the bottom of the loess section, and forms a distinctive marker bed that can be traced for more than 30 m across the lower part of the Gold Hill loess. The tephra bed is as much as 5 cm thick, although in most places it is broken into pods or two or more thinner layers. It was used as a datum from which local stratigraphic field measurements were taken at various points along the section.

Trenching and sampling were done to generate two new stratigraphic sequences: one about 5 m east of the long section studied by Westgate et al. (1990) and the second about 20 m to the east (Fig. 2). Both trenches were excavated to a depth of about 4 m and studied with the help of enthusiastic students (Naibert et al. 2005). The newly created loess exposures were then photographed and stratigraphically logged. At both sites, oriented samples were collected beginning at the PA tephra and continuing down to the bottom of the trenches. During sampling, a series of platforms were cut along the excavated exposure, and oriented plastic cube samples were taken at 5 cm intervals from undisturbed loess exposed in the face of the trenches for paleomagnetic analyses. Plastic vials of loose material were also collected every 2 cm for magnetic susceptibility measurements.

The oriented cubes were taken to the Paleomagnetic Laboratory at the University of Alaska Fairbanks, and successive alternating field demagnetization (11 steps) up to 100mT was applied to strip away the modern magnetic overprint and to determine the original polarity of the magnetic field at the time the loess was deposited. After some primary data analysis to locate points of interest in the section, the loess was sampled again with plastic cubes at 2 cm intervals from depths of 0.9 to 1.1 m, and from 2.9 to 3.1 m, for a more detailed examination of changes in magnetic inclination using alternating field demagnetization.

Stratigraphy and Structure

During the initial trenching and logging, it became apparent that loess just below the PA tephra had been locally involved in a series of post-depositional collapses. The PA tephra was deposited on the ground surface ca. 2 million years ago, and thus the topography and slumps that occurred near that time at Gold Hill can be reconstructed from the taphonomy of the PA tepha deposits. We note that a veneer of loose colluvium from 0.1–0.5 m thick is present on the surface at Gold Hill, but our excavations cut completely through the colluvium to expose the much more indurate early Quaternary loess. Our trenching sites were chosen specifically to determine the relationship between the deposits and stratigraphy in the trenches and the PA tephra.

Our excavations reveal the PA tephra was incorporated in local depressions and slumps in 4 distinct areas along the

30-m-long exposure. At the eastern pit, the tephra and the intercalated loess, which elsewhere are preserved in sub-horizontal beds, abruptly began to drop in elevation on each side of a 2-m-wide V-shaped depression, indicating the collapse had formed after the tephra was deposited, and that tephra and loess at the margin of the V-shaped depression was progressively slumping into the depression. Further excavations found pellets of the tephra and blocks of loess in a compact silt matrix within the depression. The V-shaped depression was excavated to a depth of 2 m where it became narrow and terminated. The morphology of the V-shaped depression, and the deformation of the sediment at the margins of the pit, are identical to modern ice wedge casts in the Fairbanks area, and the feature is interpreted as a 2 myr old ice-wedge cast.

At the western pit, a well-developed organic-rich paleosol occurs about 20–60 m thick above the PA tephra. This paleosol can be traced along much of the exposure above the PA tephra. The excavations in the western trench found bedded organic-rich sediment and loess and pods of PA tephra that had apparently collapsed into a broad depression. The organic material occurs in beds at angles up to 70°, together with loess and small pods of the PA tephra (Fig. 3). The depression is interpreted as having formed as part of a thermokarst zone.

At the far eastern of the PA exposure, a loess cliff exposed a 3-m-thick diamicton that could be traced 5 m across the section. The diamicton contained rounded to elongate silt and multi-colored paleosol clasts ranging from 0.5–10 cm in diameter disseminated in a dense, fine-grained matrix. The eastern margin of this deposit cuts across undisturbed loess below the PA tephra, and itself locally underlies the PA tephra and incorporates pods of the tephra. We interpret the diamicton as having formed by progressive collapse of wet, thawed pellets and blocks of sediment into a large thermokarst pit. Similar large pits are forming today at sites where frozen loess is thawing near Fairbanks (Shur et al. 2000). Bits of thawed ground can frequently be heard falling into thermokarst pits, and we suggest the abundant rounded clasts in this deposit accumulated in similar fashion in an ancient thermokarst collapse 2.0 million years ago.

The presence of ice wedge casts and thermokarst features below the PA tephra indicates climate in the Fairbanks cooled sufficiently prior to the deposition of the PA tephra to allow the formation of permafrost. The climate must have subsequently warmed and caused the permafrost to degrade and the thermokarst features to form. The warm period is tentatively correlated with the well-developed paleosol just above the PA tephra, as the presence of the strong paleosol records an interglacial period that occurred just after the PA tephra fall.

Paleomagnetic Record from the Trenches

New paleomagnetic data help to constrain the age of the periglacial features and the climate flucations recorded at the base of Gold Hill. The paleomagnetic data from our two new trenches predominantly display reversed magnetization, as expected in the Matuyama reversed polarity chron. Our data are generally consistent with the previously published age of the PA tephra and the paleomagnetic data from Westgate et al. (1990), and confirms that the loess below the PA tephra is indeed older than 2 million years. However, a comparison of the paleomagnetic data from our two new trenches and the trench of Westgate and his co-workers, reveals some differences. Our two new sections both contain a number of normally magnetized polarity samples that can be interpreted as recording a brief magnetic reversal within the upper part of the Matuyama chron that was not recognized in the trench studied by Westgate and his co-workers. This introduces the possibility that the creation and thawing of ice wedges and other kinds of permafrost may have disrupted the original loess deposits and affected the lateral continuity and preservation of the paleomagnetic record at Gold Hill.

Figure 3. Organic-rich silts and blocks of gleyed and unaltered loess filling a collapsed zone stratigraphically below the PA tephra in the western trench.

Our eastern trench contains a zone of magnetic polarity samples at 0.7 m below the PA tephra. The reversed signal occurs in five successive samples, leaving little doubt that it is a real reversal. Our western trench also produced evidence of this episode of normal magnetization, although it occurred in only one sample. Westgate et al. (1990) also found one point near this depth below the PA that appeared to record a transition to normal polarity, but they decided not to assign a reversal to this normal horizon. Based on the excellent signal in our eastern trench and the appearance of the same event in the two other trenches, we believe this is real polarity event. Because this is the first reversal below the PA tephra, we interpret this event as the Reunion event, dated to 2.14 million years ago.

The variability in the character of the magnetic signal between our two trenches and the Westgate trench is consistent with our recognition of ice wedge casts and thermokarst features in the loess at this depth in the loess. Since the loess below the PA tephra was locally disturbed by a cycle of formation and destruction of ground ice, the sedimentation rate and mode of deposition should vary from place to place across the exposure, just as we observe. Similarly, the low inclinations that both we and Westgate et al. (1990) observed in this area, likely reflect deformation of the sediment during the intrusion of ice wedges and slumping and relaxation of the sediment as the ground ice thawed. Indeed, when the sample locations of the paleomagnetic cubes are compared to the stratigraphic interpretations of the two trenches, it is clear the paleomagnetic samples from the eastern trench, where the Reunion event is best recorded, were taken from loess adjacent to an ice wedge cast, while paleomagnetic sampling in the western trench was inadvertently done partly excavated through a thermokarst deposit.

The short duration of the reversal ca. 0.7 m below the PA tephra in the Gold Hill loess is also consistent with our interpretation that this marks the Reunion event, as the Reunion event is consistently characterized as having been brief and transient where observed elsewhere on earth. The apparent brevity of the reversal and the lateral paleomagnetic inhomogeneity we find across the section is, therefore, supportive of our conclusion that permafrost, including ice wedges, formed and then thawed ca. 2.05 million years ago, shortly after the Reunion Chron.

Environmental Reconstruction

We collected samples for magnetic susceptibility measurements from both the eastern and western trenches. The susceptibility values averaged about 10 SI units, but systematic variations in magnetic susceptibility occurred through the sections, with massive unaltered loess having higher susceptibilities than loess from the paleosol zones. The pattern of environmental magnetism 2 million years ago closely resembles that from middle and late Quaternary loess sequences, suggesting that the susceptibility signal records both primary variations in wind strength and subsequent pedogenic alteration of the magnetic minerals in the loess (Beget 2001).

We used the ages of the PA tephra and the Reunion chron to control a linear interpolation model to estimate ages of sediments between these two well-dated points in our trenches at Gold Hill, and to evaluate the paleoclimatic inferences from the environmental magnetic record and the evidence of permafrost formation and disappearance.

The PA tephra occurs in a high susceptibility zone, and the age of the PA correlates well with a glacial interval recorded by marine isotope stage MIS 74 in global marine records (Shackelton et al. 1995). The paleosol just above the PA tephra has low susceptibility and is correlated with an interglacial episode recoded by MIS 73. The Reunion chron occurs during the MIS82-81 transition in the marine record, which is followed by a long and sustained global glacial event during MIS78 to MIS 76.

The top of the ice wedge casts and thermokarst features occurs between the PA tephra and the Reunion paleomagnetic chron, and the formation of ice wedges recorded at Gold Hill is therefore correlated with the unusually sustained glacial interval recorded by MIS 78–76. This glacial event produced a significant interval of cold climate 2.1 million years ago in central Alaska. The marine isotopic data suggests that

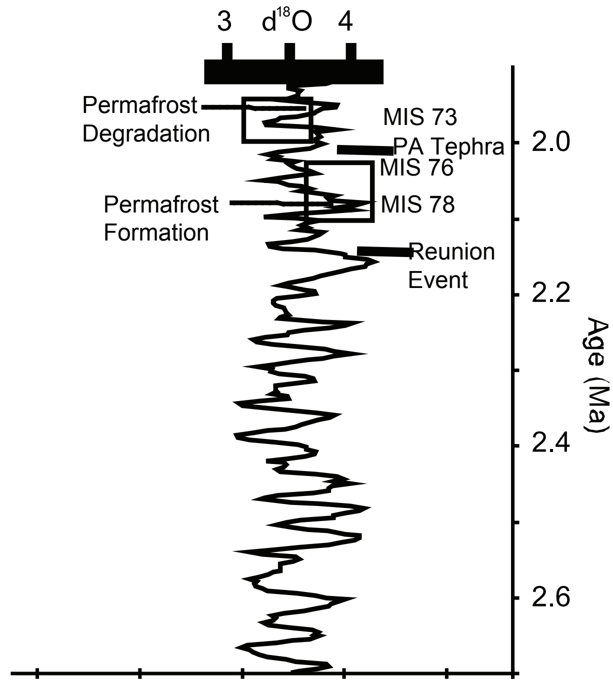

Figure 4. Standardized global marine isotopic record from Shakleton et al. (1995) covering the time period of the recorded by loess near the PA tephra at Gold Hill. Ground ice formed during a cold interval soon after the Reunion Chron (2.14 million years) and was destroyed during a subsequent interglacial interval. We correlate the cold interval with MIS 76–78 and the warm interval with MIS 73.

the MIS 78–76 glaciation was one of the longest and most intense until Middle Pleistocene time, resulting in as much as 70 m of sea level drop due to ice sheet growth on land (Pillans et al. 1998).

The fact that the PA tephra is locally incorporated in the ice wedge casts and thermokarst deposits, indicates warming and destruction of the ice wedges occurred after the PA tephra was deposited. We suggest this interval is correlative with MIS 73, a global warm interval recorded in marine records at about 1.9 million years ago. The correlations suggested by our discovery of ice wedge casts and thermokarst features, and our new age-dating model at Gold Hill, link evidence of rapid climate change in Alaska ca. 2 million years ago with the environmental magnetic proxy record of climate change from the loess, the paleosol evidence, the sedimentological record of permafrost formation and degradation, and the standard global climate record from isotopic studies of marine cores. We believe the excellent temporal correlations support the validity of our approach and the reliability of our conclusions.

Summary and Conclusions

We carried out stratigraphic, sedimentologic, and paleomagnetic studies of sediments in the lower part of the Gold Hill loess deposit, 3 km southwest of the University of Alaska Fairbanks. We report here on work done in two new trenches that were hand excavated by students participating in an NSF summer institute and by undergraduate and graduate students enrolled in the Geology and Geophysics program at the University of Alaska (Naibert et al. 2005).

The exposures in the two new trenches were photographed and stratigraphically logged. Oriented cubes and cylindrical cores were collected at regular intervals through the two new loess sections, starting from the prominent PA Tephra and extending down ca. 4 m.

The PA tephra, recently redated at 2.02 +/- 0.14 myr (Westgate et al. 2003), can be traced laterally across the exposure for 30 m, but the trenching revealed that the tephra layer was locally displaced by collapses, and was incorporated in deposits that had collected in small depressions stratigraphically below the level of the primary ash deposit. Excavation through the collapse deposits indicate that some of the collapse features are V-shaped and are interpreted as ice wedge casts, while others are broader, with irregular boundaries, and are interpreted as the products of thermokarst collapse pits.

The remnant magnetization recorded in the sets of oriented cubes and cylindrical cores taken from the two loess sections was measured at the University of Alaska-Fairbanks using a cryogenic magnetometer. Both alternating field and thermal demagnetization techniques were employed. Our data show that the section records predominantly reversed polarity, consistent with an age assignment within the Matuyama Reversed Chron. We identified a thin horizon of normal polarity at 0.7 m below the PA tephra. This event is well-preserved in our easternmost trench, but is recorded by only one point in our western trench. We correlate this event with the Reunion Chron dated to 2.14 million years ago. A transient normal polarity event at about the same stratigraphic position appears to be present in the paleomagnetic record of Westgate et al. (1990), although they did not assign it to any chron.

The variations between the paleomagnetic record of the Reunion event in these three trenches, excavated about 30 m apart, demonstrates that loess stratigraphy in this part of the Gold Hill section is complex and disturbed. This is consistent with the recognition of ice wedge casts and thermokarst features below the PA tephra. The strongest and thickest expression of the Reunion event occurs in samples taken down through undisturbed loess adjacent to an ice wedge cast in our eastern trench, while samples from our western trench intersect a thermokarst pit and show a weaker signal. More evidence of disturbance in this part of the loess section comes from low magnetic inclinations that characterize samples from this part of the section. The low inclinations are interpreted as a record of post-depositional deformation of the sediment associated with the growth of ice wedges and subsequent slumping and relaxation of the sediment as the ground ice thawed.

We also found systematic variations between magnetic susceptibility values from unaltered loess and those measured from loessic paleosols similar to those found in late Quaternary loess (Beget and Hawkins 1988; Beget 2001). The Reunion Chron and the PA tephra were used to develop a linear sedimentation rate model and to produce age estimates for the environmental magnetic record and unaltered loess interpreted as a glacial deposit and paleosols interpreted as interglacial deposits.

The stratigraphy and geochronology indicate ice wedges formed in central Alaska ca. 2.1 million years ago. The marine oxygen isotope record records a major, global glacial event at the same time, during MIS 78–76 (Shackleton et al. 1995, Pillans et al. 1998), suggesting the permafrost formed in response to global forcing. The permafrost degraded ca. 1.95 million years ago, at the same time as MIS 73, a global period of mild, interglacial temperatures.

Our study indicates that Alaskan permafrost was forming and degrading in response to changing global climate forcing by 2.14 million years ago. Some prior studies have suggested that the onset of glacial conditions in the Arctic was slow and gradual. In contrast, our work on permafrost history at Gold Hill indicates that Arctic climates have been fluctuating at the same rates and at the same times as global climate changes since earliest Pleistocene times.

Abstract

A 3D seismic reflection survey acquired by industry over the Mallik area in 2002 is used to map heterogeneities in permafrost and to determine the extent of gas hydrate occurrences beneath it. Seismic amplitude anomalies associated with lakes and drainage systems are observed in the 3D seismic data. Beneath lakes, the seismic data show weaker amplitudes, locally compromising images of the geology within and below the permafrost. On Richards Island, many of the lakes are deeper than the thickness of winter ice and have taliks that penetrate permafrost. Amplitude effects on the seismic data arise from velocity and attenuation variations associated with frozen and unfrozen parts of the permafrost. A 3D travel-time tomography algorithm was used to produce a map of the permafrost velocity structure. The 3D velocity map clearly reveals a heterogeneous velocity distribution, primarily related to thermal variations within the permafrost.

Keywords: gas hydrates; Mallik; Richards Island; seismic data; talik; tomography.

Introduction

The Mackenzie Delta area is characterized by a remarkable variability in permafrost conditions. In the central Mackenzie Delta, permafrost may be less than 80 m thick whereas in northern Richards Island it may be more than 700 m thick (Judge et al. 1987). This variability in part reflects a complex Quaternary history of surface temperatures and geologic processes (Taylor et al. 1996). As elaborated in more detail by Wright et al. (2008), lakes which cover between 20% and 50% of the landscape of the Mackenzie Delta area have played an important role in conditioning ground temperatures. Positive mean annual temperatures beneath the lakes (and indeed river channels or the ocean), if imposed for a significant amount of time, can thaw the permafrost, creating a thermal talik (above 0°C). More common perhaps, warmer permafrost beneath lakes affects the proportion of liquid water versus ice within the sediment matrix. Both conditions can modify the physical properties of sediments, affecting the propagation of seismic waves. Sediments with ice in the pore space are stiffer and characterized by higher seismic velocities whereas unfrozen sediments have lower velocities (Zimmermann & King 1986). Here, we show some effects of deep taliks on a 3D seismic reflection dataset acquired near the Mallik area on Richards Island (Fig. 1). Beneath lakes, the seismic data show weaker amplitudes, which locally compromise images of the geology within and below the permafrost. Direct seismic arrivals are used to produce a 3D velocity map of the permafrost. This map reveals a heterogeneous distribution of velocities, mostly related to variations in ice bonding within the permafrost. The 3D seismic data are also used to image and characterize gas hydrate accumulations beneath the permafrost.

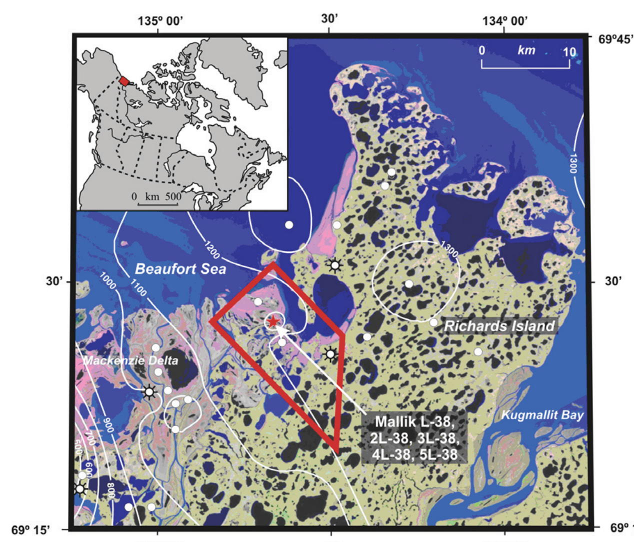

Figure 1. Location map showing the Mallik area in the Mackenzie Delta. The red polygon outlines the area covered by the 3D seismic survey used in this study. Small circles indicate well locations whereas larger circles with ticks show wells that intersected gas hydrate. Contours represent the base of the gas hydrate stability field.

Geological Setting

The 3D seismic survey used in this study is located in the western part of Richards Island in the Mackenzie River Delta on the coast of the Beaufort Sea (Fig. 1). The area straddles two physiographic regions identified by Rampton (1988), the Big Lake Delta Plain to the west which is influenced by active Mackenzie River deltaic deposition and older upland terrain referred to as the Tuktoyaktuk Coastlands. A shallow water embayment of the Beaufort Sea, referred to here as Mallik Bay, is also a dominant feature. Pleistocene sediments consisting mainly of glacial, marine, and fluvio-deltaic sediments are exposed at shallow depth beneath the Big Lake Delta plain and outcrop at the surface in the Tuktoyaktuk Coastlands. These deposits are underlain by older deformed deltaic Tertiary strata (Dixon 1995).

Interpretations of geophysical well logs from exploration wells in the area suggest that ice bonded permafrost beneath terrestrial areas is 600 to 650 m deep and that gas hydrates can occur to depths of 1150 m (Judge et al. 1987). Two major gas hydrate research well programs have been conducted at the Mallik site (Dallimore & Collett 2005) which is located at the apex of a regional anticline structure. Core studies and geophysical interpretations document that gas hydrate occurs in coarse-grained sandy sediments of the Mackenzie Bay and Kugmalit Tertiary sequences from 870 to 1100 m depth. The gas hydrate-bearing sediments are interbedded with silty sediments with little or no gas hydrate.

Approximately 50% of the surface area within the 3D seismic survey is affected by lakes, river channels, or the Mallik Bay. While no detailed bathymetric data are available, point soundings suggest water depths varying from less than 0.5 m to more than 6 m.

3D Seismic Data

The upper 2 s of a 3D seismic reflection dataset acquired during winter in 2002 has been made available to the Mallik 5L-38 science program through partnership with a joint venture of BP Canada Energy, Chevron Canada Resources, and Burlington Resources Canada. The 3D data were acquired with a combination of vibroseis and dynamite and covers approximately 130 km^2 that include four gas hydrate targeted wells and four industry wells drilled in the 1970s. The 3D acquisition geometry was designed to image conventional hydrocarbon accumulations located beneath permafrost and gas-hydrate zones (deeper than 1100 m). The initial data processing also focused on the imaging of the conventional gas-bearing structures, and the resulting 3D volume provides poor reflection images of the permafrost (above 600 m) and low fold in common-depth-point gathers in the gas-hydrate depth range (900–1100 m). For this study, we chose a dataset reprocessed to maintain the relative true-amplitude character of the data (Riedel et al. 2006).

Several areas of reduced seismic amplitude are observed in the true-amplitude 3D seismic dataset at depths exceeding 1 km (Fig. 2). Understanding these low-amplitude anomalies

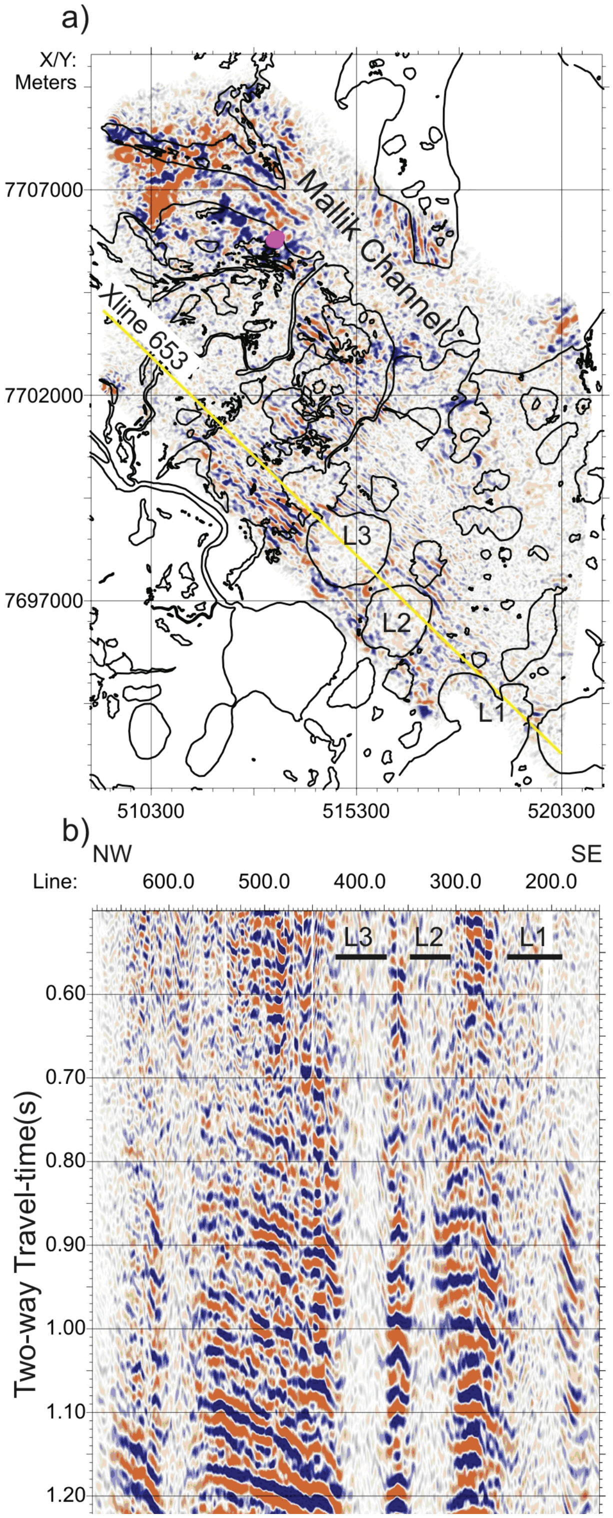

Figure 2. (a) Time slice from the true-amplitude 3D seismic data at 800 ms (approximately 1100 m). The purple dot shows the location of the Mallik wells. (b) Cross-line 653 showing reduction of amplitude beneath the lakes. The location of cross-line 653 is shown in (a) (yellow line). Colors represent seismic amplitudes (blue: negative amplitude; red: positive amplitude).

(also referred to as washout zones) is important for any gas-hydrate related interpretation. In the marine environment, wide-spread amplitude blanking has often been attributed to the presence of gas hydrate (Holbrook et al. 2001). At Mallik, the low seismic amplitude areas in the gas hydrate stability field (200 to 1100 m) may not indicate the presence of gas hydrates but instead likely result from variations of physical properties in permafrost, and more specifically to property changes associated with deep taliks.

A time slice from the 3D true-amplitude dataset, with an overlay of the hydrology, is shown in Figure 2. The time slice is located beneath the permafrost near the base of the gas hydrate stability field at 800 ms (approximately 1100 m depth). Areas of seismic blanking or reduced seismic amplitude are coincident with the location of large lakes. A seismic cross-section (Fig. 2b) shows that the reduced amplitudes beneath the lakes extend down to 1.3 seconds. Some reflections are also truncated underneath water bodies. This is particularly evident near the Mallik channel (Fig. 2a) and near lakes located in the southeast part of the time slice (L1, L2 and L3 on Figs. 2a, b). Some deeper water areas of Mallik Channel do show a response similar to that seen beneath the lakes (Fig. 2a). However, the river channels and many smaller lakes less than 300-400 m in diameter show no seismic amplitude reduction. Similar observations are made for shallow water areas located offshore.

The effect of ice bonding on seismic velocity is well documented. In water-saturated and unconsolidated sediments, velocity of P-waves varies significantly as a function of the fraction of pore water that is unfrozen (Zimmermann & King, 1986). Sediments with only ice in the pore space can have P-wave velocity as high as 4200 m/s whereas as sediments mostly filled with water have velocities near 1800 m/s. Other factors such as composition, density, porosity, and pressure also affect P-wave velocity of sediments. As reviewed by Wright et al. (2008) large lakes in the Richards Island area can have a significant talik beneath them. It is expected that sediments beneath those lakes will have a larger proportion of unfrozen water in the pore space and will be characterized by lower P-wave velocities. The unfrozen or partially unfrozen areas also attenuate seismic waves propagating through them more severely (the amplitude of waves in those areas is reduced more rapidly than within frozen permafrost) producing low amplitude areas in Figure 2.

Areas with lower velocity delay seismic waves propagating down to and up from deeper reflective geological structures. These delays, because they occur at shallow depths, must be taken into account during data processing to produce the most accurate images of deeper geological structures, and quantitative information about the velocity distribution of the permafrost is required to estimate proper static corrections. The velocity distribution can also provide information about the internal structure of the permafrost.

Velocity Structure of Permafrost

Direct P-wave travel-time tomography is used to produce a 3D velocity map of the permafrost. Tomographic inversion of first arrival travel-time data is a non-linear problem since both the velocity of the medium and the ray paths in the medium are unknown. The final solution is typically obtained by repeated applications of linearized inversion until model parameters (velocities) explain the observations (travel-times) within satisfactory criteria. More details about the tomography method can be found in Ramachandran et al. (2005).

The tomographic inversion of direct seismic arrivals resulted in a velocity model covering the area of the 3D survey and extending down to a depth of 500 m which is about 100 m above the base of permafrost. This model is divided into 50 m cubes. Approximately one million direct arrival travel-times were manually picked and used in the tomography. Figure 3 displays two depth slices from the reconstructed velocity model. The shallowest slice at 100 m shows a heterogeneous permafrost with P-wave velocities ranging from 1500 to 5000 m/s. As expected, lower velocities are found underneath lakes and drainage system and they likely correspond to areas of unfrozen permafrost. The deeper slice at 250 m is more homogeneous but still shows lower velocities beneath some lakes and the Mallik channel. At that depth, velocities beneath most lakes are slightly higher and may indicate the presence of a greater proportion of ice in the pore space of sediments, possibly related to a thermal gradient within some taliks. Some of the low-velocity areas beneath the lakes extend down to approximately 300 m (not shown) and have an inverted-cone shape (Fig. 4).

One way to assess the constraint on the velocity model is to count the number of rays passing through each cell. A large number of rays per cell is usually indicative of a well-constrained velocity. Figure 5 shows a depth slice at 100 m with the number of rays per cell. At this depth, all cells are cut by a large number of rays, except at the edge of the 3D velocity slice. At greater depths, the number of rays per cell is significantly lower. This is a result of the maximum source-receiver separation used during data acquisition. Larger source-receiver separations would be required to map velocity variations near the base of permafrost with travel-time tomography.

Gas Hydrates

Gas hydrate accumulations located onshore in Arctic permafrost regions are seen as a potential source of natural gas. Most known gas-hydrate occurrences in the Mackenzie Delta and Beaufort Sea areas were indirectly discovered or inferred from conventional hydrocarbon exploration programs. One of these occurrences, the Mallik gas hydrate field (Fig. 2), has received particular attention over the last 10 years. Two internationally-partnered research well programs have intersected three intervals of gas hydrates and have successfully extracted sub-permafrost core samples with significant amounts of gas hydrates (Dallimore & Collett

2005). The gas hydrate intervals are up to 40 m in thickness and have high gas hydrate saturation sometimes exceeding 80% of pore volume of unconsolidated sand with average porosities ranging from 25% to 40%. The gas hydrate intervals are located on the crest of the anticline between 900 m and 1100 m depths and do not exhibit large dips. Here, we refer to the three gas hydrate intervals as Zones A, B, and C (Dallimore & Collett 2005). Zone A is the shallowest gas hydrate interval whereas Zone C marks the base of the gas-hydrate occurrence at Mallik.

Sonic logging data acquired in two boreholes at Mallik show that P-wave velocity of sediments increases with concentration of gas hydrates (Guerin & Goldberg 2005).

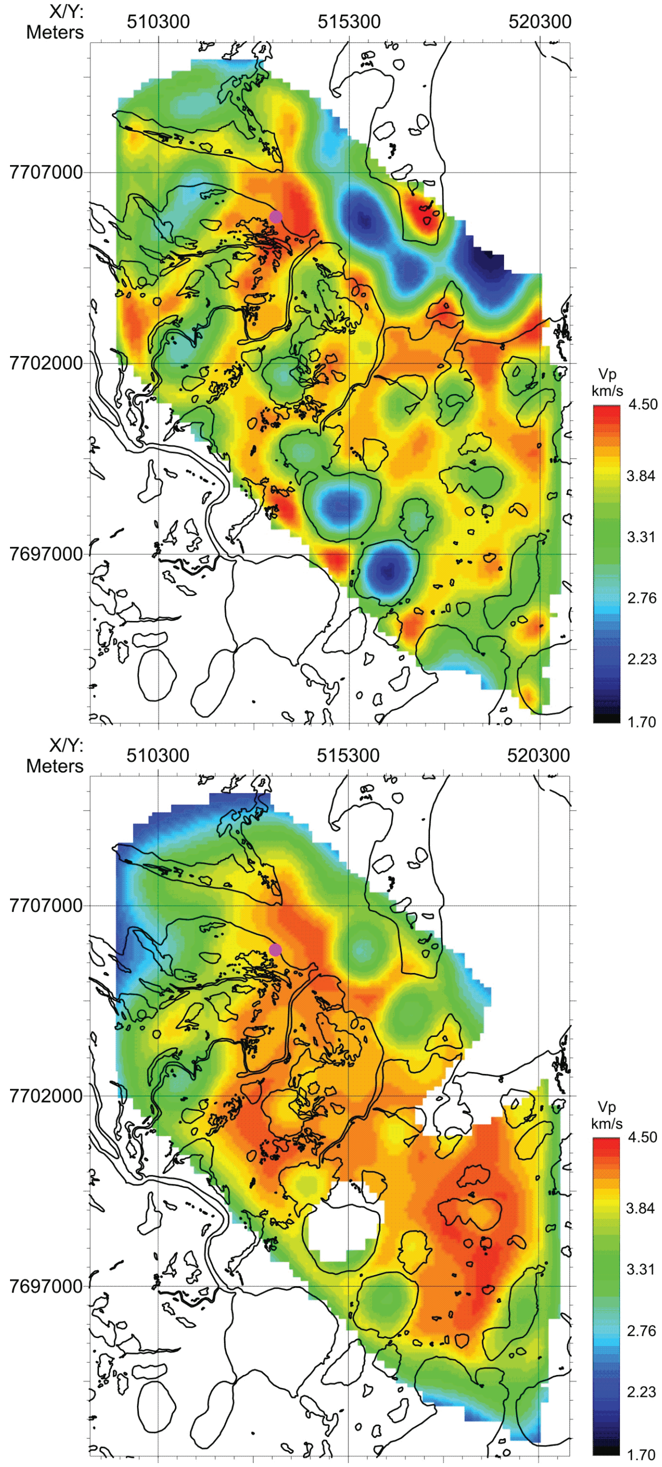

Figure 3. Depth slices through the 3D velocity model obtained from direct arrival travel-time tomography (top: depth slice at 100 m; bottom: depth slice at 200 m). Low-velocity areas are found beneath large lakes and deep water channels. The no-data areas on the deeper slice correspond to low-velocity zones not traversed by first-arrival rays which follow the fastest trajectory. Low-velocity zones will tend to be under-sampled as depth and source-receiver separation increase.

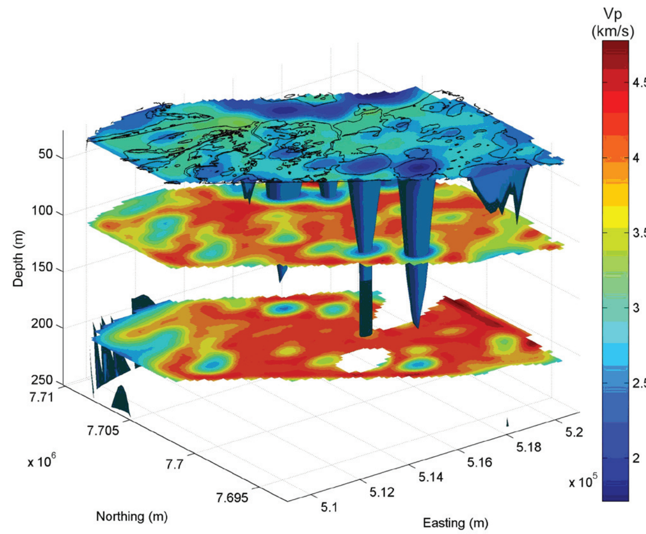

Figure 4. Plunge view to the NE showing three velocity slices (at 25 m, 100 m, and 200 m), natural drainage system and iso-surfaces set at 2.4 km/s. The iso-surfaces have an inverted-cone shape and are located beneath lakes and the Mallik water channel.

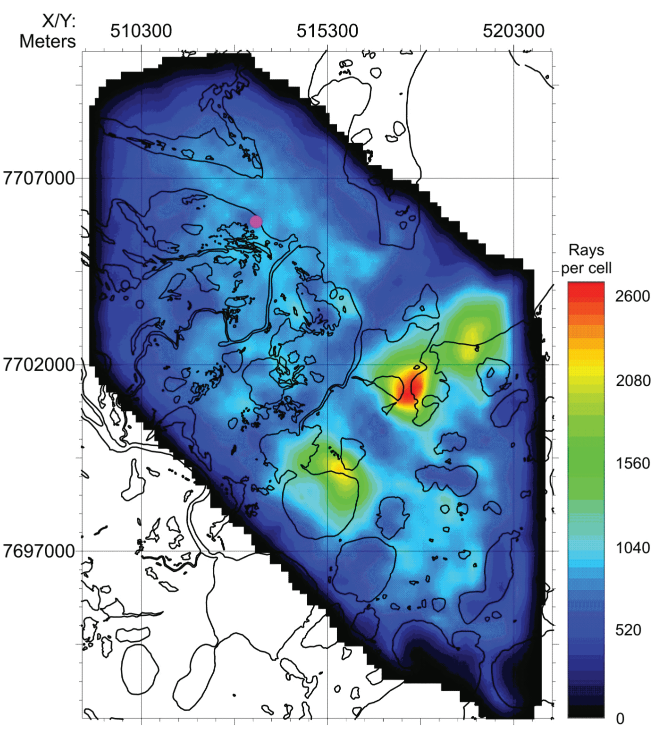

Figure 5. Depth slice at 100 m showing the number of rays per cell that constrained the velocity model shown in Figure 3. A large number of rays per cell is an indication of well-constrained velocity.

P-wave velocities range from 2400 m/s in sediments having no gas hydrates to 3200 m/s in strata with 80% pore occupancy by gas hydrate. This strong velocity contrast makes gas hydrates detectable with surface seismic reflection methods when they are found beneath the permafrost. They are difficult to detect when located within permafrost because of the limited or lack of velocity contrast with frozen sediments. On Mallik seismic records, the hydrate-bearing sediments are seen as bright reflections relative to a lower-amplitude surrounding background. Fortunately, there are no deep lakes close enough to the Mallik well site to distort seismic images.

While successfully used for determining in-situ properties of gas hydrates, boreholes alone cannot confirm lateral continuity of any of the three hydrate zones, which is required to provide reliable estimates of the resource in place. Here, we also used the 3D seismic data to assess the seismic characteristics of the zones to help define the lateral extent of the gas hydrates away from the wells. At the same time, we also wish to assess the influence of the local geology on the distribution of gas hydrates. Our seismic characterization approach relies strongly on well-log data in the gas hydrate intervals, seismic-to-well correlation, and acoustic impedance inversion. The seismic inversion generated an acoustic impedance (product of density and velocity) image of approximately 1.5 km^2 area around Mallik 5L-38 by matching a reflectivity model to the seismic data. We further extracted P-wave velocities from the impedances assuming no lateral variability in the density of the sediments. Overall the density is relatively constant throughout the entire gas hydrate interval and averages 2100 kg/m^3. We have attempted to convert P-wave velocity to gas hydrate concentration in pore-space by using the effective medium theory by Helgerud et al. (1999), in which gas hydrate supports the sediment matrix but does not cement sediment grains. In general, a very good correlation between the Mallik 5L-38 P-wave velocity logs and the inverted P-wave section is found for Zones B and C. Figure 6 shows maps of the inverted P-wave velocity for Zones B and C. Zone C reveals a complex pattern with large variation in P-wave velocity over distances less than a few hundred meters. This complex pattern could certainly be explained by lateral sediment heterogeneity and by spatial limitations of small-scale faults and other discontinuities. Zone C is more continuous and extends over a larger area than Zone B. P-wave velocities locally exceed 2900 m/s and correspond to sediments with high gas hydrate saturation (above 60%). These highly saturated sediments cover approximately 0.25 km^2. The area of highest gas hydrate concentrations for Zone B follows a N-S trend. Zone B is less continuous than Zone C and covers an area of approximately 0.1 km^2. The extent and geometry of Zones B and C defined from impedance inversion suggest that local geology plays a significant role in the distribution of gas hydrate at Mallik.

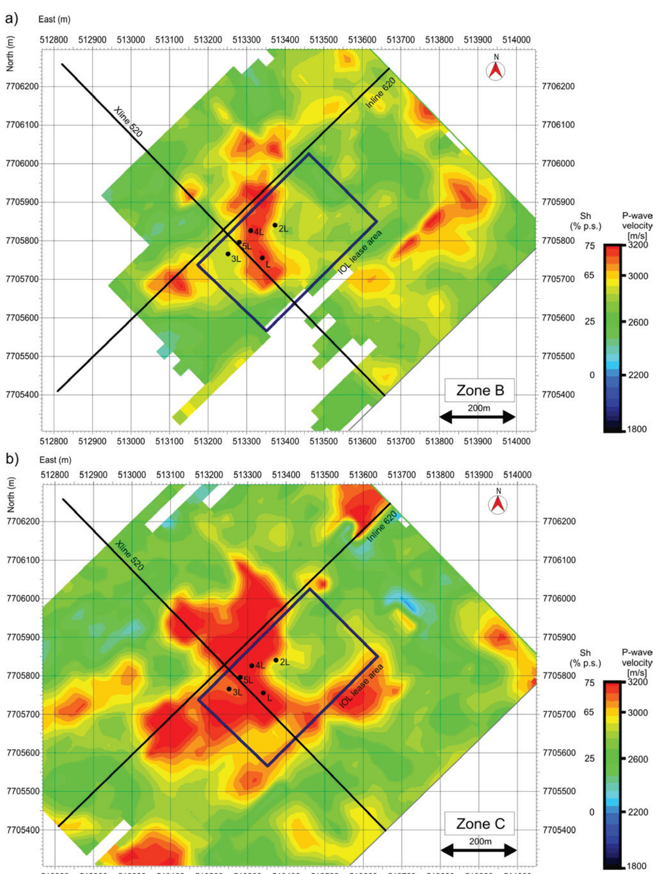

Figure 6. Velocity Map obtained from acoustic impedance inversion showing the extent of gas hydrate Zones B (top) and C (bottom). Color code shows P-wave velocity in m/s and gas hydrate concentration in percent of pore space (% p.s.). Gas hydrate Zone C is structurally complex with a center area of highest P-wave velocity and related gas hydrate concentration underneath the Mallik well sites. Zone B extends over a much smaller area than Zone C and is distributed along a N-S axis.

Conclusions

Lower seismic amplitudes are observed on the 3D Mallik data beneath some lakes and water channels. Amplitude effects on the seismic data arise from velocity and attenuation variations associated with frozen and unfrozen parts of the permafrost. A 3D velocity map of the permafrost obtained with direct arrival travel-time tomography indicates that some of the low-velocity areas beneath the lakes have an inverted-cone shape and extend down to approximately 300 m. Beneath the permafrost, results from acoustic impedance inversion indicate that sediments with high gas hydrate saturation near the Mallik well site extend over an area of 0.25 km^2 and suggest that lateral and depth-dependent geology variations play a significant role in the distribution of gas hydrates.

Massive Ground Ice on the Ural Coast of Baydaratskaya Bay, Kara Sea, Russia

N.G. Belova, V.I. Solomatin, F.A. Romanenko
Lomonosov Moscow State University, Faculty of Geography, Moscow, Russia

Abstract

Massive ground ice on the coast of Baydaratskaya Bay (Kara Sea) is exposed on the western (Yugorski) side near the mouth of the Ngoyu-Yacha River. It reaches 7 m in thickness and lies in sandy stratum. The isotopic and chemical composition of the ice, complicated ice structure with several types of ice, ice deformations, and the lacustrine-alluvial origin of host sediments suggest a burial origin for the massive ice beds. Sands with massive ice are underlayed by clayey stratum which is related to the Kara diamicton stratigraphic unit. Massive ice beds are supposed to be the remains of outlet glaciers from Pai Khoi or Polar Ural, which were buried in lacustrine-alluvial (fluvioglacial) sediments in the Late Weichselian; this area wasn't covered by the Barents-Kara Ice Sheet at that time.

Keywords: Barents-Kara Ice Sheet; Late Weichselian glacial maximum; massive ground ice; paleogeography; Russian Arctic.

Introduction

It is now known that massive ground ice exposures on the coast of Baydaratskaya Bay (Kara Sea) are found in just one section – on Yugorski (western) side near the mouth of the Ngoyu-Yacha River (Fig. 1). The origin of these ice formations remains sharply controversial both locally and globally. There are two main points of view on massive ice origin: it could be buried glacial ice (in particular, basal ice of ice sheets) or intrasedimental ice, formed in pre-existing sediments. Any paleoreconstructions in this area would be imperfect without taking into account the origin of massive ice. For the purpose of making the question of massive ice origin clear at a local scale, an integrated study of thick (up to 7 m) massive ice beds was conducted 2005–2007 along the coastal bluffs of the area. The host strata and the relation to massive ice, ice structure, chemical composition of ice and host sediments, and isotopic composition of the ice have been studied to solve this problem.

Quaternary history of the study area

The Yugorski peninsula was supposed to be overridden by the Barents-Kara Ice Sheet no later than 90–80 ka BP, Marine Isotope Stage 5a–b (MIS 5a–b), i.e., at Early Weichselian. The Late Weichselian glacier limit didn't attain this area (see Fig. 1; based on Svendsen at al. 2004). During Holocene warming, this region was essentially reshaped by increased thermokarst activity (Romanenko et al. 2001).

Host Sediments: Stratigraphy and Relation with Massive Ground Ice

Composition and stratigraphy of host sediments

Near the mouth of the Ngoyu-Yacha River, the ridgy plain with an altitude of 27–35 m above sea level (a.s.l.) comes out to the Baydaratskaya Bay coast. In the coastal zone, this surface is strongly dissected by numerous thermokarst depressions known locally as "khasyreys" (The term is of Nenets origin (northwestern Siberia); an analogous term of Yakut origin is "alas"). The altitudes of many khasyreys are lower: up to 15–20 m. The elevated surfaces that have remained unaffected by thermokarst occupy a minor area compared to dissected ones.

The stratum of heavy consolidated fractured clays with scarce rounded boulders underlies many sections (Fig. 2), but on most of studied area it lies below sea level. In the upper part, clays are silty and contain occasional thin sand laminas (up to 0.5 cm thick) with fragments of shells.

Composite sandy stratum with clay bands, folds, lenses of well-rounded pebbles and gravel with fragments of sea shells overlap the clay unit at a stratigraphic disconformity (Fig. 2). The chemical composition of aqueous extract shows that this stratum is fresh (Fig. 6). The stratification features indicate the formation of these sediments by fluctuating stream activity. The alternating pebbly gravel layers with clayey layers, as well as the results of chemical analysis, indicates continental and coastal formational environments. Z.V. Aleshinskaya (pers. com.) came to the conclusion about the alluvial origin of the sandy stratum following analysis of diatom composition. On the pollen and spore diagram, the redeposited pollen of *Betula* sect*. Albae*, and *Pinus* is rather abundant, and there exists pollen of *Fagus* and *Juglans*. Spectra of a similar composition were detected in deposits of the Eemian-Early Weichselian (MIS 5d–e, c. 100–130 ka BP) of the Pai Khoi Ridge (Northern Ural); this may imply that a considerable part of spores and pollen was redeposited from older Pleistocene sediments (Andreev et al. 1998).

Gravel lenses and bands in the sandy stratum perhaps represent erosion activation phases on adjacent areas of the Polar Ural. Numerous facies boundaries in sandy-gravelly-pebbled stratum are possibly determined by alluvial redeposition on the lacustrine-alluvial plain. The ^{14}C dates from sandy sediments unaffected by thermokarst were 22 500±400 (detritus, GIN-13795) and 44 900±1100 (wood, GIN-13796) ^{14}C years BP. Peat lenses, which were formed during increased thermokarst activity at the surface of the sandy stratum, is characterized by a continuous

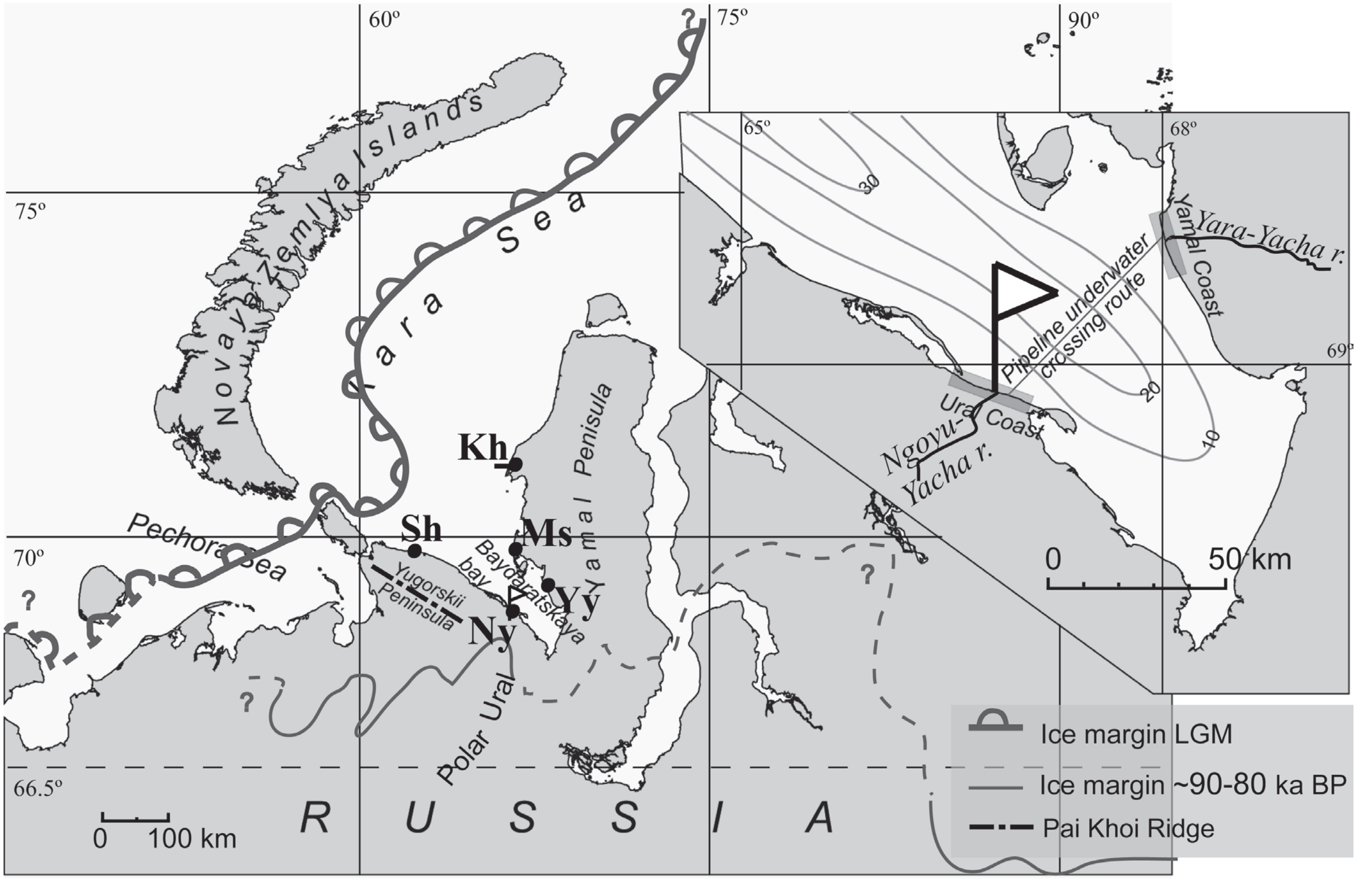

Figure 1. The area of investigations (marked by flag). Ice limits of the Late Weichselian glacial maximum (LGM) and Early Weichselian glacial maximum (90–80 ka BP) according to Svendsen et al. (2004). Ny – Ngoyu-Yacha River, Kh – Kharasavey River (northern Kara diamicton limit), Sh – Cape Shpindler, Ms – Marresale Station, Yy – Yara-Yacha River.

dated series (9 dates) from 10,900±120 (MSU-1362) and 8,210±110 (GIN-7862) to 4,140±70 (WAT-2895) ^{14}C years BP (Romanenko et al. 2001). It confines the period of sandy stratum formation at 11,000 yr BP.

On the opposite coast of Baydaratskaya Bay, near the mouth of the Yara-Yacha River, the same sandy stratum is exposed on coastal bluffs. Radiocarbon analysis using two *in situ* peat samples from lake sediments yielded an AMS radiocarbon age of 28 650±280 (AA-20 497) and 29 750±520 (AA-20 498) ^{14}C years BP (Gataullin & Forman 1997); and 19 560±330 ^{14}C years BP (GIN-8561) (Romanenko et al. 2001). It could be formed in the Middle-Late Weichselian (Romanenko et al. 2001). This confirms Middle-Late Weichselian age of sandy stratum on investigated area.

Relations between massive ground ice and host sediments

The principal singularity of the sandy stratum, which forms the surface with altitudes of 27–35 m a.s.l., is massive ground ice. Ice bodies are confined mainly to the highest parts of the unit that are least modified by thermokarst. They are recovered as close to the water edge, as near the highest altitudes of this surface – up to 15 m a.s.l.. Maximum dimensions of these massive ground ice bodies is up to 7 m thick (Fig. 3) and 150 m along the coastline.

Massive ground ice lies generally conformably with host strata. But fairly often the upper contact cuts the layers in the massive ice; in other words, this contact is erosional or it is a thaw unconformity. The erosional nature of the contact is obvious when massive ice is overlaid by several meters of sands with clear fluvial bedding (Fig. 4). Sometimes the upper contact is marked by c. 0.2 m of clay; thus it can be secondary.

At the lateral contact the ice bed is tapering out by ice layers, which are also conformable with host deposits (Fig. 2). Directly under the massive ground ice the deformed ice bands, dykes and elongated lenses are found with thicknesses up to 0.7 m; they disrupt the sand stratification or lie conformable with enclosing sediments. The ice of the bands and lenses is mostly transparent, often laminated owing to inclusions of host sediments, which lie in laminas parallel to ice bands. Tubular bubbles (c. 1 mm diameter and ≤2cm long) were often observed orthogonal to ice bands.

Cryostructures of Massive Ground Ice

Massive ice beds are composed of several types of ice. The majority of ice beds consists of laminated ice. This ice type is characterized by close alternation of layers (with 5–15 cm average thickness) of relatively transparent ice and muddy ice. The latter is due to suspended sand, clay

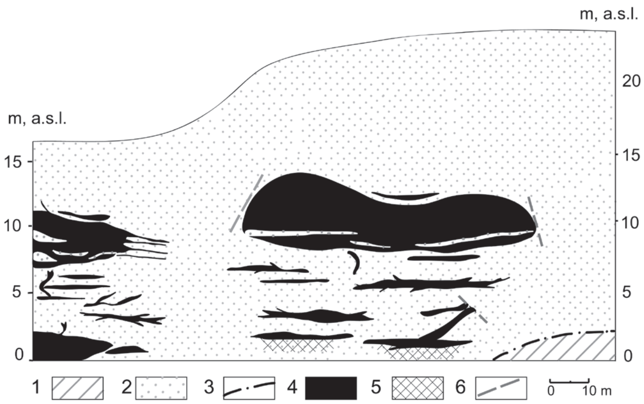

Figure 2. Stratigraphy of coastal bluffs (general scheme). 1- clays with boulders, 2 - sandy stratum, 3 – sediments strata's boundaries, 4 – ice, 5 – icy sediments, 6 - unclarified ice boundaries.

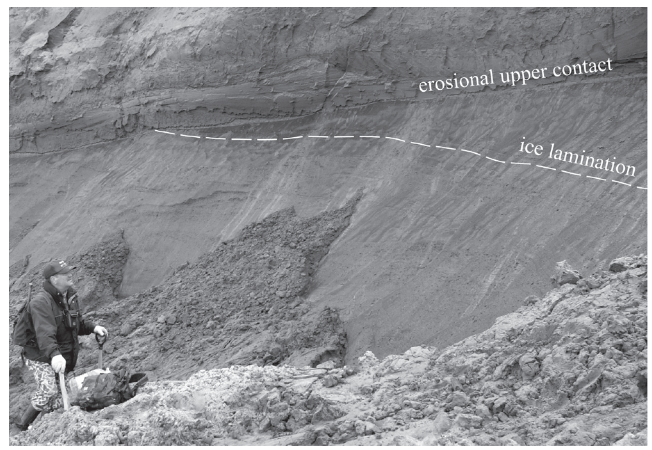

Figure 4. Erosional upper contact of massive ground ice (4 m thick). Ice bed is overlain by 8 m of sands.

and silt aggregates, several mm in diameter, and rounded or amorphous silty-clayey fragments up to several cm across (Fig. 5 a,b).

In the lower parts of the ice beds the mud content is usually higher than in the upper parts, and the laminations therefore become less distinct. Here it can be distinguished as the muddy ice subtype. Clay, silt and sand material in the ice beds corresponds to sands, silts and clays which enclose the massive ground ice. Generally, the layering of massive ground ice is subhorizontal, although it is more correct to note that it is subparallel to the upper ice bed boundary. Laminated ice has an average crystal diameter of 0.5–1.0 cm, and crystals are mostly isomorphic. In muddy ice layers with a great amount of sandy particles, the crystal size is much smaller. The laminated ice type becomes more complicated in places due to folds of different scales (Fig.5b), transparent ice inclusions, or sandy and clayey layers.

Thus, at the upper contact of the thickest massive ice bed, the upper 2 m of laminated ice are crumpled in recumbent folds above a subhorizontal shear plane. The limbs of the folds have amplitude of about 1 m.

Besides the laminated ice in the massive ice beds, there are also transparent and bubbly ice types (Fig. 5 c,d). Bubbly ice (bubbles are usually spherical, 0.5–3.0 mm diameter) is typical of the upper ice beds, and in the coastal section it gradually replaces laminated ice. By contrast, the transparent ice appears often to break through and sometimes draw apart the subhorizontal ice lamina. The thickness of such seams is up to 0.5 m; they often lie nearly vertically and sometimes bifurcate along several subparallel seams. In section they can have the form of a fold (Fig.6).

Transparent ice in its middle part often includes clay bands parallel to its boundaries (Fig. 5d, 6). The crystals of transparent ice can be 25 cm across.

For massive ground ice, independent of the ice type, clayey and sandy layers of different thickness (from several cm up to 0.5 m, usually about 10–20 cm) are typical. Thick ground layers are more frequent in the lower reaches of the ice beds; these layers can lie parallel to each other, form lenticular structures, and sometimes cut the subhorizontal ice layers.

Chemical and Isotopic Composition

Chemical analysis

In 2005–2007, the massive ice beds, ice bands and lenses in the underlying sediments (melt ice) and host sediments (from sediments aqueous extract) were sampled for chemical analysis. All the samples turned out to be fresh water– the mineralization of all of them is less than 200 mg/l. But composition and the ratio between different chemical ions varies substantially (Fig. 7). In massive ground ice, Ca^{2+} and Na^{+} cations and HCO_3^- (rarely SO_4^{2-}) are predominant. But in ice bands and lenses from below the massive ice beds HCO_3^- is completely absent. Aqueous extract from sediments shows that here chemical composition is somewhat different – Ca^{2+}, K^+, Na^+ and SO_4^{2-} predominate.

Isotopic analysis

The first results of stable isotope measurements in massive ice beds near the mouth of the Ngoyu-Yacha River were obtained concurrent with discover in 1990 (Konyakhin et al. 1991). Based on this data, the ^{18}O isotope values vary from -17.5 to -25.5‰ (relative to SMOW standard) in transparent ice and from -18.4 to -22.4‰ in bubbled ice. The analytical results of samples from 2006 confirmed the significant spread

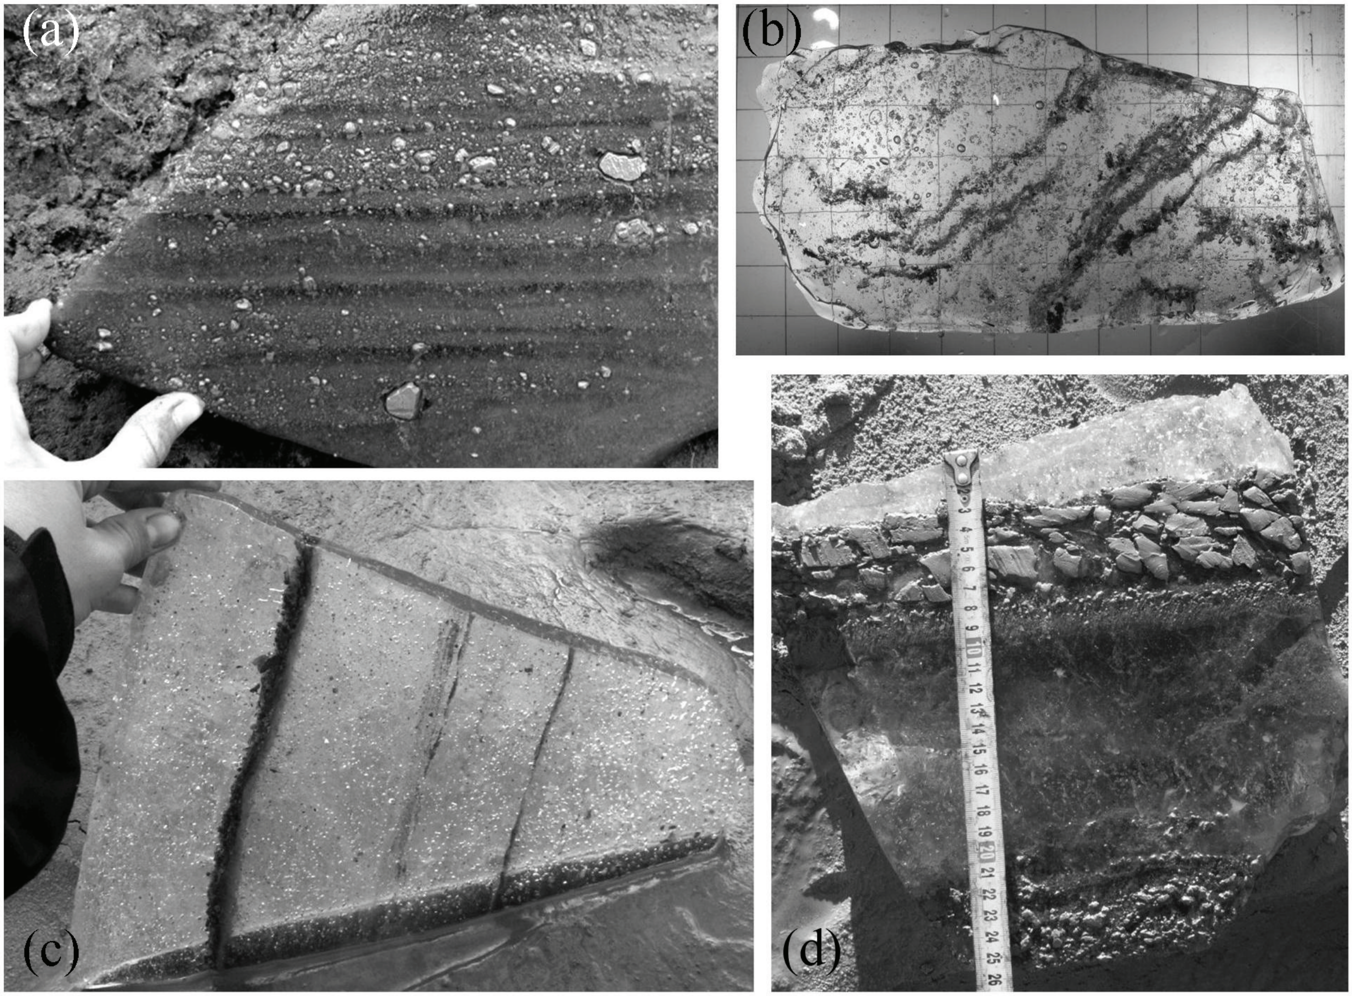

Figure 5. Types of massive ice: (a) laminated ice; (b) laminated deformed ice (1 cm mesh); (c) bubbly ice; (d) transparent ice with clayey band.

of values established earlier. A massive ice bed, 3.5 m in thickness, has been sampled in one vertical section at every 30–40 cm (Belova et al. 2007). Sampled ice is homogeneous; it is presented by laminated type except for the upper 30 cm where it slips into laminated, but clearer, bubbly ice. Here the dispersion turned out to be significant—at about 7‰ for $\delta^{18}O$ and about 45‰ for δD (Fig. 8).

Interpretation and Discussion

Composition and stratigraphy of host sediments

The lowest stratigraphic unit in the sections studied is represented by clays with boulders, and this unit can be related to the Kara diamicton. It is an informal stratigraphic unit first defined near Marresale station by V.N. Gataullin (Gataullin 1988; see Fig. 1). Kara diamicton is widespread on the western Yamal Peninsula, but has yet to be identified north of 70º50′N (Kharasavey River mouth; Forman et al. 2002). Near the Marresale station its uppermost facies is represented by massive to crudely stratified clayey silty diamicton without any glaciotectonic structures and with random pebbles and occasional sand horizons <1 cm thick. This description is almost identical to that for one of the clay units near the mouth of the Ngoyu-Yacha River. At Marresale station, the upper facies of the diamicton is interpreted by investigators as a supraglacial meltout till formed by the release of glacial debris from stagnant glacier ice. Based on finite radiocarbon and luminescence ages of ca. 35,000 to 45,000 yr obtained from the immediately overlying Kara diamicton Varjakha peat and silt (informal unit), the last glaciation was >40,000 yr ago (Forman et al. 2002). Thus, at the study area, the last large-scale glaciation was presumably also earlier than Middle Weichselian.

In such a case, massive ice beds in a sandy unit overlying what is probably Kara diamicton couldn't be the remains of a large ice sheet. Furthermore, they lie in lacustrine-alluvial sediments, so the lack of typical moraine deposits can be explained by their origin as remains of local glaciers (probably outlet glaciers of local Ural glaciation). This fact is confirmed by implication of spore-pollen spectra data, which is similar to Eemian-Early Weichselian one in Pai Khoi Ridge deposits (central part of Yugorski peninsula, northern part of Ural). Based on dates of the enclosing sediments, this glaciation could have occurred in Late Weichselian (MIS 2).

In the northern part of the Yugirski peninsula at Cape

Figure 6. Fold formed by transparent ice in laminated ice with subhorizontal bedding.

Shpindler (Fig. 1), a somewhat similar assumption was made. Possibly glacier ice was flowing northward from the hills in the Pai-Hoi uplands on the Yugorski Peninsula, 468m a.s.l., which may have acted as an ice sheet nucleation area during the Early Weichselian glaciation (Svendsen et al. 2004). However, at the study area it is difficult to assume the same scenario because typical moraine sediments are absent.

The unconformable upper contact of the massive ice unit in some places can be the result of thaw layer deepening or increased thermokarst activity during Holocene warming. But in many sections where the surface is unaffected by thermokarst and massive ice is overlaid by more than 8 m of sediments, this unconformity was evidently formed at the same time as the massive ground ice. This fact contradicts the intrasedimental hypothesis of massive ice formation but can be explained within the framework of a burial origin.

The ice bands and lenses and dykes in the host sediments most likely were formed by segregation and injection processes during permafrost aggradation following the burial of portions of the outlet glaciers.

Ice structure

The ice types described here can be observed in the case of buried glacier or under intrasedimental ice origin. Similar ice types were described in other massive ice exposures; for example, in massive ice at Tuktoyaktuk Coastlands in western Arctic Canada, which is supposed to be buried basal ice of the Laurentide Ice Sheet (Murton et al. 2005). There the laminated type of ice from this study can be related to aggregate-poor ice facies altering with pure ice facies.

Ice deformations, which are poorly explained by the intrasedimental hypothesis of massive ice origin, provide much stronger evidence of massive ice burial. For example, the observed folded transparent band could be formed as a result of ice removal in horizontal flatness, which deformed a previously intact band (such transparent bands form in bodies of contemporary glaciers).

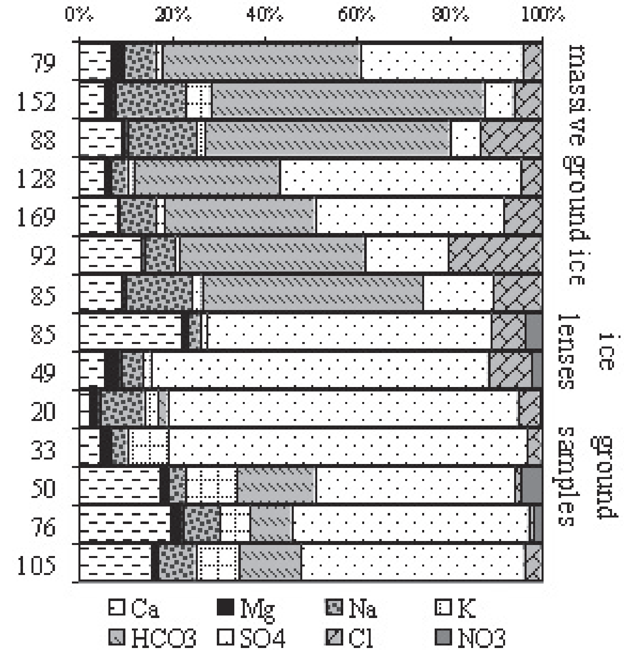

Figure 7. Mineralization (Y-axis, mg/l) and percentage of chemical components in massive ice, host sediments and ice bands and lenses in host sediments.

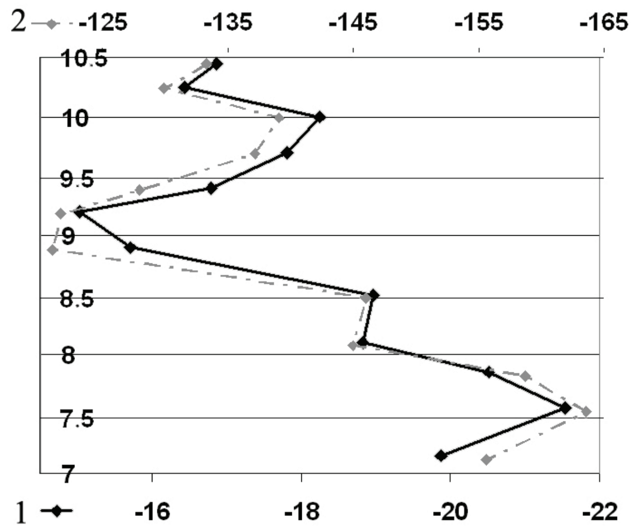

Figure 8. Vertical profiles of the ^{18}O (1) and D (2) isotope values in the massive ground ice body 3.5 m thick. Y-axis shows altitudes, a.s.l.

Chemical and isotopic composition

The chemical composition of massive ice and host sediments is slightly different, which testifies against the hypotheses of underground origin of massive ground ice.

Ice bands and lenses are similar to sandy strata by the ratio of chemical components' content, which confirms their intrasedimental origin. The absence of HCO_3^- in these ice formations is typical for stagnant water (Alekin 1970). It supports the formation of these lenses in a closed system during freezing and consolidation of enclosing lacustrine-alluvial sediments.

The rather large amplitude of oscillation of the ^{18}O and D isotope values tells about the impossibility of this massive intrasedimental ice bed forming only by the segregation process. On the contrary, this data doesn't contradict the possibility of basal glacial ice burial.

Conclusions

Based on these data, we can suppose that the complicated sandy-pebble stratum, which encloses massive ground ice, was formed in conditions of periglacial lacustrine-alluvial flat with the demolition of the material from adjacent parts of the Polar Ural. During Middle-Late Weichselian, as the result of intensive entry of alluvial-proluvial or fluvioglacial sediments and reformation of river channels ice bodies, apparently remnants of Ural's outlet glaciers could be buried. Later on they were periodically destroyed by thermokarst and buried again, which caused complicated construction of ice beds. The last regional glaciation occurred earlier in this area, probably during Early Weichselian.

Abstract

Gravel was used as one of the effective measures to decrease the temperature of embankment during construction of the Qinghai-Tibet Railway. Thermal conductivity is one of the most relevant material parameters needed for the design and construction of roads and railways, especially in permafrost regions. We report on the measurement of the thermal conductivity of gravel (with grain size between 5 cm and 8 cm, which was widely adopted during construction of the Qinghai-Tibet Railway) using Thermal Properties sensors (TP02) made in Netherlands, which allowed a direct measurement of local thermal conductivity. Two conditions of the gravel are preformed: (1) natural convection exists in the gravel, and (2) there is only heat conductivity in the gravel by setting the boundary temperature and constrained convection using agar gel embedded in the gravel. We describe the data evaluation and present the results of the experiments.

Keywords: agar gel; gravel; natural convection; permafrost regions; Qinghai-Tibet Railway; thermal conductivity.

Introduction

In many physical and engineering problems thermal conductivity of the materials used is one of the key parameters that, to a high extent, control the thermo-physical behavior of the system. For example, during construction, the distribution of artificial or naturally generated underground heat determines the stability of the roadbed and thus the safety of the pathways. This is especially important in permafrost regions, like the areas transected by the Qinghai-Tibet Railway. The permafrost layer of the road contains high ice content, making it susceptible to consolidation if thawing occurs. If thawing consolidation takes place beneath engineering structures such as roadway embankments and buildings, the consolidation of the foundation soils typically results in instability and failure of the structures.

Thawing-unstable permafrost provides a very significant challenge to engineers working on the Qinghai-Tibet Railway. Over the years, techniques for avoiding damage to engineering structures because of thaw settlement have remained high on the research agenda for the Chinese government and scientific researchers, although the railway was test run on July 1, 2006. Roadbed embankments typically have a large influence on the thermal regime of the ground when they are constructed in permafrost regions. In order to maintain the stability of the embankments, gravel embankments and slopes are used to avoid thawing-settlement in permafrost regions. But there is some dispute over temperature decreasing degree of various conditions for the complicity of the thermal conductivity determination.

Goering (1996, 2000) studied temperature decreasing of gravel embankments in winter using the dynamic of porous medium. Temperature reductions will reduce or eliminate the tendency for the subsurface permafrost to thaw, thereby protecting the embankment structure from damage due to thaw-settlement. Due to the macropore characteristic of the gravel, cool and warm air in winter and summer can change reciprocally, shielding heat (Sun & Ma 2003). Under the condition of temperature fluctuation and knowing the heat diffusion coefficient of the gravel, thermal conductivity can be obtained by calculating the equivalent heat capacity (Sun et al. 2002, 2005). Therefore, thermal conductivity is a key heat parameter in indicating the heat condition for designing the gravel embankments and slopes. Thermal conductivity of the various materials can be obtained by experiment, but it is difficult to gain the conductivity for gravel of large grain size. However, Thermal Properties sensors (TP02) supplied by IWF and produced by the Hukseflux company allow direct measurement of local thermal conductivity. This research has resulted in a number of indoor experimental studies which can be utilized in field research and numerical modeling of the convection embankments for protecting a wide variety of structures from thawing-settlement damage. Nevertheless, many unsolved problems still remain.

Experimental Apparatus and Materials

Experimental apparatus

The goal of our experiments was to measure the thermal conductivity of gravel used in roadbed engineering. The tests were performed in a thermally controlled environment, namely a climate chamber (Fig. 1). The chamber allowed establishment of a homogeneous temperature environment in the range of -40°C to +70°C. The inner size of the chamber is approximately 100 cm × 100 cm × 100 cm. Two big fans on the inside back of the chamber are used to control the temperature of the chamber to a prescribed value. Also, the air humidity inside the chamber can be controlled externally and set to a given temperature. During operation the power device of the chamber must be cooled by a cold water circuit.

The second major device used in the experiments was the sample container (Fig. 2). It is of rectangular shape (70 cm × 70 cm × 35 cm) and its sides are thermally insulated. The bottom of the container is connected to a circuit which connects to a cooling machine working with alcohol as the cooling agent. The bottom temperature of the container can be set to a certain value, so the upper and bottom temperature of the sample in the container can be controlled by setting the temperature on the chamber and the cooling machine to whatever temperature gradient wanted for the experiments.

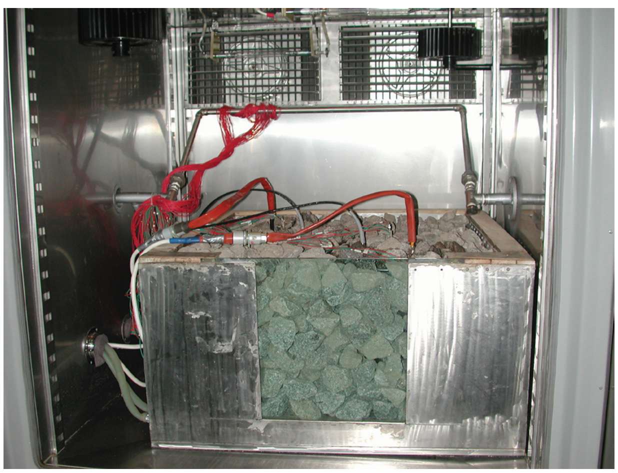

Figure 1. Climate chamber and container used in the experiments.

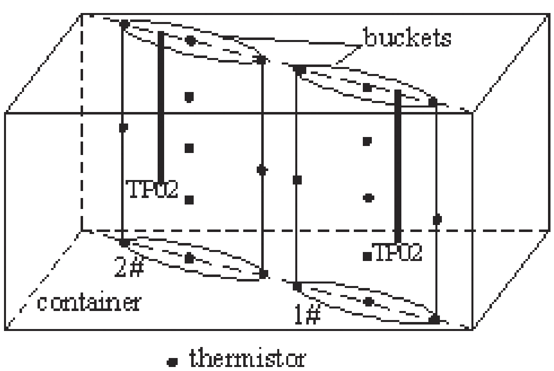

Figure 2. Schematic charts of the experimental apparatus.

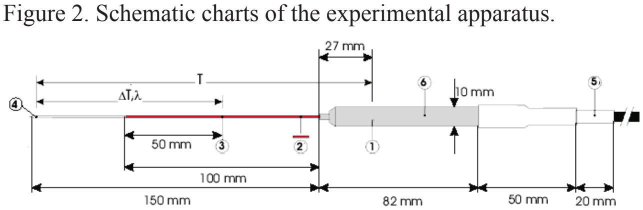

Figure 3. Dimension and buildup of Hukseflux TP02 thermal conductivity probes, which were used to obtain the thermal conductivity data presented in this paper. The sensors including the needle are hermetically sealed in a stainless steel casing, which makes them suitable also for vacuum application.

The third device used was two big stainless steel buckets 32 cm in inner diameter and 30 cm in height. The buckets were filled with gravel and put in the diagonal place of the container; the container was filled with gravel, too.

Measurement sensors

Two types of sensors inserted in the gravel were used in our experiments for measuring the thermal conductivity λ. Thermistors were distributed among the gravel uniformly, which can be seen in Figure 2, to monitor the temperature variations of the gravel during the periods of cooling and heating. The other sensors are two TP02 probes (Fig. 3), which were put in the two buckets. It allows a classical method of getting the thermal conductivity value. The sensor needle of the Hukseflux TP02 probe consists of a needle with two thermocouple junctions (one of which acts as a reference) and a heating wire. It is inserted into the medium that is investigated. In the base, a temperature sensor is mounted. The probe has a heater resistance per meter of 75.52 Ω, a length of 150 mm, and a diameter of 1.5 mm. Its maximum operating temperature is T_{max} = 135°C. To get reasonable results of thermal conductivity, the sensor has to be inserted into the sample at least to the upper end of the thin needle, better up to the base. The principle relies on the unique property of a line source: after a short transient period the temperature rise, ΔT, only depends on heater power, Q, and medium thermal conductivity, λ:

$$\Delta T = (Q/4\pi\lambda)(\ln t + B) \tag{1}$$

with ΔT in K, Q in W/m, λ in W/mK, t the time in *s* and B a constant.

The thermal conductivity can be calculated from two measurements at t_1 and t_2 (Seiferlin et al. 1996). For TP02, both t_1 and t_2 are higher than 60s, and typically 100s apart. Now ΔT the temperature difference between t_1 and t_2

$$\lambda = (Q/4\pi\Delta T)\ln(t_2/t_1) \tag{2}$$

The signal of TP02 is the function of the natural logarithm of time. The different steps of signal analysis for evaluating the thermal conductivity from the measured temperature signal of a heated thin-wire sensor can be seen in Figure 4. In every individual measurement, the graph in the logarithmic time scale should also be visually inspected to see where the linear part heat can be used for the evaluation of λ.

To estimate the length of the transient part of the signal, one can use the following formula (Hukseflux TP02 manual):

$$t_{transient} = \frac{10D^2}{a} \tag{3}$$

Hereby, the transient time is proportional to the medium thermal diffusivity a, and the probe cross section (D is the diameter).

Experimental procedure

The gravel we used in our experiment is widely adopted in the convection roadbed along Qinghai-Tibet Railway. The porosity of the gravel with grain size of 5 cm–8 cm has been experimentally determined as n = 0.48. Figure 2 also shows the schematic charts of the experimental apparatus used in our experiment. We filled the two buckets (#1 and #2) and the container with gravel at random. It was possible to make a large number of measurements over a number of days under this condition, when the cooling fans of the chamber were switched off temporarily and thus no forced air convection took place in the chamber.

In order to investigate the thermal conductivity of gravel without convection, we used agar gel, filling the pores of gravel. It was also used for calibration in the experiments. This is a water gel, of which the ingredients can be bought in every pharmacy. The agar itself does not significantly influence the thermal, but eliminates the effects of convection. At 20°C and 0°C, its thermal conductivity is 0.60 W/mK and 0.57 W/mK, respectively. The temperature dependence of the thermal conductivity is 0.0015 W/mK/°C.

Two different grain size gravel measurements were done at room temperature. After the investigation, the calibration of the probes was performed.

Data Evaluation

The criterion for natural convection

The Rayleigh number is a key similarity parameter investigating the natural convection in the porous medium (Sun et al. 2004). Whether natural convection will take place depends on the shape and the boundary of the porous medium. Based on the research on the convection of gravel, the Rayleigh number is defined as

$$R_a = \frac{\rho_0 g \beta K H \Delta\theta}{\mu \alpha_t} \tag{4}$$

It is the product of Darcy number $D_a = K/H^2$ and the Rayleigh number of pure fluid $Ra' = \beta g\ H^3\Delta\theta/\mu a_t$, where ρ_0 is the density of the pore air (kg·m^{-3}), g is gravity acceleration (m·s^{-2}), β is the coefficient of thermal expansion (K^{-1}), and K is the permeability of the gravel (m^2), which is difficult to obtain, and generally it is estimated by the semi-rational formula as follows (Goering, 1998):

$$K = \frac{1}{5}\left[\frac{(1-n)^2}{n^3}\left(\frac{f_0}{100}\sum \frac{p_m}{d_m}\right)^2\right]^{-1} \tag{5}$$

where f_0 is the shape factor of gravel ranging from 6.0 of sphere to 7.7 of corner edge shape, and p_m is the percent of average grain size, d_m, in gravel. In the experiments, the permeability of the gravel is 4.83 × 10^{-6}m^2 determined experimentally. H is the height of the gravel (m), and $\Delta\theta$ is the temperature difference between the lower and upper boundary in the experiment (K); μ is dynamic viscosity of the pore air (N·s·m^{-2}) influenced by temperature, and it is of 1.158 × 10^{-5} N·s·m^{-2}～1.700 × 10^{-5} N·s·m^{-2} under the temperature of between -20° to 40°, and a_t is the volumetric heat capacity of the pore air (m^2·s^{-1}).

There is a critical Rayleigh number, Ra_c, depending on the shape and boundary conditions of the porous medium (Bear 1972). When Ra is less than Ra_c, the component of air among gravel is zero, so there is only pure heat conductivity; however, natural convection is taking place when Ra is greater than or equal to Ra_c. The critical Rayleigh number Ra_c can be calculated under different boundary conditions (Kong et al. 1996). In the experiments, it is a two-dimensional square region, all-around waterproof, and boundary temperatures are stable with side insulation, so $Ra_c = 4\pi^2 = 39.47$. The Rayleigh number, Ra, is 67.83 in the minimum temperature difference between the lower and upper boundary, greater than the critical Rayleigh number, Ra, 39.47; so before filled with agar gel during the experiment, heat conductivity exists in the gravel, but natural convection as well.

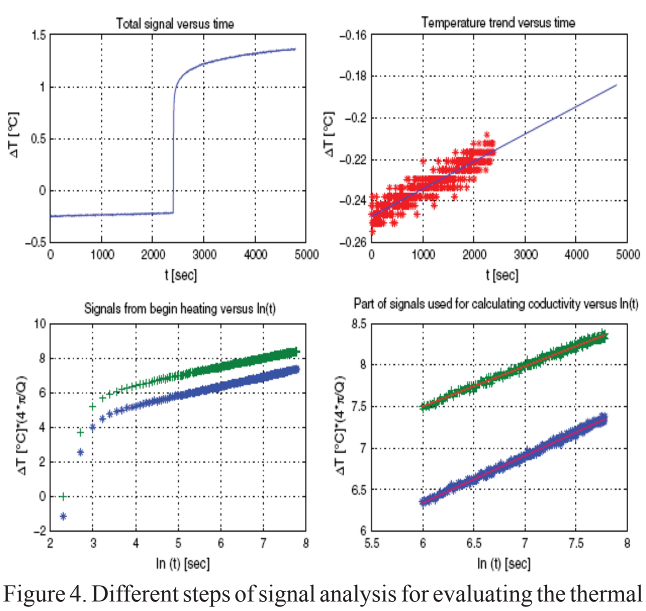

Figure 4. Different steps of signal analysis for evaluating the thermal conductivity from the measured temperature signal of a needle probe. Upper left: measured temperature increase in response to sensor heating. Upper right: evaluation of the general temperature trend in the sample before heating. Lower left: corrected (green) and uncorrected (blue) temperature increase in response to sensor heating over a logarithmic time coordinate; only the heated part of the signal is plotted here. Lower right: part of the signal used for the evaluation of the thermal conductivity.

Thermal conductivity of gravel with convection

Figure 5 shows the variation of thermal conductivity of existing natural convection in gravel. It can be seen that the thermal conductivity increases in positive temperature and decreases in negative temperature, so it is good for heat exchange in summertime for road stability in permafrost regions. There is the same trend in the temperature gradient (Fig. 6). It means that there exists natural convection to a negative temperature gradient (bottom temperature is grater than the upper temperature), and there is only heat conductivity to a positive temperature gradient (bottom temperature is lower than the upper temperature). Under this condition, the bottom temperature is higher than the upper boundary temperature. Due to the existence of natural convection, the heat transferred from the lower to upper is greater than the conditions where there is only heat conductivity. With the increasing of the temperature gradient, the effect is more obvious. The advantage of gravel roadbeds and slopes is active protection of the permafrost, especially in summertime with high temperatures. The results can be used in numerical modeling of the variation of temperature field of the roadbed.

From the experiment graph of the thermal conductivity of gravel with convection, we know the thermal conductivity with convection, but in our experiment using TP02 probes, we do not know how much the convection affects the thermal conductivity, namely temperature.

Thermal conductivity of gravel filled with agar

Our experiments with gravel, agar gel, and the composite sample (gravel with air, and gravel with agar gel filled) offer the possibility to test some simple formulas predicting the conductivity of two component samples practically, since we have both conductivity measurements of the single components and measurements of the sample containing both components in a known volume ratio.

In order to eliminate the effects of convection, the thermal conductivity measurements were done by filling the gravel with agar gel. The thermal conductivity of the composite sample is 1.6 W/mK in positive temperature, and 3.0 W/mK when freezing. Then the simplest way to predict the effective conductivity of the composite sample would be

$$\lambda = n\lambda_a + (1-n)\lambda_s \tag{6}$$

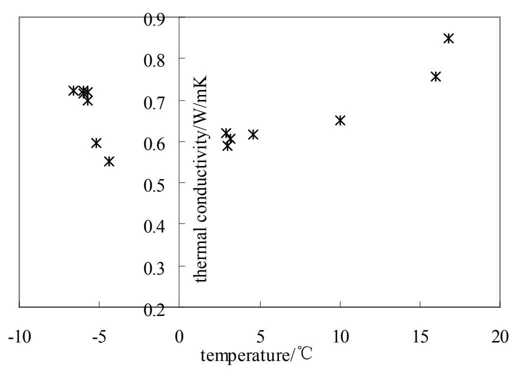

Figure 5. The variation of thermal conductivity with temperature when there is existing natural convection.

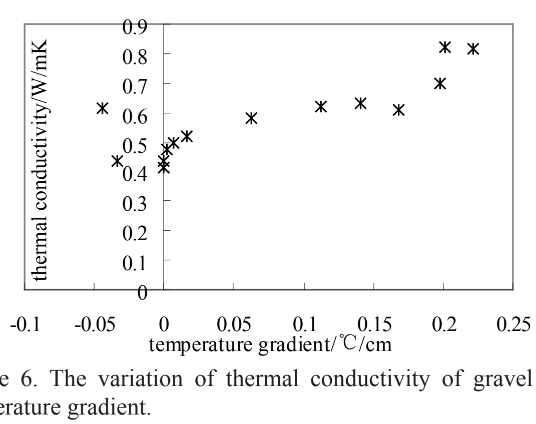

Figure 6. The variation of thermal conductivity of gravel with temperature gradient.

where n is the porosity of the gravel (equivalently n is the volume ratio filled with the agar gel); λ_a is the thermal conductivity of agar gel, and the change is very little with temperature; and λ_s is the conductivity of granite stones.

The porosity n of the composite sample (respectively the fraction filled by the agar gel) has been experimentally determined as $n = 0.48$. The calculation value of the thermal conductivity of gravel filled with agar gel is 1.692 W/mK in positive temperature, and 2.964 W/mK when freezing.

Different grain-size thermal conductivity measurement at room temperature

At room temperature, different grain size gravel measurements were done. One is of grain size between 1 cm and 2 cm, and the porosity of it is 37.9%; the other is of grain size between 2 cm and 4 cm, and the porosity is 40%. It can be seen from Figure 7 that the bigger the grain size or porosity, the greater is the thermal conductivity.

Conclusions

1. The thermal conductivity measurements of gravel using TP02 probes give a simple and direct way to obtain results. To the temperature and the temperature gradient with air convection, the thermal conductivity increases in positive, and decreases in negative.
2. With the agar gel filled and using one simple formula, the calculation value of the thermal conductivity of gravel is 1.692 W/mK in positive temperature, and 2.964 W/mK when freezing.
3. The bigger the grain size or porosity, the greater is the thermal conductivity.
4. We studied the thermal conductivity of gravel with air convection, but it is still a question as to how much the convection affects the thermal conductivity and the temperature in the roadbed. A solution to this is expected in our future work.

The Effect of Near-Freezing Temperatures on the Stability of an Underground Excavation in Permafrost

Kevin L. Bjella , P.E.
Cold Regions Research and Engineering Laboratory, Fairbanks, AK, USA

Abstract

Changes in tunnel geometry have occurred to the Cold Regions Research and Engineering Laboratory (CRREL) Permafrost Tunnel in Fox, Alaska, since excavation in the mid-1960s. Frozen silt deformation has occurred in the rear of the horizontal adit, and a portion of the gravel roof in the lower winze chamber has detached from the silt strata above. Both of these deformations are attributable to thermal changes in the facility that have raised the overall temperature to near-freezing. Temporary modifications to the air-chilling system have decreased the temperature to an average of -7.0°C for the winter months and -3.5°C for the summer months, and early data from a monitoring program indicate the creep rate has slowed significantly.

Keywords: creep; frozen gravel; frozen loess; ice wedges; massive ice; permafrost tunnel.

Introduction

The CRREL Permafrost tunnel is located 16 km north of Fairbanks in Fox, Alaska (Fig. 1).The facility consists of a 110 m long horizontal adit excavated in frozen loess and a 45 m long winze that extends obliquely down to the underlying frozen gravels. Changes have occurred to the geometry of the tunnel since the excavation was conducted in the mid to late 1960s. Specifically deformation of the frozen silt has occurred in the rear of the adit, and a rooffall of the gravel layer has occurred in the room at the bottom of the winze. Investigation of the deformation was conducted in May of 2006 to ascertain what measures could be taken to prevent further deformation (Bjella et al., in press).

Background

This tunnel is composed of two portions: the adit (a nearly horizontal passage from the surface into a mine), which was driven by the U.S. Army Corps of Engineers using continuous mining methods in the winters of 1963–64, 1964–65, and 1965–66 (Sellman 1967), and the winze (an inclined adit), which was driven by the U.S. Bureau of Mines from 1968 to 1969 using drill and blast, thermal relaxation, and hydraulic relaxation methods (Chester & Frank 1969).

The adit was driven into a nearly vertical silt escarpment at the margin of Goldstream Creek Valley. This valley was historically mined for placer gold, and the escarpment was created by this activity. The geology consists of silt deposits that are Wisconsin to recent in age and eolian in nature derived from the Alaska Range. The silts overlie gravels of Nebraskan age derived from the surrounding hills of the Yukon–Tanana Upland terrain, and they in turn overlie Pre-Cambrian Birch Creek schist bedrock (Sellman 1967). The natural surface over the axis of the tunnel rises gently from the top of the 10 m escarpment and preferentially drains towards Goldstream Creek to the west and Glenn Creek to the north. The overburden is approximately 8 m deep at the rib-sets near the portal, 12 m deep at the rear of the adit, and approximately 17 m deep over the gravel room.

The tunnel contains many periglacial features found in fine-grained permafrost, such as thick segregated ice, massive ice (ice wedges and thaw ponds), and erosional and climate change boundaries marking depositional events, all of which are readily seen in the walls and roof of the adit and winze. The mode of permafrost formation was generally syngenetic, and the ice wedges are probably segments of larger ice wedge polygon complexes. Sellman (1967) suggested that two major silt units with separate ice wedge development exist in the adit. Moisture contents for the silt range from 39% to 120% with an average of 77% (Sellman 1967). The lower winze gravels have an average moisture content of 13.5% (Law 1987).

When the tunnel was constructed, it was realized that warm summer temperatures would adversely affect the stability of the facility, and therefore a mechanical air-chilling unit was installed. This unit, which is housed outdoors,

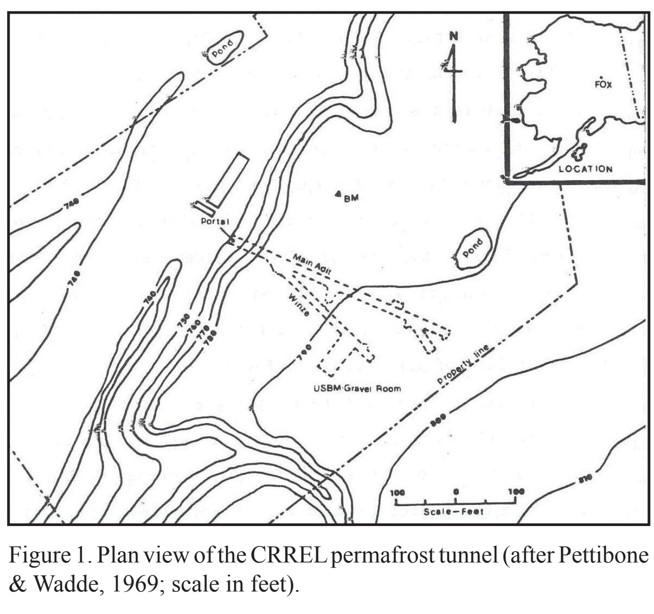

Figure 1. Plan view of the CRREL permafrost tunnel (after Pettibone & Wadde, 1969; scale in feet).

circulates liquid refrigerant through a series of loops that are embedded in the active layer over the portal bulkhead. One of these loops is circulated through a blower unit that hangs inside the tunnel between the bulkhead and the rib-sets and this serves to cool the interior air. This mechanical system was designed to run only during the months when outdoor ambient temperatures are above freezing.

Now inaccessible at the end of the adit are three approximately 1 m diameter ventilation shafts that were augured down from the surface to the tunnel. These were designed to aid in natural convection cooling in the winter while the portal doors were opened. These were problematic to maintain, as surface water would migrate along the shaft, thaw the permafrost, and form a conduit for surface water to travel to the tunnel, eventually occluding the vent. Each subsequent vent was installed after the failure of the previous. Sometime after 1993, the last of the three vents froze shut and has not been operable since. To aid in cooling the rear of the adit since that time, fans have been used to circulate the winter air after opening the portal doors.

The continuous mining method utilizing the Alkirk Miner simultaneously cut two 2 m circular arcs, side by side. After this pass was complete to the end of the adit at 110+00 (110 m, where 0+00 is the inside wooden bulkhead), a portion of the floor was lowered using a Joy 10 RU coal cutter, which resembled a large, multi-angle chainsaw. This started near the bulkhead and continued to approximately midway at 50+00, where the floor begins to incline noticeably to meet the elevation of the Alkirk pass at 62+0.5. The winze begins at 30+00 and drops obliquely at an incline of 14% for 45 m, passing into the gravel unit and ultimately into the weathered bedrock, where the Gravel Room was excavated (Pettibone 1973). At the time of excavation, portions of the Gravel Room roof consisted of a gravel layer up to 2 m thick below the overlying silt unit (Garbeil 1983).

Silt deformation

Beginning at the portal and moving towards the face (rear), the adit retains the original excavated geometry. An examination of the area near the portal reveals that this location has not experienced any appreciable deformation, probably because of the proximity to the portal doors during winter cooling and the proximity to the mechanical chilling unit during summer cooling. At 50+00, the "switch room," measuring 6×6 m, was excavated on the south side of the adit, and it appears that the roof in this area may have dropped some amount corresponding to the 12 m roof span. A transverse-oriented crack, about 4 cm wide, crosses the roof in this area. It is ice-filled, which suggests a cyrostructural origin and not a tension crack from deformation. Otherwise, from the portal to approximately 75+00, there is no perceptible deformation to suggest structural instability. In fact, for most of this portion of the adit, the Alkirk Miner profile is still visible in the roof, suggesting that the material is relatively stable and has not moved or deformed since the time of excavation.

At approximately 75+00 the roof begins to perceptibly sag and at 80+00 fallen slabs of silt up to 0.25 m in thickness are lying on the floor; the adit is then completely blocked by low-hanging and fallen soil layers at 90+00 (Fig. 2). The overhead layers of soil delaminate from the bedded soil above and creep down towards the floor hanging from the wall/roof intersection. This portion of the adit has evidence of paleo-alluvial deposition and erosion (Sellman 1967) where the poorly-graded silt contains interbedded layers of gravelly sandy silt, millimeters to centimeters in thickness. These layers are the preferential locations of the overhead detachment yielding the laminated structure (Bjella et al., in press). The slow deformation towards the floor can then give way to an abrupt release of portions up to 4 m^2 when the tensile strength of the soil is exceeded on either end of the catenary. Except near the portal, approaching the face, and in close proximity to cryological ice features, the silt in the adit and upper 30 m of the winze appears to have undergone little deformation since emplacement and retains a massive cryological structure appearance. No subsidence is noticed at the surface directly above this deformation.

The winze was excavated using drill and blast methods starting at a low hanging ledge at 30+00. This ledge was the pullout location for the shuttle car used to move waste material out of the adit from the Alkirk machine. Because of the excavation method, the winze retains a much rougher appearance than the adit and is shallower in geometry. There is no evidence through the entire length that this ramp has undergone deformation to any significant degree.

Gravel deformation

The Gravel Room, which is located at the foot of the winze and extends to the southwest, was the focus of subsurface mining studies in the late 1960s. The room is 9×21 m and was excavated in the gravel and bedrock below the overlying silt unit. This silt/gravel boundary at the time of excavation was approximately 2 m above the level of the roof of the Gravel Room. It was recognized that this gravel material, with its much higher unit weight than the silt unit to which it is bonded (2080 kg/m^3 for the gravel vs. 1600 kg/m^3 for the silt), could separate and fall in rooms of large roof span.

Investigators have repeatedly studied this parting potential through the years, with two investigations utilizing a warming study to understand the temperature dependence on creep and separation of the two soil units (Pettibone 1973, Garbeil 1983, Huang 1985, 1986). Two multiple-position borehole extensometers were installed during the 1983 study, with one end anchored in the silt unit and the other anchored in the gravel roof. Specific parting of 0.0084 mm/d was noted between the silt and gravel units when temperatures achieved their highest readings of -1.9°C during the study. Overall vertical closure rates for the room during April 1983 were 0.010 mm/day at -3.7°C, and in July 1983 the closure accelerated to 0.053 mm/d at -1.9°C.

The Gravel Room roof fell to the floor, approximately 25 m^3, after a 6.2 Richter magnitude earthquake struck the Fairbanks region in October 1995. The boundary of the dropped material is coincident with the wall that was installed to facilitate warming of the roof in 1983 and is shown in Figure 2. No subsidence is noticed at the surface due to this roof fall.

Additional observations

On the north side of the adit at 80+00 is a 5×5 m side area referred to as Sayles's Room (also called the Crystal Room). It is divided from the adit by a lumber frame and a heavy tarpaulin, and inspection revealed a large ice wedge on the western wall that widens where it meets the roof and then spreads out to almost room-width across the roof towards the adit. The adit at this stationing is overlain by massive ice, but to what degree is uncertain. The roof in Sayles's Room is supported by a 3 m long steel beam resting on 15×15 cm timbers, which are the remnants of previous creep testing.

Opposite Sayles's Room on the southeast end of the adit, at approximately 95+00, a 16×6 m crosscut exists that departs at a 36° angle. This room is now inaccessible because of the deformation in the adit, and anecdotal information implies that an ice wedge feature is exposed in the southwest wall of this room adjacent to the adit. Also, in the north wall of the adit at 75+00, there is a complex configuration of massive ice consisting of ice wedges, pond ice, and 5 to 15 cm -thick ice lenses. Because of the close proximity of the adit deformation, the Sayles's Room ice wedge, the cross-cut ice wedge, and the massive ice complex at 75+00; and based on the polygonal nature of ice wedge complexes (Williams & Smith 1989, Murton & French 1994), this intersection may be coincident with the near-center of an ice wedge polygon complex (Bjella et al., in press).

Analysis

Creep reference locations

Creep reference locations were installed in May of 2006 to specifically measure the change in dimension of selected areas of the facility. Seven were established in the adit and two in the winze and were designed to be measured with a metal tape extensometer which measures the relative distance to the nearest 0.01 mm. Each location consists of four attachment points of 0.95 cm diameter × 20 cm long lag eye-bolts screwed into the soil. Two of the points are located at mid-height of opposing walls, approximately perpendicular to the axis of the tunnel. The other two are located in the roof and floor in the same plane as the wall points, and are approximately mid-distance between the walls. The locations are prefixed with *A* for adit or *W* for winze and numbered starting with "1" continuing toward the face. Location A3 consists of only floor and roof points.

The creep stations are shown in Figure 2 and listed in Table 1 with distances from the bulkhead. The stations in the winze are measured from adit location A1. There have been three measurements conducted at all locations starting in May of 2006, with the most recent in July of 2007. The results of the measurements are listed in Table 1. On either side wall near

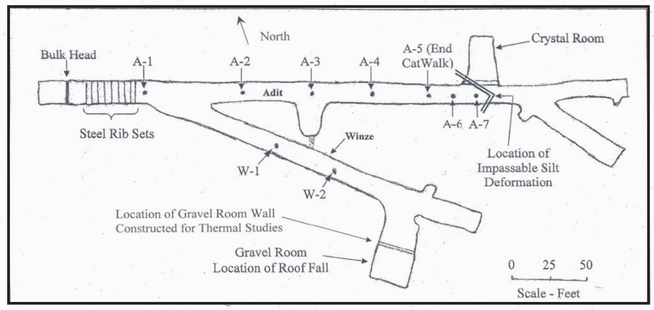

Figure 2. Detailed tunnel plan showing locations of deformation and creep monitoring locations (scale in feet).

the bulkhead are 0.95 cm lag bolts located in vertical 10×10 cm timber posts and these serve as a permanent extensometer reference location to verify continued accuracy of the tape extensometer measurements.

Wu (1985) measured nineteen vertical and nine horizontal convergence stations in both the adit and winze over a 287-day period. Four vertical and two horizontal points appear to have been within approximately 3 m of the newly established creep reference locations in the adit. Two vertical and two horizontal points appear to have been within these same limits of the newly created creep reference locations in the winze. Wu's locations, total convergence, and rate are listed in Table 1.

Temperatures

In May of 2006, temperature measurements were taken utilizing thermistors located approximately every 3.0 m horizontally and at 1.0 m vertically from the floor, both in the air and at soil depths of 0.15 m, 0.40 m, and 0.60 m. The tunnel air near the portal was approximately -3.0°C, and the rear adit air was approximately -1.7°C. The temperature gradient near the portal was 5.6°C/m with depth into the wall, with the ambient air colder than the wall. The gradient at 83+00 was 0.42°C/m, with the ambient air warmer than the wall. The crossover (0°C/m) where the temperature of the ambient air is the same as the wall temperature takes place at approximately 75+00, where the silt deformation begins. The temperature at the top of the winze was -3.0°C, the bottom of winze -2.7°C, and the Gravel Room measured -2.2°C. The mechanical cooling unit was delivering approximately -5.0°C air, and it is unknown at what depth into the wall the soil temperature reaches equilibrium with the local permafrost.

Pettibone (1973) reported that in February of 1969 the gravel room was approximately -8.3°C, and in March it was -6.7°C. During the period mid-April to mid-June 1969 the temperature was -3.9°C. Linnell & Lobacz (1978) reportthat immediately after tunnel excavation the face experienced temperatures down to -9.0°C in the winter months when natural convection was being utilized through the vent system.

Temperatures measured by Wu from October 4, 1983, to February 28, 1984, show that the adit roof in the area corresponding to A4 to A7 ranged from -3.8 to -2.5°C with

Table 1. Creep measurements.

the warmest temperatures at the end of the measurement period. The winze roof temperatures in the area of W1 to W2 for the same period ranged from -5.2 to -3.1°C, again with the warmest temperatures at the end of the period. Johanssen (1993) details the beginning of silt deformation that has altered the wooden frame for the door leading into Sayles room, and he reports the rear of the adit is approaching 0.0°C. At that time the vent system was operable; therefore, this system must have become unusable after that date. It is unknown if the mechanical system has degraded over the years, but it could be assumed that the system has only decreased in efficiency.

The temperature distribution measured in May of 2006 (-3.0°C at the portal, -1.7°C rear of adit) demonstrated that the air delivered in the summer from the chilling unit and the winter ambient air from the open portal doors was not being circulated to the rear of the adit or bottom of the winze in an effective manner. Because of this, starting on July 17, 2006, air temperatures at the front of the adit near A1, back of the adit near A6, and bottom of the winze near W2 have been recorded daily. The wall soil temperature near A4 at a wall depth of 0.15 m and 1.5 m above the floor has also been measured since that time. A plot of this data from Jan. 1, 2007 to March 19, 2007 is shown in Figure 3. Previous studies (Wu 1985, Law 1987) have shown considerable seasonal temperature variations of approximately 4°C, and daily variations of up to 1.0°C, and this was confirmed by our measurements.

Discussion

The larger scale deformation that has been occurring in the CRREL Tunnel for the last two decades appears to be attributable to the gradual increase in tunnel temperatures due to air-handling issues. No measurements or comparisons have been made to determine if a correlation exists with recent climate change. In an effort to slow deformation, a portable blower unit with 45 cm -diameter flexible ducting delivering approximately 0.55 m^3/sec was placed outdoors of the portal and routed approximately 60 m down the adit in February of 2007. The blower unit was moved inside the tunnel under the chilling unit when the chilling unit was turned on for the summer season. The point in time when the blower was first added is shown in Figure 3, and the temperatures decreased substantially to -7.5°C at the back of the adit by March 19, 2007, twelve days prior to the second creep reference location measurements. The temperatures during the third creep reference location measurements on July 29, 2007, averaged -3.5°C for the air near station A6. The creep rate at the rear of the tunnel has slowed by a factor of approximately 3 from the second measurement to the third, and the rate for the winze locations during the same period has slowed by approximately a factor of 2. This creep rate reduction corresponds with the modifications to the cooling system.

To illustrate temperature sensitivity in the near freezing range from -2.0° to -1.0°C for ice-rich fine-grained soil, we compare three uniaxial constant-stress tests (creep) conducted by the author on intact CRREL Tunnel cores

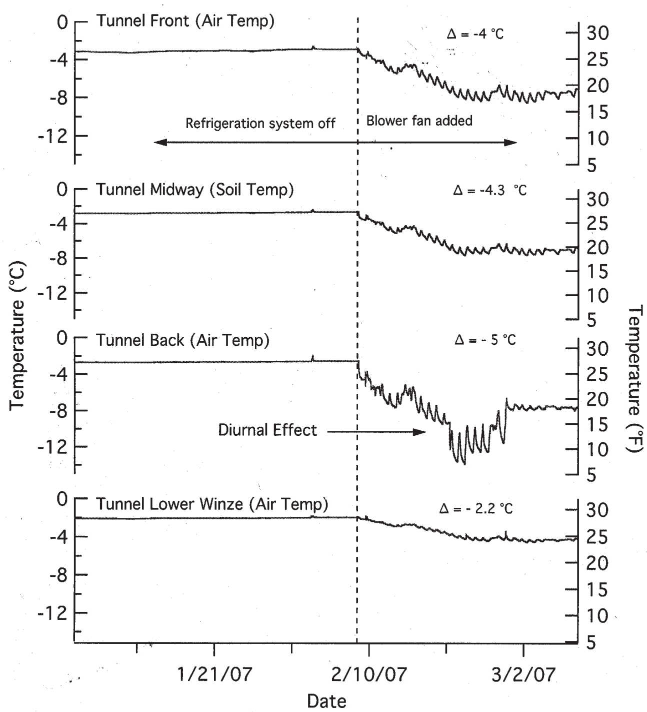

Figure 3. Tunnel facility temperatures.

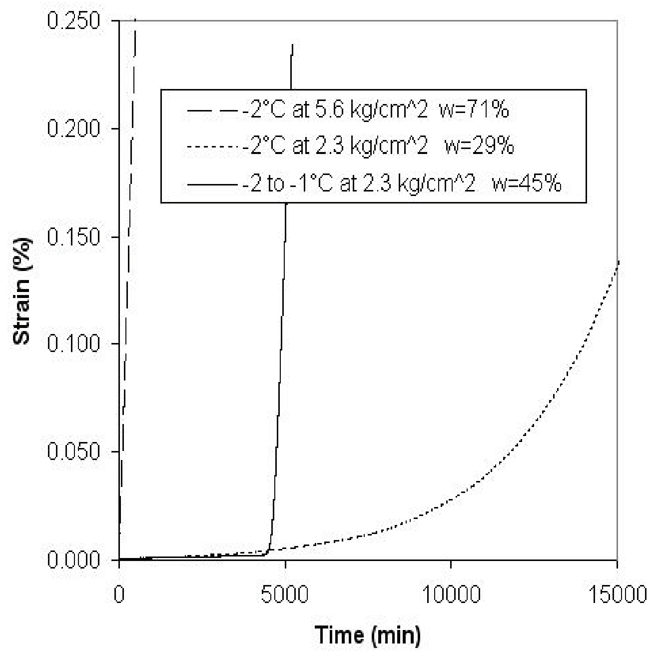

Figure 4. Temperature dependence of tunnel silt.

measuring 100.0 mm in length and 55.0 mm in diameter. These cores were taken from the left wall at approximately 74+00 and 0.3 m above the floor. One test was conducted at an axial stress of 5.6 kg/cm^2, and the second at 2.3 kg/cm^2 (approx. stress due to overburden), both at a constant -2.0°C. The third test was conducted at 2.3 kg/cm^2 with a temperature step from -2.0 to -1.0°C at 4500 min. For the third test the strain rate accelerates from 4.0 x 10^{-9} (s^{-1}) to 3.0 x 10^{-6} (s^{-1}) in 18 hr (Fig. 4).

In another example of temperature sensitivity, Zhu & Carbee (1987) conducted uniaxial constant-stress tests with remolded CRREL Tunnel silt. For medium density samples of approximately 1.2 g/cm^2 and moisture contents of 43%, it was found that for an applied stress of approximately 7.0 kg/cm^2, the time to failure dropped from 29,000 min at -2.0°C, to 70 min at a temperature of -1.0°C.

Conclusions

The adit deformation coincides with the reduction of facility cooling via natural convection and forced mechanical chilling, which has raised the rear adit air temperature to near freezing. This is in comparison to temperatures measured after excavation in the late 1960s. In addition it appears the rear of the adit is composed of a higher density of cryological structures than is evident in the rest of the facility. Exactly how the structural integrity of the frozen silt with emplaced massive ice bodies is affected by warmer temperatures is at best very complex. However, it can be assumed that across the soil mass as a whole, the non-homogenous thermal conductivity and strength properties due to these ice bodies, and the silt deformation caused by the emplacement, only serves to weaken the total soil mass, especially at the soil/ice margins.

This higher density of massive ice features is coincident with a change in soil gradation towards the rear of the adit, from poorly-graded silt, to poorly-graded silt with interbedded layers of larger grain size, resulting in preferentially weaker -bonded frozen soil. These weaker bonds and massive ice/soil margins are the location for detachment when the temperature is raised to near zero.

The winze and Gravel Room experience warmer temperatures than historical for the same reasons as the adit. These warmer temperatures have weakened the bond between the frozen gravel comprising the roof and the silt unit above, causing detachment during a past dynamic event. These warmer temperatures, large roof span, and historical parting studies have contributed to this parting.

Due to the addition of the blower and ductwork, there has been a reduction in rear adit temperature to an average -7.0°C for the winter months, and -3.5°C for the summer months, which has reduced the creep movement by a factor of 3. The temperature reduction in the winze has reduced the creep by a factor of 2. Continued reduction of the temperature to a maximum of -5.0°C for all portions of the facility during all seasons would be expected to reduce the deformation to the slower rates experienced prior to the extreme deformation of the rear of the adit.

Acknowledgments

Stephanie Saari and Art Gelvin of CRREL contributed greatly to the information provided in this report. The tunnel upgrades and ongoing data collection would not have been as successful and efficient without their specific and dedicated technical expertise.

Also, we wish to thank Dr. Gang Chen of the University of Alaska Fairbanks, Department of Mining Engineering, and Dr. Scott Huang of the University of Alaska Fairbanks, Department of Geological Engineering, for the use of the tape extensometer and general comments.

Abstract

Only 0.35% (49,800 km²) of Antarctica is ice-free. We have divided the continent into nine major ice-free regions and estimated the distribution of permafrost by form: (i) buried ice within the upper 100 cm; (ii) ice-cemented permafrost with the surface within the upper 70 cm; (iii) ice-cemented permafrost with the surface below 70 cm; and (iv) dry-frozen permafrost with the surface below 70 cm. For each of these categories, permafrost distribution was divided into continuous, discontinuous, and sporadic or no permafrost. Based on preliminary analysis, 43% of the ice-free areas contain ice-cemented permafrost in the upper 70 cm, followed by dry-frozen permafrost (41%), and buried ice (13%). Permafrost is continuous throughout East Antarctica and along the Antarctic Peninsula and the surrounding islands at elevations generally above 40 m a.sl. Along the Antarctic Peninsula, discontinuous permafrost exists at elevations between 40 and 20 m a.s.l, and permafrost is either sporadic or lacking below 20 m a.s.l.

Keywords: ANTPAS; Antarctica; dry-frozen permafrost; ice-cemented permafrost; permafrost mapping.

Introduction

Only 0.35% or 49,800 km² of the Antarctic region (≥60ºS) is ice-free (Fig. 1). At 24,200 km² the Transantarctic Mountains (TAM), which extend 2,600 km from North Victoria Land (69ºS) to the Roberts Massif in the upper Scott Glacier region (86º30′S), are the largest ice-free area (Table 1).

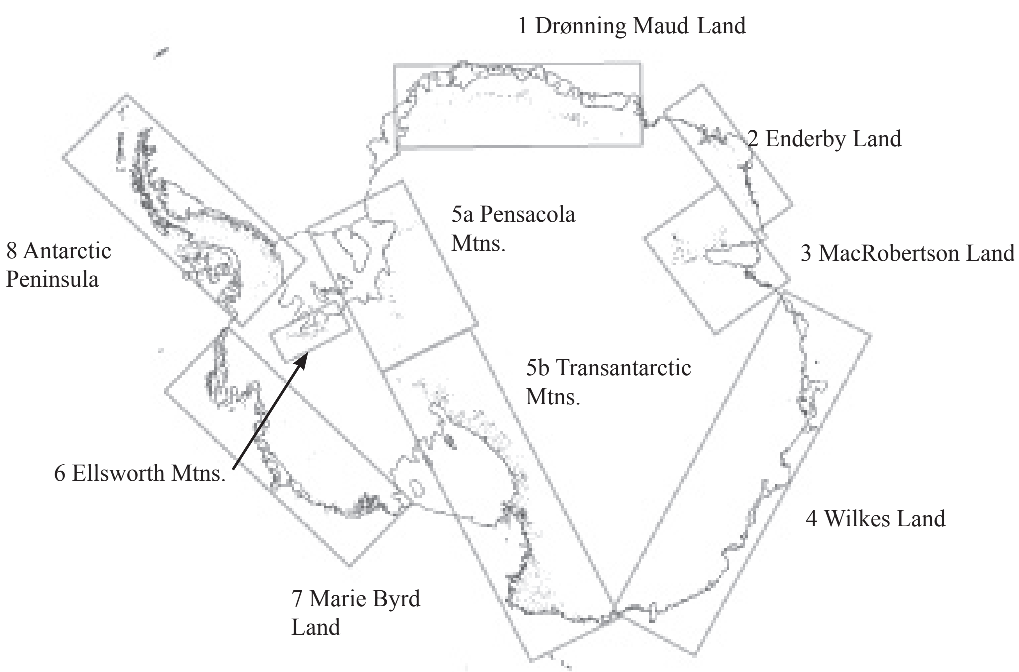

Figure 1. Major ice-free regions of Antarctica (after Greene et al. 1967). Ice-free areas are shown with dots, with each dot accounting for 15 km². Areas delineated using the Antarctic Digital Database V. 4.0 and ArcGIS V. 9.1 by D. Smith of the Australian Antarctic Division.

The Antarctic Peninsula and its offshore islands constitute the next largest ice-free region at 10,000 km2 (Table 1), followed by MacRobertson Land, Drønning Maud Land, and the Ellsworth Mountains. The Pensacola Mountains, Enderby Land, Marie Byrd Land, and Wilkes Land each contain 1500 km2 of ice-free area, or less.

Bockheim (1995) prepared the first permafrost map of ice-free areas in Antarctica. He showed that permafrost was limited to ice-free areas and that all of East Antarctica and most of West Antarctica contain continuous permafrost. Discontinuous permafrost was present from 66ºS to 63ºS along the Antarctic Peninsula and its offshore islands. Sporadic permafrost was limited to the South Orkney Islands. Zotikov (1963) showed the distribution of subglacial permafrost in Antarctica.

The following is a review of permafrost conditions in Antarctica by region. In the Sør Rondane Mountains of Drønning Maud Land (region 1), ice-cemented permafrost occurs at depths ranging from 7 to 80 cm, and dry permafrost is common (Sekyra 1969, Vtyurin 1986, Matsuoka et al. 2006). McNamara (1969) reported the top of ice-cemented permafrost at 75 cm in Enderby Land (region 2) and a limited amount of dry-frozen permafrost. Since the climate in MacRobertson Land (region 3) is comparable to that of Enderby Land, we suggest that the permafrost conditions are likewise comparable. It is likely that dry-frozen permafrost exists in the southern Prince Charles Mountains. Wilkes Land (region 4) contains two major ice-free areas, the Bunger Hills and the Windmill Islands. According to Blume & others (2002), the top of ice-cemented permafrost occurs at 30 to 80 cm throughout the Windmill Islands.

Observations from the Pensacola Mountains (region 5a) (Parker et al. 1982) imply that the ice-cemented permafrost surface occurs at 20 to 45 cm. In that dry-frozen permafrost exists in the Ellsworth Mountains, which occur at a similar latitude and proximity to the Ronne Ice Shelf, it is likely that dry-frozen permafrost exists in portions of region 5a.

For convenience we subdivided the Transantarctic Mountains (TAM; region 5b) into three subregions based on latitude: North Victoria Land (69º30′–75ºS), the central TAM (75º–80º30′S), and the southern TAM (80º30′–86º30′S). Campbell & Claridge (2006) reviewed permafrost properties throughout the TAM, noting that the active layer ranges from <5 cm in inland and upland regions to 80 cm in coastal areas. The moisture content of ice-cemented permafrost is greatest in coastal areas, where snowfall and regelation are common, and lowest in inland areas, where the moisture content may be <1%. In North Victoria Land (NVL), the active layer ranges from 10 to 30 cm in thickness (Guglielmin 2006). Whereas ice-cemented permafrost and buried ice are common, dry-frozen permafrost was not observed in NVL (Guglielmin & French 2004). However, in the Rennick Glacier-Talos Dome areas of interior NVL, ice-cored moraines are common beside blue-ice glacier margins (Denton et al. 1986). Elsewhere the surface of ice-cemented permafrost occurs at 8 to 70 cm; dry-frozen permafrost exists in the Morozumi Range.

Early permafrost studies in the central TAM largely were limited to observations and measurements of the growth of patterned ground (Berg & Black 1966, Black 1973), and core logs collected in 1970–1975 during the Dry Valley Drilling Project (DVDP) (McGinnis 1981). Using a combined dataset that included nearly 1000 shallow (<1.5 m) excavations, Bockheim & others (2007) provided a map at a scale of 1:2 million showing the distribution of permafrost in the MDVs. Their data suggested that about 55% of the permafrost was ice-cemented, 43% was dry-frozen, and buried ice comprised at least 2% of the ice-free area. Permafrost form was related to climatic zone, age of sediments, and local site factors.

The Ellsworth Mountains (region 6) can be divided into the Heritage Range, which contains localized areas of glacial drift, and the Sentinel Range, which contains primarily arétes and nunataks (Denton et al. 1992). We were unable to find information about permafrost conditions in Marie Byrd Land (region 7).

The Antarctic Peninsula (region 8) can be divided into five latitudinal subregions: (1) Palmer Land and Alexander Island (68–76ºS), (2) Graham Land and the Palmer Archipelago (63–68ºS), (3) the James Ross Archipelago (65º30–67ºS), (4) the South Shetland Islands (61–63ºS), and (5) the South Orkney Islands (60–61ºS). Permafrost depths bear a strong relation to latitude along the Antarctic Peninsula. Along the Trinity Peninsula and offshore islands, the surface of ice-cemented permafrost occurs at 25 cm (Everett 1976). In the South Shetland Islands, the top of ice-cemented permafrost exists at 25 cm to more than 100 cm, with about 50% of sites examined having permafrost in the upper 70 cm (López-Martínez et al. 1996, Serrano et al. 1996, Bölter et al. 1997, Blume et al. 2002, López-Martínez & Serrano 2002, Vieira et al. 2007). The surface of ice-cemented permafrost occurs at 40 to 200 cm in the South Orkney Islands (Holdgate et al. 1967, O'Brien et al. 1979).

To address the need for a permafrost map for Antarctica, a joint committee was appointed at the Seventh International Conference on Permafrost in Zurich by the International Permafrost Association (IPA) and the Scientific Committee on Antarctic Research (SCAR). In November 2004 the International Workshop on Antarctic Permafrost and Soils, sponsored by the U.S. National Science Foundation, was held in Madison, Wisconsin. A task force under the auspices of ANTPAS, the Antarctic Permafrost and Soils group (http://erth.waikato.ac.nz/antpas/) was established to begin preparing a permafrost and ground-ice map of Antarctica, with subgroups responsible for key ice-free areas. This manuscript is in response to this mandate and is intended to accompany these maps.

Methods

Ice-free areas in Antarctica, defined here according to the Antarctic Treaty (http://www.scar.org/treaty) as all lands >60ºS, were delineated using the Antarctic Digital Database version 4.0 (http://www.add.scar.org/) and ArcGIS 9.1 by D. Smith of the Australian Antarctic Division. Ice-free areas were divided into nine regions using the subdivisions of

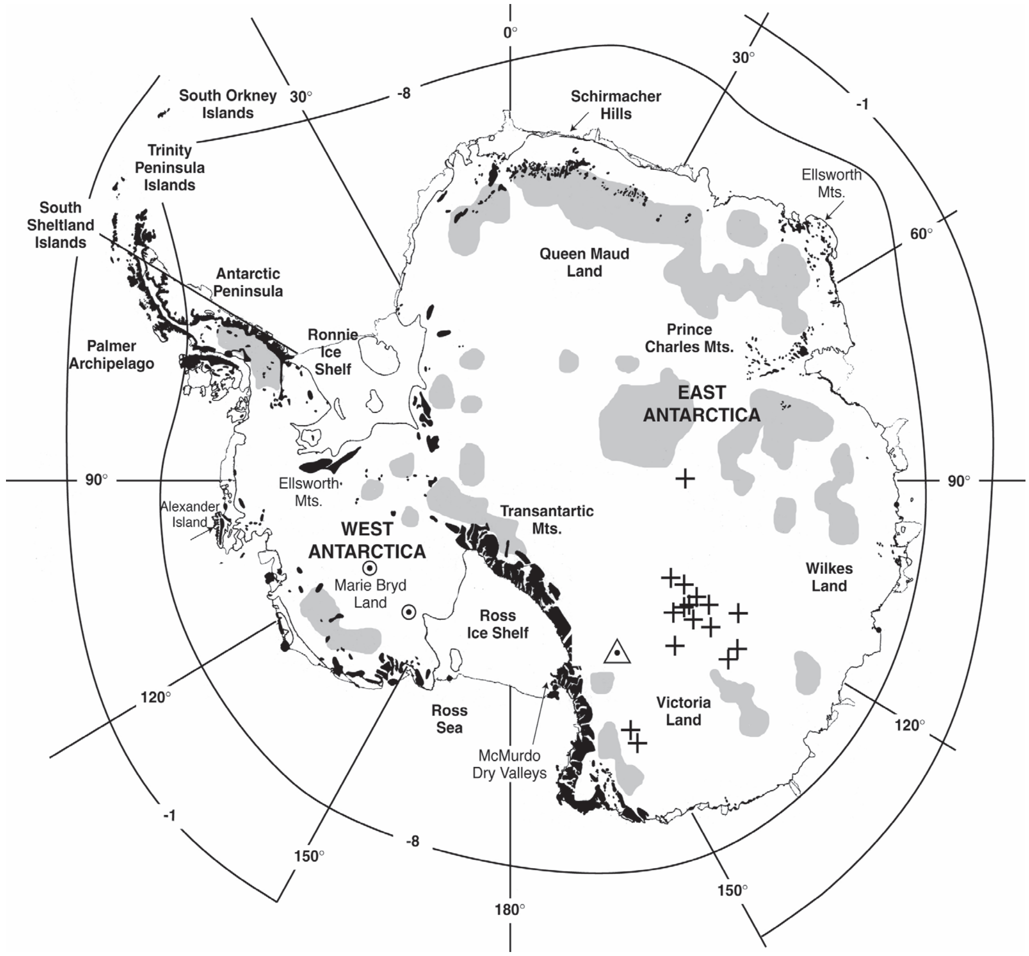

Figure 2. Provisional distribution of permafrost in Antarctica. Ice-free areas are shown in black; grey areas represent the likely location of subglacial permafrost; and crosses indicate the existence of subglacial lakes. The -1°C and -8°C isotherms represent the likely distribution of discontinuous and continuous permafrost, respectively, based on correlations from the Northern Hemisphere (Bockheim 1995).

Greene & others (1967) (Fig. 2). Expert permafrost scientists working in Antarctica were contacted and asked to assist in preparing the following legend: (i) buried ice within the upper 100 cm; (ii) ice-cemented permafrost with the surface within the upper 70 cm; (iii) ice-cemented permafrost with the surface greater than 70 cm; and (iv) dry-frozen permafrost with the surface below 70 cm. For each of these categories, permafrost distribution was divided into

(i) continuous, (ii) discontinuous, and (iii) sporadic or no permafrost. The legend included a color scheme for permafrost maps. In Antarctica, the active layer either grades into ice-cemented permafrost or, in dry areas, into dry-frozen permafrost. In the latter case, the active layer can only be differentiated from dry-frozen permafrost from temperature monitoring.

The distribution of permafrost form by region was determined from the ANTPAS database for regions 4, 5b, 6, and 8 (Table 1). To determine permafrost distribution for the remaining regions, we utilized published data from regions 1, 2, 3, and 7 and inferences from diagnostic ground criteria for regions 5b and 7. These criteria included a stippled pattern and medial moraines on 1:250,000 topographic maps for ice-cored drift and strongly developed patterned ground on high-resolution land satellite images and proximity to stream, lakes, and ponds for ice-cemented permafrost. The remaining areas, particularly in interior mountains and broad central valleys, were assigned to dry-frozen permafrost. The 20 m contour was used to delineate areas where the top of ice-cemented permafrost occurred below 70 cm along the Antarctic Peninsula and its offshore islands.

We were unable to locate sufficient permafrost information for mapping regions 2 (Enderby Land), 3 (MacRobertson Land), 5a (Pensacola Mountains), and 7 (Marie Byrd Land); however, we provide brief summaries of information existing for these areas. Maps (not included in this brief report) were developed for the more-studied regions 1, 4, 5b, 6, and 8, which account for about 38,000 km2 or 85% of the ice-free areas in Antarctica. Because of insufficient data, we were unable to show permafrost thickness and temperatures on the maps.

Results

More than 80% of the ice-free area of Antarctica contains continuous permafrost (Table 2). Discontinuous and sporadic permafrost occurs only along the tip of the Antarctic Peninsula and its offshore islands.

The dominant permafrost form is ice-cemented permafrost within 70 cm of the surface, accounting for 43% of the ice-free area in Antarctica. Ice-cemented permafrost is prevalent in coastal areas, including Wilkes Land, Enderby Land, and the Antarctic Peninsula and its offshore islands, and accounts for 60%–93% of the area (Table 2). In terms of total area, ice-cemented permafrost within 70 cm of the surface is most abundant in the Transantarctic Mountains (8000 km^2) and the Antarctic Peninsula (6000 km^2).

Dry-frozen permafrost accounts for 41% of the total ice-free area (Table 3) and is most abundant in Queen Maud Land, the Pensacola Mountains, and the Ellsworth Mountains, accounting for 59%–65% of the area (Table 1). The Transantarctic Mountains contain 11,600 km^2 of dry-frozen permafrost, 57% of the total area.

The total area of buried ice is not completely known. We suggest that this form of permafrost comprises 13% of the total ice-free area (Table 2). Buried ice is most abundant in the Transantarctic Mountains and along the Antarctic Peninsula. Deep (>70 cm) ice-cemented permafrost primarily occurs in coastal areas of East Antarctica and along the Antarctic Peninsula

Discussion

Permafrost is dominant in ice-free areas of Antarctica, which contain till-covered and bedrock surfaces occupying 49,800 km^2 of the entire continent. The distribution of permafrost in continental Antarctica is continuous except along the outer Antarctic Peninsula (ca. ≤63ºS) with the

northern boundary roughly following the -8ºC isotherm for mean annual air temperature. Recent findings (Serrano & López-Martinez 2000, Vieira et al. 2006) have validated Bockheim's (1995) proposal that the southern limit is defined by the -1ºC isotherm for mean annual air temperature. In the South Shetland Islands discontinuous permafrost exists at elevations between 40 and 20 m a.s.l, and permafrost is either sporadic or lacking below 20 m. In this area, altitude, topography, soil characteristics, and slope orientation affect permafrost occurrence and distribution.

In the South Shetland and South Orkney Islands, the active layer thickness appears to be strictly related to surface characteristics such as snow distribution and vegetation type and coverage (Cannone et al. 2006).

Ice-cemented permafrost within the upper 70 cm is the dominant form in Antarctica, accounting for 43% of the ice-free area. This type of permafrost occurs in coastal areas and adjacent to water bodies and on predominantly younger land surfaces throughout the continent. Dry-frozen permafrost is unique to Antarctica and occurs on predominantly older land surfaces especially in broad valleys in the McMurdo Sound area and inland mountains throughout the continent. It accounts for 41% of the ice-free area. Buried ice is ubiquitous in Antarctica in ice-cored moraines of Holocene age along major outlet glaciers and the coast. Ice buried by drift occurs along the Polar Plateau. Buried ice overlain by ablation till occurs sporadically and in places in thought to be of Miocene age (Sugden et al. 1999).

Conclusions

This text is intended to accompany maps at different scales depicting permafrost and buried ice of the Antarctic region (≥60ºS). Based on our analysis, 43% of the ice-free areas contain ice-cemented permafrost in the upper 70 cm, followed by dry-frozen permafrost (41%), and buried ice (13%). Permafrost is continuous throughout East Antarctica and along the Antarctic Peninsula and the surrounding islands at elevations above 40 m. Discontinuous permafrost exists at elevations between 40 and 20 m, and permafrost is either sporadic or lacking in coastal areas below 20 m.

Abstract

With potential development of the Mackenzie Gas Pipeline in northern Canada, it becomes increasingly necessary to understand all aspects of the permafrost environment affected by this project. A major concern with development is terrain disturbance within the Kendall Island Bird Sanctuary, resulting in an alteration of the subsurface thermal regime. Warming of the subsurface could lead to the melting of excess ground ice causing further subsidence. A combination of Ground Penetrating Radar (GPR) and remote sensing data were used to map the distribution of excess ground ice. The volume of wedge ice was calculated and then combined with a high-resolution digital elevation model to determine the location and amount of potential subsidence that could be induced by melting of subsurface excess ground ice. Although the distribution of excess ice in the Big Lake area is not uniform, its presence is substantial enough that melting may result in significant terrain alteration.

Keywords: Big Lake; digital elevation model; ground penetrating radar; ground subsidence; ice wedges; Mackenzie Delta.

Introduction

Several large hydrocarbon fields have been discovered in the Mackenzie Delta area, NWT, Canada (Fig. 1). One of these is the Taglu gas field which is estimated to contain 2.8 trillion cubic feet of natural gas and natural gas liquids (Imperial Oil Resources Limited 2004). The Taglu field is located within the Kendall Island Bird Sanctuary. Alteration of the landscape in this area could alter sensitive bird habitat.

There is concern that with alteration of the landscape there will be a disturbance of the subsurface thermal regime which could lead to the melting of ground ice. The objective of this research is to estimate the volume of ice contained within ice wedges in order to calculate the potential subsidence and terrain disturbance that could result from the warming of the subsurface. This study focuses solely on ice wedges as they contribute to significant volumes of excess ice in the study area.

Ice wedge formation has been widely studied (Mackay 1974, Murton & French 1993, Murton 2001). However, estimating ice wedge volume has remained difficult as measuring the depth and shape in the subsurface is usually limited to coring. Obtaining core data is expensive and logistically very difficult at Big Lake, so alternative methods were used in an attempt to quantify ice wedge volume. Their linear dimensions and width are in some cases relatively easy to measure photogrammetrically, but their depth is difficult to measure by drilling due to the narrow shape of the wedge.

Previous studies (Arcone et al. 1982, Kasper 1996, Hinkel et al. 2001, Fortier & Allard 2004, Munroe et al. 2007) have shown that it is possible to identify the location of ice wedges using Ground Penetrating Radar (GPR). However, estimates of ice wedge volume have not been determined using GPR. For this project we use GPR and a geographic information system to measure the length, width, and depth of the ice wedges and estimate the total volume of ice and maximum potential subsidence.

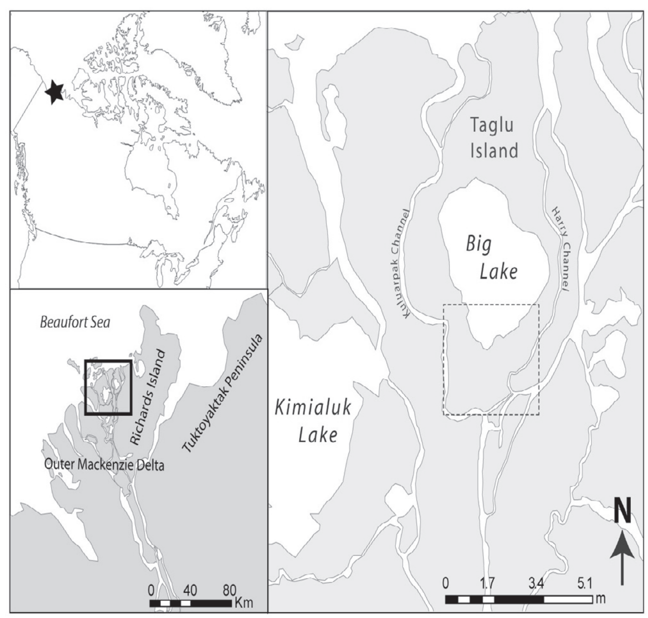

Figure 1. Location of the study area in the outer Mackenzie Delta, NWT, Canada. The study site, located south of Big Lake, is outlined with a dashed line.

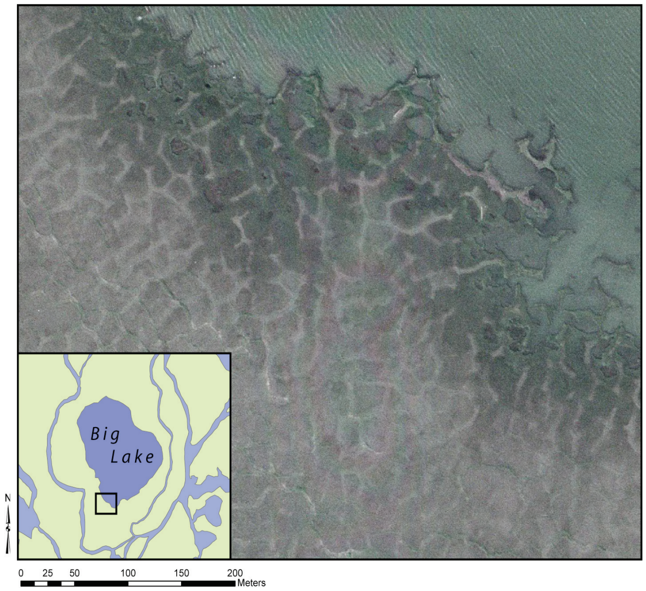

Figure 2. A portion of the aerial photo that shows the surficial expression of ice wedges in the southern portion of Big Lake.

Excess Ground Ice and Land Subsidence

Extraction of natural gas, and subsequent reduction of reservoir pressure, has previously been shown to cause subsidence of the overlying sediment (Geertsma 1973, Doornhof 1992, Teatini et al. 2005). At the Taglu site subsidence from gas extraction is estimated to be a maximum of 0.38 m in the center of the subsidence bowl (Haeberle et al. 2004). However, these estimates do not account for the thawing of permafrost and melting of excess ground ice (Haeberle et al. 2004, Haeberle et al. 2005). The center of the subsidence bowl is located just south of the southern shore of Big Lake; therefore it is likely that subsidence will lead to inundation of the surrounding terrain and expansion of the lake. With inundation, the water will act as a heat source and warm the subsurface (Williams & Smith 1989). If excess ground ice is present, a warming of the subsurface could result in a positive feedback mechanism of excess ice melt causing further subsidence.

Study Area

The Mackenzie Delta is the second largest arctic delta in the world and is a product of the largest river in Canada, the Mackenzie River. The delta is composed of many islands one of which is Taglu Island (Fig. 1). This region of the delta was likely ice free around 12.5 ka BP (Duk-Rodkin & Lemmen 2000). Permafrost beneath the Island extends 500–620 m (Taylor et al. 2000). On the southern tip of Taglu Island a Circumpolar Active Layer Monitoring (CALM) grid indicates an average active layer depth of 95 cm (average from 1998–2002)(Brown et al. 2003). Shallow drilling data indicated fine-grained sand overlain by silt and a thin layer of organic peat. Excess ground ice in the form of ice lenses ranges from 20–50% by volume in the upper 6 m (Traynor & Dallimore 1992).

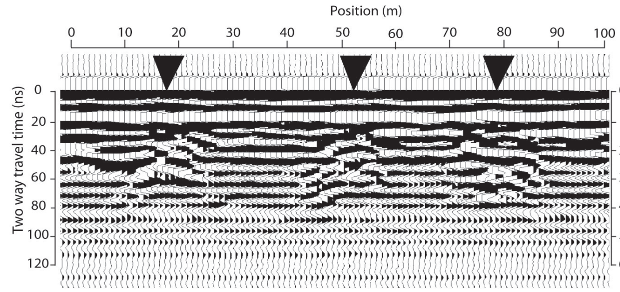

Figure 3. A 100 MHz GPR profile that shows the location of ice wedges. The ice wedges are indicated by the triangles above the profile.

The most prominent feature of Taglu Island is Big Lake which occupies 25% of the island (Fig. 1). Big Lake lies between two levees created by Kulurpak channel to the west and Harry channel to the east. The low lying land surrounding the lake is periodically flooded in the spring when the river overtops the levees. Flooding also occurs in the fall due to flooding from infrequent storm surges. However, Big Lake is cut off from the main channel for most of the year making it a low closure lake (Mackay 1963). The lake is surrounded by low centered, (Traynor & Dallimore 1992) non-oriented ice wedge polygons with an average diameter of approximately 20 m.

This study focuses on the southwestern shore of Big Lake where the estimated subsidence bowl is centered and the largest amount of data is available. The borders of the study area were determined by the availability of elevation data and the extent of the modeled subsidence bowl.

Methods

Volumetric estimates of ice wedges have previously been determined using aerial photos (Pollard & French 1980). However we use a combination of remote sensing and geophysical data to estimate the volume of ground ice. Aerial photography was used to determine the length and width of the ice wedges (Fig. 2) and GPR data were used to determine ice wedge depth. From these three variables, the volume of ice can be estimated using:

$$V = ½ * L * W * (D-D_{AL}) \qquad (1)$$

where L is the total length of ice wedges visible on the aerial photographs, W is the average width of the ice wedges, D is the average depth of the ice wedges, and D_{AL} is the average active layer depth. This is assuming a triangular cross-section of the ice wedges. Field observations from the study area suggest that a triangular cross-section is a reasonable assumption (Mackay 1963).

The GPR response to ice wedges is based on the dielectric contrast between frozen sediment and ice. Radar patterns produced by ice wedges include secondary reflections from the reverberation of energy within the ice and hyperbolic reflections from the wedge acting as a point source (Arcone et al. 1982). Hyperbolas are frequently centered at the top

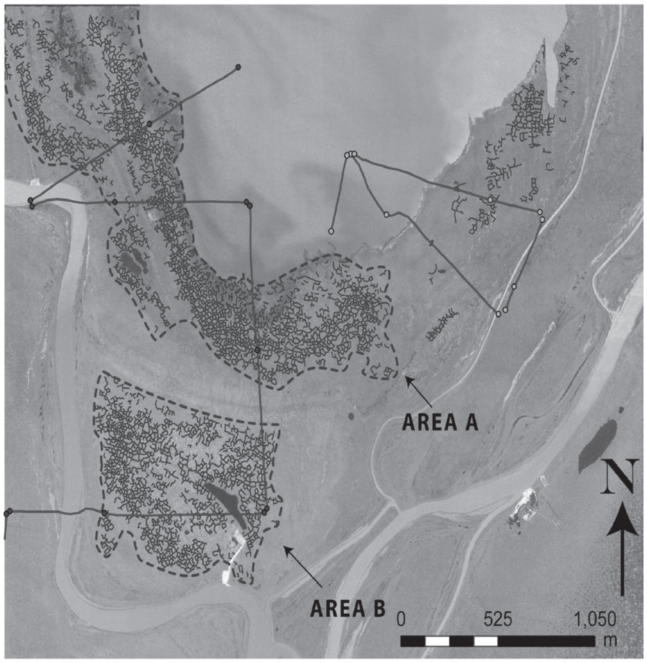

Figure 4. All the ice wedges digitized in the study area. The two areas where ice wedges are concentrated are outlined with the dashed line. Area A is the focus of this paper. The GPR transects surveyed in this study are indicated by the solid black lines.

(Fig. 3) and at the base of the ice wedge (Fortier & Allard 2004).

In March of 2007, GPR data was collected at the Taglu site using a PulseEKKO 100 with 100 MHz antennas and a 400 V transmitter. The GPR antennas were pulled behind a Tucker Sno-Cat® traveling at a constant speed of 5 km/hr. The vehicle was able to keep a steady speed higher than the resolution of the GPS. Data were collected in continuous mode and the average step size was 0.9 m. A total of 22 GPR transects were collected around the southern half of Big Lake (Fig. 4). The location of the GPR transects was determined with a GPS receiver that automatically tagged every trace with its position and elevation as it was collected. An average velocity for frozen sediment (0.1 m/ns) was used to convert travel time measurements to calculated radar depth.

Aerial photographs (Indian and Northern Affairs Canada 2004) of the southern portion of Taglu Island were used to identify the spatial extent of ice wedges (Fig. 4). The photographs were taken in August 2004 and have a resolution of 1.25 m. Every ice wedge was digitized to measure the length, which was used to calculate the total length of all visible ice wedges within the study area. To determine the average width, the trough of the ice wedge was measured from aerial photos. The trough width is not always equal to the actual ice wedge width however they are often comparable as shown in the data of Kokelj et al. (2007). Measurements were made at the mid-point between the junctions of the ice wedge using the measure tool in ArcGIS.

Ice wedge depths were calculated from the hyperbolic reflections caused by the base of the wedge. The depth to the bottom of the ice wedges was more difficult to determine since it was not always possible to interpret the basal reflections of the wedges from the GPR profile.

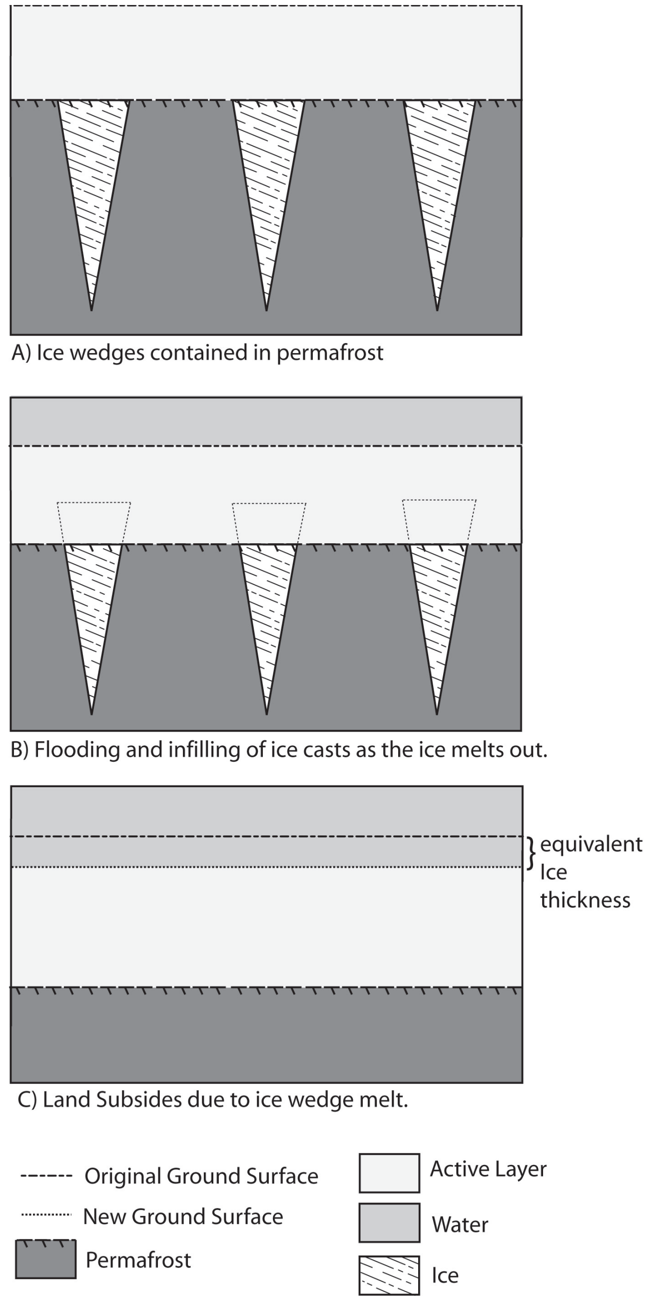

Figure 5: Schematic illustration of ground subsidence caused by flooding of the landscape (A), deepening of the active layer (B), and melt of the equivalent ice thickness (C).

Here we consider the worst-case scenario where all of the volume of ice melts. Little research has been conducted to address the nature of ground subsidence caused by ice wedge degradation. Therefore, a uniform approach to ground subsidence was adopted. The term *equivalent ice thickness* was used to represent the estimated volume of ice wedge ice uniformly distributed over the study area (Fig. 5). The ice wedge volume was divided by the total area underlain by ice wedges in Area A to determine the equivalent ice thickness. The equivalent ice thickness was then applied uniformly over Area A and subtracted from a digital elevation model

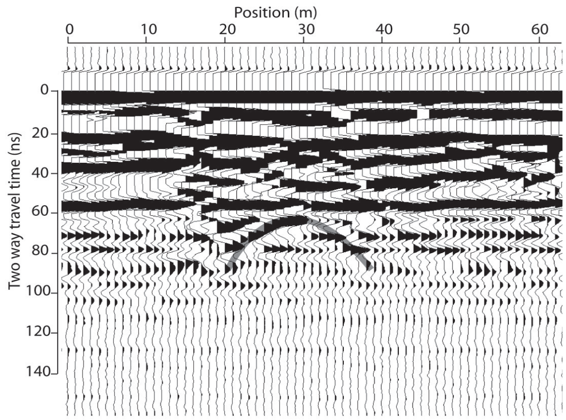

Figure 6. A portion of a GPR transect that shows the bottom of an ice wedge (highlighted). The bottom of the ice wedge is at the top of the hyperbola.

(DEM). The draft version of a DEM created from 1:30,000 air photos was obtained from the Northwest Territories Centre for Geomatics. The vertical accuracy of the DEM is ±1.5 m and is therefore not sufficient to obtain accurate results of subsidence due to ice wedge melting. However, we use it here for illustrative purposes since it is the best available dataset. DEMs developed from LiDAR are more appropriate for these types of analyses, but there are no publicly available data for this location.

Results

The ice wedges in the study area were primarily concentrated in two locations; the southwestern edge of Big Lake (Area A) and the southern portion of Taglu Island (Area B) (Fig. 4). Since the area of ice wedges closest to Big Lake would be most affected by lake expansion, Area A was the focus of this investigation. The total area of Area A is 2,940,040 m^2. The total length of ice wedges in this area was 95,525 m. The average width of the ice wedges was 3.9 m ±0.5 m (n = 225, max. = 5.8 m, min. = 1 m). The ice wedges ranged from 3.5 to 4 m in depth (n = 12) (Fig. 6). Minimum and maximum subsidence scenarios were both calculated as the number of ice wedge depth measurements was limited.

Using Equation 1 the volume of ice in Area A was calculated to be 471,655 m^3 using the minimum depth estimate and 754,650 m^3 using the maximum depth estimate. These volumes were then divided by the total area of Area A to calculate equivalent ice thicknesses of 0.17 m and 0.27 m for the minimum and maximum scenarios.

Figure 7 illustrates the effect of surface subsidence from the melt out of ice wedges on surface topography and shore location.

Discussion

The potential resultant area flooded by the melt out of ice wedges is likely to be irregular in character; however, with a uniform subsidence using the previously discussed equivalent ice thicknesses, a minimum of 274,790 m^2 of land would be flooded by ice melt alone (Fig. 7). With the

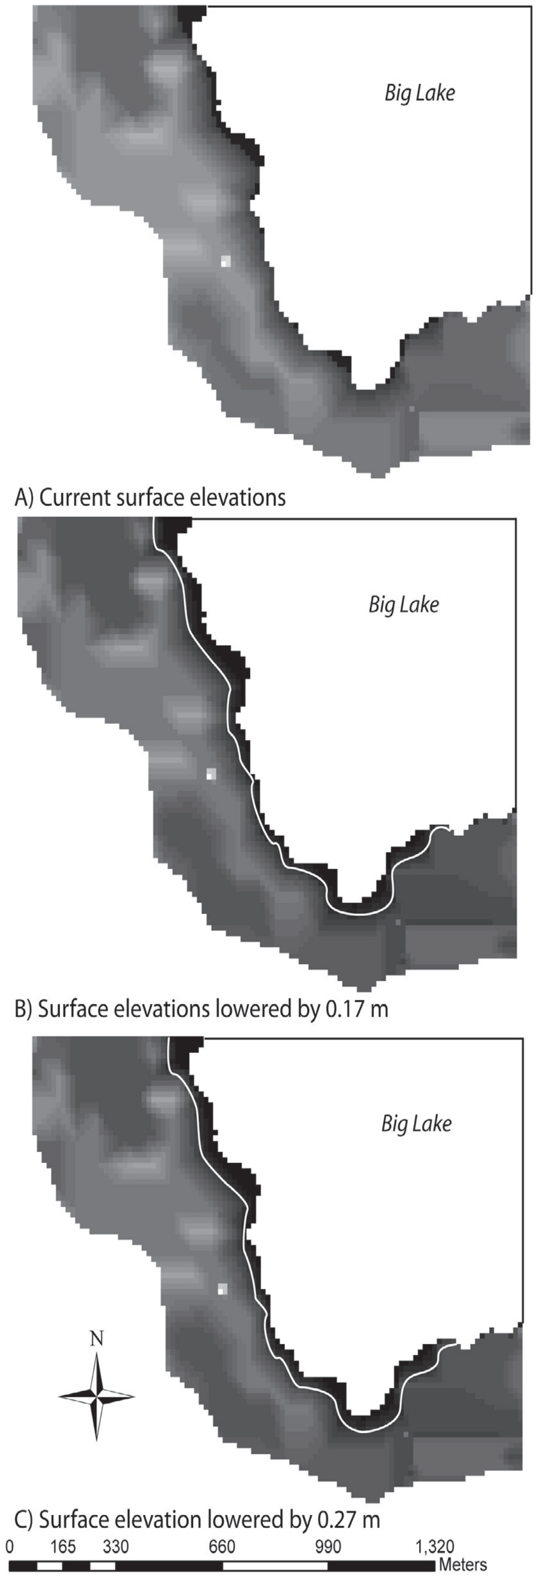

Figure 7. Topography of Area A to the southwestern edge of Big Lake. A) Displays the current terrain elevations (Northwest Territories Centre for Geomatics 2004), B) surface elevations minus 0.17 m and C) surface elevations minus 0.27 m. The 0.9 m white line in B and C indicates the extent of lake expansion. The water level at Big Lake, according to the dataset is 0.9 meters above sea level (m a.s.l.) therefore anything below 0.9 m a.s.l. will become flooded.

Figure 8. Flooded ice wedge polygons in the Mackenzie Delta. Subsidence appears to be spatially variable.

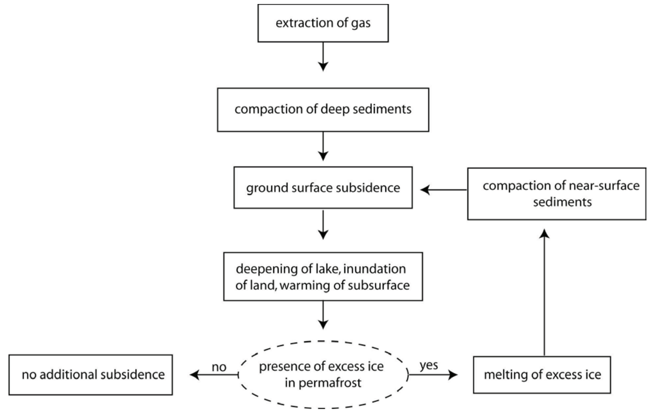

Figure 9. Flow chart illustrating the positive feedback that could be initiated by ground subsidence induced by natural gas extraction.

maximum depth scenario 343,715 m^2 would be flooded. The shoreline would move inland by over 75 m in some locations. These estimates are based on land below 0.9 m a.s.l. becoming flooded as that is the lake level from the DEM. Under a scenario of irregular subsidence concentrated at the zones immediately surrounding the central axes of the wedges, much greater flooding would occur reaching completely across Area A. Figure 8 illustrates another area in the Mackenzie Delta where irregular flooding of ice wedge polygons has occurred.

This study focused only on a small area on the southern part of Taglu Island due to the availability of elevation data and imagery. Ice wedges can also be seen on the northern portion of Taglu Island, therefore there is potential for ice wedge melt and flooding over a greater area surround the lake. Additionally, smaller bodies of ice, such as ice lenses, were resolved from GPR profiles. These ice lenses, if melted, would also cause ground subsidence.

For this initial estimate, subsidence was calculated using the equivalent ice thickness, therefore, the spatial variability in ice content is not taken into account. The actual character of subsidence may play a significant role in determining the resultant topography and the extent of flooding. Additionally, it is possible that the ice at depth could be maintained even with a deepening of the active layer. Consequently, we have calculated the worst case scenario where ice wedges completely melt. It should also be noted that these maps do not take into account the modeled subsidence bowl caused by natural gas extraction, as discussed earlier.

If considering the compounded effects of ground subsidence caused by both ice wedge melt and natural gas extraction over half of the study area would be flooded. Subsidence caused by gas extraction is estimated to be up to 0.38 m (Haeberle et al. 2004). If this subsidence were to occur a positive feedback loop could be initiated (Fig. 9). With initial subsidence, flooding could occur causing melt of excess ground ice leading to further subsidence and flooding. However, it must be acknowledged that there is also the potential that permafrost and ice wedges could remain stable and potentially even cool if flooding remains shallow.

Although the objectives of this research focused on assessing subsidence due to ice wedge melt, there are other potential causes of terrain disturbances. For example, climate warming could cause a deepening of the active layer and the melting of ground ice. Eustatic sea level rise and changes in the magnitude of seasonal flooding could also lead to excess ice melt. There are other processes that could result in changes of surface elevation such as isostatic rebound, sediment compaction, and frost heave.

This work builds on the study of Pollard and French (1980) which only used aerial photos and estimations of ice wedge depth. The result of this current research provides an initial attempt to estimate ice wedge volume using a combination of aerial photos and GPR data. Further verification of ice cross-sectional area, geometry near the junction of ice wedges, the character of ice wedge degradation due to flooding, and excess ice in other forms is required to further refine the quantification of excess ice and impact of subsidence and flooding.

Conclusions

Estimation of excess ice content from drilling is time consuming, difficult, expensive, and only provides point source data. Using GPR and aerial photographs, an estimation of ice wedge ice volume can be made over a large area in a relatively short time. The surficial expression of ice wedges at this location made it possible to measure their total length and width from aerial photographs. GPR was used successfully to identify the base of the ice wedges and determine ice wedge depth. By combining this data, the total volume of excess ice contributed by ice wedges was estimated. Applying these estimates to a DEM allowed for predictions to be made of the role of ice wedges may have on terrain subsidence and subsequent flooding. At the Taglu site the estimated ice volume is significant enough that if the subsurface warms and melts excess ice, subsidence leading to extensive flooding of land could occur.

Abstract

The most common landforms associated with the creep of Alpine permafrost are the rock glaciers, the morphology of which reflects the complex processes of the internal deformation of the ice and debris mixture. In the present study, a terrestrial LIDAR device was employed to scan, at a sub-decimeter resolution, the surface of the Laurichard active rock glacier (Southern French Alps). Two points-clouds were generated at one-year interval (Sept. 2005 and Sept. 2006) and processed in order to produce two high-resolution digital elevation models (DEMs) and to compare them. Different methods were used in order to extract small-scale topography, quantify interannual surface changes, and determine the kinematic behavior of the creeping mass. For a better understanding of rock glacier dynamics, the results have also been compared to the geodetic measurements annually over a 20-year period, and to the geophysical evidences of rock glacier internal structure.

Keywords: alpine permafrost; French Alps; high-resolution DEM; LIDAR; rock glacier morphology; surface kinematics.

Introduction

The long term, steady-state and slow deformation of ice-supersaturated sediments, which generates specific landforms called rock glaciers, is dependent on various parameters such as the ice/debris mixture thickness, the local slope angle, the ice and water content, or the depth of the basal shear zone (Haeberli 1985, Barsch 1992, Arenson et al. 2002, Haeberli et al. 2006). Recent investigations have also suggested that, at an interannual scale, the main controlling factor of rock glacier deformation rate may be the thermal state of the permafrost body (Ikeda 2004, Roer et al. 2005, Kääb et al. 2006).

Previous studies on rock glacier surface kinematics have classically used remote-sensing techniques (Kääb et al. 1998, Kaufmann et al. 2005), which provide a good spatial resolution but only on mid- to long-term trends of the creeping activity, or geodetic surveys (Delaloye 2004, Lambiel & Delaloye 2004, Kaufmann et al. 2006), which are often carried out at an annual time-scale but with a limited spatial resolution.

Recent development of the LIDAR (Light Detection And Ranging) technique allows fast and accurate acquisition of the topography with very high resolutions. Using terrestrial devices, several millions of points may be acquired in one day, and entire slopes (≈10^4 m^2) and landforms may be scanned. Therefore, it appears a promising tool to produce high-resolution digital elevation models (HR-DEMs) that have, until now, rarely been used to study surface changes and related processes in the glacial (Bauer et al. 2003, Avian & Bauer 2006) or periglacial geomorphology.

In this study, a medium-range terrestrial LIDAR was employed during two successive years to scan the surface of a rock glacier.

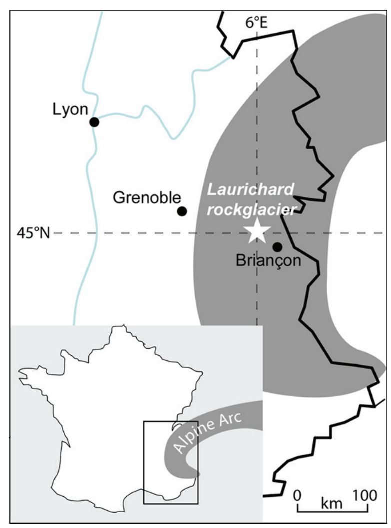

Figure 1. Location of the Laurichard rock glacier, in the Southern French Alps.

The investigated landform is the Laurichard rock glacier in the Southern French Alps (Fig. 1), which is a 500 m long, tongue-shaped, active rock glacier. As it is surveyed since 1979 with annual geodetic measurements of 28 marked blocks (Francou & Reynaud 1992), its mean surface velocities are known to range from 0.2 m/yr at the root and at the front to 1.2 m/yr in its steepest central part.

Beyond the necessity to test the applicability of the terrestrial LIDAR on a very rough and complex terrain, the main goals of this study were to perform multi-scale morphometric measurements, to quantify the interannual surface changes, and to determine the kinematic behavior of the creeping mass.

Acquiring High-Resolution DEM in an Alpine Environment

Data acquisition

The device (Ilris-3D, Optech; wavelength: 1500 nm) used in the present study is able to acquire 2500 points per second, with a centimetre accuracy (8 mm at 100 m) and at a maximal range of about 1000m. The limiting factors that can reduce the LIDAR measurements quality are the presence of non-reflective surfaces, such as snow, and the occurrence of very humid or foggy atmospheric conditions.

The small-scale morphology of the rock glacier, composed of extensive (longitudinal ridges) or compressive (transversal convex ridges and furrows) flow structures, has made it imperative to multiply the angles of view. Hence, during the two field campaigns (September 2005 and September 2006) four stations and 14 to 17 scenes (between 1 and 4 per station) were necessary each time to scan the whole surface of the rock glacier and to minimise shadowed areas (Fig. 2). In addition, five fixed points, outside the rock glacier, were measured with DGPS (Differential GPS), enabling a centimeter precision for the georeferencing of each DEM.

With a mean resolution of 7 cm (it varies according to the distance between the LIDAR and the target) two clouds of 10–15 millions points were generated.

Data processing

The raw datasets, that consist in x, y, and z coordinates (reflectance and colorimetric information have not been used), have to undergo several processing steps before being usable for further treatments. The PolyWorks (© InnovMetrics 2005) software, dedicated to the processing of 3D point clouds, was hence used to:

1. align and adjust the scenes together, thanks to common overlapping areas,
2. reduce the redundancy where a high density is not necessary,
3. grid the data to obtain either a polygonal model or a regularly spaced model,
4. georeference one polygonal model, thanks to using the DGPS points by the manual recognition of the blocks, and
5. align the two polygonal models on their common stable parts.

Finally, three types of processed data are available for further analysis: initial point clouds (17 in 2005, 14 in 2006, plus the 2 final aligned ones); two polygonal models (one per year); and two regularly-spaced models (one per year, at resolution of 0.5 and 1 m).

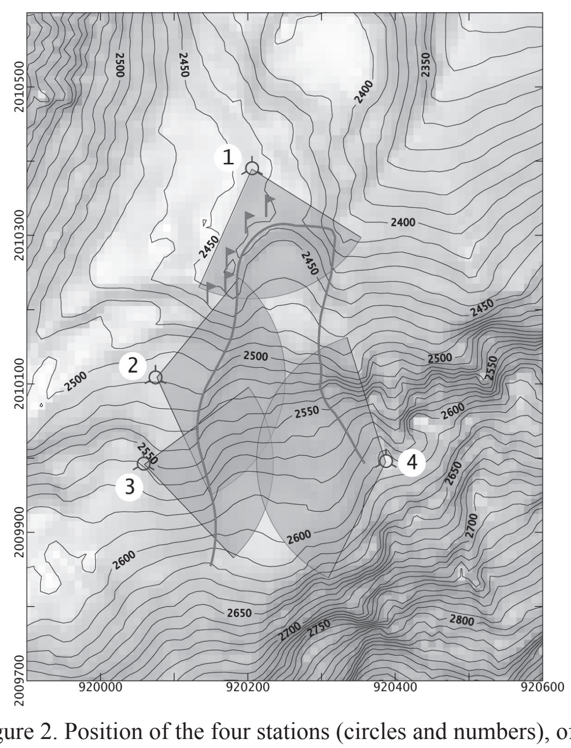

Figure 2. Position of the four stations (circles and numbers), of the corresponding scanning windows (circle portions) and of the fives fixed points (flag) used to scan the surface of the rock glacier (bold line). Geographic coordinates and elevations are in meters.

The Use of High-Resolution DEM to Quantify Rock Glacier Morphology and Surface Kinematics

Morphometric analysis of the rock glacier

Because of the presence of snow on the upper part of the rock glacier during the 2006 campaign, only the 2005 data were used.

First, a detailed map of the main morphological features has been established and verified in the field (Fig. 3). Interesting elements, such as the limits of the different flowing units or the variable roughness of the surface, can be extracted.

Second, the use of morphometric parameters has allowed a fine quantitative description of the rock glacier topography. Slope, microtopography (μz) after Kääb (2005), and roughness (ρz) index were computed along the main flow line by the following formulas:

$$\mu z_n = \frac{\sum_{n+2}^{n-2} z_n}{5} - \frac{\sum_{n+25}^{n-25} z_n}{51} \tag{1}$$

$$\rho z_n = z_n - \frac{\sum_{n+10}^{n-10} z_n}{21} \tag{2}$$

This allows several parts with homogeneous morphometric characteristics to be distinguished (Fig. 4):

a) the scree slope at the contact between the rock wall (slope >37°) is marked on its upper part by a deep concavity, which actually corresponds with the "randkluft" of the rock glacier (massive ice is commonly observed);
b) the upper convex part of the central slope where transversal microtopography is almost absent due to high, extensive flow;

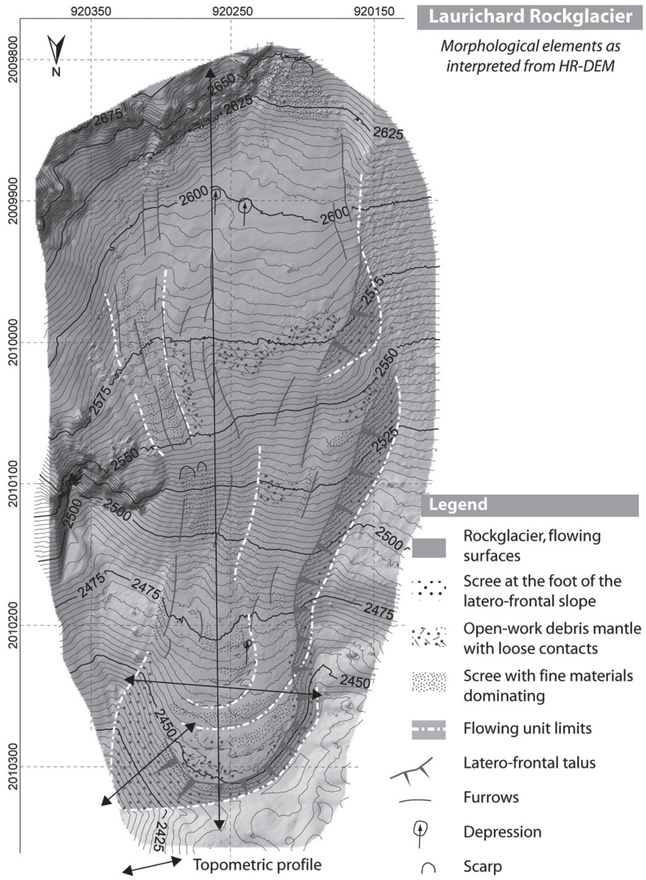

Figure 3. Morphological map of the rock glacier from the 2005 HR-DEM. Coordinates are in meters and equidistance of the contour lines is 2.5 m. Please note that, for aesthetic reasons, north as been placed at the bottom.

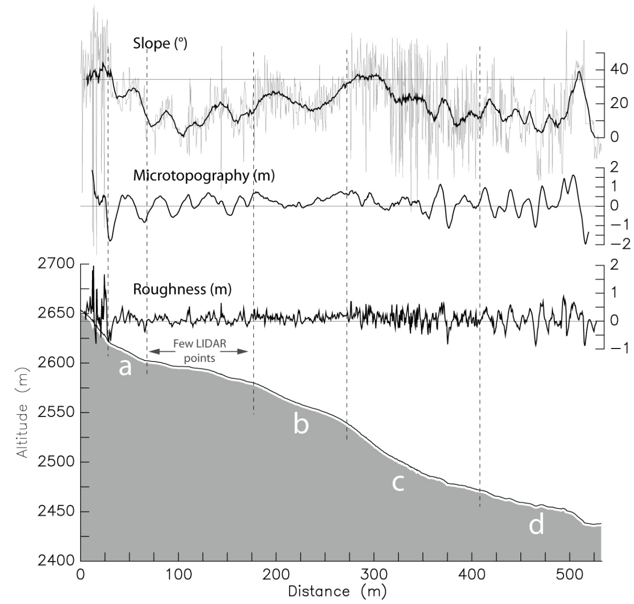

Figure 4. Longitudinal profile of the rock glacier with computed values of slope, microtopography, and roughness.

c) the lower concave part of the central slope, which is characterized by a high roughness, related to the presence of numerous large boulders and, at the bottom, by transverse ridges and furrows;

d) the gently sloping tongue of the rock glacier shows several ridges, and the roughness index suggests smaller boulders.

As a rock glacier is commonly interpreted as a creeping mixture of debris and ice (Haeberli 1985, Barsch 1992), it may be assumed that those morphometric measurements partly reflect the dynamics of the landforms.

Long-term deformation of the rock glacier

The digitizing of contour lines obtained through photogrammetric restitution of 1975 aerial photos (topographic map IGN 3436ET, 1:25000) has provided a DEM (at a grid resolution of 10 m) of the rock glacier region. The comparison between this 10 m DEM (which displays quite poor accuracy of +/-5m) and the 2005 HR-DEM allows us to roughly estimate the characteristics of the Laurichard rock glacier flow (Fig. 5). It appears that the frontal zone has advanced by about 11 m, displacing a volume of rock and ice of approximately 50,000 m^3 in 30 years. An interesting feature is the clear inflexion of the flow towards its right, in a local valley axis.

Interannual comparison of HR-DEM

Due to the coarse detritic cover of the rock glacier, made up of decimeter to meter-sized boulders without fine material, the surface roughness appears to be greater than the spatial resolution of the HR-DEM. Furthermore, the variability of the point density, from place to place and from one HR-DEM to the other, may lead to an heterogeneous quality of the reproduction of the surface by the models. Thus, as a smoothing of the "noisy" blocky surfaces would have induced an additional inaccuracy and would have limited the detection of infra-meter surface movements, direct comparisons were performed by two different means.

With the first method, the PolyWorks software computes the distance between each cell of the 2005 polygonal model and the closest cell of the 2006 polygonal models. A directional constraint is set by a 3D vector which specifies in which direction the comparisons have to be performed. Thus, maps of "directional differences" can be computed for various 3D vectors.

This method shows some of the main components of the surface movement, such as the downstream progression of the ridge that appears to be larger in the main flow axis of the landform (Fig. 8). The larger movement on the right side of the rock glacier seems also to be confirmed, and the fall of blocks from the top of the front or the individual movements of big boulders can be easily detected.

The second method consists in the use of topographic profiles along which 2005 and 2006 surfaces are compared. Vertical changes as well as horizontal differences can then be computed.

Specific patterns of rock glacier movement can therefore be visualized. The frontal advance is detected by the uprising of the surface, which decreases toward the foot of the talus (Fig. 6 A). Erosion by the fall of blocks from the upper part of the front is also perceptible at some places by a lowering

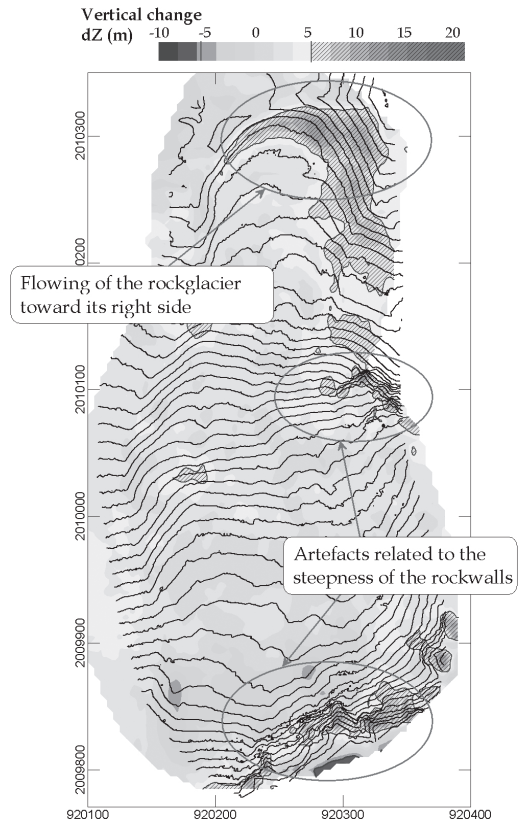

Figure 5. Vertical changes (in meters) between 2005 HR-DEM and 1975 DEM.

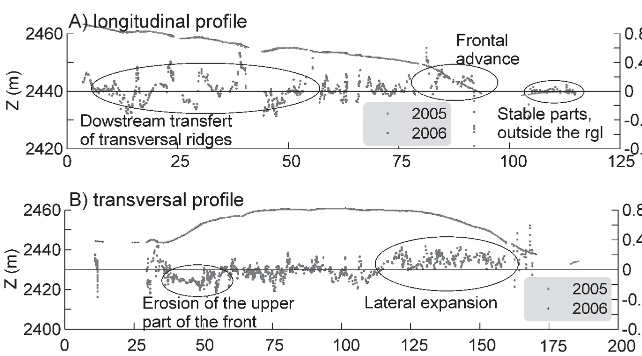

Figure 6. Vertical changes between 2005 and 2006 on a longitudinal and a transversal profile.

of the surface at the top and a subsequent rising at the foot, which corresponds to the deposit.

This method also permits to quantification of the downstream progression of the ridges (from 0.2–0.6 m/yr on the tongue) and the advance of the latero-frontal talus that appears to range from 0–0.6 m/yr (Fig. 7).

Discussion on the Rock Glacier Dynamics and Discussion

The rock glacier advance

The latero-frontal edges of the rock glacier were frequently perpendicular to the line-of-sight of the LIDAR, and this has locally improved the quality of the HR-DEM and facilitated surface changes quantification on those specific sectors.

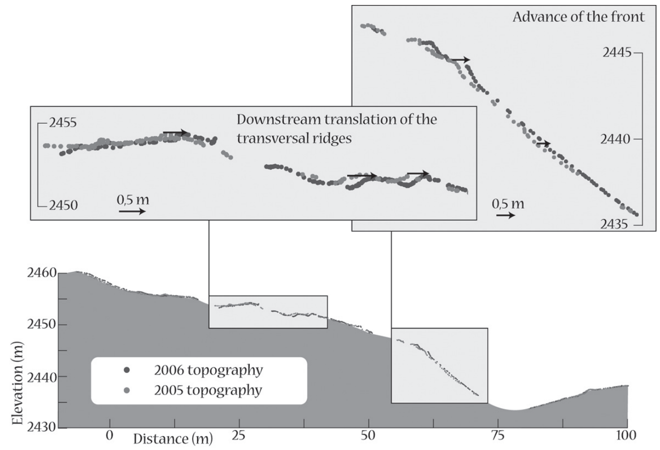

Figure 7. Surface changes between 2005 and 2006 on a longitudinal profile showing the tongue of the rock glacier.

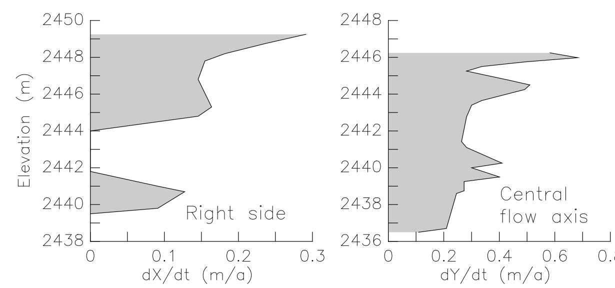

Figure 8. Vertical profiles showing the horizontal advance rate of the latero-frontal edges of the rock glacier (see Fig. 3 for location).

Hence, measure of the horizontal movement of visible boulders allows the drawing up ofvertical profiles of the advance of the rock glacier edges (Fig. 8). Those show an increase of the advance rate toward the top of the front, as well as marked ruptures that are visible at different levels in the profiles.

Although this kind of measurement has to be carefully interpreted due to the roughness of the surface and to individual boulder movements that may introduce noise in the values, several remarks can be made concerning the advance of the rock glacier.

First, the linear to parabolic shape of the vertical profiles is similar to those observed by Kääb & Reichmuth (2005) on the front of two rock glaciers. For the Murtèl case, they found that its frontal part is affected by a downslope creep of a surface layer (which acts as a "conveyor belt") and a thaw settlement that reveal an excess ice content of about 60%–70%.

Second, the presence of a non-moving layer is observed within the vertical profiles of the right side of the Laurichard rock glacier. This may approximately correspond to the level of the bedrock (as suggested by surrounding evidence) and may be interpreted as evidence of the presence, immediately above, of a shear zone (Arenson 2002) where a large part of the total deformation occurs.

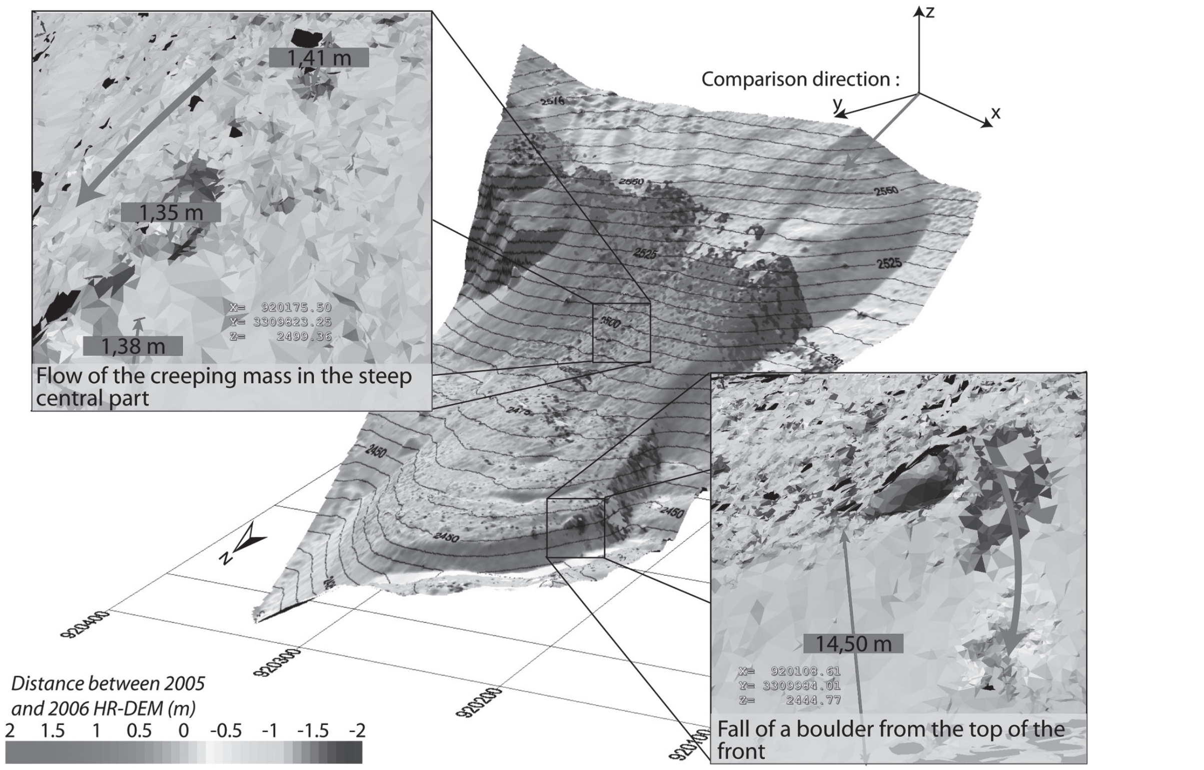

Figure 9. Map of the "directional difference" (direction of comparison shown in the upper right corner) between 2005 and 2006 HR-DEM. The inserts present some details of typical surface changes, such as the individual movements of boulders in the steep central part or the fall of a block from the front. The downstream progression of the ridge is also clearly visible.

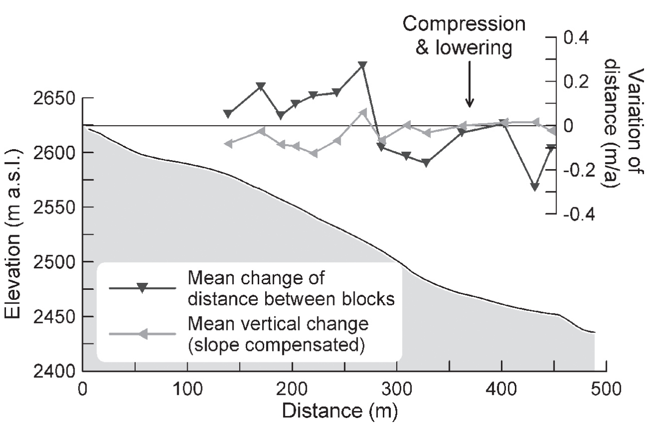

Figure 10. Surface variations of the Laurichard rock glacier after the long-term geodetic survey (mean 1986–2006 values).

Implications for the long-term geodetic survey

The annual measurements with the LIDAR device have suggested that the flow of the rock glacier may partly turn to its right, following a local valley axis. Between 1975 and 2005, the right side of the rock glacier advanced by about 14 m (+/-5 m) in that direction, and the corresponding 2005–2006 advance was around 0.3 m on the top of the latero-frontal talus.

Therefore it can be assumed that the surface changes observed with the long-term geodetic survey along the main axis of the rock glacier (Fig. 10) will reflect this specific behavior.

As a consequence, the small mean lowering of the surface (indicated by the calculated slope compensated variation of surface, data from 1986 to 2006) which accompanies the local compression of the tongue has to be interpreted in different ways. It may be a consequence of the global dynamics of the rock glacier, as well as an impact of the thaw settlement that would be associated to the global warming of the last two decades.

Conclusion

The terrestrial LIDAR technique has been employed to produce two high-resolution DEMs of the Laurichard rock glacier in two successive years. The morphology of the landform has been analyzed, thanks to mapping and to morphometric parameters. The depicted flowing structures clearly reveal the creep of the ice and debris mixture. This has also been studied through interannual comparisons of the HR-DEM, which allows general or detailed quantification of the surface kinematics of the rock glacier. By comparing with the results of a long-term geodetic survey, it appears that more detailed studies, for example with a regular (every 5 years) survey of the rock glacier, are necessary to develop models of the rock glacier dynamics.

Acknowledgments

This work has been possible thanks to collaboration between the Institute of Alpine Geography (Grenoble, France) and EDYTEM laboratory (Le-Bourget-du-Lac, France). The authors are indebted to R. Delunel, J. M. Krysiecki, and

A. Rabatel, as well as to the "Chalet-Laboratoire" of the Lautaret Pass (S. Aubert, P. Choler) for their help during the field campaigns. The unpublished data of the geodetic survey of Laurichard have been made available by the courtesy of L. Reynaud and E. Thibert.

Abstract

Among various factors, permafrost and frost-thaw cycles play an important role for the stability of steep rock slopes in high alpine regions. Climate change in general and local temperature and precipitation trends in particular are likely to influence permafrost and, consequently, also the stability of rock walls. As stress relief following deglaciation can be excluded at Aguille du Midi (France), rockfall activity is mainly related to changes in permafrost and frost-thaw cycles. To put modern observations of possible climate-induced rockfalls into perspective, information on past rockfall activity is required. In this study, we investigated a combination of surface exposure dating and spectrometry to derive a correlation between rock surface ages and their spectral properties in homogenous lithology. The surface ages found varied from less than 2,000 years to around 40,000 years, and showed a clear correlation with reflectance behavior in the range 380–580 nm. These results may be a first step towards the possible generation of spatial data fields of age distribution in steep rock walls. This may provide deeper insights into spatial and temporal rock-wall development of permafrost in high alpine permafrost environments.

Keywords: cosmogenic nuclide dating; permafrost; reflectance spectroscopy; steep rock slope stability; surface exposure dating.

Introduction

Permafrost thaw is an important process which affects the stability of steep bedrock slopes in many alpine areas (cf. Haeberli et al. 1997, Gruber & Haeberli 2007). Slope failures, like rockfalls, landslides and debris flows, that are assumed to be triggered by changes in the permafrost conditions are known from numerous locations in high mountains and especially in the Alps (e.g., Haeberli 1992, Deline 2001, Noetzli et al. 2003, Schiermeier 2003, Gruber et al. 2004a). These processes cover magnitudes from small rockfalls to huge rockslides (Bergsturz). In comparison with debris-covered slopes, rock faces react quickly to climate change. This is due to the absence of a block layer (Mittaz et al. 2000, Hoelzle et al. 2001) and corresponding direct coupling of surface and subsurface conditions, combined with low water content and small transfer of latent heat during melt. This rapid reaction, together with the effect of destabilization, makes rockfalls due to permafrost degradation a likely and perceivable impact of climate change in the near future (Gruber et al. 2004a).

While recent advances in permafrost modeling have enabled the derivation of permafrost maps for steep bedrock (Gruber et al. 2004b), information about long-term rockfall activity is required to put recent observations and changes in temperature into a long-term perspective.

Besides radiocarbon dating and luminescence methods, the usage of cosmogenic nuclides has become a central technique to gain information about landform ages and landform-modification processes such as rockfalls. An overview of the spectrum of dated landforms and commonly used nuclides is given, for instance, in Gosse & Phillips (2001) and in Ivy-Ochs & Kober (2006). In relation to glacio-geomorphological questions, the determination of ^{10}Be- and ^{26}Al-concentrations in the surface of moraine boulders and polished bedrock is of great interest. Ivy-Ochs et al. (2006) summarized results from the European Alps. Whereas, numerous ages from late glacial moraines are available, data from polished bedrock (indicating deglaciation at higher altitudes) or from areas that were not glaciated during the Last Glacial Maximum (LGM) are sparse. Except for investigations in the Grimsel Pass region in central Switzerland (Ivy-Ochs 1996, Kelly et al. 2006), so far no dating has been carried out at higher-elevation sites.

Remote sensing techniques with multispectral and hyperspectral sensors are widely used to investigate different aspects of mountain areas. Kääb et al. (2005) provide an overview of air- and spaceborn remote sensing methods that are applicable for glacier and permafrost hazard assessment and disaster management. Other approaches discuss methodologies for mapping glacio-geological features such as trim lines or terminal moraines in order to reconstruct glacier changes and related past climate (e.g., Huh et al. 2006). Spectral field measurements and airborn hyperspectral data have enabled an approach to date and map other geomorphic features such as arid and semi-arid alluvial fans (Crouvi et al. 2006). The development of a rock coating significantly influences the overall reflectance of the surface. The redness of rock material or soil is directly related to the age. In oxidizing environments and increasing weathering time, color hues become redder and chromas become brighter (rubification). This fact is, among others, used in the calculation of the profile development index which gives a direct indication of soil age (e.g., Harden, 1982, Goodman et al., 2001).

In this paper, we present a pilot study to investigate the potential of combined imaging spectrometry and exposure dating to derive approximate surface ages in steep bedrock walls of homogeneous lithology. The geometric and radiometric correction of hyperspectral imagery over steep terrain is challenging but generally possible (cf. Gruber et al. 2003). The spatial data fields of estimated age resulting from this method would allow deriving the area and relative frequency of surfaces that belong to a certain age class and that are uninterrupted by older surfaces over a certain distance. This information is related to the frequency of rockfall events during a certain period and is a useful long-term background for assessing whether presently observable, large rockfall shows an unusual abundance as suggested by the relevance of permafrost for slope stability.

Our hypothesis is that the surface ages in this high alpine region can be directly related to the redness of the rocks. The redder a rock surface is, the higher the age that should be measured.

Geological and Physical Setting

Aiguille du Midi (3842 m a.s.l.) is situated some four kilometres south of Chamonix in the Western Alps in France. Whereas most of the peaks surrounding Chamonix are only reachable by making trips of several days with high alpine equipment, Aiguille du Midi is easily accessible by cable car and therefore an ideal study site.

Geologically, this area is part of the Mont-Blanc massif (Spicher 1980) and is made up of the so-called Mont-Blanc Granite with an age of roughly 300 Ma (von Raumer & Bussy 2004, Bussy et al. 2000). This granite type is of a very quartz-rich quality and thus suitable for surface exposure dating with ^{10}Be.

During LGM, the uppermost part of the Aiguille du Midi SSE-face, where the samples were taken, was most probably not glaciated. Paleogeographical reconstructions based on trimline mapping by Coutterand & Buoncristiani (2006) and Kelly et al. (2004) showed that Aiguille du Midi was, during this time, a Nunatak bounded in the east by the Mer de Glace, in the north by the Glacier de l'Arve, and in the west by the Glacier des Bossons. Apart from local glaciations in the less steep parts of the wall, the influence of glacial ice masses on exposure ages can be excluded.

We chose our sampling sites based on visually identifiable differences in color on photographs taken from a helicopter.

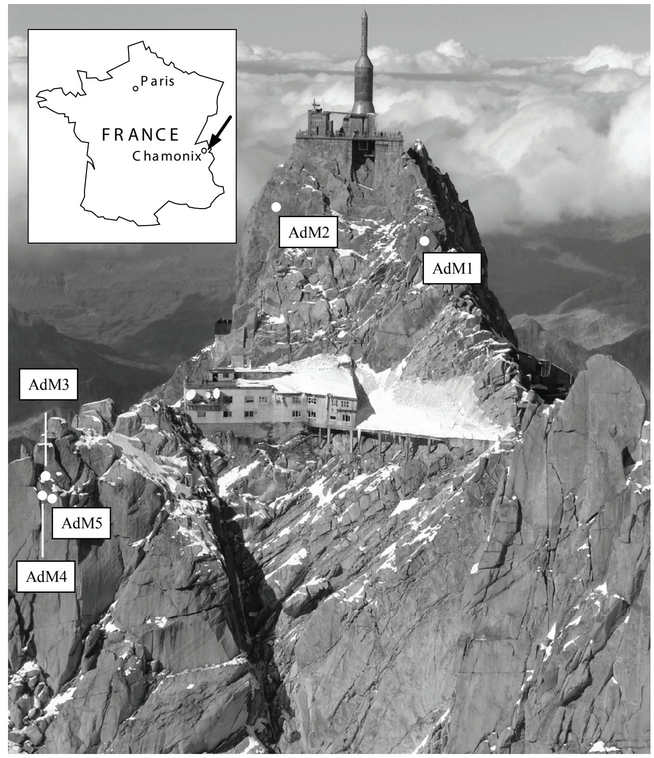

Figure 1. Overview of the sampling locations at Aiguille du Midi.

The hypothesis was that intensively red-colored parts in the rock wall were exposed to weathering over a longer time period than fresh gray ones, and consequently should have a higher age. This assumption is based on field observations at the adjacent Drus, where, besides several smaller events, a huge rockfall occurred in 2005 (Ravanel 2006). The gray-colored area that came to light clearly contrasts to the surrounding, more or less reddish, and obviously older parts of the wall.

Sample AdM1 was taken at a conspicuously red spot, whereas AdM2 was gathered from a gray part of the wall, where no red coloring was seen. AdM4 and AdM5 can be placed somewhere in between with respect to color. Thereby, sample AdM5 presented a more intensive coloration than AdM4. All these sampling places had a slope ≥ 79°. The slope at AdM3 was, however, only 49°. This sample was the only one that was partly covered by lichen, probably due to an increased water availability resulting from melting snow. For this reason spectral analysis was not applicable, and AdM3 was not taken into account for further interpretation. We concluded that the rock surfaces should have the following order of age: AdM1 > AdM5 >AdM4 > AdM2.

Rock samples were taken with hammer, chisel, and a drilling machine. After Masarik & Wieler (2003), marginal sampling places were excluded in order to avoid edge effects. To calculate the influence of shielding caused by the surrounding topography, azimuth-dependent angles were extracted from the map.

Methodology

Surface exposure dating

Approximately 500–1000 g of each rock sample were crushed and sieved. A grain-size fraction of 0.5 to 1 mm was used. Pure quartz was separated by selective chemical dissolution (Kohl & Nishiizumi 1992, Ivy-Ochs 1996). This method is based on the fact that feldspars and micas dissolve in 4% HF more quickly than quartz does. At least six HF steps were used to obtain very pure quartz as reflected by the low Al concentration (less than 100 ppm). ^{9}Be carrier was added to the dried quartz, which was then completely dissolved with concentrated HF in a microwave. Be and Al were separated using a cation exchange column. The Be hydroxides were precipitated, dried, and calcined at 850°C to BeO.

The $^{10}Be/^{9}Be$ ratios were measured at the ETH/PSI Zürich Tandem Accelerator Mass Spectrometry (AMS) Facility (Synal et al. 1997).

In order to calculate ^{10}Be ages, a simple exposure history was assumed, specifically that all ^{10}Be measured was produced in the rock surface during the latest period of exposure and that the rock surface did not suffer significant erosion. Any earlier exposure, even at greater depth below the original surface, will make the "measured" age an upper limit for the true exposure age of the sample's surface.

Ages were calculated using the ^{10}Be production rate of 5.1 ± 0.3 atoms gram-1 year-1 at sea level and high latitude (Stone 2000). Production rates were scaled to the specific sample locations according to Stone (2000) and corrected for sample thickness (assuming an exponential depth profile) and topographical (skyline) shielding (Dunne et al. 1999) (Table 2).

Laboratory reflectance spectroscopy

Rock surface spectra were measured in the laboratory using an ASD FieldSpec Pro Fr spectro-radiometer, a Spectralon reference panel, and a Thermo Oriel irradiance source. The hematite spectrum was taken from the Jet Propulsion Laboratory (JPL) Spectral Library (HEMATITE 0-1A). In order to identify absorption features for measurement, continuum removal was applied to the data. This is a means of normalizing reflectance spectra to allow comparison of individual features from a common baseline. Continuum removal (Clark & Roush 1984, Kruse et al. 1985, Green & Craig 1985) was performed in ENVI 4.1 to facilitate the comparison of individual absorption features between different objects. In this method, a convex hull (the continuum) of a reflectance spectrum is divided by the spectrum itself and thus results in values ranging from 0-1. The convex hull is built utilizing straight line segments that connect local reflectance maxima.

Elemental composition by X-ray fluorescence measurements

The elemental composition of the rock samples was analyzed by X-ray fluorescence (XRF) spectrometry. After crushing the rock samples to a size of <1mm, around 10 g of rock material were milled to <50 µm in a tungsten carbide disc swing mill (Retsch® RS1, Germany). 4 g of rock powder was mixed with 0.9 g of Licowax® C Micro-Powder PM (Clariant, Switzerland), pressed into a 32 mm pellet, and analyzed using an energy dispersive XRF spectrometer (SPECTRO X-LAB 2000, SPECTRO Analytical Instruments, Germany).

Table 1. Elemental composition of the samples.

	Samples Aiguille du Midi 1-5					Statistics	
Element [%]	AdM1	AdM2	AdM3	AdM4	AdM5	Mean	SD
CaO	0.87	0.87	1.44	1.17	1.31	1.13	0.26

Total	99.02	94.61	93.49	99.43	92.89		

Elemental composition of the samples based on XRF measurements. Values are converted into oxide contents. LOI = Loss on ignition. The low standard deviation (SD) values indicate a comparable composition and demonstrate the homogeneity of the lithology.

Table 2. List of samples and calculated surface exposure ages.

	Samples Aiguille du Midi 1-5				
	AdM1	AdM2	AdM3	AdM4	AdM5
Elevation (m a.s.l)	3800	3810	3750	3740	3740
Sample thickness (cm)	2.5	3.5	5.5	2.5	4.0
Surface dip (°)	85	85	49	79	79
Quartz (g)	58.13	57.03	58.26	56.77	56.68
^{10}Be (10^4 atoms g^{-1})	157.63	6.03	24.28	24.84	28.28
Measurement error (%)	3	9.2	5	4.6	5.2
Production rate not corrected (atoms g^{-1} yr^{-1})	75.59	76.00	73.57	73.17	73.17
Shielding factor	0.559	0.559	0.898	0.627	0.627
Production rate corrected for shielding, sample thickness and surface dip (atoms g^{-1} yr^{-1})	41.24	41.11	62.85	44.77	44.34
^{10}Be date (yr)	**38,600±1200**	**1,470±140**	**3,870±200**	**5,560±260**	**6,390±330**

Samples organized by sample name. The reference production rate is scaled for sample altitude and latitude after Stone (2000) and corrected for sample thickness (assuming exponential attenuation of cosmic rays at depth and an attenuation length of 150 g cm-2) and skyline shielding (Dunne et al. 1999).

Results

Elemental composition

Results from XRF measurements show after conversion into oxide contents a very similar composition (Table 1.). The high quartz content of the Mont-Blanc granite is represented by high amounts of SiO_2. Other important constituents of the rock samples are Al_2O_3 and potassium oxide. The total values of over 90% mean that almost all possible compounds were measured.

The comparable composition of the samples is an important indication that observed differences in color are not due to inhomogeneities in lithology.

Surface exposure ages and comparison with measured spectra

The intensively red colored sample AdM1 shows the highest age, followed by AdM5, AdM4, and AdM2, where no coloring occurred. This is in agreement with the above-stated hypothesis and the sample description (Table 2).

Generally, the ^{10}Be ages, especially AdM1, are remarkably old, and the differences in age are very big. But these ages have to be interpreted as maximum exposure ages of the rock surface, as long as erosional processes can be excluded.

Looking at the measured spectra (Fig. 2), a well-pronounced correlation between surface exposure ages and the corresponding spectral signature in the range of approximately 380–580 nm is identifiable after continuum removal. As a reference, a piece of unweathered fresh rock was also analyzed (AdMf).

According to the visual impression, the curve progression of AdM2 is shaped very similarly to the one of the unweathered sample. With increasing surface exposure ages and thus more pronounced weathering, a decrease in feature depth is ascertainable. A comparison with the continuum-removed spectrum of hematite permits the conclusion that the spectra evolution with increasing age is influenced, at least partly, by hematite formation (Fig. 2). Thus, hematite content and its effects on rock surface color can be interpreted as the main feature required in regard to the generation of spatial data fields of age distribution in rock walls.

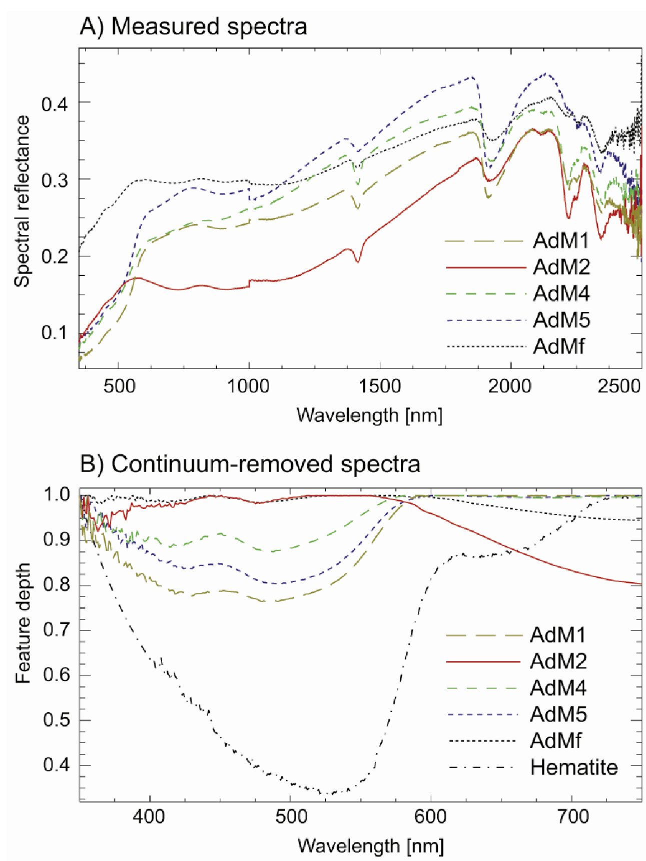

Figure 2. Measured and continuum-removed spectra. The arrow indicates the influence of the Fe-Oxide content with age.

Discussion and Conclusions

We showed that analyzing spectral properties of rock surfaces in steep walls with homogeneous lithology may be a tool to estimate the age distribution and related past rockfall activity in high alpine environments. The redder a rock surface, the longer this rock was exposed to weathering. In numerous cases, the correlation of rockfall initiation to changes in the permafrost conditions is rather weak, and related forecast and mitigation possibilities are limited (Gude & Barsch 2005). Not only permafrost thawing but also other processes like general frost-thaw activities (physical weathering), seismic (neotectonic) activity, or stress relief following deglaciation could induce rockfalls. Furthermore, non-erosive cold-based glacier ice can complicate the erosion history of rock surfaces (Briner et al. 2006). Due to the topographic situation of the investigated sites, however, at least one process affecting the stability of rock walls can be excluded. A stress-relief following deglaciation of (cold-based) glacier ice did not occur because no glaciers covered the rock walls during (and after) the LGM. Rockfall is predominantly due to permafrost changes and frost-thaw activities. Although neotectonic activities have been rather low, their influence on rockfalls cannot be fully excluded. The used approach, therefore, will not allow direct reconstruction of past permafrost conditions. However, it can give indications about past and present-day rockfall activities. From this, the influence of permafrost on rock wall stability can be deduced at least partially. Inasmuch as global warming in general and local temperature and precipitation trends in particular are likely to influence the permafrost significantly, the stability of rock walls will also be affected.

The relationships found look promising; however, they certainly represent only a first impression and further investigations in this field will be necessary to establish this approach as a commonly usable application. Doubtless, of great importance is the enlargement of the survey sample size in order to be able to generate statistical correlations between surface exposure ages and spectral properties. Therefore, the latter have to be translated into quantifiable values.

In the present study, we tried to keep as many factors constant as possible. Potential follow-up studies will have to deal with the influence of variable slope aspect and altitudes and different lithologies. Steep places at high elevations should be preferred. Sampling locations that are situated too low are not suitable due to lichen growth disturbing the spectral signal. The same is true for flat spots where snow cover can develop more easily and remain for a longer time. A fundamental problem will be the difficulty in accessing appropriate sites. There is, however, great potential for further efforts.

Acknowledgments

This research is supported by the Swiss National Science Foundation grant number 20-109565/1. We would like to thank Jürg Schopfer for providing support in the spectro lab. Easy access to Aiguille du Midi was possible thanks to the generous help of the Compagnie du Mont Blanc (Chamonix) and particularly of Emerick Desvaux. We are, furthermore, indebted to Anne Hormes and to an unknown reviewer for their helpful comments on an earlier version of the manuscript.

Abstract

The main field experiments and modeling results of heat and moisture transfer processes of the Arctic and Antarctic are reviewed, following the historical development. Agreement exists that heat is mainly transferred via conduction in Arctic and Antarctic soils, but that latent heat and vapor migration are important factors for the thermal dynamic. Factors determining amount and type of heat transfer are soil water content and temperature gradient between atmosphere and soil.

Keywords: Antarctic; Arctic; heat transfer; permafrost; thermal processes; water transfer.

Introduction

An apparent discrepancy exists between numerical modeling results and field observations indicating water and vapor transfer in frozen soils. The latter includes depth hoar formation under snow, direct measurements of vapor flux out of the ground (e.g., Santeford 1978, Woo 1982), desiccation of upper soil layers (Hinzman et al. 1991) and ice growth from field and lab experiments (Parmuzina 1978, Chen & Chamberlain 1988) and accumulation of ice at the base of the active layer/top of permafrost (Yershov 1998, Solomatin & Xu 1994).

Due to page limits, we review available literature on heat and water transfer processes in Arctic and Antarctic soils only; thus results from alpine, high elevation and temperate regions are excluded from this paper. Furthermore, we limited the review of heat and water transfer modeling to studies for which field data are available.

The very different climate conditions in the Arctic and Antarctic are reflected in the soil systems. While Arctic soils generally have free liquid water in active layer during summer, Antarctic soils are hyperarid in the dry valleys around the Ross Sea but gradually approach wetter conditions towards the east and Antarctic Peninsula (Beyer et al. 1999 and references within). These differences are reflected in motivation and approaches to model water and heat transport processes thus both regions are described separately. A quantitative understanding of the processes underlying the thermal and hydraulic dynamics of permafrost soils is paramount to anticipate consequences of a changing atmospheric forcing as well as to improve the parameterization of the soil-atmosphere interaction in climate models.

Thermal dynamics of permafrost-affected soils

The major stages for the seasonal thermal dynamics of the active layer at a permafrost site consists of four different characteristic periods: (i) cold period, (ii) warming period, (iii) thawed period, (ix) isothermal plateau. During the *cold period*, temperatures are well below 0°C. Most of the soil water is frozen and the entire ground may be considered as a solid medium. With the sun rising in late spring and the onset of snow melt, ground temperatures rise quickly, soil water content changes following the soil freezing characteristic curve. This *warming period* is terminated by the thawing front, a macroscopic phase boundary that separates partially frozen ground from the completely unfrozen soil during the *thawed period.* The propagation of the thawing front consumes a large proportion of the energy input from the positive net radiation. As the energy balance becomes negative in fall, the soil cools down to 0ºC starting to freeze from the surface. Upon further cooling the reverse phase transition sets in, from liquid to solid. It releases large quantities of latent heat and thereby opposes the cooling. This leads to a rapid equilibration of the temperature at 0 ºC in the entire thawed zone, indicated by the practically vertical isotherms. This is often referred to as the closing of the zero-curtain (Outcalt et al. 1996, Outcalt et al. 1990). As the active layer turns isothermal, large quantities of latent heat need to be removed to allow further cooling. This leads to the *isothermal plateau* where soil temperatures stay near 0 ºC for an extended time. It is eroded from above and from below, where temperatures in the air and in the underlying perennial ice are well below the freezing point. Eventually, the isothermal plateau disappears, giving way to the *cooling period* where regular conduction removes the remaining surplus heat from the active layer. It is transferred through the snow layer, which is a major modulating factor, to the atmosphere.

While thermal processes may be the same in wet soils of east Antarctica and Antarctic Peninsula, in the hyperarid soils of dry valleys the isothermal plateau due to release of latent heat does not exist. However, based on changes in air temperature and lack of incoming radiation, temperature gradient in soils reverses in October, which causes a quasi-isothermal soil during a short period of time (Hagedorn et al. 2007, Pringle et al. 2003) but this isothermal temperature is well below 0ºC.

Heat and water transfer processes

Permafrost-affected soil can potentially have five components (soil matrix, ice, water vapour, water, air). Conduction, heat transfer through gradients, is widely accepted to be the dominant mechanism of heat transfer in soils. Other nonconductive heat transfer mechanisms associated with the convection of water, either in the liquid or in the vapor phase, are possible with appropriate gradients (pressure, gravitational, density, vapor pressure, and chemical). A good summary of potential heat transfer processes in permafrost affected soils is provided by Kane et al. (2001). They summarized the importance of non conductive heat transport based on data sets from Alaska as the following: (i) infiltration and refreezing of water in frozen soil accelerates warming of soil; (ii) free convection of fluids is not an important heat transfer process; (iii) migration of water and vapour could be important but has not been quantified yet. The large value of the enthalpy of evaporation, which exceeds that of melting by a factor of 7.4, makes vapor an efficient means for the transport of thermal energy.

Heat and Water Transfer Processes in Permafrost-Affected Soils: Arctic

Most of the available English-language literature up to the end of 1990s is reported from Alaskan sites and is based on temperature and electric potential measurements and one dimensional thermal diffusion modeling. When the snow cover becomes isothermal and snow melt starts during the warming period, the soil rapidly warms at all depths, presumably because of the infiltration and refreezing of snow melt water and of migrating vapor into the frozen soil. Most studies agree that nonconductive heat transfer processes must be responsible for the rapid warming of the soil (Putkonen 1998, Hinkel & Outcalt 1994).

Conversion of latent heat is thought to be most important during the summer when moisture evaporates from the surface and the active layer thaws. Evaporation consumes 25–50% of the total incoming energy at a Siberian study site on Northern Taymyr peninsula (Boike et al. 1998) and 30–65% in northern Alaska (Kane et al. 1990). According to Outcalt et al. (1998), evaporative cooling at the surface of the active layer was responsible for the deviation between observed and modeled soil temperatures of the active layer and upper permafrost. Thawing of the active layer is another important sink for thermal energy. It consumes up to 40% of the total net radiation at the Siberian site (Boike et al. 1998). Generally, a high percentage of the total heat flux into the ground (between 70 and 100% is converted into latent heat (Rouse 1984, Boike et al. 1998). Conduction of heat, transport of thermal energy by convection of water, either in the liquid or vapor phase, has been discussed. Hinkel et al. (1993) identified infiltration of summer precipitation as an effective method to transfer heat to the base of the active layer, especially in drained, organic soils. Pore water convection during the summer thaw period, driven by the density inversion of water, has been proposed as the initiator for the formation of sorted circles (Krantz 1990, Ray et al. 1983), but Hallet (1990) argued that this process is unlikely and that it has not been observed in finer-grained sediments typically found in patterned ground. Putkonen (1998) calculated a Peclet number much smaller than 1 for this site and concluded that advection of heat due to water motion is negligible.

When net radiation decreases during the fall, the soil is cooled to a practically isothermal condition, the so-called zero curtain at 0°C. The large amount of latent heat which must be removed from the profile through an almost isothermal soil stabilizes soil temperatures at 0° for a prolonged time. Hinkel & Outcalt (1993, 1994) suggested that internal distillation driven by osmotic gradients transfer heat across this isothermal zone. In contrast, Romanovsky & Osterkamp (2000) accurately predicted soil temperatures for sites in Central and North Alaska during the freeze back using a conductive heat exchange model by including effects of unfrozen water and therefore excluding moisture migrating as a transport mechanism. Snow melt infiltration was the only non conductive heat transfer responsible for soil warming.

Putkonen (1998) estimated that the maximal possible vapor and latent heat flux under given soil thermal properties was two orders of magnitude smaller than conductive heat transport, hence being insignificant for western Spitsbergen. Through the application of electronic instrumentation measurement techniques, such as Time Domain Reflectometry for determination of soil moisture in frozen soils, highly precise and frequent temperature and moisture data have been obtained from various field sites. Roth & Boike (2001) found an excellent agreement between projected and measured temperatures for the cold period which demonstrates that during this time, heat transport on Spitsbergen (Bayelva site) can be described by effective conduction. Furthermore, they found that the production of latent heat and the associated migration of water vapor is an important agent in the thermal dynamics at this site for all four periods and that it is the dominating process in the isothermal plateau since heat conduction is practically negligible there. Unimpeded vapor migration is possible down to some 0.9 m, restricted by a massive ice rich layer. This contrasts findings of sites for which it was stipulated that upon closing of the zero curtain, internal distillation and water advection cease for the rest of the winter (Hinkel & Outcalt 1994, Romanovsky & Osterkamp 2000).

Differences in latent heat production using the model by Roth & Boike (2001) were presented by Overduin & Kane (2006). Their patterned ground site, covered by mud boils, is located in Northern Alaska (Galbraith Lake). One of the contrasting differences in winter heat transfer processes was the continuous latent heat production after freeze back until spring in the middle part of the profile It is hypothesized that water advection in the frozen soils was possible through the unfrozen water film attached to the soil particles. Subsequent freezing of water was the source of the latent heat production, resulting in ice formation and large heave rates in the center of the mudboil. While these two Arctic sites are very similar in terms of soil parent material, surface cover and topography, the soil water/ice content and climate conditions vary. Firstly, the site at Galbraith lake is water saturated, thus the pore spaces are filled with ice during winter. The soil at the Bayelva site is water saturated only in the lower part of the profile below about 0.7 m depth. Secondly, Galbraith, located in the Arctic climate is much colder (average January air temp. ~ -24°C) compared to the warmer, maritime influenced Svalbard climate (average January air temp. ~ -13°C). In addition, Galbraith has no or little snow cover, whereas the Bayelva site experiences a snow depth up to about 1 to 1.5 m, modulating the ground thermal regime and thus reducing the thermal gradient between air and soil temperature. It is postulated that the large temperature gradient at Galbraith Lake was also responsible for the large heave (up to 12 cm) which is about an order of magnitude higher compared to the Bayelva site (about 2 cm).

Heat and Water Transfer Processes in Permafrost-Affected Soils: Antarctic

Due to the very dry climate in dry valley soils of Antarctica, the majority of water is present as ice which occurs 0.1 to 0.5 m below surface in approximately 36% of soils in Antarctica (Bockheim 2002). Liquid water is limited to scarce infiltration after snow events (Friedman 1978, Gooseff et al. 2003), water films adsorbed to grain boundaries (Anderson & Morgenstern 1973), and to brines in ice cement (Dickinson & Rosen 2003). Only a small fraction of water is present as water vapor, which is the phase that is transported between atmosphere, soil pore space and ice. The main motivation to study vapor transport and thermal regime in Antarctic soils of Dry Valleys is to estimate the stability of subsurface ice in Antarctic soils, since this ice is important for geomorphologic development of patterned ground formation, e.g. contraction cracks (Sletten et al. 2003) and since Antarctic soils are the best terrestrial analogue to Martian soils (Schorghofer 2005).

Sugden et al., (1995) and van der Wateren & Hindmarsh (1995) did the first back on the envelope calculation of vapor transport to evaluate the stability of ground ice using steady state vapor diffusion modeling. Both yielded very different results; Sudgen et al. (1995) used geothermal gradients to determine soil and ice temperature and assumed vapor saturated atmosphere. He estimated sublimation rates of 10^{-4}mm a^{-1}; van der Wateren & Hindmarsh (1995) used meteorological data and assumed vapor unsaturated atmosphere and estimated a rate of 1 mm a^{-1}. This fast sublimation rate could be confirmed in a more detailed modeling approach by Hindmarsh et al. (1998).

McKay et al. (1998) calculated vapor transport using soil temperature, air temperature and relative humidity records collected at Linnaeus Terrace (1550 to 1700 m elevation). Parameters like tortuosity and porosity were determined on investigated soil material. Thermal conductivity was modeled from temperature profiles and yielded 0.6±0.1 $Wm^{-1}K^{-1}$ for dry soil and 2.5±0.5 $Wm^{-1}K^{-1}$ for ice cement which are close to values determined by Putkonen et al. (2003). Based on Fick's diffusion they found that ice is lost at rates at ~0.2 mm a^{-1}, highlighting the very dry atmospheric conditions in the dry valleys. Based on a comparison between frost point of atmosphere and ice cemented soil they suggest that increase of 40% moisture to all humidity values could stabilize ground ice.

Schorghofer (2005) modeled ice sublimation in Beacon Valley (~1500 m asl.) constrained by climate and soil temperature data and found rates comparable to those of McKay et al. (1998). He found that advection caused by changes in surface pressure has negligible effect on sublimation. By exploring possible scenarios to stabilize subsurface ice, he suggests a decrease in annual air temperature by 5°C or increase in relative humidity of 50%, a rather unrealistic value.

Hagedorn et al. (2007) modeled vapor transport based on multi-year climate and soil temperature record in Victoria Valley which is about 400 m asl. and where ice occurs 0.2 to 0.4 m below surface. Vapor transport is calculated using Fick's diffusion incorporating a reaction term for ice precipitation and allowing vapor diffusion into the ice cement. Initially a linear vapor density gradient between ice cement and atmosphere was assumed. Using this approach they yielded sublimation rates close to those observed by McKay et al (1998). However, part of the vapor is transported from ice surface into the ice cement and most of it precipitates in upper ice cement slowly closing the pore space. Transient ice will form in dry soil during winter but completely disappears during beginning of summer. Snow cover will reduce vapor loss to atmosphere but to completely offset sublimation rates it would need to remain for several months. As suggested by McKay et al. (1998) and Schorghofer (2005) they also found that decreasing air temperature or increasing moisture will reduce sublimation but those scenarios do not seem to be very realistic under current climatic conditions. The most likely process which stabilizes ground ice in Antarctica seems to be occasional recharge by snow melt water.

Studies modeling thermal conductivity and heat fluxes based on field measurements are rare in Antarctic soils of the Dry Valleys. Putkonen et al. (2003) measured the sensible heat flux based on the difference between measured net radiation and ground heat flux in Beacon Valley using in situ measurements of soil thermal properties and 1-dimensional thermal conductivity model (Putkonen 1998). At this site, soils consist of ~20 cm dry sublimation till underline by massive ice. They found that mean annual ground heat flux is close to zero indicating long term thermal equilibrium. The annual mean net radiation is positive (24 Wm^{-2}) suggesting a net advection of sensible heat into atmosphere from this area. Measured values for thermal conductivity in dry debris are ~2 times smaller (0.2 $Wm^{-1}K^{-1}$) as values found from modeling (see above 0.4 $Wm^{-1}K^{-1}$). The difference between modeled and measured values may well be in the range of the instrument uncertainty.

Pringle et al. (2003) used temperature data collected on three sites from Table Mountain with different lithology and ice contents to calculate apparent thermal diffusivity (ADT). They found strong dependence of ADT with abundance of ice and determined an ice-fraction dependency of heat capacity of 1.7 to 1.8 $MJm^{-3}\,°C^{-1}$ causing a range of conductivity of ice rich soils between 2.5 to 4.1 $Wm^{-1}\,°C^{-1}$. Pringle et al. (2003) treated the heat transfer as purely conductive due to the very dry conditions and absence of liquid water. The lower value of heat conductivity is in good agreement with values from Putkonen et al. (2003) found for the massive ice. The generally low thermal conductivity found in Antarctic soils is an order of magnitude lower as in Arctic soils (6-26 times lower) reflecting the very dry conditions.

Summary and Future Potentials

Arctic versus Antarctic heat and water transfer processes

Other than during freeze back and snow melt infiltration, heat is largely transferred through conduction in soils at both regions. In non saturated Arctic soil, vapor migration occurs during all thermal periods while water advection occurs in frozen saturated soils. In dry Antarctic soils, vapor diffusion is a main process of water transport. The total amounts of water transferred are generally rather small; however, over longer terms could be significant, for example for the formation of patterned ground features (for example circles, ice wedges).

Snow melt is an important event for recharge of ground ice in Antarctica and a significant latent heat input for Arctic soils.

Factors affecting the heat transfer processes

The main factors determining the heat transfer are (i) phase composition of soil (specifically available pore space) which enables vapor diffusion and/or water advection (ii) the temperature gradient between atmosphere and soil which is largely affected by the snow cover.

What should happen next?

We need further detailed case studies (experimental and modeling) to face the challenge of highly nonlinear and strongly coupled processes which lead to a complex phenomenology. We still lack accurate methods for measuring relevant state variables of the system, for example the phase density of ice or water vapor, and even more so by the lack of sufficiently accurate instruments for measuring fluxes of thermal energy and of water. The processes of water and heat dynamics in permafrost soils, i.e. their potential relative weight should be assed quantitatively which is a topic of a future publication

Acknowledgments

We would like to thank Pier Paul Overduin for discussion about this topic.

Abstract

In this study, a two-directional freeze-thaw (TDFT) algorithm is used to estimate the hydraulic conductivity and storage capacity of permafrost-affected soils. The physically based TDFT algorithm is based upon the Stefan equation. The algorithm is driven by both the surface temperature and temperature at a specified depth and uses physical properties of the soil (bulk density, porosity, soil moisture, organic and mineral fraction, and freezing temperature of water) as input variables. The TDFT is tested in a wet valley bottom and along a relatively dry hill slope in the Imnavait Creek Watershed, Alaska. Results indicate that the timing of thaw/freezeback periods, the maximum thaw depth, and latent heat effects are accurately simulated. Using the TDFT algorithm to derive hydraulic variables is an improvement from the previous methods used to represent the active layer in hydrological modeling studies.

Keywords: active layer; hydraulic conductivity; hydrologic modeling; permafrost; porosity.

Introduction

In (sub-) arctic environments, most biologic, geomorphic, hydrologic, and ecologic processes take place within the active layer —the thin soil layer above the permafrost that seasonally freezes and thaws (Kane et al. 1991, Hinzman et al. 1998, Woo 2000). The depth of the active layer, as well as the rate of seasonal freezing and thawing, is dependent upon a number of factors including soil properties (thermal conductivity, bulk density, moisture content, vegetation type/thickness), meteorologic conditions (air and surface temperature, presence of snow cover), and disturbance (either anthropogenic or natural disturbance such as wildfire) (Woo 1986). As each of these factors are spatially and temporally variable, the position of the freeze-thaw interface is also spatially and temporally variable (Woo & Steer 1983).

Hydrologically speaking, the (sub-) arctic environment is unique in that the thermal and hydrologic regimes of the soil (permafrost versus non-permafrost) can vary greatly over short horizontal spatial scales, with depth, and over time. It is well documented that the hydraulic conductivity of ice-rich permafrost soils can be several orders of magnitude lower than their unfrozen counterparts (e.g., Burt & Williams 1976, Kane & Stein 1983). Furthermore, ice-rich conditions at the freeze-thaw interface significantly reduce the permeability of the soil, effectively limiting the soil water capacity of the soil (Dingman 1975, Woo 1990).

However, the point and hill slope scale understanding of permafrost soils, specifically the effect of the freezing and thawing of the active layer on hydrologic proceses, have not been adequately or systematically incorporated into meso-scale hydrologic models (Vörösmarty et al. 1993). Representation of the active layer in previous modeling studies includes switching soil properties for the winter and summer periods (Sand & Kane 1986) and use of a simple square root of time function to estimate the active layer depth (Zhang et al. 1998, Schramm et al. 2007). Thermal models are absent in most hydrologic models because of computational time requirements and complexities in model coupling.

Fox (1992) introduced a physically-based one-directional freeze-thaw (ODFT) algorithm for estimating the position of the freeze-thaw interface. The ODFT is driven by surface temperature. Woo et al. (2004) modified the ODFT by inverting the equations and driving the algorithm in two-directions by using temperatures at the surface and at a specified depth in the soil column. This two-directional freeze-thaw (TDFT) algorithm improves the representation of the freeze-thaw interface during the freezeback period.

The objective of this paper is to present a method for estimating hydraulic conductivity and effective porosity (proxy for soil storage capacity) using the TDFT algorithm.

Methods

Overview of the TDFT algorithm

The main difference between frozen and thawed soils is the difference in hydraulic conductivity and storage capacity, both a function of amount of pore ice in the soils (Woo 1986). In our conceptualization of the arctic hydrologic regime, frozen soils are represented with a very low hydraulic conductivity, while thawed soils within the active layer are represented with a larger hydraulic conductivity. Effective porosity (P_{eff}) is used as a proxy for storage capacity. In frozen soils, the presence of pore ice reduces the effective porosity of the soil.

The freeze-thaw interface in the active layer is determined using the TDFT algorithm. The physically-based TDFT algorithm is based upon the Stefan's equation of heat conduction (Jumikis 1977). One of the assumptions of the Stefan equation is that sensible heat effects are negligible. This assumption typically holds in soils with high moisture contents (Lunardini 1981). The algorithm requires inputs for each soil layer: specified depth, bulk density, porosity, fraction of organic and mineral soils, soil moisture content, the threshold for freezing the soil moisture, and minimum unfrozen water content in frozen soils. For each soil layer, the thermal conductivity and the energy required to freeze or thaw that soil layer is calculated. The algorithm is driven by the surface temperature and temperature at the bottom of the soil column. At each time step, the energy available to freeze/thaw the soil is determined using a simple 'degree-day' formulation. The amount of energy available is compared to the amount of energy required to freeze/thaw a soil layer. The total amount of freezing or thawing of the soil layers is determined by the total amount of energy available from the surface and at the bottom of the soil column. The procedures for determining the thermal conductivity, the energy available for freezing/thawing the soils, and determination of the total freezing and thawing of the soil layers are described in detail in Woo et al. (2004). In our formulation, the TDFT is slightly modified such that soil thawing from the bottom of the soil column is not allowed.

Estimation of hydraulic properties

The next steps are to estimate the freeze-thaw interface, the hydraulic conductivity, and the effective porosity. After each time step, the total thawed thickness and frozen thickness (D_t and D_f, respectively) of each soil layer are determined. The position of the freeze-thaw interface is estimated for each soil layer, from the surface downward, by evaluating the thermal condition of the neighboring soil layers. For example, if soil layer X_{+1} is completely frozen ($D_t = 0.0$), while soil layer X_{-1} is completely thawed (D_t = soil layer thickness), then we assume that the active layer is developing and the position of the freeze-thaw boundary is located at D_t depth from the top of the soil layer, X. By evaluating each soil layer after each time step, multiple freeze-thaw interfaces within the soil column are possible.

Once the D_t and D_f are determined for each soil layer, the hydraulic conductivity for each soil layer is estimated using a simple weighting function. For each soil layer, the frozen and thawed hydraulic conductivity are specified. If the entire soil layer is either frozen or thawed, the appropriate hydraulic conductivity is assigned to that soil layer. If the freeze-thaw interface is located within a soil layer, the horizontal (K_H) and vertical hydraulic (K_V) conductivities are determined using simple weighting functions:

$$K_H = \frac{K_f D_f + K_t D_t}{D} \tag{1}$$

$$K_V = \frac{D}{\left[\dfrac{D_f}{K_f} + \dfrac{D_t}{K_t}\right]} \tag{2}$$

where $K_{f,d}$ are the frozen and thawed hydraulic conductivities, and D is the total thickness of the soil layer.

The effective porosity for each soil layer is simply estimated from the fractional components of the soil layer:

$$P_{eff} = 1.0 - F_m - F_o - F_{ice} \tag{3}$$

where $F_{m,o,ice}$ are the fractional components of mineral, organic, and ice.

Results

Evaluation of the TDFT

The TDFT algorithm is tested in the Imnavait Creek Watershed, Alaska (68°30′N, 149°15′W). Two sites, one in a valley bottom and one along a hill slope, are selected for testing. Compared with the hill slope site, the valley bottom site has a thick surface organic layer (0.3 m versus 0.2 m) and has a high soil moisture content. Table 1 shows the soil properties used to test the TDFT. The soil moisture content of each soil layer is the linear interpolation of field measurements to the center of each soil layer.

The surface temperature sensors used in the valley and hill slope sites are located at 2 and 7 cm below the land surface, respectively. Ground temperature measurements, located at 98 and 69 cm below the ground surface, were used for valley bottom and hill slope sites. In our simulations, the ground temperature can only be used in the soil freezing process (soils are not allowed to thaw from depth).

Initial simulations resulted in an underestimation of the maximum thaw depths at each site, probably as a result of underestimation of the amplitude of fluctuation of the ground surface temperature. The timing of the beginning of thaw/freezeback process was also slightly offset from measured field data. To better estimate ground surface temperatures, the near-surface soil temperatures were estimated via extrapolation of amplitude to the surface (Fig. 1). This resulted in an amplification of annual surface temperature fluctuation by 5% at the valley bottom and by 38/27% for temperatures above/below 0°C at the hill slope site. We explain the difference in amplitude by differences in near-surface moisture availability. Compared to the dry hill slope site, the wet valley bottom site has a high thermal diffusivity in the near surface soils. The combination of the high thermal diffusivity as well as the near proximity to the ground surface result in a much smaller surface temperature adjustment at the valley bottom site. Figure 2 displays the simulated freeze-thaw interface compared with measured soil temperatures and soil moisture content at each site.

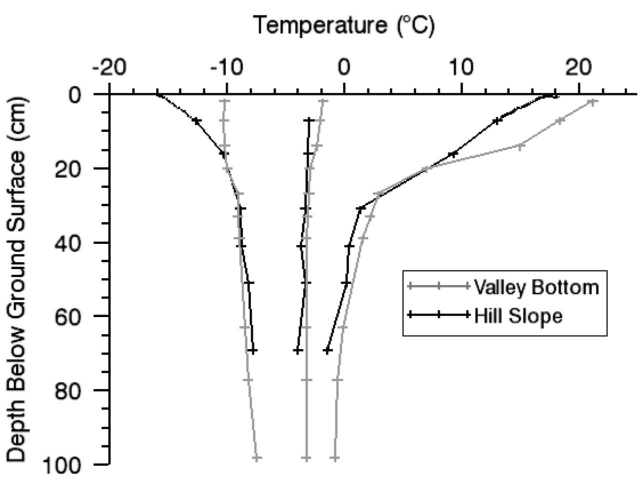

Figure 1. Trumpet curves showing the minimum, maximum, and average temperatures at the valley bottom site (light line) and hill slope site (dark line) for 2003. The "+" indicates location of measurements.

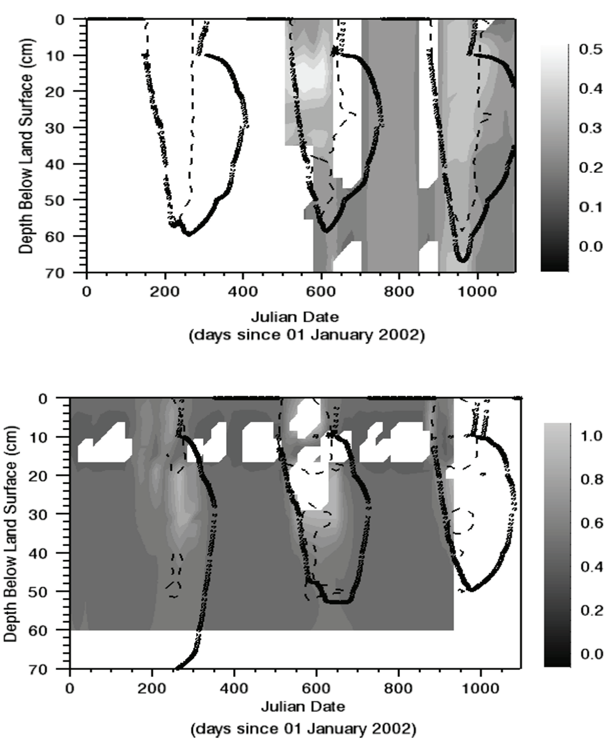

Figure 2. Comparison of the simulated freeze-thaw interface (dark dots) in the valley bottom (top panel) and hill slope (bottom panel) sites with the -0.1°C isotherm (dark dashes) and unfrozen soil moisture content (background). Color bar indicates volumetric soil moisture content. Solid white regions indicate missing data.

For these simulations and comparisons, daily temperature and soil moisture data measured at 12:00 are used. Results indicate that for most years, the TDFT algorithm is able to simulate the beginning of thaw, the maximum thaw depth, and freezeback period. The latent heat effect during the freezeback period is also represented. Estimated porosities derived from these simulations are shown in Figure 3.

Discussion and Conclusions

The seasonal freezing and thawing of the active layer and the associated changes in hydraulic properties are defining features of arctic hydrologic systems. Despite the known importance of the active layer in hydrologic systems, it has been poorly represented in meso-scale hydrologic models. The TDFT algorithm provides a foundation for estimating the freezing and thawing of the soils, hydraulic conductivity, and storage capacity of the soils.

The TDFT, based upon the Stefan equation, assumes that sensible heat effects are negligible. Care must be taken when applying the TDFT in drier areas, where sensible heat fluxes may be an important component of the energy balance. A basic understanding of the physical system being modeled is critical before applying the TDFT.

Using the TDFT to estimate hydraulic properties is an improvement over previously used methods in that 1) changes in the thermal and hydrologic regimes are continuously and adequately captured over time; 2) the ability to simulate the freezeback period allows for longer (year-to-year) simulations, whereas the other methods such as using the

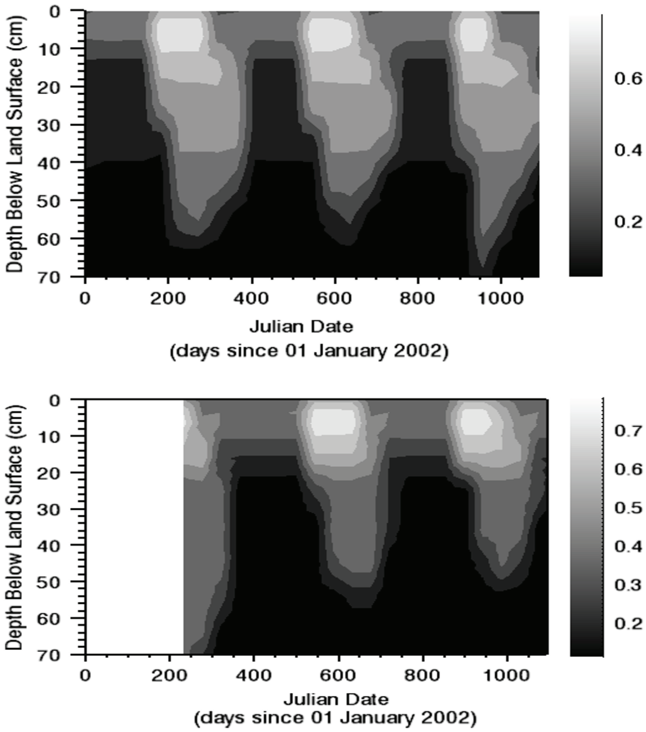

Figure 3. Simulated soil porosity at the valley site (top panel) and hill slope (bottom panel). Solid white regions indicate missing data.

square root of time function is only able to simulate the thawing process; 3) the TDFT is physically based, requiring no prior calibration; and 4) the TDFT is computationally cheap.

The depth and rate of thawing/freezing of the active layer are both spatially and temporally variable. As a result the hydraulic properties of the soils are spatially (x-, y-, and z-directions) and temporally (both short and long term) variable. Accurate freeze-thaw boundary simulations using the TDFT algorithm are highly dependent upon accurate surface temperature data. In order to take full advantage of the TDFT derived variables in (spatially-distributed) meso-scale models, a method needs to be developed to obtain accurate spatial and temporal surface temperatures from within the modeling area.

Abstract

Various technical solutions for foundations and anchors of infrastructures in permanently frozen ground are examined. Focus is placed on different categories of infrastructures and their sensitivity to changing subsurface conditions, primarily caused by modifications in the ice and water contents of the permafrost. The requirements for infrastructures with high safety standards such as cableway stations and pylons are determined by factors including the mass of the building, its serviceability, dynamic forces engendered by the cable mechanism, and the bearing capacity of the ground. In contrast, the conditions for a structure such as an alpine hut are mainly given by the relatively low mass of the building, snow loads, wind effects, and the bearing capacity of the ground. It is crucial that design considerations involve an integral approach and take into account the influences of global warming and the more intensive time and cost factors required to complete a project.

Keywords: anchor; bearing capacity; foundation; mountain permafrost; serviceability.

Introduction

Changing subsurface conditions represent the main problem for infrastructures in mountain permafrost. The reasons for changing subsurface conditions can be global warming, construction work, an existing infrastructure, or a combination of these, and can lead to permafrost ice warming, melting, and finally to complete degradation. After the soil and rock characteristics, ice content and temperature strongly affect the subsurface conditions and play a vital role in controlling the deformation behaviour and the bearing capacity of infrastructures.

On the other hand, the serviceability determines the maximal allowable vertical and horizontal displacements of an infrastructure. The serviceability requirements depend on building categories (Table 1). Cableway stations and pylons or pipelines are highly sensitive to differential displacements, resulting in a higher urgency for repairs after displacements, whereas communication structures (e.g., telecommunication antennae) or alpine huts and mountain restaurants react less delicately. Therefore, the building category controls the differential deformation sensitivity or the serviceability respectively.

Combining the controlling subsurface conditions with the serviceability of an infrastructure is an essential step in the development of an adequate foundation concept. In addition, the mass of the building, snow loads, dynamic loads and the influences of present and future global warming must be considered. Depending on the subsurface and load conditions, anchor reinforcements for the foundation may be necessary. In this paper, we examine engineering solutions for foundations and anchors for various building categories in mountain permafrost.

Design Considerations

Time and cost intensity

The time and cost intensity required for the construction of infrastructure in mountain permafrost is higher in comparison with infrastructure located in permafrost-free terrain. The site investigation in particular requires a longer period of time. If the first site study indicates a possible permafrost occurrence, the preliminary study should take in account further *in situ* investigations to determine the characteristic geotechnical parameters. In addition to the typical examinations regarding the foundations, measurements of temperature and deformation should be carried out for at least one year prior to construction. With the resulting data, a first evaluation of the ice content, ground temperature, active layer thickness and deformation rate can be carried out. Sustainable design considerations can only be ensured with this crucial information.

The following additional factors can also have a time and cost-increasing effect: the obtention of approval to build outside an official construction zone; the environmental impact assessment of the projected structure; climatic conditions such as snow, air temperature or altitude; the logistics like accessibility and transportation; and the short time frame available for construction at high altitudes. All these factors account for a significantly higher time and cost intensity for infrastructures in mountain permafrost.

Effects on the ground and structure

For the design of infrastructure in mountain permafrost it is important to consider the effects on the ground. The main effects are due to the dead and live loads induced by an infrastructure. Other effects include heat input/thermal disturbance from building activity or the long-term thermal and mechanical influences of the infrastructure itself and those caused by global warming. Excavation activities also affect the ground. A warming of the excavated slope can cause instabilities and rockfall. In summary, there are mechanical influences (load), which change the stress condition, and there are thermal influences (heat exchange), which can change the geotechnical parameters of the ground. An appropriate design must take into account the geotechnical and thermal effects with respect to the bearing capacity, sliding and toppling (ultimate limit state [ULS]). The definition of ULS is satisfied if all design loads are below the ground resistance calculated for the section under consideration (Swisscode SN 505267).

The effects of modifications on the structure itself are as important as the effects on the ground. The allowable effects with respect to the deformation and creep rates are dependent on the serviceability of the infrastructure, which is usually defined in the service criteria agreements (Swisscode SN 505267) as an allowed inclination angle of a structure due to differential settlements. This inclination angle consists of a ratio of the differential settlement to the size (length) of the structure. In Table 1 the sensitivity limits for serviceability are given for different building categories. Not incorporated in Table 1 is the time factor, such as how fast a displacement takes place. Other effects on the structure, such as natural hazards in the vicinity or geotechnical and technical difficulties, are determined by the risk analysis. The aim of the latter is to identify all kinds of risks that could influence both the construction and use of an infrastructure. A consideration of all these effects on the structure is necessary for the design with respect to the serviceability (serviceability limit state [SLS]).

The ultimate and serviceability limit states result in two allowable values for the foundation pressure or anchor tension. Depending on the smaller value, the size and shape of a foundation or the type and length of an anchor are determined. Hence, only an integral design consideration, which includes all the above-described factors, ensures the sustainability of an infrastructure.

Table 1. Assessment of different building categories with the sensitivity limit for serviceability and the need for repairs.

Building categories	Sensitivity limit for serviceability: Uniform displacement	Sensitivity limit for serviceability: Differential displacement[1]	Urgency for repairs after displacement
Cableway station	moderate	high	high
Cableway pylon	moderate	high	high
Communication structure	low	high	moderate
Mountain hut	low	moderate	low
Mountain restaurant	low	moderate	moderate
Pipeline	high	high	high
Snow supporting structure	low	moderate	moderate

[1] e.g., leading to tilting and cracking of the structure.

Impact of global warming

Global warming shows an elevation dependency, whereby the warming at high elevation sites in the Alps may be more pronounced than at low elevations (Beniston & Rebetez 1996). The exact consequences are difficult to define, but the general warming tendency will lead to long-term degradation of mountain permafrost and a deepening of the active layer. Warming permafrost ice increases the creep ratio and decreases shear strength, which can lead to more pronounced mass movements. Melting of the permafrost ice induces horizontal (creep) and vertical displacements (settlement) and elevated pore water pressures (Andersland & Ladanyi 2004, Esch 2004). Ice segregation can cause uplift of infrastructures and terrain and lead to rock instabilities. These various impacts of global warming on an infrastructure in mountain permafrost must be considered during the design process with respect to the total service life of a building.

Technical Solutions

Shallow foundations

Foundation systems depend on load and subsurface conditions as described above. A shallow foundation transfers building loads to the ground very near the surface. Shallow foundations include, for example, single foundations, strip foundations, and slab-on-grade foundations. Therefore, if the subsurface consists of stable rock or the design loads are rather small, a shallow foundation type is suitable. In mountain permafrost, shallow foundations are common, because the subsurface conditions often consist of stable rock with high strength. On this account, cableway stations and pylons, mountain restaurants, and huts are often built with a shallow type of foundation such as single, strip or slab-on-grade foundations. Figure 1 shows the strip foundation of the

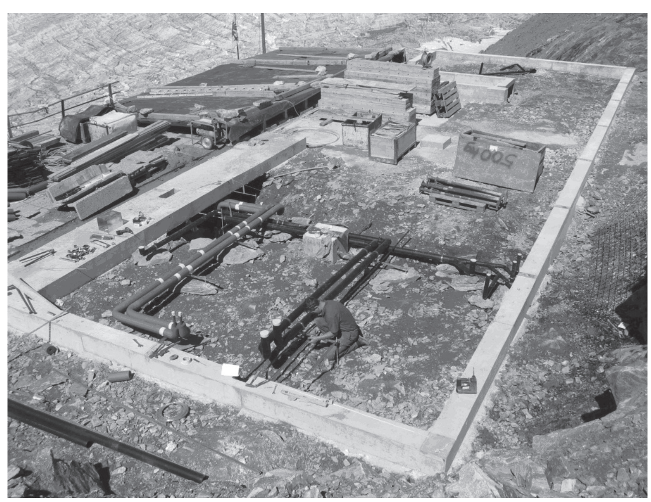

Figure 1. Strip foundation of new Finsteraarhorn mountain hut, Swiss Alps (Photograph: Ruch Architects, Meiringen 2003).

new Finsteraarhorn SAC (Swiss Alpine Club) mountain hut in the Swiss Alps.

Other reasons to choose a shallow foundation wherever possible are the complicated accessibility and transportation of heavy equipment for the excavation and material to the construction site. Shallow foundations are less complicated to implement than deep ones and therefore cheaper compared to all other types of foundations.

Deep foundations

As their name suggests, deep foundations are distinguished from shallow foundations by the depth to which they are embedded into the ground. The main reasons a geotechnical engineer would recommend a deep foundation over a shallow one are large design loads, high ice contents, warm permafrost at shallow depth or other site constraints such as unstable and complex geology. Deep foundations in mountain permafrost include drilled piles, shafts and piers. Drilled micropiles are often used for the construction or restoration of cableway stations and pylons. Permafrost degradation and active layer deepening can lead to a decrease in the bearing capacity of the ground, requiring additional anchors for the stabilisation of an existing structure – depending on the building category and its sensitivity limit for serviceability. In mountain permafrost the most practicable way to carry out this type of stabilisation is to drill a hole, place a threaded bar (micropile) and inject grout under high pressure into the surrounding clefts and fissures to increase the stability and bearing capacity. This is not a sustainable solution but it helps to allow continuation of the operation of an infrastructure without altering its location. For cableway stations and pylons in particular, this approach represents a cost-efficient and thus attractive way of restructuring.

Flexible structures

The latest technical experiences indicate that for locations with ice-rich permafrost, flexible systems are best adapted to meet the serviceability requirements. Laterally adjustable cableway pylons or three-point bearings for structures such as cableway stations (Phillips et al. 2007, Walser, pers. com.) and mountain restaurants are examples of these. Differential settlements within a three-point bearing do not generate internal constraints; this type of system can therefore extend the service life of a structure. Figure 2a shows one of the three-point bearings of a mountain restaurant in Ischgl, Austria. If settlement occurs, the steel construction can be uplifted hydraulically and steel plates can be inserted between the concrete support and the steel structure (Fig. 2b). The repositioning in this particular case takes place once a year and can be carried out in a few hours.

Snow nets (snow supporting structures) represent another flexible solution that is ideal for mountain permafrost. The hinged supports are mounted on ball joints, which allow them to swivel in a certain range. This behavior is particularly useful in creeping permafrost terrain and raises the service life of this type of avalanche defense structure (Phillips 2000). Experience in the Swiss Alps over the last decade shows that it is not sustainable to construct snow nets if the creep rates exceed 5 cm/year (Margreth 2007) and that floating foundations (steel bed plates) should be used in strongly creeping permafrost (Phillips & Margreth 2008, this proceedings).

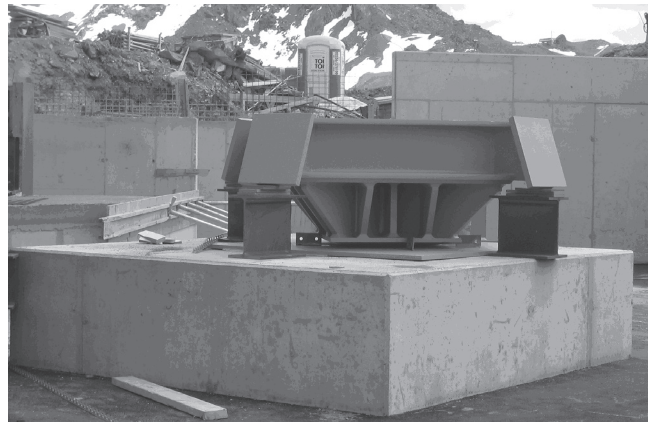

Figure 2a. Point bearing of a steel structure on a single concrete foundation, Ischgl, Austria (Photograph: M. Walser, Ischgl 2004).

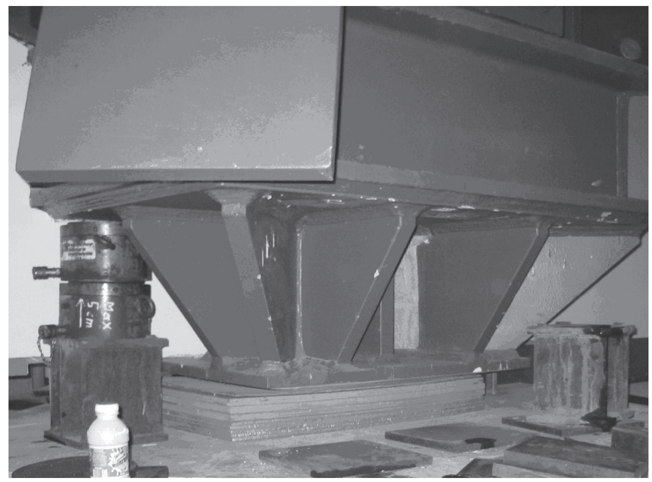

Figure 2b. Repositioning point bearing with hydraulic press, inserted steel plates, Ischgl, Austria (Photograph: M. Walser, Ischgl 2005).

Substrate structure

It is common practice to modify the substrate structure if necessary by replacing poorly graded material or broken rock with a well-graded gravely material. The modified substructure helps to uniformly distribute the load over an inhomogeneous surface. Compaction should take place in layers with a water content of the material close to the w_{opt} (Phillips et al. 2007). This facilitates the compaction work and increases the compactness of the packing (Soil Compaction Test, ASTM D698, Proctor 1933). A reinforcement consisting of steel nets or geotextile is possible. The reinforcement increases the bearing capacity, resulting in a higher design load and an even load distribution.

Insulation and cooling systems

To prevent heat transfer into the permafrost body (e.g.,

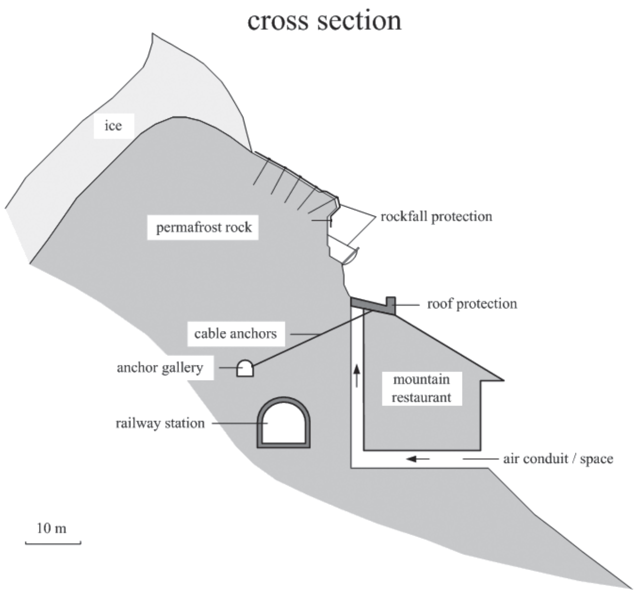

Figure 3. Scheme of air conduits, anchorage and anchor gallery, Jungfraujoch, Switzerland (after Keusen & Amiguet 1987).

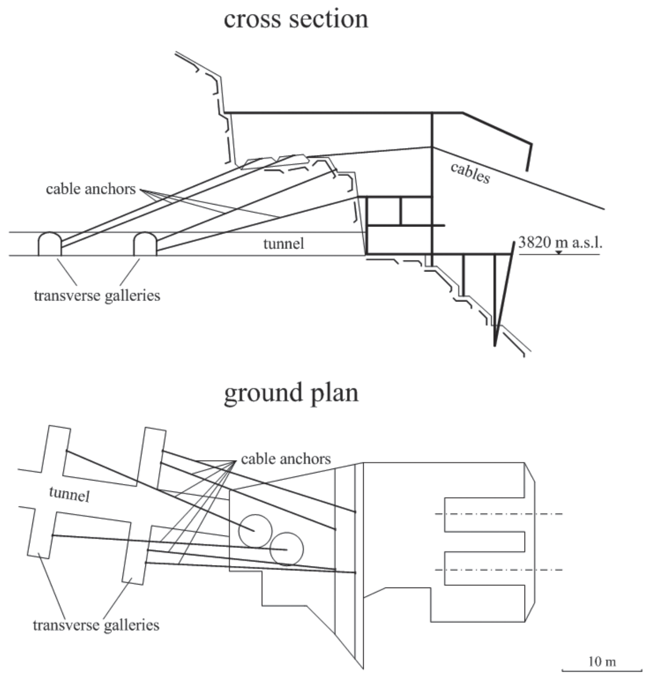

Figure 4. Scheme of anchorage including the transverse galleries, Klein Matterhorn, Switzerland (after Keusen & Haeberli 1983).

hydration heat emanating from curing concrete or conductive heat transfer from a heated structure above), a layer of insulation with high compressive strength (e.g., extruded polystyrene) should be placed between the foundation and the ground. Air conduits/spaces beneath a foundation and external wall represent another solution to protect the underlying permafrost (Fig. 3). These passive cooling systems are common, whereas experience with more sophisticated passive cooling systems (e.g., thermosyphons) is practically non-existent in the Alps. Active cooling systems (e.g., powered ventilation system) are used in individual cases but are not widespread in mountain permafrost infrastructures.

Anchors

Ground anchors normally consist of steel reinforcing bars or cables with a grout coating or a grout anchorage body (tieback). Rock or soil anchors can be installed prestressed or non-prestressed, respectively—prestressed is common practice. The non-prestressed are soil or rock nails and usually fully grouted. The force transmission of an anchor is based on a frictional bond between the grout and the surrounding ground. Anchors therefore react in a sensitive manner to changing subsurface conditions such as permafrost warming accompanied by loss of ice. The main implication of warming is reduced shear strength of anchors that can lead to a decreasing external bearing capacity and consequently, to accelerated deformation or failure of the supported structure.

The subsurface conditions, the size of the induced force and the risk potential of a failing structure determine the anchoring concept. In mountain permafrost most of the designed anchors are tied in bedrock. High stress and strain anchors with a large risk potential, such as those used for cableway stations and other exposed infrastructures, should be installed within an anchor gallery to avoid problems associated with injection anchors (e.g., freezing of grout, changing subsurface conditions) and to allow anchor replacements. Where possible, monitored anchors and load cells should be used. Figures 3 and 4 show two possible solutions for anchor galleries. In Figure 3, the rockfall and snow load roof protections of the mountain restaurant, Jungfraujoch, Switzerland, anchored with several high stressed cable anchors are illustrated (Keusen & Amiguet 1987). Figure 4 shows the traverse galleries from the access tunnel, used for anchorage of the cables and steel construction of the cableway station, Klein Matterhorn, Switzerland (Rieder et al. 1980, Keusen & Haeberli 1983). Drilling and prestressing of the anchors as well as the continued observation of the anchors occurs from the anchor gallery. This design approach ensures reliable monitoring, resulting in a higher factor of safety. Small stress and strain anchors such as those used for mountain huts, defence and communications structures, with a smaller risk potential, can be carried out with standard anchors without an anchor gallery. Margreth (2007) describes the important criteria and implications to install an anchor in mountain permafrost such as e.g., warming of the mixing water to a certain temperature to allow the curing of the injected grout in the anchor hole before freezing takes place.

In either case a monitoring and maintenance concept is highly recommended. It is compulsory for all prestressed permanent anchors to have accessible anchor heads over their service life. For high stress and strain anchors a permanent monitoring with load cells is a desirable objective. Likewise, there should be an anchor system redundancy, in order to allow maintenance work without safety reduction or interruption of operation.

Conclusions

The design consideration has to incorporate that the time and cost factors are higher for construction of an infrastructure in mountain permafrost in comparison with an infrastructure located in permafrost-free terrain. In particular the logistics such as the accessibility and transportation contribute to increasing time and cost for infrastructures in mountain permafrost. The necessity of undertaking extensive geotechnical investigations at least one year in advance of the start of construction also significantly extends the design and construction phase. The influences of present and future global warming, including the natural hazards involved, must be considered in the design of mountain infrastructure as well.

Various engineering solutions in mountain permafrost are affected by global warming and have been modified or restructured. Flexible technical solutions are well adapted to permafrost undergoing modification. In some cases, inappropriate technical solutions have been used and various mistakes have been made. Hence, development of guidelines for infrastructures in mountain permafrost is necessary to limit both cost and risk factors. The Swiss Federal Institute for Snow and Avalanche Research SLF is currently developing recommendations for infrastructures in alpine permafrost which should be published in 2009.

Acknowledgments

Abstract

In arctic streams, permafrost may influence hydrological and biogeochemical processes that control carbon and nutrient dynamics. We examined interactions among these processes in a fast-flowing, cobble-bottom stream and a slow-flowing, peat-bottom stream near Toolik Lake, within the foothills region of the Brooks Range, Alaska. Using a combination of ground penetrating radar, physical probing, and conservative solute injection experiments, we found that the thaw depths within the cobble-bottom stream were considerably deeper than in the peat-bottom stream. The maximum extent of hyporheic penetration followed a similar trend, but in both streams the hyporheic depth was less than the maximum extent of thaw. Hyporheic regeneration of N and P (estimated as mass fluxes) were in reasonable stoichiometric agreement. However, regeneration of C (estimated by whole-stream metabolism) was much greater than regeneration of either N or P, indicating considerable internal recycling of these essential elements.

Keywords: biogeochemistry; hyporheic zones; nutrients; thaw bulbs; tundra streams..

Prior to our current research, virtually nothing was known about hyporheic dynamics in Arctic streams draining areas with continuous permafrost. Substantial evidence from temperate streams suggests that the hyporheic zone can be an important site of organic matter turnover and a source of regenerated nutrients. However, permafrost exerts strong influences on surface processes that we initially thought might alter the structure and function of the hyporheic zone in Arctic streams. However, initial results reported by Edwardson (1997) and Edwardson et al. (2003) showed that hyporheic dynamics in the Kuparuk River, on the eastern North Slope of Alaska, were similar to those observed in temperate streams. In particular, we found that geomorphic profiles of stream channels (longitudinal more so than lateral) provide the necessary hydraulic gradients to drive hyporheic exchange through the streambed, as shown by Harvey and Bencala (1993) and Kasahara and Wondzell (2003). We also showed that biogeochemical processing in the hyporheic zone was important, potentially supplying from 14 to 162% of the benthic N uptake requirements in the Kuparuk River.

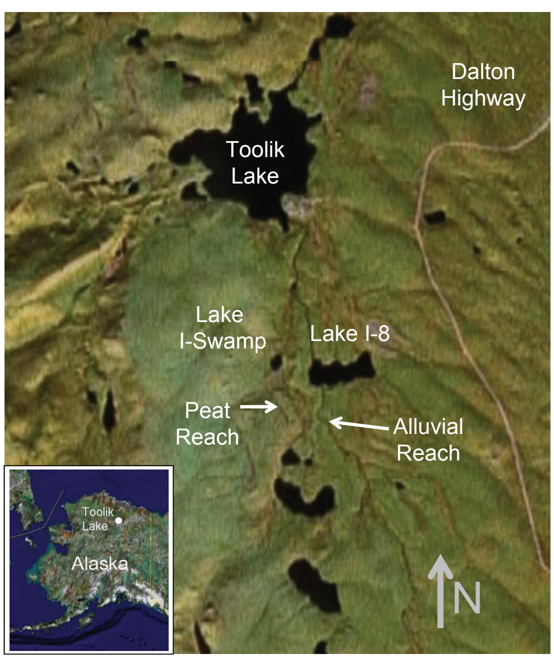

Figure 1. Location of the study streams. (Colored illustration available on CD-Rom.)

The purpose of this paper is to integrate the results of our work on hyporheic dynamics in tundra streams with results from a separate study of whole-stream metabolism in similar streams. These two studies provide insight into interactions among carbon, nitrogen, and phosphorus dynamics in the hyporheic zones of arctic tundra streams that overlie continuous permafrost.

Site Description and Methods

Study sites

The study area (Fig. 1) was located on the North Slope of the Brooks Range in Alaska, near the Toolik Field Station (68°38′N, 149°36′W), about 180 km south of the Arctic Ocean. Two common stream geomorphologic types occur on the tundra landscapes in this area: (a) high-gradient, alluvial streams with alternating riffle-pool sequences and (b) low-gradient, peat-bottom streams with a "beaded" morphology in which large, deep pools are connected by narrow, deep runs. We located two streams that represent these contrasting tundra stream types and that lie parallel to each other within a series of lakes and connecting streams that flow north into Toolik Lake. Kling et al. (2000) referred to these two stream reaches as the inlets to Lakes I-8 and I-Swamp in the I-Series. These two streams are of the same order, have the same aspect, and drain similar landscapes. They differ in that the alluvial reach has a higher gradient and drains an area that has no lakes, while the peat stream has a lower gradient and drains an area with several lakes.

Ground penetrating radar

We used ground penetrating radar (GPR) to establish the boundary between the thawed sediments in the active layer under the stream (the thaw bulb) and permafrost (Bradford et al. 2005, Brosten et al. 2006). We used a commercial pulsed radar system with 200 MHz antennas and high-powered transmitter (1000V) to maximize penetration beneath the streambed. The antennas and GPR control equipment were placed in the bottom of a small rubber boat, and pulled steadily across the stream and banks on either side while triggering the radar at a constant rate. While acquiring data, we were careful to maintain a steady pull rate while minimizing downstream drift. Additional details of GPR data acquisition are provided by Bradford et al. (2004). In addition to acquiring the radar profiles, we measured depth to permafrost on the stream banks and shallow (<0.5 m) margins of the streams by pressing a metal probe through the active layer to the point of refusal.

Solute injection experiments

We performed solute injection experiments (SIEs) using Rhodamine WT (RWT) in June and August 2005 in each stream to determine the extent of hyporheic exchange within the thaw bulb. A metering pump dripped RWT into the stream at a constant rate at the top of the reach until the surface water RWT concentration reached a plateau in the fully mixed zone of the streams (20–50 downstream from the injection point). During each SIE, and for a period following the tracer injection, surface and subsurface water were sampled at regular intervals. Subsurface samples were obtained via a set of nested mini-piezometers that spanned the depth of the thawed zone in each stream (3 depths in the alluvial stream and 2 depths in the peat stream). For the alluvial SIE, samples were taken every 20 min for the first hour, and every 30 min hourly thereafter, until the end of the experiment (~2.5 h). The peat SIE was longer, and so the later samples were taken approximately every two hours to the end of the experiment (6 and 9.7 h in two experiments). Samples were returned immediately to the laboratory for analysis of RWT concentration using a Turner Designs 10-AU fluorometer. For each mini-piezometer location, a tracer breakthrough curve (RWT concentration vs. time) was obtained for the surface water and each subsurface location sampled for each SIE. We used these data to establish the depth and timing of surface water penetration into the hyporheic zone of the two stream reaches. Details for these approaches are provided in Zarnetske (2006), Zarnetske et al. (2007), and Greenwald (2007).

Water chemistry

Four times during the summer of 2005 (Alluvial: 29 June, 4 July, 1 August, 15 August; Peat: 27 June, 1 July, 29 July, 10 August), surface and subsurface water from 9 sub-sites within both streams were sampled and analyzed for concentrations of nitrate (NO_3), ammonium (NH_4), soluble reactive phosphorus (SRP), dissolved oxygen (DO) and dissolved organic carbon (DOC). For each stream, the results from the first two sampling dates were averaged and reported as June data, and the results from the last two sampling dates were averaged and reported as August data. Early summer chemistry data were paired with the June SIE data, and late summer chemistry data were paired with the August SIE data.

Concentrations of DO in surface and subsurface water samples were measured in the field with a WTW Oxi 340i handheld dissolved oxygen meter. The reported accuracy for this dissolved oxygen meter is +0.01 mg/L (WTW, Weilheim, Germany). However, under the conditions in which we used this equipment, we assumed a more conservative estimate of accuracy of +0.1 mg/L. All other water samples were filtered through 0.45 μm, 25 mm diameter, cellulose acetate syringe filters and kept on ice for transport to the laboratory.

Ammonium and SRP analyses were done within 48 hours at the Toolik Field Station. Ammonium analyses were performed using the orthophthaldialdehyde (OPA) method (Holmes et al. 1999). SRP analysis was performed using the colorimetric molybdate blue method (Murphy and Riley 1962). Nitrate samples were immediately frozen at the field station, then transported to the University of Vermont's Rubenstein Ecosystem Science Laboratory in Burlington, Vermont, USA, where they were analyzed within 6 months by the cadmium reduction technique (Askew & Smith 2005, p. 123). DOC samples were preserved with 6N hydrochloric acid to a pH of 2, transported to the Ecosystems Center in Woods Hole, Massachusetts, USA, and analyzed by the persulfate-ultraviolet method within 6 months (Baird 2005, p. 23). We combined the RWT tracer and water chemistry data to estimate net nutrient regeneration rates using methods described by Greenwald (2007).

Whole-stream metabolism

We calculated net ecosystem metabolism (NEM) with the whole-stream, open-system, single station approach described by Marzolf et al. (1994) as refined by Young and Huryn (1998). We measured reaeration using the sound pressure method developed for these streams by Morse et al. (2007). Estimates of ecosystem respiration (ER) were corrected for the presence of low light levels at solar midnight, as described by Cappelletti (2006). Gross primary production is the difference between NEM and ER (where ER <0; i.e., a consumption of DO).

Results and Discussion

Stream characteristics

Despite their close proximity (less than 1 km), the two study streams were geomorphically distinct. Both streams are underlain by permafrost. However, the gradient of the alluvial stream was 0.7%, and the substrate was a mix of cobble and boulders, while the gradient of the peat stream was 0.03%, and the substrate was a mix of peat and silt (Fig. 2).

We used ground penetrating radar (GPR) to image the progression of thaw depth from May–September 2004 in the thawed zone under the alluvial and peat streams (Brosten et al. 2007). Permafrost depths interpreted from GPR data were constrained by both recorded subsurface temperature profiles and by pressing a metal probe through the active layer to the point of refusal. We found that the thaw bulb developed differently within the two stream environments. Thaw depths within the alluvial stream increased in thickness up to 2.5 m by the end of the summer (Fig. 3) but to a maximum of only 1.5 m (and generally <1 m) in the peat-bottom stream (Fig. 4). By late August and early September, the alluvial site began to refreeze. while the peat-bottom site continued to thaw; thaw depths had not receded at the peat-bottom sites by our last site visit in September. These results indicate distinctly different responses to the seasonal thermal input. Rapid heat absorption and loss occurs in the cobble-bottom alluvial stream while peat insulates the permafrost and introduces a lag in the seasonal thermal profile.

Using conservative tracer additions, we found that transient storage indicators such as mean storage residence time, storage zone area, hydraulic retention, and storage exchange rates were sensitive to discharge and strongly correlated with total stream power (Zarnetske et al. 2007). However, the relationship between transient storage and extent of thaw was less clear. Transient storage indicators increased with increasing thaw depths under base- and low-flow conditions, but these relationships diminished at high flow. We found good correlations between the Darcy-Weisbach friction factor of these channels and several metrics of transient storage, in agreement with previous studies (e.g., Bencala & Walters 1983, Harvey & Wagner, 2000). We found that stream power was a good predictor of transient storage characteristics because it normalizes simple characteristics of hydraulics and morphology, thereby allowing better comparisons across streams that differ widely in these characteristics (Fig. 2). Our results in arctic streams are comparable to those in temperate streams (Legrand-Marcq & Laudelout 1985, D'Angelo et al. 1993, Harvey et al. 2003) indicating that our findings are likely transferable to non-

arctic streams.

Hyporheic exchange depths in the cobble-bottom and peat-bottom streams (Fig. 5) were constrained in part by depths of thaw beneath these two streams and in part by the texture of the substrate, both of which are controlled by stream gradient. In the cobble-bottom stream–which had a greater depth of thaw–stream water penetrated the hyporheic zone to a depth of up to 54 cm. In the peat-bottom stream, which had a much shallower depth of thaw, the actively functioning hyporheic zone was limited to a depth of 10 cm or less. In both streams, we found that the maximum extent of hyporheic penetration was much less than the maximum extent of thaw.

Combining our estimates of hydraulic exchange between the open channel and the hyporheic zone with analyses of hyporheic nutrient concentrations in these reaches (Table 1) provided an estimate of hyporheic regeneration. Total N regeneration in the alluvial reach was about 9.3 µmoles m^{-2} h^{-1}, primarily as nitrate (7.9 µmoles m^{-2} h^{-1}). The P regeneration rate was 0.54 µmoles m^{-2} h^{-1} for N:P regeneration molar ratio of 17:1. Total N regeneration in the peat stream was 5.3 µmoles m^{-2} h^{-1} based on a release of ammonium (6.8 µmoles m^{-2} h^{-1}) and an uptake of nitrate (-1.5 µmoles m^{-2} h^{-1}). The P regeneration rate was very low, at 0.05 µmoles m^{-2} h^{-1} for an N:P regeneration molar ratio of 105:1. Thus, hyporheic regeneration in the alluvial reach was in approximate stoichiometric balance (16:1), while regeneration of P in the peat stream was considerably less than expected.

The ratios of N and P regeneration can also be compared to estimates of hyporheic C processing based on whole-stream estimates of ecosystem respiration measured in these stream reaches in a previous year (W.B. Bowden, unpublished data, 2001). Cappelletti (2006) observed that even in a modestly productive river (the Kuparuk River), the vast majority of total ecosystem respiration could be attributed to hyporheic respiration. Ecosystem respiration in both stream reaches was similar at ~30 mmoles m^{-2} h^{-1}. Thus, the observed C regeneration ratios relative to N and P were roughly 3 orders of magnitude greater than the expected C:N (~7:1) and C:P (~106:1) ratios. This suggests that a considerable quantity of N and P liberated in the course of decomposition in the hyporheic zones of these streams is reutilized before it leaves the hyporheic system.

Table 1. Connectedness-weighted, season-averaged concentrations of nutrients in the hyporheic zones of the alluvial and peat stream reaches. See Greenwald (2007) and Greenwald et al. (in press) for details about seasonal nutrient concentrations.

Nutrient	Stream type: Alluvial	Stream type: Peat
Nitrate (µM)	5.75	7.49
Ammonium (µM)	0.20	0.52
Phosphate (SRP) (µM)	0.02	0.03

These results show that gradient strongly influences the spatial and temporal extent of thawed sediments in streams that drain permafrost-dominated landscapes. Gradient controls substrate particle sizes, which in turn controls the hydraulic and—peat is deposited—the thermal conductivities of stream substrates. Thus, steeper streams have coarser substrates and conduct heat energy and water more effectively to depth than is the case in less-steep streams that accumulate fine organic sediments. The result is that the thaw bulb (active layer) below alluvial streams is deeper than it is beneath peat streams. For similar reasons, the zone of active hyporheic exchange is thicker in alluvial streams than it is in peat streams. However, we found that the thaw depth was thicker than the zone of active hyporheic exchange in both stream types.

The hyporheic zones in these streams were biogeochemically active. In the alluvial reach, the hyporheic zone was a source of NH_4, NO_3, and PO_4 and a sink for DO. In the peat stream, the hyporheic zone was a strong source of NH_4, a weak source of PO_4, and sink for NO_3 and DO. The total regeneration of N and P was in reasonable stoichiometric balance in the alluvial reach, while in the alluvial reach less P was regenerated than expected based on the N regeneration. However, based on C regeneration (respiration), far less N and P were regenerated from the hyporheic zones of either stream than expected. This suggests the potential for substantial re-immobilization of N and P mineralized from organic matter decomposition in the hyporheic zones of these streams. The relative importance of net nutrient regeneration from the hyporheic zones of these streams versus internal recycling of nutrients within these hyporheic zones is still poorly known. In addition, it is not clear how factors such as geomorphic form, stream network characteristics (e.g., stream order), or landscape characteristics (e.g., young versus old glacial ages) influences this balance.

Acknowledgments

We thank Julia Larouche, Kenneth Turner, Joel Homan, Tom Crumrine, and Adrian Green for field and laboratory assistance and Alan Howard for statistical advice. Kenneth Edwardson contributed valuable information and insight to our comparisons of net nutrient regeneration rates in North Slope streams. We also thank the staff of the Toolik Field Station and VECO Polar Resources for logistical support. Abstract

Field investigations were undertaken to study the geomorphology and permafrost conditions of more than 20 methane-venting pockmark features in a pond west of Middle Channel, Mackenzie Delta. The flux of methane to the atmosphere from these pockmarks is estimated to be 5.07 x 10^5 m^3 yr^{-1}. Terrestrial permafrost around the pond is ~60 m thick and likely formed within Holocene deltaic sediments. However, the site is located only 2 km from a major permafrost boundary where permafrost thickens over a short distance to more than 400 m. Mean annual pond-bottom temperature is above 0°C, creating the potential for talik formation, and hence gas migration pathways, beneath the pond. Isotopic analysis indicates that the methane is of thermogenic origin, and is similar in composition to the gas of the nearby Niglintgak gas field.

Keywords: climate change; gas hydrates; Mackenzie Delta; methane seeps; pockmarks.

Introduction

Interest in the occurrence of greenhouse gases within permafrost, particularly methane, has grown in recent years with the consideration of the effects of climate warming and the continued expansion of engineering activity in the Arctic. The potential release of methane as free gas fluxing from arctic lakes is recognized as a possible positive climate change feedback mechanism (Walter et al. 2006), as is gas release from dissociating gas hydrates beneath transgressed areas of the Arctic Shelf (Taylor et al. 2002, Paull et al. 2007). Gas leakage from deeper hydrocarbon occurrences are also of interest in areas underlain by large sedimentary basins. Finally, shallow occurrences of free gas have been recognized as a potential geohazard to hydrocarbon exploration and development (Collett & Dallimore 2002).

This paper describes a number of small gas seeps and one prolific seep which occur in a pond in the outer Mackenzie Delta, NWT, Canada (Fig. 1A). The site is of historical interest, as natural gas was first observed discharging from the pond in 1963 by Dr. Ross Mackay (pers. com. 1991). During the course of three field seasons approximately twenty small gas seeps and one large seep have been investigated. The large seep has a conical bed form depression similar to pockmark features described offshore (Hovland & Judd 1988). This paper describes permafrost conditions, geomorphology and geotechnical properties of the site, and quantifies the geochemistry and gas flux from the large seep.

Permafrost and Physiographic Setting

The depth of ice-bonded permafrost in the outer Mackenzie Delta has been estimated from geophysical well logs, hydrocarbon exploration wells (Smith & Judge 1993), and deep sounding electromagnetic transects (Todd & Dallimore 1998). Ground temperature data are also available from instrumented wells (Taylor et al. 1998). Using these data, the base of ice-bonded permafrost and intervals where stable methane hydrate can occur was modeled with physiographic boundary constraints.

Permafrost distribution beneath terrestrial areas is variable (Fig. 1A), reflecting a complex Quaternary paleoclimate and depositional history (Taylor et al. 1996). To the east of Middle Channel, older pre-Holocene sediments outcrop or occur at shallow depths beneath a thin veneer of Holocene deltaic sediments. Permafrost beneath land areas is 250 to 600 m thick. To the west of Middle Channel, Holocene deltaic sediments dominate the near-surface geology, and permafrost thins over a few kilometers to approximately 60 m (Fig. 1B). Reflecting this spatial change in ground temperatures, methane hydrate is not stable to the west of Middle Channel, whereas to the east, the base of the methane hydrate phase boundary may be 400 to 700 m deep (Fig. 1C).

The pond containing the pockmarks is 3 km from the Beaufort Sea and is connected to Middle Channel to the east via a small side channel and to the Beaufort Sea via a meandering channel to the west. The pond is tidally influenced and is highly turbid in summer due to the inflow of silt-laden Mackenzie River waters. The terrain in the vicinity of the pond is <2 m above sea level, and thus the site is susceptible to flooding during river breakup and Beaufort Sea storm surges. Pond sediments consist of uniform, dark brown mud with occasional organic inclusions including twigs and rootlets.

Estimates of the shallow terrestrial ground temperature regime are available from a temperature cable ~5 km south

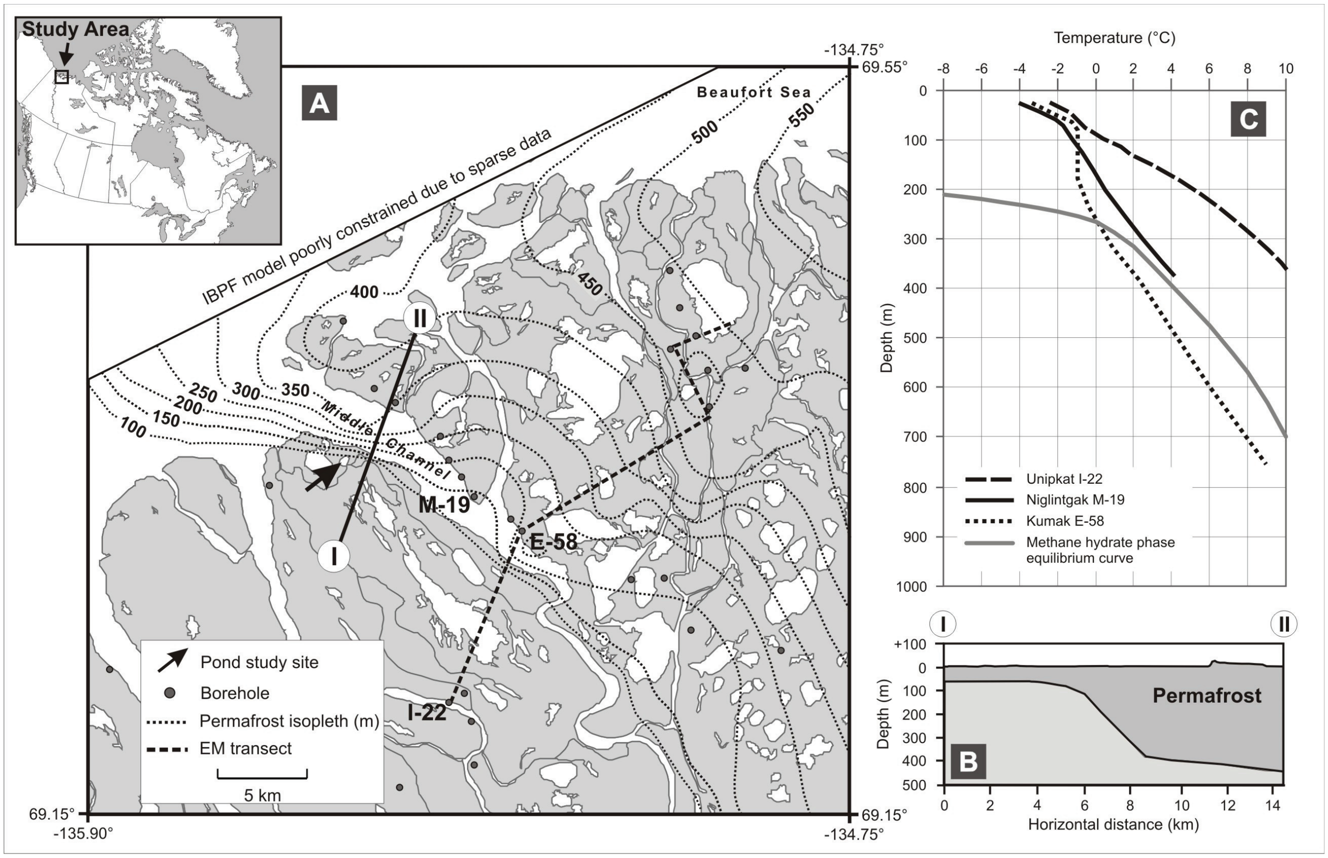

Figure 1. (A) Outer Mackenzie Delta near Middle Channel showing pockmark research site. Contours are of the base of ice-bonded permafrost, modeled using interpretations from geophysical well logs (Smith & Judge 1993), a deep sounding electromagnetic transect (Todd & Dallimore 1998), and boundary constraints established from the surficial geology. (B) The depiction of the base of permafrost from point I to II has been derived from the modeled data. (C) Ground temperatures from three instrumented wells (Taylor et al. 1998), methane hydrate phase equilibrium curve is from Sloan (1998).

of the pond site (Dyke, pers. com.) and a deeper installation 12 km south of the site (Dallimore & Matthews 1997). These studies reveal mean annual ground temperatures of this portion of the outer Mackenzie Delta are -4 to -6°C. Mean annual air temperatures measured at a site 20 km to the east are approximately -11°C (National Snow and Ice Data Centre 2007).

Vemco Minilog-T temperature loggers (temperature range -4 to +20°C, resolution 0.1°C) were deployed at the bed of the large pockmark site to record daily bottom water temperatures. The annual mean bottom temperature from August 10, 2006, to August 10, 2007, at ~9 m depth was 4.1 ± 0.1°C. Water depths of the main pond are generally <1.5m, and as a result, late winter ice typically contacts the bed in these areas lowering the annual mean temperatures to 2 to 3°C.

Bathymetry and Pockmark Morphology

The pond investigated in this study is heart-shaped and 25 hectares in surface area. Water depths vary from 1–2 m with the exception of the large seep/pockmark feature which is ~10 m deep. During the summers of 2006 and 2007, ~20 small but continuously active seeps were observed within the pond. Typically these seeps had surface bubble plumes which were 0.5 to 1.5 m in diameter. Physical inspection of six of these seeps revealed that sediment strength in the vicinity of the seeps was very weak, with 0.3 to 1.0 m deep conical depressions in the pond bed. Many seeps were discharging gas through orifices that were approximately 5 cm in diameter. In addition to the continuous seeps, small episodic gas discharges were observed throughout the pond, and occasionally on land, suggesting that gas is venting to the surface over a large area.

A boat equipped with a LCX-19C sonar and Global Positioning System (GPS) system was used to collect a series of survey transects over the large seep and the surrounding area. The bubble plume area at the surface of this seep varied from 2 to 5 m in diameter. The plume within the water column was visible from the sonar acoustic data as an area of intense acoustical backscatter due to the sonic reflection of the bubbles. Examination of the sonar data adjacent to the plume as well as several data points that penetrated the plume enabled the construction of depth interpolations, where the sonar data were giving false bottom data due to the strong reflection of bubbles from the plume. A digital terrain model was generated from the corrected sonar data (Fig. 2). The pockmark feature was ~10 m deep and conical in shape with a diameter of about 24 m at 3.5 m depth tapering to a flatter base of ~5 m diameter. The slopes were relatively steep with average dips of 20 to 25° (mean 22.4 ± 0.7°). The volume below a depth of 3.5 m was approximately 5400 m³.

Bearing Strength of Pockmark Sediments

A Seabed Terminal Impact Newton Gradiometer (STING) was used to estimate the dynamic bearing strength of the lake bed sediments across the main pockmark feature. This device measures the kinematic dynamics of the probe during the deceleration as it penetrates bottom sediments (Mulhearn 2002). The STING was configured with a 1 m shaft and a 35 mm foot. A boat survey transect was established using a taught surface line. The instrument was allowed to free-fall from the water surface at 1–3 m intervals along the transect line. Each point on the transect consisted of four discrete drops that were averaged to yield a mean. The instrument sampled every 0.0005 seconds allowing construction of a bearing strength vs. depth profile.

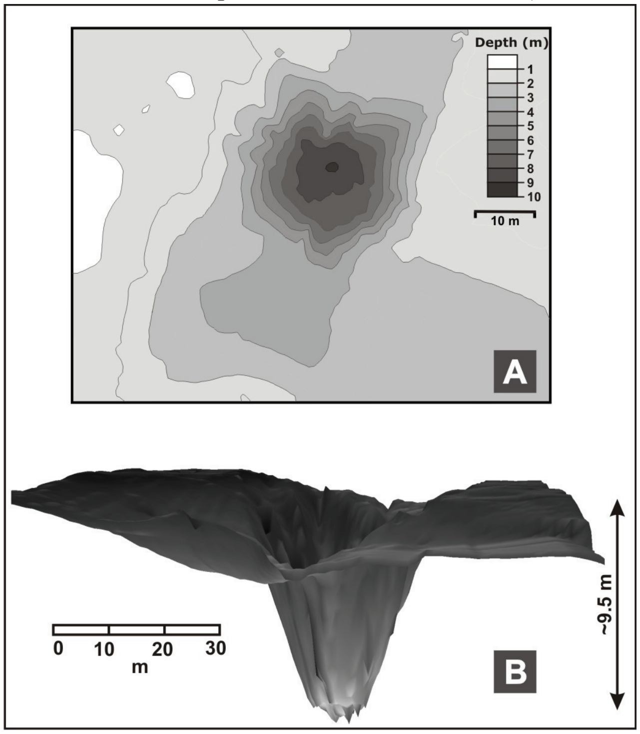

Figure 2. (A) Plan view and (B) sun-shaded perspective view of seep digital elevation model generated from sonar transects.

Figure 3 shows an east–west transect of 12 STING deployments across the pockmark feature. With the exception of deployments 11 and 12, the sediments from 0–25 cm depth are very weak, with bearing strengths below 20 kPa. At many sites (i.e., deployment 5, 6, 7, and 9, 10) the water sediment interface is barely discernible, and the bearing strength vs. depth shows only a small increase to maximum depth of penetration (limited by frictional effects). Several deployments do show some change in bearing strength vs. depth which are interpreted to be harder sediment layers. No STING measurements were obtained outside of the pockmark. However, estimates of the surface bearing strength in the shallow areas of the pond were made by several walking/wading transects. For the most part, the sediment interface could bear a person's weight, suggesting that near-surface bearing strengths likely exceed 200 kPa. STING data from the channel to the south of the pond showed near-surface bearing strengths as high as 400 kPa.

Gas Flux Measurements

Summer

An instrument was developed to measure gas flux from the large seep site (Fig. 4). The flux instrument, which was modified over several field seasons, consisted of a gas collection funnel and a chimney assembly.

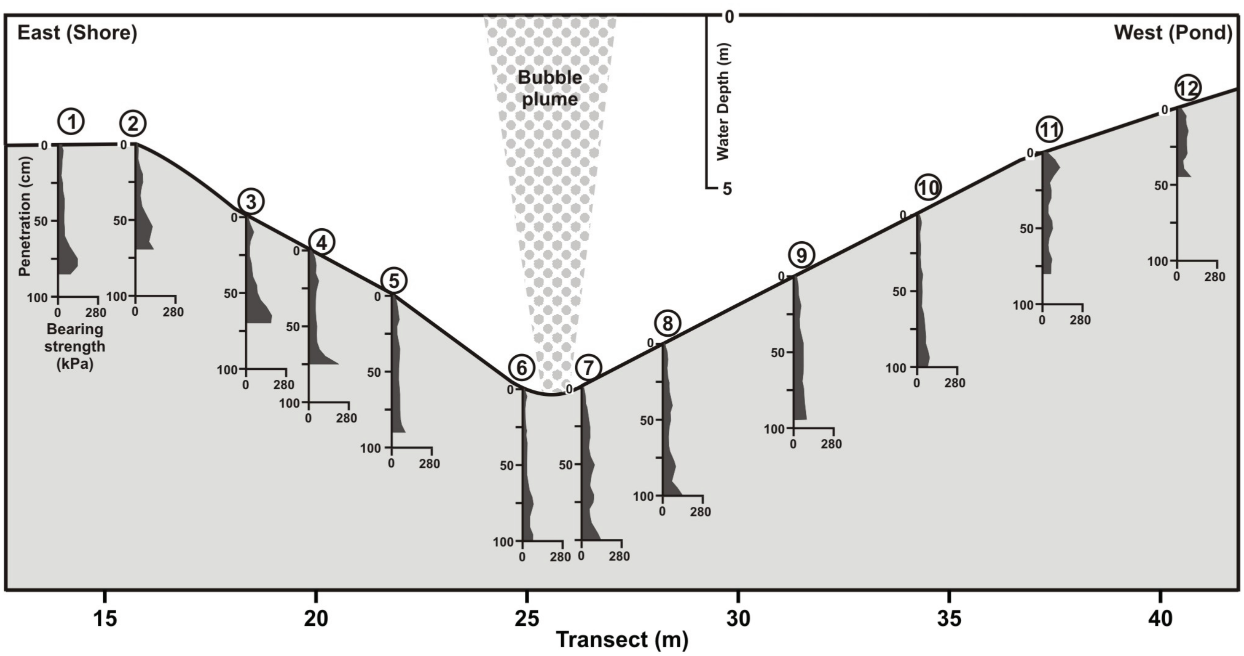

Figure 3. Seabed Terminal Impact Newton Gradiometer (STING) transect of seep. Profiles are averaged from four individual penetrations at each site.

Gas flow was measured with an airflow anemometer which was installed in the centre of the 10 cm chimney assembly. Anemometers are routinely used by industry for measuring flow through ducts. The anemometer internally logged data at 1-second intervals. To verify this measuring technique, the anemometer was calibrated at the Alaron Instruments wind tunnel calibration facility with an estimated instrument accuracy of ±3%. Calibration coefficients were applied to the raw data to produce corrected data. Further bench testing of the chimney assembly was undertaken by utilizing a 10 cm tube outfitted with a calibrated ultrasonic time of flight system. Airflow was measured by both the anemometer and the ultrasonic system with flux results yielding equal values at steady state flow.

The gas plume consisted of an upwelling convection current of gas bubbles and entrained water. The plume diameter and intensity at the surface varied constantly, shifting its position as much as 2 m over intervals of minutes. For this reason the collection funnel deployed in 2007 had a 9 m cross-sectional dimension with much of the funnel submerged to reduce wind and wave loading.

Figure 4. Seep collection flux meter used in 2007. Instrument consists of a 9 m collection funnel, most of which is submerged to reduce wind and wave loading, and a 10 cm chimney assembly in which the airflow anemometer was housed.

Figure 5 presents data from a 40 min deployment in August 2007. The data show 1-minute averaged flux rates between 0.36 and 0.86 m^3min^{-1}, with mean of 0.59 m^3min^{-1} and a standard deviation of 0.09. Marked increases and decreases in flux over a period of minutes are consistent with visual observations at the surface and measurements with a smaller collection funnel carried out in 2006.

Fall/winter

Field visits to the pond seep site were carried out in the fall and late winter. In late October, approximately 10 cm of ice had formed over the main pond, covering all but the main pockmark area where turbulence had resulted in a 19 m diameter ice-free area as measured by a laser range finder. While in some other locations in the outer Mackenzie Delta, holes in the ice persist through the winter, by March the only evidence of the large seep was a slight doming of the ice surface and the conspicuous occurrence of tension cracks radiating out from the dome. Drilling through the ice near the centre of the seep revealed ice thickness of less than 50 cm; in contrast, typical pond ice thicknesses were 1.2–1.8 m. While preparing for a through-ice ROV deployment in March 2007, a pressurized pocket of gas was penetrated at the ice-water interface which discharged a column of gasified water ~10 m high for about 1 minute.

Attempts to measure winter flux were undertaken by placing the chimney assembly directly over a 25 cm auger hole through the ice. The flow rates varied significantly as gas accumulated under the ice plate before venting in strong bursts. These bursts were short-lived lasting about 1 second followed by short periods with low flow, or even back flow, as water drained back into the auger hole. Burst intervals were

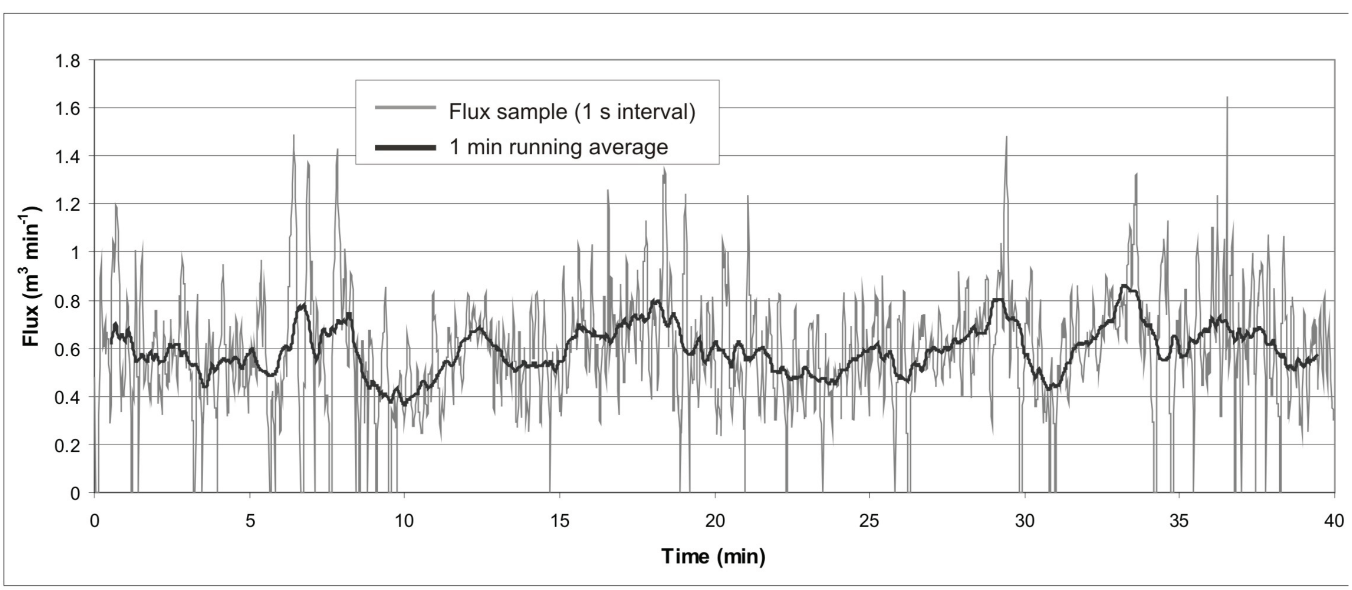

Figure 5. Flux data collected in August 2007. Grey line depicts flux data sampled at 1 s sampling interval. Black line shows the 1 min running average flux.

[2]Nig field	9000	N/D	981900	N/D	6900	N/D

[1] SS = Gas samples collected from large seep; [2] Nig = Niglintgak gas field sample (Shell Canada Ltd. 2004a); N/D = no data

every 2–5 seconds as observed from recorded video. The measured gas flux values were influenced by the constrains of the ice plate, the possible release of gas through the radial ice cracks and the small diameter of the auger hole and were therefore too complex to resolve credible flux rates.

Geochemistry

The * [18]O and *D composition of mixed waters collected over the seeps were found to be identical to local surface water elsewhere in the pond and channels. This suggests that there are no large discharges of deeper connate waters associated with the seeps. The hydrocarbon gases from the pond seep are mainly methane with minor higher hydrocarbon homologues (Table 1). The carbon isotopic content of the methane suggests that it is of thermogenic origin. The carbon dioxide isotopic composition, however, is very light. Under some circumstances, if methane oxidation is a dominant process, then methane of microbial genesis may be mistaken for thermogenic methane. While the carbon dioxide isotope values are unusual, further evaluation of the data shows that the volume of methane is quite large relative to carbon dioxide, which is the opposite of what would be expected from the process of methane oxidation. In addition, the ethane carbon isotopic composition is of thermogenic origin. Thus the balance of data suggests the hydrocarbon gases have a thermogenic origin. The Niglintgak gas field produces a similar dry gas and may be the ultimate seep gas source.

Discussion

Formation of pockmark features

The presence of free gas in unconsolidated sediments can reduce the effective stress regime and, in turn, the sediment-bearing capacity. Identification of small orifices with almost no sediment strength, and the weak bearing strengths recorded by the STING survey over the large seeps suggest this possibility. Video from a winter ROV survey showed light sediment and fine organic material being liberated from the sediment interface into the water column by gas discharge. In some cases, gas discharge was associated with exposed root mats and organic debris which were free of sediment. The weakening of the strength of the sediments and the force of gas bubbles at the sediment interface provide a mechanism for the mobilization and exhumation of the bottom sediments and seems a possible factor in the formation of the pockmark features described.

A simple three-dimensional model can be constructed assuming 60 m of ice-bonded terrestrial permafrost with mean annual temperatures of -4°C, a basal temperature regime of 1°C for the 600 m diameter pond and 4°C for the 30 m diameter main pockmark. Applying a similar modeling methodology to that described by Taylor et al. (this volume) a through-going talik is created through the terrestrial permafrost if the pond existed on the landscape for 1000 years. The gas migrations appear to be associated with networks of root mats and organic debris. These networks may create vertical gas migration pathways, which may be a factor affecting the location of the seep/pockmarks within the larger pond.

Source of gas feeding the seeps

The seeps described in this paper are quite remarkable in both the volume of gas released and their apparent longevity. Based on an average flux rate of 0.59 $m^3 min^{-1}$, the large seep is releasing 3.10 x 10^5 m^3 of methane (2.99 x 10^5 m^3 at 0°C, 1 bar) on an annual basis. Short-term flux measurements carried out on several of the small seeps suggest rates for some of these are as high as 0.13 $m^3 min^{-1}$. In total, for the entire pond area (1 large seep, 20 small seeps), we estimate at least 5.07 x 10^5 m^3 (at STP) of gas is released annually. As the large seep feature has a similar appearance, and is virtually in the identical location to that observed by Dr. Mackay in 1963, it is not unreasonable to assume that during the past 44 years 2.23x10^7 m^3 (at STP) or almost 0.8 billion ft^3 of gas has been released from the 21 seeps. Clearly a significant source of gas accumulation is feeding these seeps continuously.

The closest known conventional gas field is the Niglintgak field located approximately 5 km to the east. This field, which contains approximately 2.8 x 10^{10} m^3 (~1 TCF) of recoverable gas, forms one of three anchor fields for the proposed Mackenzie Valley Gas pipeline project. The gas-bearing horizons occur at 760 m depth (Shell Canada Ltd. 2004b), with a similar dry gas chemistry to the pond seep samples (Table 1). Smith and Judge (1993) have identified gas hydrates in several Niglintgak wells at depths as shallow as 660 m. Assuming vertical gas migration is most likely where permafrost is absent and gas hydrate is not stable, the abrupt transition to the west of Middle Channel (Fig. 1) is an obvious potential lateral migration path to the near surface. However, further investigation is required to confirm this.

Conclusions

The following conclusions can be drawn from this study:

1) Approximately 20 small and 1 very large gas seeps have been characterized at a small terrestrial pond in the outer Mackenzie Delta;
2) The hydrocarbon gases being released are predominantly methane with minor higher hydrocarbon homologues (Table 1). The carbon isotopic content of methane and ethane indicates that the gas is of thermogenic origin;

3) Pockmark features are formed in the pond bed by vertical gas migration, causing sediment weakening and exhumation. The small seeps typically have small 0.5–1.0 m deep pockmarks, while the large seep has a 10 m deep pockmark;
4) Flux of methane to the atmosphere from these seeps is estimated to be 5.07 x 10^5 m^3 annually which, when considered over 44 years of activity, suggests a large supply of gas at depth;
5) The permafrost setting of the pond likely exerts control over the migration of gas to the surface with the site occurring at a major permafrost/gas hydrate boundary. The proximity of a large gas field down-dip and the similarity of gas geochemistry suggests a candidate for the source of the gas is the Niglintgak gas field.

Acknowledgments

The fieldwork is supported by the Polar Continental Shelf Project and the Aurora Research Institute. Financial support has been provided by the Panel for Energy Research and Development and the Geological Survey of Canada. Larry Greenland and William Hurst are thanked for their excellent field assistance. Mark Nixon's knowledge and field experience were very much appreciated. Dr Ross Mackay is gratefully acknowledged for his suggestion to embark on the study.

Abstract

Despite the fact that warming in the Arctic has been greater than the global average and hydrological changes may provide important feedback responses to global climate, until fairly recently many global climate models that used to generate future climate projections have neglected the influence of permafrost on water and energy exchange in high latitude regions. At the scale of such models, the complexities of representing water and thermal exchange in permafrost systems are further compounded by the necessity for computational efficiency, coarse spatial resolution and the inability to fully describe the current state of the system. In this presentation, we explore successes and on-going challenges in simulating seasonal and decadal permafrost dynamics for the arctic region, with specific examples based on simulations using the Variable Infiltration Capacity (VIC) model, a macroscale land surface scheme. Considerable challenges still exist in appropriate definition of boundary conditions and with respect to near-surface runoff generation.

Keywords: Arctic; ground ice; hydrology; modeling; permafrost; wetlands.

Introduction

Observations of dramatic hydrologic change in permafrost environments in recent years have led to increased interest in the large-scale interactions of permafrost with surface water hydrology under a changing climate. Opposing changes in Siberian lake extent have been observed, which can be attributed to differences in discontinuous versus continuous permafrost by allowing or preventing drainage (Smith et al. 2005, Grippa et al. 2007). Observed trends in streamflow in some north-flowing arctic rivers, particularly in the winter season, may also be associated with increasing seasonal thaw and the melt of excess ground ice (Adam & Lettenmaier 2008, Cherry et al. 2006). In addition, there is continued evidence that the treatment of permafrost in the land surface schemes of global climate models can yield large sensitivities in remote teleconnections for future climate scenarios (Saha et al. 2006, Gagnon & Gough 2005). Although mathematical models of permafrost have existed for quite some time, many of these modeling efforts are poorly suited for investigating the complex interactions of the active layer hydro-thermal regime and water and energy interactions governing hydrologic response across the circumpolar arctic (Ishikawa & Saito 2006).

Representation of the spatial distribution of permafrost, particularly in alpine areas, has often relied on GIS-based empirical/statistical relationships to estimate the probability of permafrost presence at gridded locations based on proxy variables, such as snow basal temperatures (Julian & Chueca 2007), air temperature (Juliussen & Humlum 2007) and terrain parameters and land cover (Etzelmueller et al. 2007). These techniques have recently also been extended to non-alpine domains (Anisimov et al. 2002).

The state of the art in permafrost temperature modeling is typically associated with the detailed multi-dimensional modeling performed in the design of cold regions engineered structures (Zhang et al. 2006) or the evaluation of complex physical structures (Noetzli et al. 2007, Ling & Zhang 2004). Such models are often not capable of hydrologic analysis so physically detailed. Spatially distributed watershed models suitable for permafrost domains have also been developed (Zhang et al. 2000, Kuchment et al. 2000). These can be extremely useful for investigation of hydrothermal interactions at the scale of small watersheds, but more regional application is limited due to the required computational times.

Presently, the representation of permafrost within global climate models primarily includes a finite difference or finite element solution of the heat diffusion equation. The PILPS 2(e) land surface model intercomparison experiment compared simulated output from 23 land surface schemes applied to the Torne-Kalix River basin in Northern Sweden, an area of seasonally frozen ground. At the time of that experiment (2002), 16 of the 21 participating models represented soil freezing through some implementation of the heat diffusion equation (Bowling et al. 2003). The remaining models either did not include soil freezing or used a temperature index to restrict soil water movement. Due in large part to computational considerations, however, these early attempts at including physically-based permafrost algorithms within GCMs required simplifications regarding boundary and initial conditions, the energy effects of phase change and the number of solution elements.

The objective of this paper is to document the current representation of permafrost within the Variable Infiltration Capacity (VIC) model (version 4.1.0 r5), macroscale hydrology model/land surface scheme that has been adapted for applicability in arctic domains, and to explore the sensitivities and limitations of the current approach.

The Variable Infiltration Capacity Model

The variable infiltration capacity model

The Variable Infiltration Capacity (VIC) model is a water and energy balance hydrologic model suitable to application at large scales, typically applied at grid scales ranging from 0.125–2.0 degrees latitude by longitude (Nijssen et al. 2001, Su et al. 2005). It is similar to land surface parameterization schemes used in regional and global climate models, however, the VIC model is typically applied in an off-line mode, using historic meteorological observations or downscaled and bias-corrected climate model output, then calibrated and evaluated with respect to observed surface hydrology. General model structure is documented in Liang et al. (1994, 1996), Cherkauer and Lettenmaier (1999), and Cherkauer et al. (2003). In this section we wish to document the model structure as it pertains to simulation of surface water hydrology in permafrost domains.

Soil thermal solution

The core of the soil thermal solution is a finite-difference solution of the heat diffusion equation (Cherkauer & Lettenmaier 1999). The thermal solution takes into account the energy associated with phase change and freezing point depression by the soil matrix. Infiltration, percolation and baseflow are calculated based on the total and unfrozen soil moisture contents. The finite difference solution includes specification of thermal nodes that are independent of the model soil moisture layers, allowing for flexibility in the specified depth to the bottom boundary and number of solution nodes.

In addition, the bottom boundary condition can be specified as either a constant temperature or zero flux boundary. Typically, a constant temperature boundary condition is invoked by fixing the mean temperature of the annual thermal damping depth (approximately 3–4 m depth). A zero flux boundary condition is applied at a solution damping depth at least three times deeper than the thermal damping depth.

Figure 1 illustrates the influence of the bottom boundary condition on the equilibrium temperature profile. For the base simulation (gray, solid line) the model was run with a no flux boundary condition at a depth of 25 m, and spun-up for 100 years of constant 1998 weather conditions. Observed meteorology, soil temperature and soil conditions from the Betty Pingo research site, near Prudhoe Bay, Alaska, collected by the Water and Energy Research Center (WERC) at the University of Alaska Fairbanks (UAF) were used. The black line represents a similar simulation, using a 4 m damping depth, with the bottom temperature set equal to the final 4 m temperature derived from the no flux solution. The dashed lines represent repeated 100 year simulations, with an imposed air temperature gradient of 0.094°C/decade, chosen to represent the recent observed rate of change in the Arctic (Polyakov et al. 2003). It was anticipated that this example would illustrate that under the imposed temperature trend, the no flux boundary condition would allow the profile temperatures to migrate away from the equilibrium solution, while the constant temperature boundary would not. What is perhaps more striking is that in both cases, the constant temperature solution diverges substantially from the no flux equilibrium profile, resulting in colder (and more reasonable) near-surface temperatures. The zero flux boundary condition appears to be allowing the accumulation of excess heat in the bottom of the soil column, leading to excessive warming in long-term simulations. This could illustrate that a constant flux boundary, that would pass this excess heat to the deeper soil layer would be more appropriate (Zhang et al. 2003). Or it may be due to solution error associated with the choice of damping depth such as that documented by Alexeev et al. (2007). Both of these will be explored in the future.

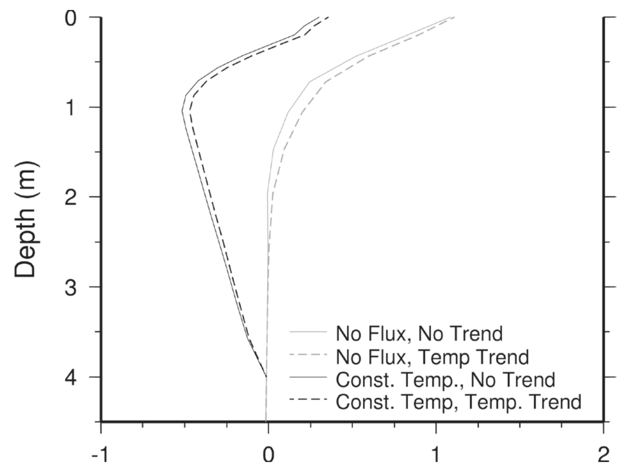

Figure 1. Illustration of the choice of boundary condition (no flux or constant temperature) on the soil temperature profile at equilibrium. Simulations were run for 100 years under constant 1998 conditions (solid lines). Simulations were then repeated (dashed) with an imposed air temperature trend of 0.094°C/decade.

Solution dynamics and node distribution

The original VIC thermal solution used an explicit solution technique with iteration at the top boundary to close the surface energy balance. The imposed node distribution allowed for three fixed nodes in the top 20 cm of soil, with nodes linearly distributed between 20 cm and the specified damping depth. Both of these simplifying assumptions contributed to model instability, particularly in the presence of dry soils or extreme temperatures. Rather than solve the heat equation explicitly for each node, an implicit Newton-Raphson method has been implemented to solve soil temperatures and ice contents simultaneously. In the rare event of non-convergence, the method defaults to the explicit solution. Because the greatest variability in temperature occurs at the near surface thermal nodes, the nodes are distributed exponentially with depth.

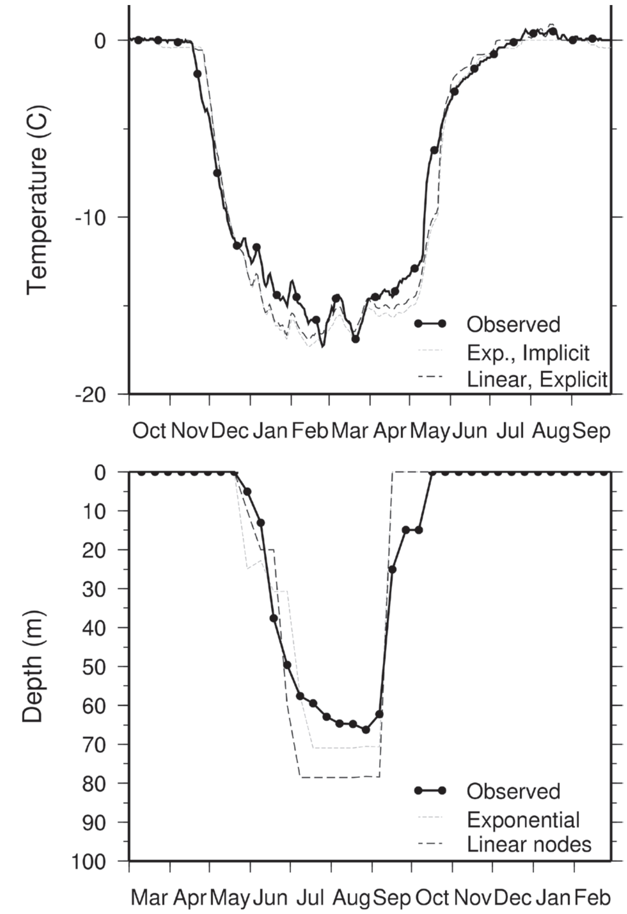

Figure 2. Example application of the VIC model to a point centered on the WERC Betty Pingo research site near Prudhoe Bay Alaska. (top) Simulated and observed 60 cm soil temperatures and (bottom) The location of the simulated and observed 0°C isotherm.

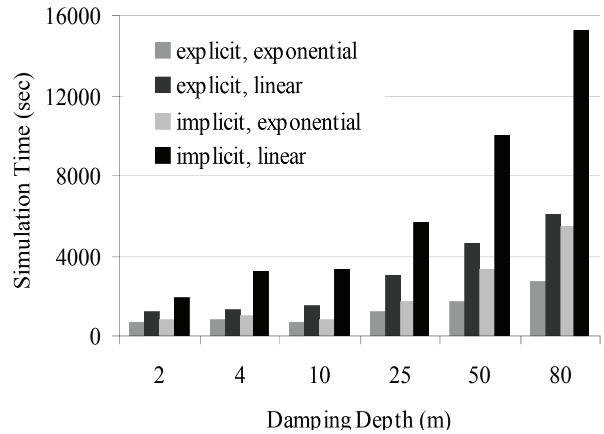

Figure 3. Comparison of system CPU times for a 100 year simulation with different damping depths using the explicit and implicit solutions and exponential and linear node distributions.

A grid transformation is performed in which the physical system exists in exponential space, while the heat equations are solved in linear space.

As shown in Figure 2 (top), when sufficient solution nodes are specified, there is negligible difference between the temperature solutions obtained from either the exponential or linear node distribution. This example utilized a constant temperature boundary at 4 m, with 20 solution nodes. Observed temperatures are taken from the WERC Betty Pingo site. The implicit or explicit solution also does not influence the predicted temperature. The benefit of the exponential node distribution is realized in more typical simulations, utilizing fewer nodes (Fig. 2). In this case, only 7 solution nodes were used, and it can be seen that by concentrating more nodes in the area of maximum change, the exponential node distribution is better able to capture the depth of the observed 0^oC isotherm.

Fewer solution nodes are advantageous with respect to total simulation time, as illustrated in Figure 3. In this case the model was run for several damping depths, with the number of solution nodes adjusted for each depth. With a linear distribution, the number of nodes was set equal to the damping depth plus 8, while only 1/3 as many nodes were used for the exponential distribution (with a minimum of 6 nodes). Overall the implicit solution is more time consuming than the explicit solution, in part because the implicit solution currently updates temperature dependent variables with each iteration, while the explicit scheme does not. By reducing the total number of solution nodes, however, the exponential distribution reduces the overall simulate time so that the implicit, exponential solution is faster than the explicit, linear solution.

Excess ground ice and ground subsidence

Excess ground ice, defined as an ice concentration above what could be held as liquid water in the soil column where the ground completely thawed, exists in various parts of the Arctic. As excess ice melts in response to climatic warming, the ground collapses and the excess meltwater is expelled to the surface. Because of ground subsidence, the water-holding capacity of the soil column is diminished. An excess ground ice and ground subsidence algorithm has been introduced to the VIC model. Each layer of the soil column is initialized with an ice fraction, which may exceed the soil porosity. Figure 4 illustrates how the expanded column depth is calculated based on the input soil column depth and ice fractions.

The expanded column depth does not change until the ice fraction to porosity ratio falls below a pre-specified ratio, f_{ice}. Even at very low temperatures, there can be a small amount of liquid water in the soil column due to freezing point depression (cf. Eq. 14 of Cherkauer & Lettenmaier 1999), therefore f_{ice} should be set to a value somewhere between 0.5 and just below 1.0, with a lower value causing subsidence to occur at warmer temperatures. After subsidence, all parameters dependant on the soil layers are updated.

Surface water interactions

As shown by Ling & Zhang (2003), shallow arctic thaw lakes can be significant sources of heat to sub-lake taliks and the surrounding permafrost. Surface water storage in small (sub-grid) lakes and wetlands is represented in the VIC model utilizing an input depth-storage relationship to determine

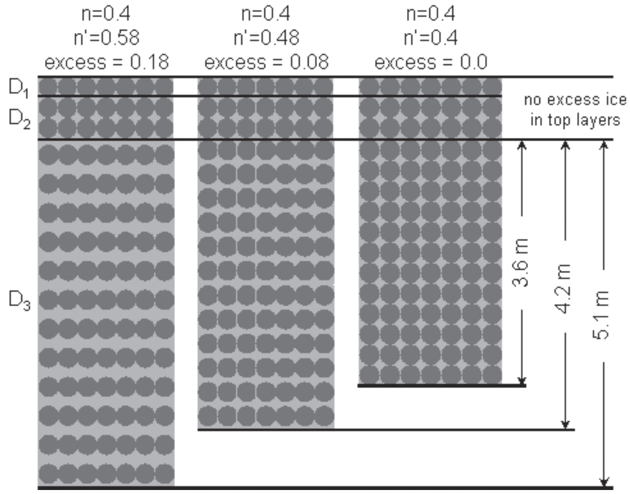

Figure 4. Example of an application of the VIC excess ice and subsidence algorithm in which the excess ice fraction in the third soil layer is initialized to 0.18 (left column). As the excess ice melts, the depth of the third soil layer decreases, and the effective porosity (*n'*) also decreases. Once effective porosity reaches soil porosity (*n*), the soil no longer subsides (right column).

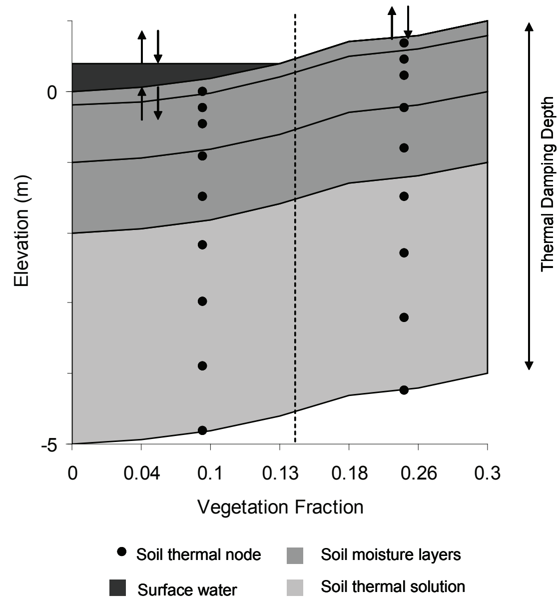

Figure 5. Illustration of the soil thermal solution for the wetland fraction of a VIC grid cell. The flooded fraction is determined using the land surface profile input as a depth-area curve. Soil temperatures are resolved independently for the flooded and upland fractions and then averaged.

spatial variability in surface water extent based on the stored volume (Cherkauer et al. 2003). The temperature profile and evaporation from stored water is resolved using an implicit one dimensional thermal model, based on Hostetler & Bartlein (1990). The original model assumed a no flux boundary condition at the lake bottom and did not resolve sub-lake soil temperatures. As illustrated in Figure 5, recent enhancements to the lake algorithm extend the thermal solution into the soil column, with a bottom boundary condition determined by the soil thermal model. Solar radiation through shallow water and conductive heat transfer from the water to the soil are balanced by the ground heat flux at the soil/water interface. The number of thermal solution nodes in the surface water is variable depending on water depth. To resolve energy instabilities in very thin water layers, the lake algorithm collapses to solve together with the surface soil layer, similar to the solution for thin snowpacks described by Cherkauer et al. (2003). This enhancement allows for exploration of the interaction of surface water storage and the soil thermal regime within the macroscale model. These interactions are further explored in Chiu et al. (these proceedings).

Discussion

Long-term simulation of the soil temperature profile requires a computational damping depth that greatly exceeds the thermal damping depth. The use of exponentially-distributed thermal nodes that are separated from the soil moisture layers results in reduced computation time, while the application of an implicit solver for the sub-surface heat equation results in greater numerical stability. There are still many issues to explore regarding the selection of appropriate damping depths and the start-up time required to

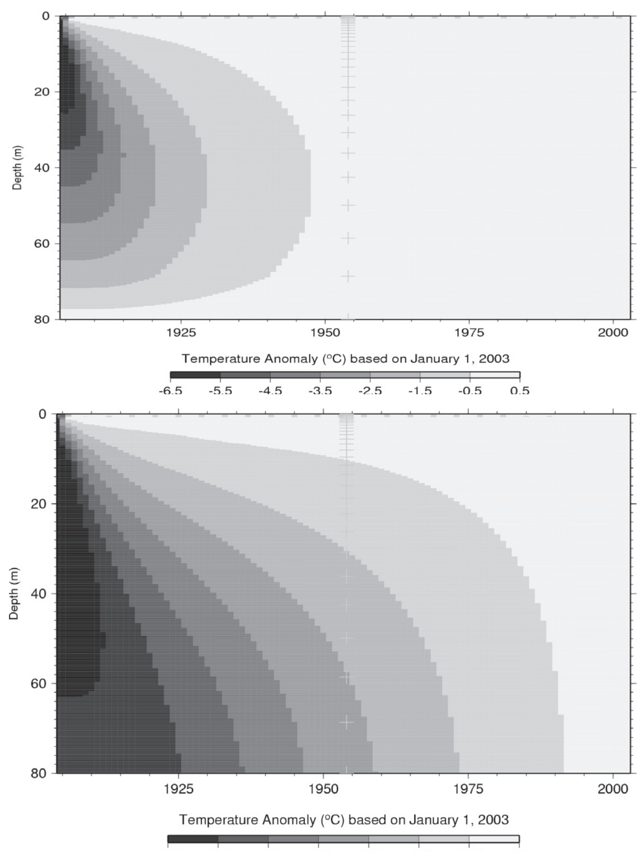

Figure 6. Assessment of the simulation time required to remove start-up anomalies with an implicit solution using exponentially-distributed nodes (shown by cross-hatches): constant temperature boundary condition (top), zero flux boundary condition (bottom).

reach stability. Figure 6 shows the temperature anomaly over time at each solution node for both the constant temperature and zero flux boundary conditions. The implicit solution and exponential node distribution were used in both cases. Temperature anomalies were calculated as the difference between the temperature on January 1 of each year, and the temperature on January 1 of the last year of simulation, so that small anomalies imply a temperature equilibrium has been reached. For the constant temperature scenario, equilibrium is reached after about 45–50 years of simulation. With the zero flux solution, it is not clear that equilibrium is reached after 100 years of simulation.

Summary

Recent studies have explored issues of computational stability, the role of excess ground ice, and permafrost/wetland interactions within the VIC land surface model. Representation of excess ground ice which exceeds the porosity of the undisturbed soil is essential for duplicating the water balance in some watersheds, especially those experiencing significant permafrost change. In other regions, the interaction between permafrost and surface water storage can be explored by resolving soil thermal fluxes under surface lakes and wetlands. These computational advances allow initial exploration of the role of large-scale permafrost-hydrology interactions on the dynamics of surface water and ground ice storage. Considerable challenges still exist in identifying the role of scale in permafrost representation, and with respect to near-surface runoff generation and the interactions between permafrost change and wetland extent.

Future work will proceed in several areas, including:

- Understanding of the problem of excessive warming in the no-flux boundary solution.
- Improved representation of runoff dynamics in permafrost areas, including the representation of subsurface water movement as a perched layer on top of the frozen transitional zone.
- Interaction between the ground subsidence algorithm and the wetland surface elevation profile, allowing dynamic increases in wetland extent associated with permafrost melt.

Effects of Soil Cryostructure on the Long-Term Strength of Ice-Rich Permafrost Near Melting Temperatures

M.T. Bray

University of Alaska Fairbanks, Departments of Civil and Environmental Engineering, Fairbanks, Alaska, USA

Abstract

Stress relaxation tests were performed to look at the effect of cryostructure on the long-term strength of ice-rich permafrost. Cryostructures of tested soils include micro-lenticular, remolded-massive, reticulate-chaotic, and wedge ice. Soils with remolded-massive structure shows long-term strengths three to four times greater than undisturbed soils, suggesting that data extrapolation from remolded soils to undisturbed soils can be non-conservative. Samples with reticulate-chaotic structure showed higher long-term strength in the tested temperature range than samples with micro-lenticular structure and wedge ice structure. Long-term strength relationships with temperature are presented.

Keywords: long-term cryogenic structure; cryostructure; ice-rich; long-term strength; permafrost; stress relaxation.

Introduction

Only a few published studies include information on the long-term strength behavior of ice-rich permafrost. In most cases, remolded samples are used for a variety of reasons. Remolded samples usually contain a *massive* cryostructure unless special efforts are made to create a different cryostructure. The cryostructure is the pattern of ice inclusion found in a frozen soil. Soils with *massive* structure may, but in many instances for ice-rich permafrost, do not represent the actual permafrost soil that is present. It has been recognized that the texture has an influence on the resulting strength and creep behavior (e.g., Sayles & Carbee 1981). A few studies have investigated the creep behavior of ice-rich permafrost samples (undisturbed cores) (Arenson & Springman 2005, McRoberts et al. 1978, McRoberts 1988, Savigny & Morgenstern 1986). Savigny & Morgenstern (1986) briefly explored the effects of cryostructure on the behavior of clay permafrost and found that the prominent ice veins or lenses had a large impact on the resulting creep behavior. Research in Russia showed that the orientation of segregated ice in frozen soil also had an impact on the shear strength (e.g., Pekarskaya 1965, Vialov et al. 1965). Shear strength in the direction of ice lenses was lower than the shear strength perpendicular to ice lenses.

The primary purpose of this program is to examine the impact of cryostructure on the long-term strength of ice-rich permafrost.

Materials and Methods

Soils and cryostructure

The soils used in this testing program are taken from the CRREL permafrost tunnel at Fox, Alaska. A detailed discussion of the permafrost geology and cryostructures is presented by Bray et al. (2006).

Permafrost in the CRREL permafrost tunnel is ice-rich, syngenetic permafrost deposit of Pleistocene age and is commonly referred to as the "Ice Complex" or "Yedoma" (Shur et al. 2004). This syngenetic permafrost deposit is characterized by sediments that typically contain 40–60% segregated ice by volume and large, 2–5 m wide, dark colored ice wedges. The syngenetic permafrost is representative of the original permafrost formed during deposition and sedimentation. The other defining feature of the tunnel is that extensive secondary modification occurred due to thermal-fluvial erosion that operated preferentially along the ice wedges. The resulting deposits are characterized by epigenetic permafrost with cryostructures that are different from the original syngenetic permafrost.

Cryostructures within the tunnel deposits are strong indicators of the original syngenetic and secondary refrozen deposits. *Micro-lenticular* cryostructure is the primary diagnostic cryostructure of the original permafrost. *Layered* and *lenticular-layered* cryostructures are also characteristic of the original permafrost. The modified permafrost deposits either contain *massive* or *reticulate-chaotic* cryostructures. In this study, soils with *micro-lenticular*, *massive* (i.e., *remolded-massive)*, and *reticulate-chaotic* cryostructures were used (Fig. 1). Also included is massive *wedge ice.*

Micro-lenticular cryostructure consists of thin, straight to wavy lenticular shaped ice lenses that essentially saturate the soil. Lenses are less than 0.5 mm in thickness and usually less than 4–10 mm long. Microscopic analysis shows that the soil particles are essentially suspended in an ice matrix. Typical water contents by weight are 90–130%. Frozen bulk densities range from 1.26 to 1.34 g/cm^3. *Horizontal micro-lenticular* and *vertical micro-lenticular* cryostructure is referred to below. Horizontal indicates ice lenses are perpendicular to applied principal stress. Vertical indicates ice lenses are parallel with applied stress.

Massive cryostructure consists of silt cemented together without visible segregated ice. Microscopic analysis from *massive* structures in the tunnel silts show that ice in excess of pores does exist, indicating that the soil was in a supersaturated condition when refrozen. This was confirmed by gravimetric water contents between 50–70%. Saturation for these soils is normally 30–40%.

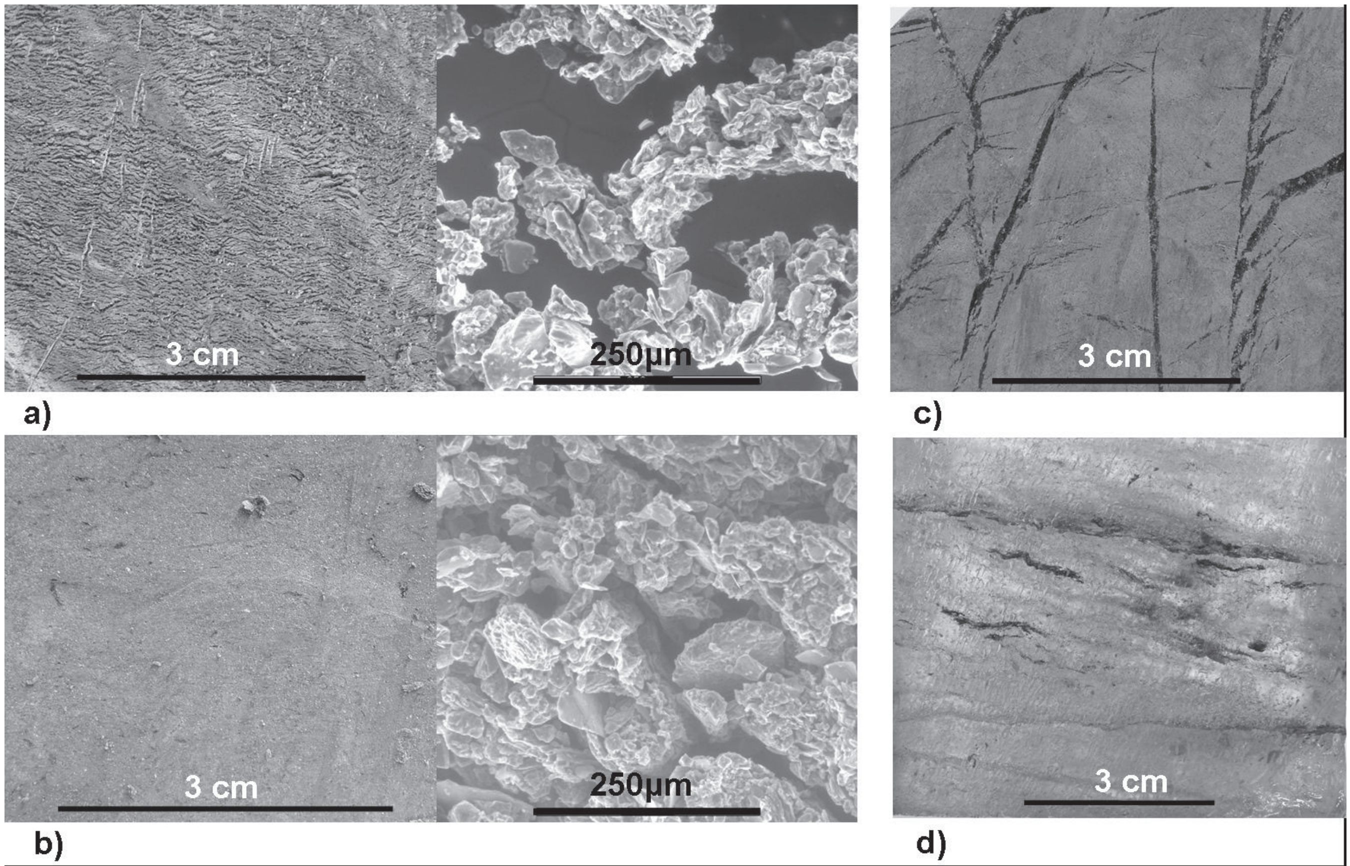

Figure 1. Images of cryostructures: a) *Micro-lenticular* cryostructure. To the right is a micro-scale image taken with an ESEM, b) *Massive* cryostructure. To the right is micro-scale image taken with an ESEM. c) *Reticulate-chaotic* cryostructure consists of larger ice lenses with massive soils between them, d) *Wedge ice*. Dark inclusions are foliation planes and sedimentation zones. Typically they run from 0° to 15°. Scales are indicated.

Remolded-massive structure represents a soil that has been reconstituted and then frozen quickly to produce *massive* cryostructure. A slurry was prepared and placed in a plastic cylinder. The sample was then vibrated to increase settlement. The sample was allowed to drain 24 hours under gravitation and then was frozen at -45ºC. The result was very little ice segregation and uniform *massive* silt. Frozen bulk densities range from 1.52 to 1.58 g/cm^3. Remolded samples were prepared from a slurry made of material from the CRREL tunnel, which had water contents ranging from 60–65%. Final drained water contents ranged from 48–52% by weight. This represents the lower range of water contents as seen from silts with *massive* structure found in the permafrost tunnel.

Reticulate-chaotic structure is characterized by randomly oriented ice lenses, 1–5 mm in thickness, and 1–5 cm in length. The silt between segregated ice lenses is *massive.* Frozen bulk density ranges from 1.33 to 1.51 g/cm^3. This structure most commonly occurs with clear ice deposits (non-foliated ice, thus not wedge ice) that we classify as thermokarst cave ice; another term used in the North American literature is *pool ice* (Mackay 1988 p. 87, 1997 p. 20). It occurs in the saturated sediments along the erosional-depositional surface. *Reticulate-chaotic* structure can be found in some silt deposits along the erosional surface without thermokarst cave ice, but it will always be found with thermokarst cave ice deposits in the tunnel. When found in association with thermokarst cave ice, the lenses are largest near the clear ice deposits.

Wedge ice was taken from large syngenetic ice wedges. They are brown to gray in color due to soil particles along foliations and organic staining. The wedges are generally 2–5 m in width with the bottom portions observed.

Testing

Undisturbed samples of syngenetic and epigenetic permafrost, along with samples remolded from the same silt, were tested. Relaxation tests were the main testing method and were performed on two electro-mechanical screw driven load frames.

All tests were conducted within a temperature range from -0.3°C to -3.1°C. Temperature stability was generally better than +/- 0.10°C for the duration of the tests. The two electro-mechanical screw driven frames were placed within a cold room that was maintained at -5°C. Insulated chambers were then placed around the sample. Temperature of the sample area was maintained using 20 liter recirculating water baths with temperature stability of +/- 0.10°C, by running the fluid through a convection driven heat exchanger located in the insulated chambers. These convection driven temperature controlled environments tended to promote substantial sublimation problems. In order to prevent sublimation of soil samples, latex membranes were placed around the sample with good results.

Relaxation tests

One of the primary focuses of the testing program was the utilization and application of relaxation tests. Relaxation tests allow for the testing of one sample as compared to a set of identical samples. The inherent variability of undisturbed soils made the use of relaxation tests an attractive alternative.

The relaxation tests were conducted by quickly loading (10–20 mm/min) the sample with a high capacity spring (approx. 71 kN/cm) placed in series with the sample to a prescribed stress level. The stress level was at least 50% of the instantaneous strength. The lower load applying platen was then fixed (stationary). As the elastic strain in the spring is released, the soil undergoes creep deformation and stress relaxation. Movement of the lower platen was monitored with an LVDT (i.e., machine relaxation) and two LVDT's were used to monitor the creep deformation occurring within the sample. The load was monitored with an electronic load cell. Temperatures were monitored by two thermistors at the sample surface. All data was automatically collected at 5 sec to 30 min intervals. Tests were typically run for 300 to 1000 hours. The longest test ran for about 2000 hours.

Long-Term Strength

The long-term strength can be defined as the stress above which deformations no longer attenuates (Tsytovich 1975, Vyalov 1980). Alternatively creep strengths are commonly predicted by recording the time to failure for a given stress. Failure is adopted as the transition from secondary to tertiary creep or a strain of 20% (Andersland & Ladanyi 1994). Strength versus time is plotted to represent ultimate creep strength. A direct experimental approach to determining the long-term strength is outlined by Tsytovich (1975) and Vyalov et al. (1966). The two approaches outlined are the ball plunger and the dynamometer, from which the long-term strength is defined as the stress at which deformation ceases (or a prescribed conditional stability is met). Thus, these approaches give directly the value of long-term strength.

The test procedures used in this work are similar to the dynamometer techniques. In many instances complete stabilization was difficult to reach, therefore two strain rates of 2.083 x 10^{-6} hr^{-1} and 2.083 x 10^{-7} hr^{-1} were considered as conditional stability states, as was done by Vyalov et al. (1966). The first strain rate condition will henceforth be referred to as "*stability condition 1*" and the second as "*stability condition 2*." Consequently, the definition of long-term strength in this work is the stress at which the conditional stability criterion is met.

Results and Discussion

Table 1, Figure 2, and Figure 3, show the long-term strengths as determined directly from relaxation tests based on the conditional stability criteria. Table 2 shows long-term

Table 1. Summary of long-term strengths for stability conditions 1 and 2.

vertical micro-lenticular (VML)		
Long-term strength (kPa) Stability Condition 1	Long-term strength (kPa) Stability Condition 2	Temperature (°C)
69.2	39.9	-0.77
46.0	23.0	-0.86

131.0	63.0	-0.96
123.2	60.1	-0.95
101.3	42.5	-1.86
113.6	53.4	-1.86
117.7	58.6	-3.10
113.4	59.0	-3.10

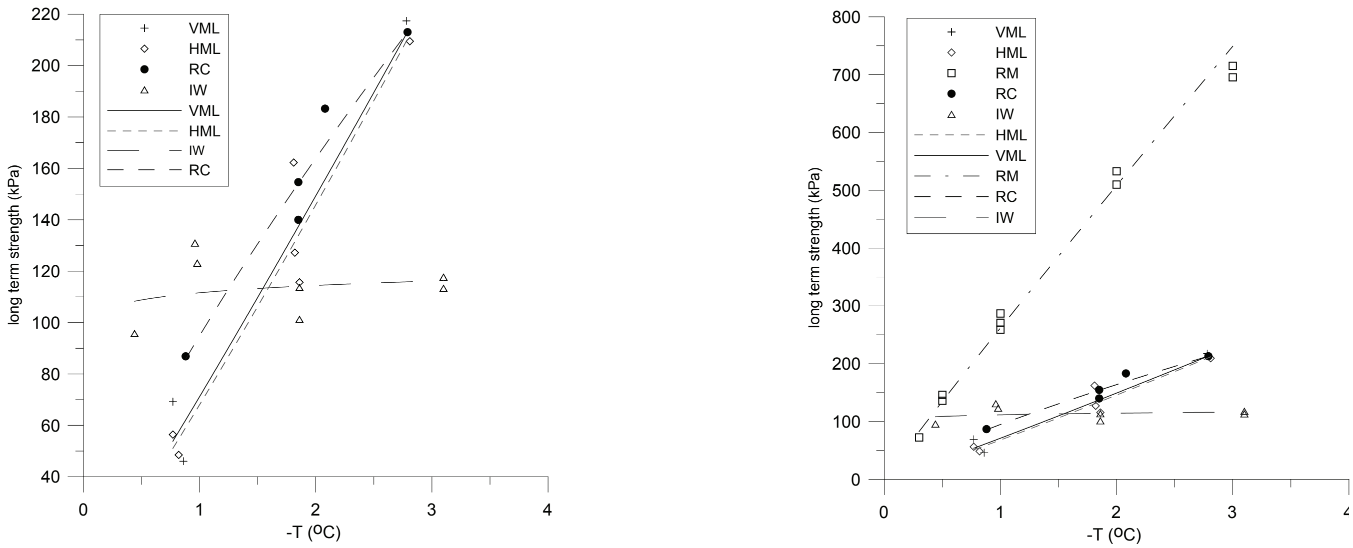

Figure 2. Long-term strength for stability condition 1.

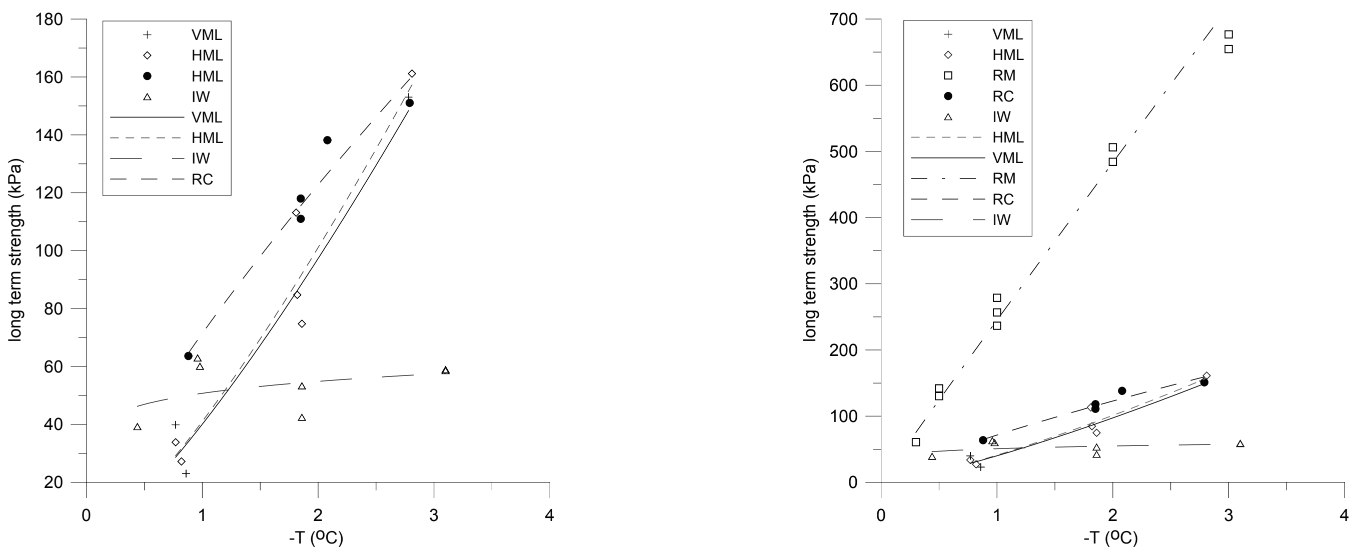

Figure 3. Long-term strength for stability condition 2.

strengths for Fairbanks silt from outside sources. Long-term strength as a function of temperature can be modeled by equation 1.

$$\sigma_{lt} = A\left|\theta\right|^{b} \tag{1}$$

where A and b are experimentally determined parameters. Values for A and b as a function of cryostructure are shown in Table 3 and 4. The value of σ_{lt} has units of kPa. A has units of kPa°C^{-b}. Temperature, θ, is the temperature in degrees Celsius below 0°C.

For soils with *micro-lenticular* structure, the value of b>1 results in concave upwards inflection of any extrapolation of the curve. The temperature range represented by this data is the zone of the most intense change in unfrozen water content. As the temperature decreases, the long-term strength generally increases at a slower rate. Therefore, extrapolation of the given equation to lower temperatures should give larger values of long-term strength than would be expected.

The long-term strength of soils with *vertical micro-lenticula*r (VML) and *horizontal micro-lenticular* (HML) structure are similar as seen from the parameters A and b as well as Figure 2 and Figure 3. Soil with *remolded-massive* (RM) cryostructure shows higher long-term strength as compared to natural soils; the strength is 3 to 4 times larger for RM soils than undisturbed soils. This is significant in that extrapolation of results from remolded soils to undisturbed soils is not conservative, based on our data.

In situ massive silts from the permafrost tunnel were not tested directly using the relaxation method. A small number of massive silt specimens were tested under uniaxial constant stress conditions. Results suggest that the in situ massive silts show higher deformation for a given stress than soils with micro-lenticular structure. Results from soils with *remolded-massive* structure should not be extrapolated to the in situ massive silts.

Table 2. Long-term strength data summary for Fairbanks silt and other ice-rich silt.

long-term strength (kPa) stability condition 1	long-term strength (kPa) stability condition 1	Temperature (ºC)	soil	source	comments
319.7	228.5	-2.0	Fairbanks silt	Yuanlin & Carbee 1987	low density, remolded
62.9	35.4	-1.7	Fairbanks silt	Thompson & Sayles 1972	Lab test on undisturbed cores
46.8	26.3	-1.7	Fairbanks silt	Thompson & Sayles 1972	Permafrost tunnel closure rates
*note: above values are based on steady state power law creep relationships					
100 Year Strength Approximations					
$\sigma_{100\ yrs}$	Temperature (ºC)	soil	source	comments	
191.2	-0.5	Fairbanks silt	Yuanlin & Carbee 1987	med. density, remolded	
343.2	-1.0	Fairbanks silt	Yuanlin & Carbee 1987	med. density, remolded	
608.0	-2.0	Fairbanks silt	Yuanlin & Carbee 1987	med. density, remolded	
864.0	-3.0	Fairbanks silt	Yuanlin & Carbee 1987	med. density, remolded	
29.3	-1.7	Fairbanks silt	Ladanyi et al. 1991	pressuremeter relaxation, field, med. strains	
133.8	-1.7	Fairbanks silt	Ladanyi et al. 1991	pressuremeter relaxation, field, low strains	
171.0	-1.0	Norman Wells silt	McRoberts et al. 1978	lab tests, undisturbed cores, ice-rich	
220.0	-3.0	Norman Wells silt	McRoberts et al. 1978	lab tests, undisturbed cores, ice-rich	

Soils with *reticulate-chaotic* (RC) structure show a slight increase in long-term strength over soils with *micro-lenticular l*structure under the temperature range tested. Extrapolation of the RC curve to colder temperatures would suggest lower long-term strengths.

The *wedge ice* (IW) shows small increase of long-term strength with temperature. Significant scatter of experimental data exists. Only at -0.44ºC is a drop in strength observed. Under the temperature range observed, the long-term strength can be considered constant. At a temperature of approximately -1.5ºC, the long-term strength of *wedge ice* falls below that of the ice-rich soils. The largest drop in long-term strength for the stability condition 2 is for *wedge ice.*

Comparison with previous works

Table 2 shows strength data for Fairbanks silt (Ladanyi et al. 1991, Thompson & Sayles 1972, Yuanlin & Carbee 1987) along with data for ice-rich silts (McRoberts et al. 1978). Data is reduced from steady state creep rates and primary creep equations. Yuanlin & Carbee (1987) worked with remolded Fairbanks silt from the permafrost tunnel. For low density (1.07–1.10 g/cm^3), the strength corresponding to stability conditions 1 and 2 were 319.7 kPa and 228.5 kPa at -2°C. Values were obtained from tests with strains rates greater than 2.88 x 10^{-4} hr^{-1}. Hundred year long-term strength (data extrapolated to 100 years) for medium density silt (1.18–1.23 g/cm^3) yielded strengths of 191.2 kPa, 343.2 kPa, 608.0 kPa, and 864 kPa at temperatures of -0.5°C, -1°C, -2°C, and -3°C, respectively. The strength data for soils with *remolded massive* structure falls between the low and medium density silts. The dry densities for soil with *remolded-massive* structure are close to the low density silts.

Ladanyi et al (1991), performed in situ pressuremeter relaxation tests in the permafrost tunnel. For medium strains, 100 year strength is equal to 29.3 kPa. For low strains, the 100 year strength is equal to 133.8 kPa. Test temperatures varied from -1.7°C to -2°C. Thompson & Sayles (1972) measured closure rates of the permafrost tunnel and performed laboratory creep tests of undisturbed soil cores. Based on steady state creep rates for laboratory tests, the strengths are 62.9 kPa and 35.5 kPa (for strain rate of 2.083x10^{-6} hr^{-1} and 2.083x10^{-7} hr^{-1}, respectively) at -1.67°C. Test strain rates were greater than 0.0018 hr^{-1}. Steady state creep conditions for the tunnel closure data yielded strength values of 46.8 kPa and 26.3 kPa. McRoberts et al (1978) reported 100 year strengths for ice-rich Norman Wells silt with strength value of 171 kPa and 220 kPa at temperatures of -1°C and -3°C, respectively. Based on water contents listed in the field study reports from the permafrost tunnel, the soil tested was most likely *micro-lenticular*. Detailed permafrost descriptions were not available. Generally, the field tests yielded lower strengths as compared to the relaxation tests in this study. It is important to note that results of the laboratory tests on undisturbed soils are extrapolations from higher strain rates under which the tests were conducted to lower strain rates. Experience indicates that extrapolation to lower strain rates generally will yield lower strengths. The low strain conditions (Ladanyi et al. 1991) are in the same range as soils with *micro-lenticular* structure. The -1°C strengths are generally higher for ice-rich Norman Wells silt as compared to soils with *micro-lenticular* and *reticulate-chaotic* structure. The -3°C long-term strengths are comparable.

Conclusions

The aim of this study was to explore the effects of the cryostructure on the long-term strength of ice-rich permafrost soils. Long-term strength data directly from relaxation tests yield comparable results to other testing methods. Soils with *remolded-massive* structure had long-term strengths 3 to 4 times greater than the undisturbed soils. In the temperature

Warming of Cold Permafrost in Northern Alaska During the Last Half-Century

Max C. Brewer
U. S. Geological Survey, 4200 University Drive, Anchorage, Alaska 99508-5021, USA
Huijun Jin
State Key Laboratory of Frozen Soils Engineering, 326 W. Donggang Rd., Lanzhou 730000 China

Abstract

Climatic warming has not resulted in measurable thawing of the cold (-5 to -10°C) permafrost in northern Alaska during the last one-half century. The maximum depths of summer thaw at five locations near Barrow, Alaska, in 2005 were within the ranges of the depths obtained at those exact same locations during the early 1950s. However, there has been a net warming of about 2°C at the upper depths of the permafrost column at two of the locations. Thawing of permafrost from above (increase in active layer thickness) is determined by the summer thawing index for the specific year, while any warming or cooling of the upper permafrost column results from the cumulative effect of changes in the average annual air temperatures over a period of years, assuming no change in surface conditions. Theoretically, thawing from the base of permafrost should be negligible even in areas of thin (about 100-200 m) permafrost in northern Alaska.

Key words: cold permafrost; climatic warming; northern Alaska; thawing.

Introduction

The U.S. Geological Survey (USGS) initiated a program for studying permafrost temperatures, based at Barrow, in northern Alaska beginning in 1949. The objective was to assist the U.S. Navy in solving some of the engineering problems being encountered in their oil and gas exploration of Naval Petroleum Reserve No. 4 (NPR-4). It rapidly became apparent that several areas of science and engineering would be involved in the solution of the problems. The Navy's problems included drilling bits frozen into wellbores, well-casing collapse, saline waters encountered in seismic shot holes in supposedly deep permafrost areas, obtaining year-around water supplies, obtaining electrical grounds for communications, overland transportation, and differential settlements and frost heaves in airstrips and in building foundations and floors.

Barrow is on the coast at the northernmost point (71°20′N) of land in Alaska (Fig. 1). It has an arctic marine climate with short, cool (maximum temperature +24°C, average about 4°C) summers and long, cold (minimum temperature -49°C) winters. The average annual air temperature was -12.2°C during the period from 1922 to 2004. The sun sets for the year on November 19 and does not show above the horizon again until January 24; it rises on May 10 and does not set again until August 2. Precipitation is light, about 53 mm of "drizzle-type" rain in summer, and 244 mm in the form of hard-packed snow, density about 0.4 g cm^{-2}, in winter (Black 1954), but the evaporation rate is low. Light winds are almost constant, fall storms are common, and blizzards occur frequently during the winter. The ocean is frozen over for 8 to 10 months of the year. The inland coastal plain is a flat-lying, treeless, roadless, tundra-covered area with a vast multitude of shallow lakes and ponds. For biologically oriented scientists, it is a priceless wetland; for engineers, it is a mosquito-infested swamp land in summer

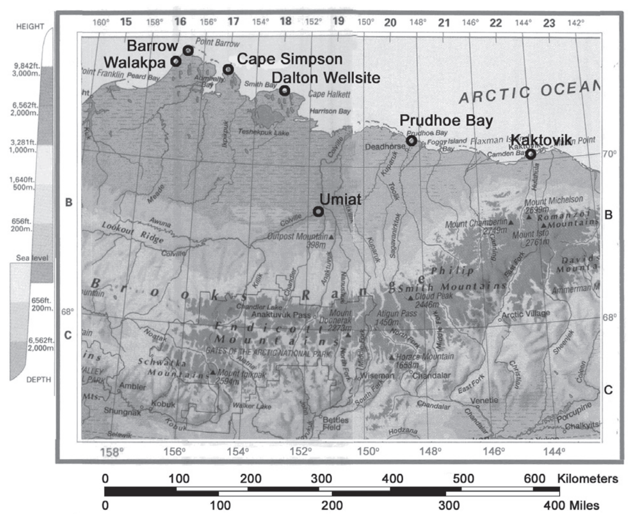

Figure 1. Permafrost study areas.

and a desolate wasteland in winter, although that is the best season for trafficability. For the Eskimo people it is, and has been for more than 6,000 years, home. The permafrost table is at depths ranging from 0.3 to about 1.0 m.

The permafrost temperatures were obtained using thermistor cables permanently frozen into the boreholes with readings obtained weekly in the shallow (0.3 to 40 m) holes, less frequently in the deeper (200 to 2000 m) oil wells abandoned during the late 1940s and the 1950s. The deeper measurements were concentrated on the solution of the problem of well-casing collapse. One very important scientific finding from those studies was that when the geothermal gradients from depth were projected upwards in some of the wells, they suggested a warming of 2 to 4°C in the upper approximately 100 m of the permafrost column (Brewer 1958a, Lachenbruch & Brewer 1959, Lachenbruch et al. 1962, Lachenbruch and Marshall, 1986, Lachenbruch et al. 1987). Lachenbruch (pers. com.) calculated that, for the warming from surface effects to have reached depths on the order of 100 m, the warming would need to have commenced about the year 1860, the estimated end of the Little Ice Age.

During the next century, an even greater change in climate in Alaska has been projected by some researchers, often using 1980 (at Barrow, the end of a mini-cooling period (Fig. 2)) as a temperature reference base. By 2100, the IPCC and HadCM2 modeling have projected a warming of 2.8°C (in the range of 1.1 to 5.0°C) in spring, summer, and fall, and 5.6°C (with a range of 2.2 to 8.9°C) in winter. Earlier measurements in more than 100 boreholes with depths ranging from 0.3 to 30 m, to more than 100 m, and on some occasions up to 650 m, on the North Slope in the 1950s and early 1960s were obtained by scientists from the USGS (Brewer 1958a, b, Lachenbruch & Brewer 1959, Lachenbruch et al. 1962, Lachenbruch and Marshal 1986, Lachenbruch et al. 1982, 1988). In addition, yearly permafrost temperature measurements were obtained along the Trans-Alaska Pipeline and at other locations in Alaska in the late 1970s (Osterkamp et al. 1994, Osterkamp & Romanovsky 1999) by a research team led by Jerry Brown, which re-occupied some of the earlier Barrow boreholes (Jin & Brewer 2002, Jin et al. 2002, Romanovsky et al. 2002), by Clow, who took over the Lachenbruch and Brewer ONPRA permafrost temperature measurement program on the Arctic Coastal Plain and Foothills (Clow & Urban 2002), and by other individuals. However, the IPCC appears to have ignored the fact that Alaska is a big area (1.5 million km^2), is surrounded on three sides by oceans/seas, that the state essentially has five climate zones, and that a cooler summer, when thawing occurs, and a warmer winter can produce a positive average annual air temperature (AAAT). Some of the reports contain a paucity of information regarding surface conditions in the areas where the temperatures were measured; the difference in snow conditions, especially the densities, preferring to use the term "temperature offset" to encompass the unknowns; vegetative covers; active layer conditions; or differences in elevations.

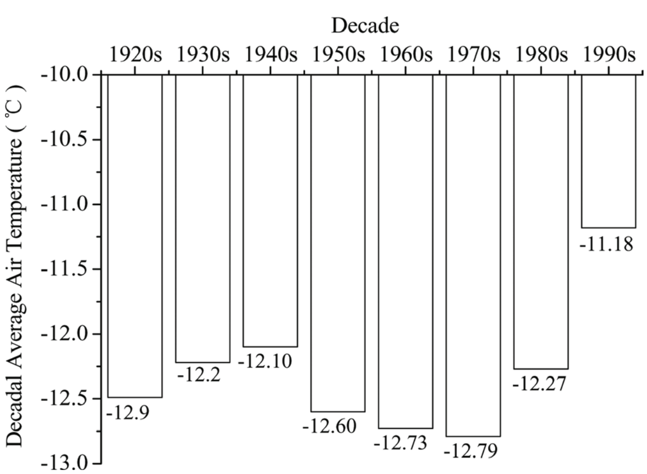

Figure 2. Decadal variations in average annual air temperatures at Barrow, Alaska, during the 20th Century.

Weather Bureau records (Fig. 2) for Barrow, Alaska, from 1922 to date indicate a decadal warming trend from the 1930s through the 1940s, a cooling from about 1950 through about 1975, the year that a major portion of the construction equipment and materials could not reach Prudhoe Bay because of the Arctic Ocean pack ice, followed by a warming trend that accelerated in the 1990s. Romanovsky provided the authors with a copy of the AAATs for Barrow from 1922 to 2004 that indicated no overall average change in the AAATs during that period.

Many modelers on climatic-warming-related degradation of permafrost have predicted significant and rapid losses of permafrost, both in thickness and areal extent in Alaska and in other regions. In so doing, the modelers have had to make many assumptions, including that the changes in air temperatures and the changes in depths to the permafrost table move in lock-step. However, the rate of dispersing the heat received downward in the permafrost profiles and the thicknesses of those profiles to absorb the heat are important factors. Of even greater importance are the complicated interactions between the atmosphere and the permafrost table, particularly those impacts involved because of the intervening poorly understood and little-studied active layer.

Study Regions

The wide, flat-lying, tundra-covered coastal plain of northern Alaska is characterized by "cold (-5 to -10°C) permafrost"; a multitude of 1- to 3-m-deep lakes; grasslands interspersed with areas of low-center ice-wedge polygons; high-center polygons adjacent to small breaks in topography, often associated with lake basins or minor drainage patterns; and meandering streams. The vegetation overlying the dominant silts and fine sands is thin (5 to 10 cm), as are the peats which are often confined to the low-center polygonal areas. MacCarthy (1952) reported an average of approximately 1 m per year of coastal erosion between Barrow and Kaktovik, approximately 560 km to the east. However, the averaging obscures the fact that the natural erosion geographically has been very uneven during the 20th century. Reportedly, the erosion has been as much as 800 m in the area of Cape Halkett (200 km east) since 1913 and a recorded 400 m at the Dalton Wellsite (Fig. 1) since 1980. The Native coastal settlements of Birnik, dating back 800 to 1000 years, and at Walakpa with an age of approximately 6,000 years still remain. The bluff at Walakapa, 17 km southwest of Barrow, retreated a measured 10.2 m between 1951 and 1997.

Umiat (69°22′N, 152°08′W, 81 m in elevation) is located in the Colville River Valley, which traverses the rolling hill country on the northern front of the Brooks Range. The vegetation tends to be tall grasses and low shrubs with birch near the river.

While the Alaskan arctic and subarctic meteorological data are sparse geographically and of limited history, the Weather Bureau's reported average annual air temperatures (AAATs) through 1954 for Barrow (-12.2°C), Kaktovik (-12.0°C), and Umiat (-12.1°C) 120 km inland were very similar, even though the first two have arctic marine environments and the latter the greater extremes of an arctic continental climate. The similar AAATs obscure the fact that the cumulative centigrade degree days of thawing for Barrow averaged 268, and for Umiat 916 during the 1950s.

Because the wind blows almost continually at Barrow, Umiat, and Kaktovak, the snow crystals are broken up and packed much like fine sand, and the snow pack develops a density of about 0.4 g cm^{-3}. The majority of the snowfall arrives during three periods: early fall before the air temperatures drop much below -20°C, during the annual early January warming period of two to three weeks, and in the late spring (April and May). Thus, its cumulative effect as a ground insulator is highly variable. Another imponderable cumulative effect is the amount of evaporative cooling of the ground resulting from the frequency, sometimes almost daily, of the July, August, and occasionally early September "drizzle-type" precipitation with the ever-present windy conditions.

Methodology

The shallow temperature cables, permanently installed, were used to investigate temperatures beneath various natural surface environments (dry grasslands, wet meadows, low- and high-center polygons, old poorly vegetated beach ridges, an active beach, shallow and moderate-to-deep lakes and lagoons, lake and ocean ice, and the near-shore Arctic Ocean) and beneath engineering structures (various types and sizes of buildings, airstrips, roads, various thicknesses of gravel fill, and beneath a recently artificially drained shallow (0.5 m) lake). Most of these study sites were located within about 8km of the Barrow Weather Station (71°18′N, 156°47′W) and thus were assumed to be impacted by relatively similar air temperatures, precipitation, and winds. The accuracy of the thermistors was 0.02°C, their sensitivity was 0.006°C. Similar shallow temperature study programs, on much reduced scales, were initiated near Umiat in 1951. The depths of thaw measurements data presented are from some of those studies, plus updates from 2001 and 2005 in northern Alaska.

Results and Discussions

Permafrost

"Cold (-10 to -5°C) permafrost," ice-wedge polygons, and wetlands are prominent characteristics of the Alaskan Arctic. The measured thicknesses of permafrost vary greatly at the same latitude, from less than 200m to an unusual thickness of 685m in the Prudhoe oilfield. Lachenbruch et al. (1987) believe that thickness resulted from anomalous thermal conductivity because of the unusual thickness of gravel swept down from the Brooks Range by the Sagavanirktok River. At Umiat, the thickness of permafrost ranges from 213 to 322m within a horizontal distance of 2.4km. That rapid change in the thickness may have resulted from changes in the course of the Colville River. Brewer (1958a) also found

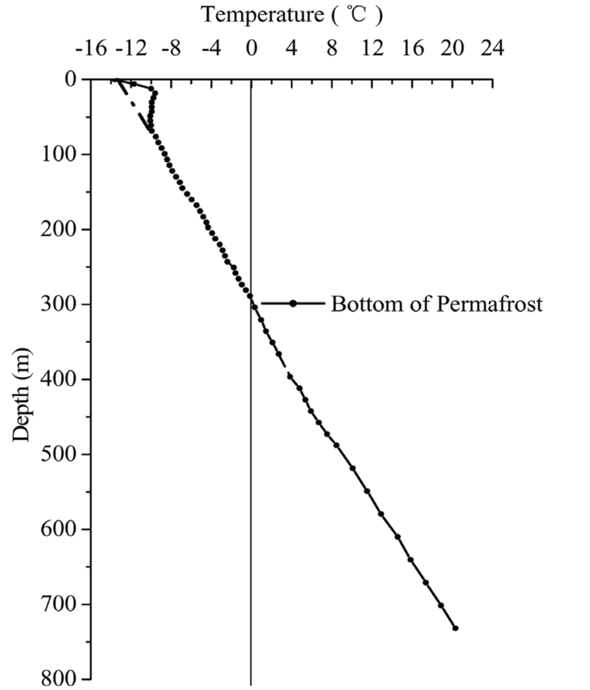

Figure 3. Thermal profile for Simpson 28 Well 112 km southeast of Barrow, Alaska. The broken line at depths of 0-80 m is the linear projection based on the thermal gradient from below.

that the temperatures at depths of 20 m (depth of significant annual change of 0.01 to 0.03°C) within a radius of 8 km from the Weather Bureau Station at Barrow varied from -7.3 to -10.7°C, to +1.0°C beneath a freshwater lake 2.8 m in depth.

The geothermal profile for Simpson Well 28 (Fig. 3) obtained two years after installation of the cables in the wellbore and, projected upwards, is one of those used by Brewer (1958b), Lachenbruch & Brewer (1959), and Lachenbruch et al. (1962) to suggest a warming of the upper part of the permafrost by 2 to 4°C during the previous century. The consistent slope of the profile below 70m suggests a remarkably steady surface environment (air temperature, precipitation, and vegetative cover) for the previous several centuries.

The geothermal profiles in Figure 4 were obtained at the end of the unusually warm 1954 summer, from within a horizontal radius of approximately 5 km near Barrow. The figure is intended to illustrate the relative impacts of various natural surface covers on the near-surface temperatures. The temperatures at 2 m are at the maximum for the year although, because of the phase lag, those below that depth will continue to rise for several weeks or months thereafter.

The permafrost temperatures at a red grass low-center polygonal area in 1954, and from a replacement cable installed in the same spot by Kenji Yoshikawa in 2001, are shown in Figure 5 (Romanovsky et al. 2002). The cumulative maximum warming indicated was 1.69°C at about the 11 m depth. The vegetative cover in Figure 5, except for the wetness (a bit drier), the area was little changed after 47 years. However, the data in Table 1 indicate a minor greater measured maximum depth of thaw (thickness of the active layer) in 1954.

The 1950s cooling (0.80°C at a depth of 4.7 m) beneath the adjacent, unusually wide polygonal trough, about 10 m distant, was much greater than at the same depth beneath the polygon. This was in spite of the fact that the trough quickly accumulated a thickness of about 1.0 m of drifted, hard-packed snow (insulating effect is over compensated by the additional time required for melting (Drew et al. 1958)), whereas the top of the polygon rarely had more than 4 to 10 cm of snow cover in winter due to the ever-prevailing winds. Permafrost temperatures at depths of 30 m at other Barrow installations indicate a cooling of 0.23 to 0.30°C during the period 1953-1960.

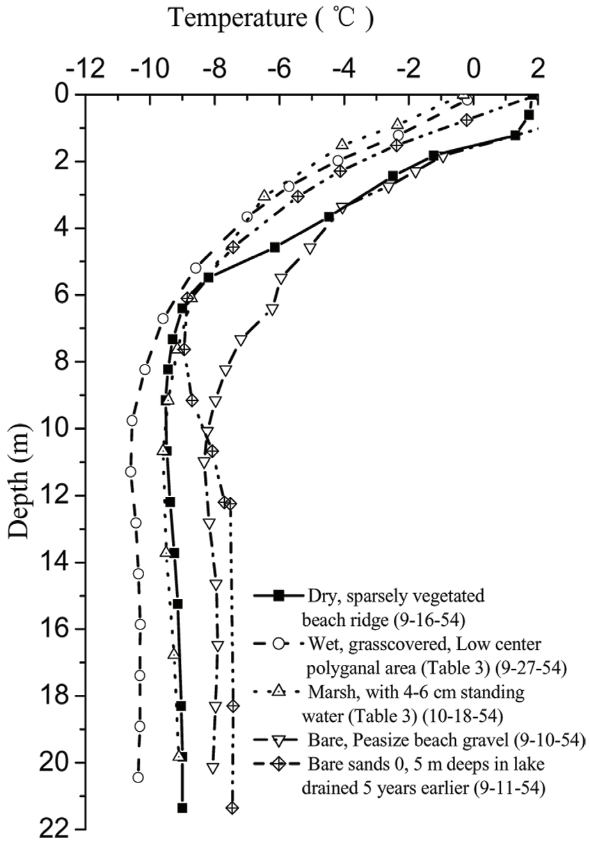

Figure 4. Geothermal profiles beneath different surface covers within a radius of 5 km, Barrow, Alaska.

The temperature profiles (Fig. 6), obtained weekly from a frozen-in cable beneath a high-center polygon, indicate a cooling of the permafrost of about 0.37°C, at 4.7m, between the years 1953 and 1960. A repeat of the measurements in 2001 indicates a cumulative warming of the permafrost at that depth of 1.66°C during the intervening 41 years.

* No visible change in surface cover during 1951-2005. This site is shown in Figure 5 and 6.

** Area had more and taller grasses in 2005.

The year 1953 had a very cool summer, and 1954 and 1957 had unusually warm summers.

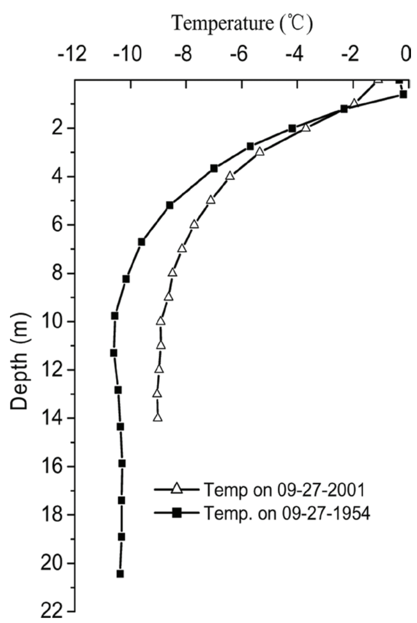

Figure 5. Geothermal profile beneath low-center polygon area with 4-10 cm standing water at Barrow, Alaska. This site had the coldest temperature measured at 20 m in Northern Alaska.

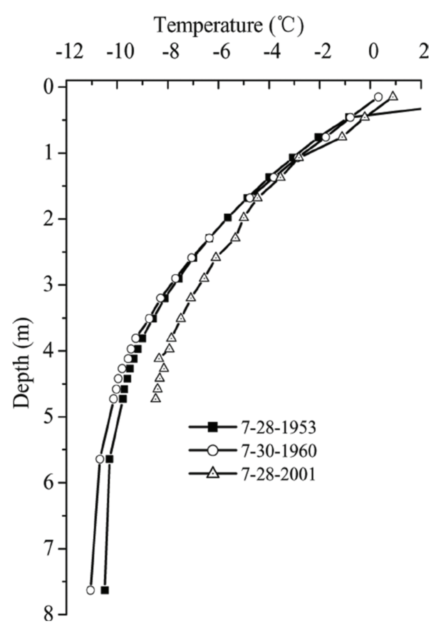

Figure 6. Geothermal profiles for a high-center polygon, Barrow, Alaska.

An illustration of the impact on permafrost temperatures resulting from modifying the surface is shown in Figure 7. Tracked personnel vehicles, traversing a moderate slope at Umiat during a spring/summer, caused the tundra in the trail to become badly damaged. The thermistor cables installed beneath the bare trail and in an adjacent undamaged area two years later indicated that the active layer beneath the trail had deepened from about 0.6m to about 1.5m, but that the annual permafrost temperatures had decreased by about 1.3°C at 6.1m. In other words, the active layer was increasing in thickness at the expense of thawing a bit of the upper permafrost, while at the same time the annual average temperatures of the underlying permafrost were decreasing. The same phenomena occur in gravel fills at Barrow, and it was the basic tenant behind the construction, in 1955, of the permanent roads and airstrips for the radar stations along the Alaskan Arctic coast and for the permanent drilling pads and other facilities constructed in the Prudhoe Bay oilfields. The 1.5m of fill cools and brings the top of the permafrost into the base of the fill in cold permafrost areas, thus providing a solid foundation.

Depths of thaw

Since deepening of the active layer and/or permafrost thaws only when the temperatures are above freezing for an extended period of time, the annual change in the thawing index tends to provide far greater insights regarding the near-surface permafrost than do the changes in the annual average air temperatures.

The cumulative °C-days of thaw at Barrow in 1950 and 1952 (Table 2) were about the same, approximating the decadal average, but the average annual air temperature in 1952 was 2°C colder than in 1950, indicating colder winter air temperatures, which have nothing to do with the thawing of permafrost or the active layer.

The maximum depths of summer thaw were obtained using a pointed steel rod, 0.64 cm in diameter, pushed to refusal (sounded like hitting concrete) at an average of 4 points at about 1 m distance surrounding the thermistor cables (Tables 1 and 3). The measurements generally were made in early September, as there usually is little thaw of permafrost, or warming of lake (Brewer 1958b, Drew et al. 1958), after the first week in August in northern Alaska.

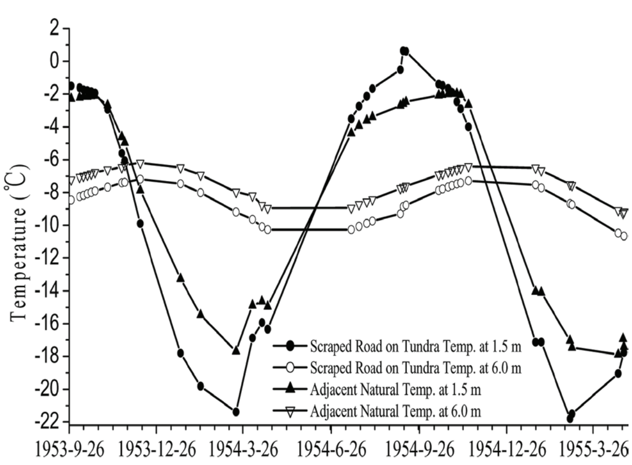

Figure 7. Time-temperature series beneath damaged and adjacent undamaged tundra, 1953-1955, Umiat, Alaska.

Summary and Conclusions

Observation over the last 50 years indicates that in Arctic Alaska there definitely has been a warming of the upper layer of permafrost, and just as definitely there has been no thawing of the permafrost during the same 50 years because the depths of thaw have remained unchanged.

Projecting temperatures upwards in permafrost is a relatively easy and scientifically repeatable way to study climate change because the equilibrium geothermal profile has long been established, the impacts of the active layer are avoided, and only heat conduction is involved. This was the approach used by Brewer and Lachenbruch in 1958, 1959, and 1962 when they noted an apparent warming of 2-4°C in the upper permafrost. The big problem is bridging the complicated active layer, which is subject to short-term cyclical changes and numerous unknown factors, to connect with the atmosphere where most climatic measurements are being obtained.

Table 2. Average annual air temperature (AAAT) and thawing index (TI) at Barrow, Alaska during 1950-1960.

Year	AAATs (°C)	TI (°C·d)
1950	-10.6	284
1951	-11.4	448

9-08-05	28.2	36.1

Brewer (1958b), Lachenbruch & Brewer (1959), and Lachenbruch et al. (1962) discussed an apparent warming of permafrost in Arctic Alaska beginning about 1860, the estimated end of the Little Ice Age, without making any predictions regarding the future. But many recent publications have discussed air temperature warming in Arctic Alaska beginning about 1980, the end of a mini-cooling period at Barrow (Fig. 2), projecting temperatures forward and suggesting worldwide implications. Projecting forward from an extreme point in a cycle would appear to be of questionable scientific validity.

Chronicling climatic change is a long-term multi-faceted endeavor that necessitates the observation of numerous potentially impinging aspects of nature, not just changes in temperature. Obtaining those needed observations sometimes is hampered by the fact that advancements in the technologies in instrumentation, communications, and transportation have outstripped the willingness and ability of researchers to obtain field observations, i.e., one can rapidly acquire data without the needed field environmental information concerning how the data may have been or are being compromised by extraneous factors.

The many mixed views on the changes in permafrost and its distribution under a changing climate have highlighted the paucity of integrated scientific knowledge and information, due to a lack of long-term observations, as recorded by Hinzman et al. (2005).

A determination of the actual effects of the active layer, which lies between the permafrost and the atmosphere and hence the correlations between the permafrost and climatic change, is the biggest problem. At least a proximate solution, which cannot be derived by imagery or modeling, is critical.

Characterization and Classification of Topsoils as a Tool to Monitor Carbon Pools in Frost-Affected Soils

Gabriele Broll
University of Vechta, Vechta, Germany
Charles Tarnocai
Research Branch, Agriculture and Agri-Food Canada, Ottawa, Canada

Abstract

Many frost-affected soils contain large pools of carbon that are very sensitive to climate change. Detailed mapping of topsoils and their spatial variability could help to improve the reliability of soil carbon data. The topsoil, which acts as the interface between vegetation and subsoil, is an indicator of ecosystem change. The objective of this paper is to give an overview of developments in topsoil/humus form characterization and classification. This information can be used to show the spatial variability of topsoils and, thus, carbon pools, as well as the biological activity in the Arctic. Identification, sampling, and analysis of representative pedons for the soil and humus forms will improve the quality of the data required for upscaling and, additionally, will provide information on the soil biocoenoses, all interacting organisms living in soil. Special requirements for frost-affected sites should be considered when topsoils are mapped.

Keywords: carbon stocks; permafrost-affected soils; seasonally frozen soils; soil biocoenoses; topsoil.

Introduction

Many frost-affected areas (perennially or seasonally frozen) with large carbon stocks are very sensitive to climate change. Topsoils or humus forms are the interface between vegetation and subsoil (Fig. 1). They can act as indicators for changes of ecosystems driven by climate change or land-use change. Up to now new approaches of international working groups to characterize and to classify topsoils and/or humus forms are ignoring frost-affected sites. On the other hand, topsoils of subarctic and arctic sites will probably change quickly due to climate warming, wild fires, and flooding.

Objectives of this paper are:

- To present developments in characterization and classification of topsoils and humus forms, which could be used in the Arctic and Subarctic;
- To show examples for spatial variability of topsoils and thus carbon pools as well as biological activity in the Arctic and Subarctic;
- To present ideas how knowledge about topsoils can help to improve the interpretation of carbon data, which is of special interest for the northern environment containing large carbon pools.

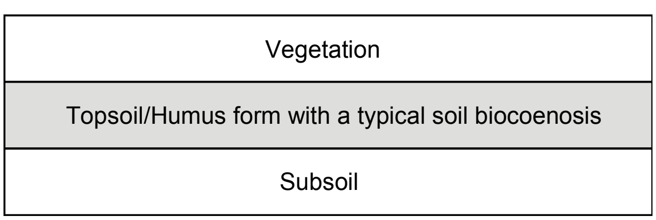

Figure 1. Topsoil as interface between vegetation and subsoil, acting as habitat for a typical soil biocoenosis and being a product of the soil organisms based on litter input and mineral components.

Characterization, Classification, and Indicator Function

Topsoils and humus forms include litter (L), in many cases organic horizons (OF/F, OH/H), and the A horizon. In agricultural areas, the A horizon is in almost all cases the only part of the topsoil. Thus, soil structure and the quality of the soil organic matter as results of the soil biological activity can be used for characterizing the topsoils. In forests usually different organic layers indicate different decomposition rates. Modeling approaches focusing on organic layers help to improve predictions for changes of carbon pools in the environment (e.g., Akselsson et al. 2005). In the Subarctic and Arctic there are different types of topsoils, from the more or less pure geological substrate to thick organic layers.

The topsoil acts as habitat for the soil organisms, and at the same time it is a product of the soil organisms. The humus form is the mirror of the soil biocoenosis, their composition, and their activity result in different decomposition rates. So why not look for the soil organisms and their activity directly? It is time-consuming as well as costly and requires specialists. This should be done for representative monitoring sites which could then serve as reference sites. Humus forms can be used as indicators for environmental change instead of the soil organisms themselves. Humus form data could be made available for large areas within a relatively short time. Their description is quite easy to learn and probably new remote sensing methods will be available in the future, but first, worldwide accepted guidelines for characterizing and classifying topsoils have to be developed.

A first step in this direction was made in cooperation with the FAO that has a draft for characterizing topsoils. One outcome of a FAO project was that in principle, a great coincidence between characterizations of humus types and

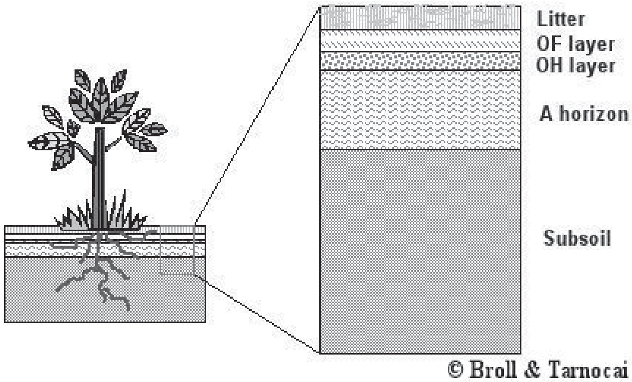

Figure 2. Appearance of carbon in the vegetation and in different soil horizons; example for non-frost-affected soils.

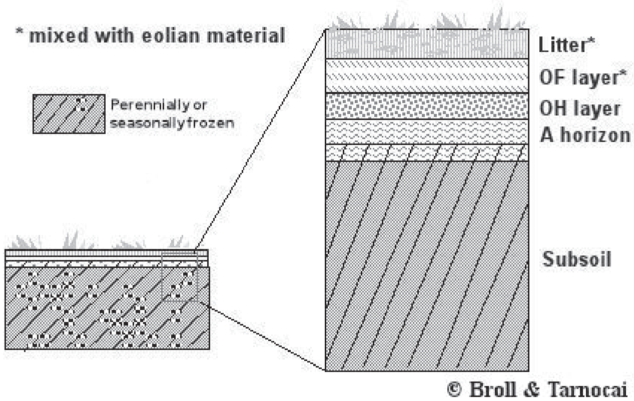

Figure 3. Appearance of carbon in the vegetation and in different soil horizons; example for static frost-affected soils.

topsoils exists which appears to be an appropriate basis for further correlation, and, finally, incorporation in the World Reference Base for Soil Resources. This could promote worldwide use of this system. In case of forest sites, the topsoil characterization can be improved by incorporation of humus typology using qualifiers for the organic layers. In case of grassland or arable land usually lacking organic layers, topsoil characterization can be improved by using qualifiers for soil biological activity in the A horizon. The biological qualifiers provide a good basis for soil quality assessment besides chemical and physical qualifiers (Broll et al. 2006).

Looking at the carbon pools specifically in non-frost-affected soils, carbon is stored in the vegetation, in the organic layers, in the A horizon, and in the subsoil, where generally only small amounts of carbon are found (Fig. 2). The carbon stocks in the topsoil depend on site conditions such as moisture.

Looking at frost-affected soils of the Arctic, especially those perennially frozen, only little amounts of carbon are stored in the actual vegetation but large amounts can be stored in the soil, both in the topsoil and in the subsoil (Figs. 3, 4).

The topsoil can have, for example, a thick moss layer on wet sites. In the boreal region, about one-third of the carbon

Figure 4. Turbic cryosols and static cryosols at Pangnirtung Pass on Baffin Island, Canadian Arctic.

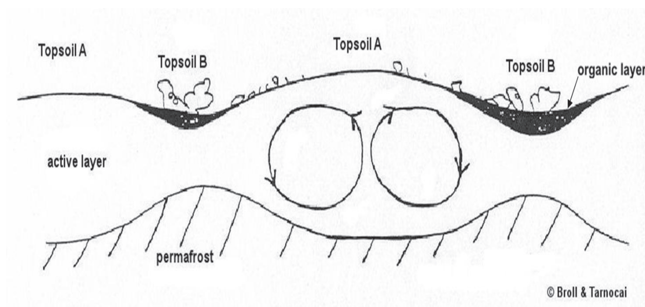

Figure 5. Turbic cryosol with two different topsoils occurring regularly in the landscape (modified after: Heal et al. 1998).

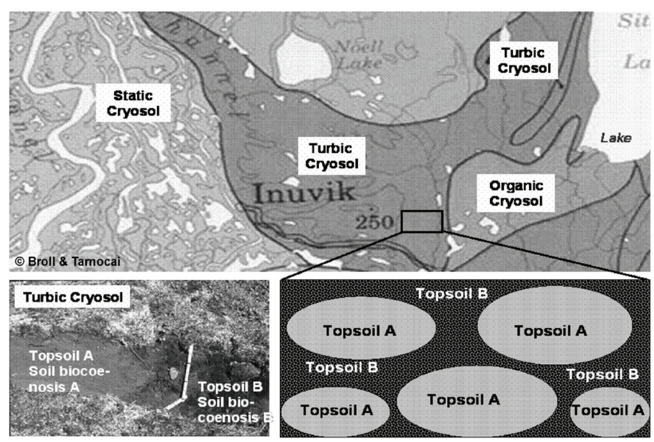

Figure 6. Distribution of Cryosols, topsoils, and soil biocoenoses in the Canadian Arctic (Mackenzie River delta area).

is in the vegetation and two-thirds in the soil. Very often the topsoil in the Arctic is enriched with eolian material. Due to formerly warmer climate along with high production of biomass, large amounts of carbon can be found also in the subsoil, where the carbon is stored in the permafrost.

Turbic Cryosols (cryoturbated, permafrost-affected soils) (Fig. 4) contain larger amounts of carbon than Static Cryosols (non-cryoturbated, permafrost-affected soils) (Tarnocai et al. 2003, Tarnocai & Broll 2008) and show even more specific

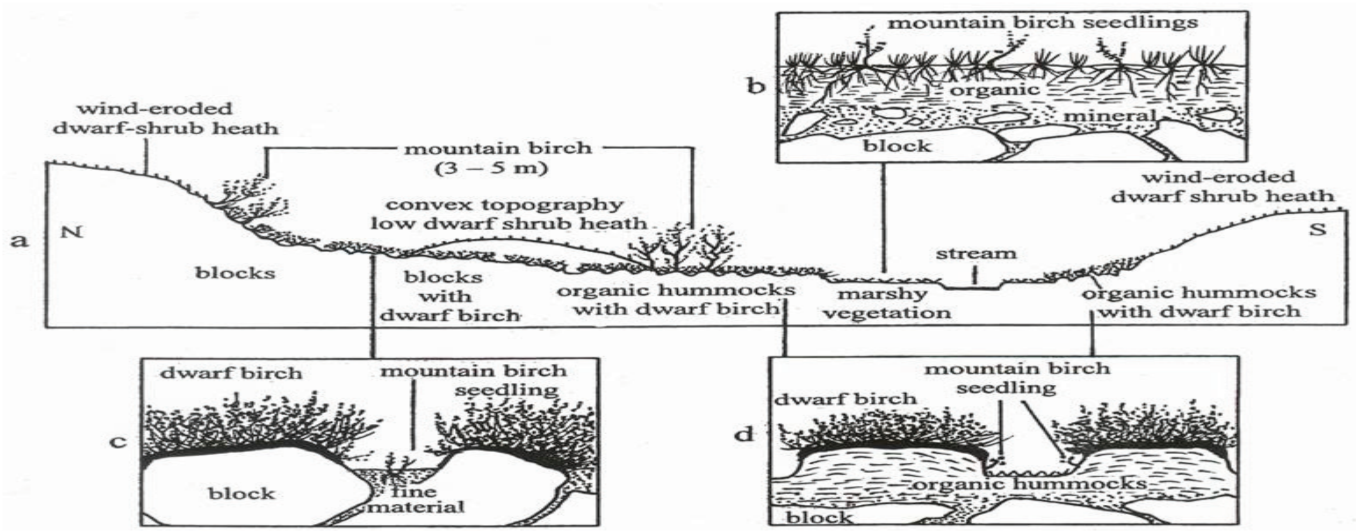

Figure 7. Spatial variability: Topsoils and carbon sequestration depending on microtopography in the Finnish Subarctic (Holtmeier et al. 2003).

Figure 8. Landscape mosaic in the treeline ecotone on Mt. Rodjanoaivi, subarctic Finland.

properties concerning carbon pools. Organic layers are drawn into the subsoil due to cryoturbation and, on the other hand, geological substrate-like till can be brought to the surface producing topsoil with very low amounts of carbon. Moreover, carbon can be enriched above the permafrost table.

In case of Static Cryosols, topsoils are relatively homogenous. In case of Turbic Cryosols two different topsoils occur (Figs. 4, 5). These topsoils are not unique for certain areas like Pangnirtung Pass on Baffin Island (Fig. 4); they are widespread in the Arctic. These frequently appearing features can be mapped in the field as well as by remote sensing and thus used for modeling and upscaling.

Spatial Variability and Upscaling

Turbic Cryosols show a regular pattern of topsoils due to cryoturbation (Figs. 5, 6). Because of insulation effects of the organic layer, the active layer under topsoil B is shallower than that under topsoil A. In general, topsoil A has low amounts of carbon whereas topsoil B contains high amounts of carbon (Broll et al. 1999). In case of climate warming, cryoturbation will stop and vegetation succession will start from topsoil B to topsoil A. At the optimum stage the plant cover will be continuous, and it will be very difficult to tell the differences between the two topsoils at the surface. On the other hand, this can be very helpful for a quick monitoring of environmental change in the Arctic.

Detailed investigations of topsoils including soil organisms (species, activity) on representative sites would enable making predictions for soil biocoenosis, decomposition, etc. for large areas. This could be interesting, especially in those areas where detailed soil mapping is already available like in the Mackenzie River delta area (Fig. 6). Similar approaches are tested in temperate regions already (Beylich et al. 2006).

This approach of upscaling soil ecological properties via topsoil mapping is relatively easy on flat areas. In mountainous areas the relief plays an important role for the distribution of soils especially because of creating different drainage and thus soil moisture conditions. This affects the topsoils and the related carbon stocks (Figs. 6, 7).

Although those sites like in the Finnish Subarctic looks quite heterogenous; a regular pattern can be identified which occurs all over in the Subarctic: dry wind-exposed heath, boulders with fine material in between, small organic hummocks etc. (Figs. 6, 7) (Broll et al. 2007).

Because topsoils are habitats for characteristic soil biocoenoses, soil ecological processes like decomposition are correlated with the topsoil type (Nadelhoffer et al. 1992, Broll 1994, Müller et al. 1999) Since the topsoil pattern shows a certain regularity, geostatistical methods could be applied to get from the plot scale to the landscape scale (Joschko et al. 2007).

Conclusions

- Topsoils are good indicators for ecosystem changes in the Arctic and Subarctic.
- Detailed information on topsoils in soil mapping protocols can improve the data quality for upscaling of carbon data, can help modeling soil ecological processes and provide information on the soil biocoenoses.
- Combination of spatial soil data with spatial humus form data and vegetation data could help to reduce the number of carbon analysis or help to extrapolating existing data.
- Identification and characterization of topsoils should be included in the Minimum Soil Dataset for Cryosols to provide first information on the biological activity of the site.
- Some existing long-term monitoring sites already include the characterization of topsoils. This knowledge can also be applied to the Arctic.

Abstract

The International Permafrost Association (IPA) was founded in July 1983, at Fairbanks, Alaska, during the Fourth International Conference on Permafrost. The four founding members were Canada, China, the USSR, and the United States. The IPA presently has 26 members. The primary purposes of the IPA are to convene international conferences to facilitate communication and to develop and exchange information related to permafrost research and engineering. Beginning in 1963, international permafrost conferences have been held in Canada, China, Norway, USSR (Russia), Switzerland, and the United States. Working groups, task forces, and committees undertake specific projects and collaborate with other international organizations. Accomplishments include establishment of the Global Geocryological Data (GGD) system, an international permafrost glossary, a permafrost map of the Northern Hemisphere, an inventory of carbon content of northern soils, bibliographies, and publication of *Frozen Ground*. Several major international programs and long-term observing networks initiated by the IPA contribute to the 2007–2008 International Polar Year (IPY).

Keywords: frozen ground; history; IPA; IPY; permafrost; periglacial.

Background

The geopolitical situation that evolved after the Second World War focused attention upon the high northern latitudes. Russian experience of permafrost conditions was more extensive, more advanced, and better documented than in North America (e.g., see Shiklomanov 2005). For example, the Permafrost Institute, a branch of the USSR Academy of Sciences, Moscow, had been established in Yakutsk, Siberia, in 1939, and Russian language permafrost texts had been published from the 1930s onwards (e.g., see Sumgin 1927/37, Shvetsov 1956). By the late 1940s and early 1950s, the importance of the Russian permafrost literature was beginning to be appreciated in North America (Muller 1943, see French & Nelson 2008). As a consequence, the USA and Canadian governments established research agencies and organizations to promote scientific understanding of these regions.

In the USA, the Snow, Ice and Permafrost Research Establishment (SIPRE) and the Arctic Construction Frost Effects Laboratory, later to become the Cold Regions Research and Engineering Laboratory (CRREL), in Hanover, New Hampshire, and the Arctic Research Laboratory (ARL) in Alaska, were established, and the U.S. Geological Survey began extensive field investigations. In Canada, the Division of Building Research (DBR), National Research Council of Canada (NRCC), the Polar Continental Shelf Project (PCSP) and the Geological Survey of Canada (GSC) started to support permafrost-related investigations in the north. The Arctic Institute of North America (AINA) was set up as a bi-national organization with headquarters in Montreal and Washington. Several monographs and publications document some of these early North American undertakings (see French & Nelson 2008).

The First International Conference on Permafrost (ICOP), held at Purdue University, Indiana, in 1963, was an initiative to promote communication and understanding between Soviet and North American permafrost scientists and engineers. This was the first major contact between Russian and western scientists (Brown & Walker 2007). The Second ICOP was held in Yakutsk, Siberia, in 1973, where it was mutually agreed that further conferences would be advantageous to all concerned. At the Third ICOP in Edmonton, Canada, in 1978, the desirability of establishing an organizational structure that would ensure the continuation of these conferences was discussed. Accordingly, the NRCC, through its Bureau of International Relations and the DBR, established a task force in 1981 to draft a set of organizational rules. This was chaired by Lorne Gold, Head of the DBR, NRCC, and the members were Fred Roots, Science Advisor, Environment Canada, John Fyles, Head of the Division of Terrain Sciences, Geological Survey of Canada, and Hugh French, Chairman, Permafrost Sub-committee, ACGR, NRCC. Representatives of the Bureau of International Relations, NRCC, provided advice at meetings of the group.

Formation of the IPA

At the Fourth ICOP in 1983, held at the University of Alaska-Fairbanks, Alaska, Hugh French, leader of the Canadian delegation, convened a special meeting of the leaders of the official delegations from the USA, USSR, and China. Professor T.L. Péwé (USA), Academician P.I. Mel'nikov

(USSR), and Professor Shi Yafeng (China) attended this meeting together with advisors (Fig. 1). Unofficially, these four countries subsequently became known as the "Big Four." It was agreed to form an international association.

The primary mandate of the newly formed association was to organize and promote international conferences on permafrost at regular five-year intervals. A secondary role was to encourage and facilitate the international exchange of scientific information among permafrost scientists and engineers. The agreement to form the association was announced at the closing ceremony; the Executive Committee consisted of Academician Mel'nikov, President, Professor Péwé, Vice-President, and Professor J. Ross Mackay, Secretary-General. The terms of office were for five years. The NRCC, through its Bureau of International Relations, agreed to provide funding to support the activities of the Secretary-General. The creation of the IPA Council was announced, and countries wishing to join the Association were asked to name an organization or representative. The Council was to

Figure 1. Participants in the founding meeting of the IPA, held at Fairbanks, Alaska, in 1983. Front row: Louis DeGoes, Li Yusheng, Shi Yafeng, J. Ross Mackay, P.I. Mel'nikov, T.L. Péwé, G.H. Johnston, N.A. Grave. Back row: Zhao Yuehai, Cheng Guodong, H.M. French, Jerry Brown. Photograph taken by J.A. Heginbottom.

meet at regular intervals, minimally at the beginning and end of each international conference on permafrost. At the closing ceremony it was immediately clear that, in addition to USA, Canada, China, and the USSR, a number of other countries were interested in becoming members of the IPA.

Three of the first acts of the Association in Fairbanks were to: (1) modify the constitution to allow for a Second Vice-President, (2) appoint a Nominations Committee in order to allow a new Executive to be elected at the 1988 Conference, and (3) plan to seek affiliation with other international scientific bodies. Dr. Kaare Flaate (Norway) was elected to the Executive Committee as a second Vice-President, and Norway agreed to host the Fifth ICOP in Trondheim in 1988.

The detailed history of the IPA is chronicled in its News Bulletin *Frozen Ground,* which started as informal notes by the Secretary General in 1986, and became a formal publication starting in 1989. All issues are found on the IPA website. The following sections report on the development and accomplishments of the Association. Hereafter, specific issues of *Frozen Ground* are cross-referenced, for example, as (FG 30). The following presents both administrative details and some of the major accomplishments of the IPA since 1983.

Administrative Activities

Council, Executive Committee, and Secretariat

Membership on the Council is through adhering national or multinational organizations as full voting members or as non-voting associates or individuals in countries where no Adhering Body exists. The IPA is governed by its Council and elected Executive Committee officers. Members of the Executive Committee are listed in Table 1. The Council currently consists of representatives from 24 Adhering Bodies and two Associate members having an interest in any aspect of theoretical, basic, and applied frozen ground research, including permafrost, seasonal frost, artificial freezing, and periglacial phenomena.

Attendance at the first council meeting on August 5, 1987, in Ottawa, Canada, included 15 Adhering Bodies together

with representatives from France (joined 1988) and Sweden (joined 1990) as observers. Other members soon followed: Denmark (1989), Spain and Southern Africa (1993), Mongolia and Kazakhstan (1995), Austria (1998), Iceland (2003), and New Zealand (2005). Portugal and South Africa were approved as Associate members in 2005. Each member pays an annual membership fee established by the Council.

The Constitution and Bylaws were adopted at the first council meeting. Since then, five modifications have been approved (December 1992, June 1998, March 2003, June 2005, Potsdam; and May 2006). These largely involved membership and working party activities.

The Council elects the Executive Committee and approves the formation and review activities of Committees, Working Groups, and Task Forces. It also approves the venue for each ICOP. The Council met in ten locations:

Ottawa, Canada (1987, FG 2).
Trondheim, Norway (1988, FG 4).
Quebec City, Canada (1990; FG 7).
Beijing, China (1991 during INQUA, FG 10).
Washington, DC (1992 during INQUA, FG 12).
Beijing, China (1993, FG 14).
Berlin, Germany (1995 during INQUA, FG 18).
Yellowknife, Canada (1998, FG 22).
Zurich, Switzerland (July 2003, FG 27).
Potsdam, Germany (June 2005, FG 29).

Starting in 1990, the Council issued a series of recommendations that include specific activities and topics of international scope (see summaries of Council meetings in *Frozen Ground*). These include statements on mapping, long-term monitoring, modeling, climate change, data acquisition and archiving, terminology, coordination with other international organizations and programs including both the Northern and Southern Hemisphere, and mid- and low-latitude mountains and plateau regions.

The Executive Committee is elected by Council every five years. Although members do not represent their own country, the four countries with significant areas of permafrost have always been represented on the Committee. A representative from the forthcoming international conference is also a member. A geographic and disciplinary balance of membership is also maintained. The first formal meeting of the Executive Committee took place in Oslo in September 1985. The Council has met formally 27 times.

The Secretary General first resided at the University of British Columbia, Canada (J. Ross Mackay, 1983–1993) and then in Washington DC, USA (Jerry Brown, 1993–1999). In 1998 the position of Secretary General was replaced by a Secretariat. This was initially located at the Institute of Geography, University of Copenhagen, Denmark (1999–2001) and is now at the University Centre on Svalbard (UNIS), Norway (2001–2009). Hanne H. Christiansen has been responsible for the Secretariat since 1999. In both locations, national research agencies and institutions have provided financial support. Major responsibilities include preparation and distribution of *Frozen Ground*, maintenance of the IPA webpage, coordination of administrative, Executive Committee and Council affairs, and international representation. The IPA web is currently hosted by the Department of Geosciences, University of Oslo.

International affiliations

The IPA became an Affiliated Organization of the International Union of Geological Sciences (IUGS) in July 1989. In 1996 the IPA and the International Geographical Union (IGU) signed an agreement that formalized a joint Periglacial Commission. This agreement recognized the longtime relationships between periglacial and permafrost researchers, the foundations of which are recorded in the pages of the Polish journal *Builetyn Peryglacjalny*. The IGU-IPA agreement was modified in 2004 with the formation of the new Commission on Cold Regions Environments.

Agreements also exist to share joint working groups, committees, or projects with the International Union of Soil Science (IUSS), the Scientific Committee for Antarctic Research (SCAR), and the International Arctic Science Committee (IASC). A Memorandum of Understanding was signed in 2004 between IPA and the World Climate Research Programme project "Climate and Cryosphere" (CliC). Although no formal agreement exists with the International Union of Quaternary Research (INQUA), close working relations are maintained with the Quaternary communities. Similarly, ties are maintained with the International Society for Soil Mechanics and Geotechnical Engineering (ISSMGE) and the newly formed International Association of Cryospheric Sciences.

Technical Activities

Conferences and workshops

Starting in 1983, the International Permafrost Association assumed responsibility for scheduling the ICOP meetings at five-year intervals. A written invitation for the proposed conference is required for IPA Council approval. The President of the IPA formally convenes the opening and closing sessions of each conference. In 1998 an International Advisory Committee for ICOP was formed to facilitate continuity in the planning of conferences. The host country is responsible for the financial support, technical organization, and publications. Field trips in or to permafrost areas are required as part of the program. The host country is responsible for the organization and financing of the conferences. The eight international conferences to date are:

First: 11–15 November, 1963, Purdue, Indiana, USA.
Second: 12–20 July, 1973, Yakutsk, Siberia, USSR.
Third: 10–13 July, 1978, Edmonton, Alberta, Canada.
Fourth: 17–22 July, 1983, Fairbanks, Alaska, USA.
Fifth: 2–5 August, 1988, Trondheim, Norway.
Sixth: 5–9 July, 1993, Beijing, China.
Seventh: 23–27 June, 1998, Yellowknife, Canada.
Eighth: 20–25 July, 2003, Zurich, Switzerland.

Over the span of these forty years, approximately 2500 individuals from 36 countries have participated in the eight conferences. Short reports on each conference, including numbers of attendees, papers in proceedings, field trips, and related publications for all eight conferences are reported elsewhere (Brown & Walker 2007). From 2008 onwards, conferences will take place on a four-year cycle with an official intervening regional conference. During the Eighth ICOP, the Troy L. Péwé Award was established to recognize the best presentation by a young researcher.

The IPA has also sponsored a number of regional permafrost conferences. These include the Fourth Canadian permafrost Conference (Québec, 1990), two European permafrost conferences (Rome, 2001: Potsdam, 2005), and the First Asian Conference on Permafrost (Lanzhou, 2006). In addition, the annual Russian geocryology conferences (e.g., Pushchino; Salekhard), and several cryopedology and soils meetings (e.g., Copenhagen, Syktyvkar, Madison, Arkhangelsk) have been sponsored by the IPA.

Workshops also play an important role in implementing IPA-related projects. The following are the major such meetings; results are reported in *Frozen Ground*:

Global Geocryological Data workshop (1994).

International workshop on processes and ability to detect change (1995).

Mountain permafrost and monitoring (1997).

International workshop on permafrost monitoring and databases (2000).

International symposium on mountain and arid land permafrost (2001).

Circumpolar Active Layer Monitoring (CALM) workshop (2002).

Arctic Coastal Dynamics workshops (annual 1999-2006).

Permafrost and Climate in the 21st Century (PACE21) workshop (2004).

Antarctic workshops (2004, 2007).

Asian permafrost mapping workshop (2006).

Working parties

Since 1998 many of the IPA activities between conferences have been undertaken by committees, working groups, and task forces (collectively referred to as *working parties*). Annual reports of working parties are published in *Frozen Ground* and archived on the IPA website. At the 1988 Council meeting in Trondheim, three standing committees and six working groups were established. New working groups were added and some goals modified prior to, or at, the 1993 Council. During the intervening years and at the 1998 Yellowknife Council meetings, major revisions were made to the organization of working parties. New guidelines were developed and included the formation of Task Forces (see FG 22). During the 2003 Council meeting, several Task Forces became working groups, and existing working groups were redefined. A total of ten working groups, several with subgroups, are presently active and are joint with other international organizations:

Standing Committees:

Data, Information and Communication

International Advisory Committee for International Permafrost Conferences

Working Groups:

Antarctic Permafrost and Periglacial Environments (SCAR)

Coastal and Offshore Permafrost (IASC and LOICZ)

Cryosols (IUSS)

Glaciers and Permafrost Hazards in High Mountains (IACS)

Isotopes and Geochemistry of Permafrost

Mapping and Modeling of Mountain Permafrost

Periglacial Landforms, Processes and Climate (IGU)

Permafrost and Climate (IGU)

Permafrost Astrobiology

Permafrost Engineering (ISSMFE)

Since 1998, working party reports covering the previous five years have been published as part of the program for the international conferences on permafrost. In 2007 a review was undertaken by an ad hoc committee on working parties to provide recommendations on the present activities and future directions. These will be discussed at the 2008 Council meetings. Future activities will be approved between then and the next regional and international conferences in 2010 and 2012, respectively.

Major Accomplishments

By 1988 the IPA was serving as a catalyst and organizer of several major international activities.

Database

A common challenge facing many field-oriented disciplines is access to international data sets and the subsequent preservation or archiving of these data. The lack of readily available, international permafrost-related data sets was recognized by the IPA prior to, and during, the 1988 Trondheim conference. A Working Group on Permafrost Data was formed and an international data workshop was subsequently convened in 1994 in Olso. The result was development of the Global Geocryological Database (GGD), the basis of which is identification and description of data sets beginning in a metadata format. The National Snow and Ice Data Center took the lead in populating the GGD with both metadata and data. For the 1998 and 2003 conferences, the compilations of the GGD were provided on CD-ROM, entitled Circumpolar Active-Layer Permafrost System (CAPS) (Barry et al. 1995, NSIDC 1998, IPA SCDIC 2003, Parsons et al. 2008). The CAPS/GGD products are available on line at the NSIDC Frozen Ground Data Center.

Terminology

By the time the IPA was established, it was clear that the major terminological problem associated with permafrost, as defined in North America, Russia, and China, arose from the fact that ground at or below 0°C may, or may not, be frozen. Put simply, permafrost is not necessarily frozen because soil and rock, for a variety of reasons (salts, pressure, etc.), may exist in an unfrozen state at temperatures below 0°C. This prompted the Permafrost Subcommittee of the Associate Committee on Geotechnical Research, NRCC, to establish a terminology working group in 1985. In its report (ACGR 1988), "cryotic" terminology was re-introduced in an attempt to accommodate the unfrozen nature of certain permafrost situations. The IPA Council approved a Working Group on Permafrost Terminology in 1988 and encouraged production of a multi-language glossary of permafrost and related ground ice terms (van Everdingen 1998). Although this glossary did not resolve the problem, the permafrost community has, for the first time in its history, a working document that describes permafrost terminology in twelve languages. This represents a major achievement.

International permafrost map

Prior to 1983, the mapping of permafrost had been undertaken using different classifications by different national organizations. The need existed for a circum-arctic map based on a common classification. An informal group representing members of the United States Geological Survey (USGS), the Geological Survey of Canada, and the Institute for Hydrogeology and Engineering Geology (VSEGINGEO), Russia, was spearheaded by the IPA Secretary General (J. Brown) and started work in the early 1990s. A generalized legend based on permafrost continuity, ground ice content, and physiography was applied to existing permafrost maps and, after several meetings and numerous editorial discussions by the authors and the USGS cartographers, a map at 1:10,000,000 was finalized and published (Brown et al. 1997). It was subsequently digitized and made available in ArcInfo. The digitized product has been used extensively by the modeling communities and others involved in climate research. Building on this existing map, a new international map based on spatial and temperature variations of permafrost terrain is a logical next step.

Observational networks

The IPA has taken the leadership in initiating and coordinating several international, long-term monitoring networks and related data acquisition programs. The IPA entered into a cooperative partnership with the World Meteorological Organizations (WMO) and the Food and Agriculture Organization (FAO) of the United Nations to facilitate development and coordination of the Global Terrestrial Network for Permafrost (GTN-P) (Burgess et al. 2000). The GTN-P consists of two components: the borehole measurements or Thermal State of Permafrost (TSP) and the Circumpolar Active Layer Monitoring (CALM) network. Both TSP and CALM are included in the IPA-coordinated International Polar Year (IPY) Project 50 "Permafrost Observatory Project: A Contribution to the Thermal State of Permafrost." This currently consists of 150 CALM sites (Nelson et al. 2004, Shiklomanov et al. 2008) and approximately 500 borehole temperature sites in both hemispheres. Also included are the boreholes developed under the PACE program (Harris 2008) and the Norwegian TSP boreholes. At least 15 countries are participating in GTN-P, primarily with national funding.

A second major network exists in the Arctic Coastal Dynamics (ACD) program. Following a 1999 workshop, a science plan under the Working Group on Coastal and Offshore Permafrost was developed and project status was approved by the International Arctic Science Committee. There are approximately 30 key coastal sites located around the Arctic Ocean. ACD developed a database of several thousand coastal segments.

Publications

In addition to those previously mentioned, numerous publications have arisen from IPA working parties, projects, and related activities. Some of these include:

Bibliographies of published literature (e.g. Brennan 1983, 1988, 1993, Mullins 2003).

An annotated bibliography on climate change (Koster et al. 1994).

Soil carbon map (Tarnocai et al. 2003).

Periglacial manual (IPA web accessible).

In addition, the Wiley journal *Permafrost and Periglacial Processes (PPP)* has published a number of special issues on mountain permafrost (PPP3), climate change (PPP4), grèzes litées (PPP6), frozen ground (PPP7), cryostratigraphy (PPP9), cryosols (PPP10), PACE (PPP12), hydrology, climate and ecosystems (PPP14); periglacial processes and instrumentation (PPP14), CALM (PPP15), PACE21: mountain permafrost (PPP15), and a special issue in honor of J. Ross Mackay at the time of his 90th birthday (PPP18).

Several other journals serve the international geocryology communities. For example, since 2002, the *Reports on Polar Research* of the Alfred Wegener Institute for Polar and Marine Research (Bremerhaven, Germany) have contained an annual issue devoted to the results of the ACD workshops. Other journals have also devoted special issues to IPA-sponsored activities: these include the *Norwegian Journal of Geography, Polar Geography and Geology, Southern African Journal of Science, Global and Planetary Change, Cold Regions Science and Technology,* and *Journal of Geophysical Research.*

Conclusions

The International Permafrost Association has established itself as a productive international organization.

Geocryology is now recognized as a cold-climate discipline that integrates permafrost science and permafrost engineering. Permafrost is recognized as an important component of the cryosphere.

Specific achievements under the IPA include the production of a multi-language glossary, publication of a digitized, circum-arctic map of permafrost and related ground ice conditions, and the establishment of the global geocryological database system and several monitoring networks.

The IPA legacy that is resulting from both the IPY and existing activities includes: (i) establishment of networks of active layer and permafrost temperature observatories, (ii) development of a sustainable geocryological database, and (iii) fostering a new generation of geocryologists through the activities of the Permafrost Young Researchers Network.

These collective activities will further develop and sustain international activities, particularly those related to the state and fate of permafrost in relation to a changing climate.

Acknowledgments

The IPA and this report contribute to the activities of the International Polar Year. Numerous individuals and organizations have contributed to the success of the IPA. Special thanks must go to the Bureau of International Relations, National Research Council of Canada, for the initial funding of the activities of the IPA Secretary General, Professor J. Ross Mackay, between 1983 and 1993, and to the U.S. National Science Foundation, USA, for funding the activities of the IPA Secretary General, Jerry Brown. Since 1998, Hanne H. Christiansen has been responsible for the successful operation of the IPA Secretariat, assisted by Angélique Prick (2005–2007), and most recently by Herman Farbrot. Funding of this Secretariat has been provided by the Danish Polar Centre, Barlindhaug, and the Research Council of Norway. Ole Humlum (University of Oslo) has provided valuable assistance and support for the IPA webpage.

Abstract

In this paper, the authors present the results of laboratory measurements of the thermal conductivity of artificial hydrate-bearing sediments under frozen conditions and atmospheric pressure. Frozen hydrate-saturated samples were maintained in a quasi-stable condition due to the so-called "self-preservation" effect of gas hydrates at negative temperatures. We determined the structure and thermal and physical properties of gas hydrate-bearing sediments, including the thermal conductivity. The results were then compared to properties of similar frozen sediments containing no methane hydrate. Experimental data showed that the thermal conductivity is very different for hydrate-bearing sediments in the self-preserved state than for similar ice-bearing sediment samples. This difference depends on the type of sediments and on structure-textural transformations which occur in the porous medium during self-preservation of hydrate-bearing samples. This difference increases with increasing hydrate saturation and volumetric hydrate content and with the decrease of dry density.

Keywords: frozen sediment; gas hydrate; hydrate-bearing sediments; self-preservation; thermal conductivity.

Introduction

Gas hydrates are ice-like crystalline substances that form from water and gas (of comparatively low molecular weight) under certain thermobaric conditions. Gas hydrates are a highly concentrated source of natural gas (mainly methane), and are considered to represent a promising new energy resource due to their extensive geographic occurrence. It is known that gas hydrates can exist naturally at both positive and negative temperature. According to drilling data and other indirect indicators, gas hydrates occur in permafrost environments in several regions of North Siberia and in on-shore/off-shore regions of the Canadian Arctic (Judge et al. 1994; Judge & Majorowicz 1992, Yakushev & Chuvilin 2000). Most known concentrations of permafrost gas hydrate occur below the permafrost table (e.g., Mallik), at temperatures well above 0°C (Henninges et al. 2005) However, several occurrences of intrapermafrost gas hydrates have been documented (Dallimore & Collett 1995, Dallimore et al. 1996, Ershov et al. 1991). It is difficult to identify and quantify gas hydrates occurring within frozen sediments using traditional geophysical techniques (mainly seismic) because of the similar geophysical response of gas hydrates and pore ice in frozen sediments. This is assumed to be due to the similarity between many of the physical properties of ice and gas hydrates (Table 1). However, the authors note that the thermal conductivity of ice and gas hydrate differ significantly, raising the possibility of employing thermal conductivity measurements to identify gas hydrates occurring within permafrost.

The anomalously low thermal conductivity of gas hydrates was discovered by Stoll & Bryan (1979), and was later confirmed by many other studies (Sloan 1998). Experimental data indicate that the thermal conductivity of gas hydrate (~0.5 $Wm^{-1}C^{-1}$) is similar to that of water (~0.6 $Wm^{-1}C^{-1}$), and is approximately 5 times lower than the thermal conductivity of ice (~2.2 $Wm^{-1}C^{-1}$).

The first technical study of the thermal properties of gas hydrate-bearing sediments was conducted by Groysman (1985), in which he compared the thermal properties of gas hydrate-bearing sandstone in the frozen and unfrozen states. These experiments indicate that the heat capacity per unit mass of frozen and gas hydrate-bearing sandstone differed little from each other, but the thermal conductivity of a gas hydrate-saturated sandstone was 70% lower than that of the frozen (ice-bearing) sample (Groysman 1985). Asher (1987) experimentally showed that the thermal conductivity of frozen sand is 80% higher then that of hydrate-saturated sand, but did not present any quantitative data about the degree of hydrate saturation of the investigated sediments. Wright et al. (2005) employed a needle probe to measure the thermal conductivities of laboratory specimens and recovered core from the gas hydrate-bearing reservoir at the Mallik gas hydrate production research site in Canada's Mackenzie Delta. Their measurements were obtained within a temperature-controlled pressurized test chamber designed to maintain thermodynamically stable gas hydrate.

Table 1. Comparison of physical properties of ice, SI and SII hydrate (Sloan 1998).

PROPERTY	ICE	STRUCTURE I	STRUCTURE II
Number of H_2O molecules	4	46	136
H_2O diffusion jump time (μsec)	21	>200	>200
Dielectric constant at 273 K	94	~58	~58
Isothermal Young's Modulus at 268 K (10^9 Pa)	9.5	8.4 (est)	8.2 (est)
Poisson's ratio	0.33	~0.33	~0.33
Bulk modulus at 272 K (GPa)	8.8	5.6	N/A
Shear modulus at 272 K (GPa)	3.9	2.4	N/A
Velocity ratio (comp./shear) at 272 K	1.88	1.95	N/A
Linear thermal expansion at 200 K (K^{-1})	56 x 10^{-6}	77 x 10^{-6}	52 x 10^{-6}
Adiabatic bulk compression at 273 K (GPa)	12	14 (est)	14 (est)
Speed Long Sound at 273 K (km/sec)	3.8	3.3	3.6
Density (g/cc)	0.917	0.91 (at 273 K)	0.94 (at 273 K)
Thermal conductivity at 263 K ($Wm^{-1}C^{-1}$)	2.23	0.49±0.02	0.51±0.02

Their data also indicated that the thermal conductivity of frozen (ice-bearing) samples is considerably higher than that of the same samples containing gas hydrate at temperatures above 0°C. They presented data on the thermal conductivity of frozen hydrate-bearing sediments with values 20–25% higher than the thermal conductivity of the unfrozen hydrate-bearing samples. Their results suggest that the thermal conductivity of gas hydrate-bearing sediments in the frozen/unfrozen state is dependent on the relative proportions of gas hydrate/ice and gas hydrate/water, respectively.

Waite et al. (2007) also used the needle probe technique to study the thermal conductivity of gas hydrate, and demonstrated weak temperature and pressure dependencies for thermal conductivity of gas hydrate. On the basis of the experimental data and analysis of published works they concluded that the thermal conductivity of hydrate-containing sediments at positive temperatures does not depend on the ratio of hydrate and water in the porous media.

Gas hydrates in frozen sediments can exist in a "relict" state for long periods of time due to the self-preservation effect (Ershov et al. 1991, Dallimore et al. 1996). The determination of in situ thermal conductivity anomalies may represent a potential exploration tool for gas hydrate identification and quantification within the upper horizons of permafrost. This notion forms the motivational basis for undertaking the experimental study of the thermal conductivity of frozen, hydrate-containing sediments under the non-equilibrium conditions ($p<p_{eq}$), as presented in this paper.

Methods

To facilitate the study of thermal conductivity of frozen hydrate-bearing sediments at negative temperature, we prepared artificial hydrate-saturated samples of sand, silty sand, and sandy loam, including samples collected from permafrost regions. A summary of sample characteristics is presented in Table 2.

For each individual laboratory test, a sample holder containing a test specimen was loaded into a high-pressure cell designed for the formation of gas hydrate within artificial or natural porous media, under controlled pressure and temperature conditions (Chuvilin & Kozlova 2005). After hermetically sealing the test cell, the cell was purged of air and charged with methane gas by slowly increasing cell pressure to about 8–10 MPa. The cell was maintained at room temperature while temperature and pressure conditions were stabilized, after which the cell was cooled to about 1–2°C. Under these conditions the process of gas hydrate formation was spontaneously initiated, as indicated by a sharp pressure drop within the cell. After the termination of hydrate accumulation within the sediment, the test cell was cooled to about -7 to -8°C, freezing any residual pore water which had not transformed to gas hydrate. The test cell was then transferred to a cold room maintained at a temperature of about -8°C. The cell was subsequently depressurized to 1 atmosphere, after which the test cell was opened and the sample removed.

The self-preservation effect of gas hydrates at negative temperatures facilitates the maintenance of the frozen hydrate-bearing samples in a quasi-stable state (at atmospheric pressure) during subsequent measurements of thermal conductivity. This also facilitates determination of the composition, structure and selected properties of gas hydrate-bearing samples, including the thermal-conductivity (λ), gravimetric water content (W_g), density and gas content. Definition of the sample's gas content was carried out by means of measurement of gas released in the course of defrosting of the sample placed in saturated NaCl solution. Then we calculated dry density (ρ), porosity (φ), volumetric hydrate content H_v (H_v=V_H·100% /$V_{sam,}$ where V_H is volume of hydrate, V_{samp} is volume of the sample), hydrate saturation S_h (S_h = H_v /φ ,%); ice saturation S_i (S_i = I_v /φ ,% where I_v is volumetric ice content). The results were then compared to measurements of the properties in samples without methane hydrates.

Thermal conductivity measurements were obtained using the thermal properties analyzer KD2, which is a registered trademark of Decagon Devices, Inc. The pocket-sized KD2 uses a single sensor (needle probe) to measure thermal conductivity and thermal resistivity of the test sample.

Table 2. Characteristics of soils.

Type of sediment	*Particle size distribution, %*			*Particle density, ρ_s, g/cm³*	*Plastic limit, W_p, %*	*Liquid limit, W_L %*	*Salinity, %*
	1–0.05 mm	0.05–0.001mm	<0.001 mm				
Silty sand	84	14	2	2.65	-	-	0.089
Sand	94.8	3.1	2.1	2.65	-	-	0.012
Sandy loam	41.8	53.7	4.5	2.7	20	33	0.693

The unit employs the transient line heat source method to calculate and display the thermal conductivity within 90-seconds. A detailed description of the transient line heat source method is presented by Bristow et al. 1994.

The small-diameter needle probe (1.2 mm diameter by 65 mm long) results in very little compaction during installation and allows for a short heating time, thereby minimizing any thermally-induced disturbance to gas hydrate or ice in the vicinity of the probe. The KD2 needle probe contains both a heating element and a thermistor. The controller module contains a battery and a 16-bit microcontroller, which automatically calculates the thermal-conductivity from temperature-time data.

The KD2 is rated for operation across a temperature range from -20 to +40°C, and measures thermal conductivity in the range from 0.01 to 2.0 $Wm^{-1}C^{-1}$ with a rated accuracy of ±5% to about 2.0 $Wm^{-1}C^{-1}$ with an accuracy ± 10%.

During the measurement, temperature increases by about 0.5°C. Since the sample temperature during measurement is in the range of -7 to -8°C, we assume that this small temperature increase does not significantly influence the phase composition of water either through ice melting or hydrate decomposition. Since the measurement is obtained at atmospheric pressure (i.e., outside of the gas hydrate pressure-temperature stability field), some portion of the hydrate in sediment pores dissociates progressively with time. However, the rate of dissociation is assumed to be very slow due to the self-preservation effect and according to our estimation does not influence the thermal field of the sample during the 90 second period of measurement.

To facilitate insertion of the needle probe, a small hole was drilled into the frozen test sample, the diameter of which corresponded to the diameter of the probe. The chilled needle probe was inserted full-length into the hole, such that a tight fit was obtained. Thermal contact between the probe and the sediment was maximized by use of a thermal paste with a thermal conductivity of 1.0 $Wm^{-1}C^{-1}$. For each sample, multiple measurements of thermal conductivity were obtained over a reasonable time period that allowed any thermal disturbances within the test sample to dissipate between measurements. With constant negative ambient temperatures being maintained, subsequent consecutive measurements were made at longer time intervals to document the change in thermal conductivity with time (assuming slow but progressive gas hydrate dissociation under the "self-preserved" condition). At the same time the gas content was determined with accuracy of 2–3%.

The KD2 thermal analyzer was also employed to measure the thermal conductivity of frozen control sediments having similar physical properties but without hydrate.

Results of Experimental Research

Frozen hydrate-containing samples of sand, silty sand, and sandy loam were prepared for thermal conductivity measurement. For each sample tested, we determined water content, dry density, porosity, gas hydrate saturation, and ice saturation. Thermal conductivity measurements (Table 3) were obtained using a needle probe and KD2 thermal analyzer.

Data from experiments indicate that the thermal conductivities of hydrate-bearing sediments were considerably lower than those obtained for similar ice-bearing sediments. The maximum difference (by more than a factor of 5) was observed for silty sand with an initial water content of 21%, and a high pore hydrate-saturation. We speculate that this large difference in measured thermal conductivities may be a reflection of the comparatively low thermal conductivity of methane hydrate forming on the surfaces bridging individual sediment particles within the bulk sediment. In the experiments conducted by Wright et al. (2005) the difference in the thermal conductivities of hydrate-saturated sand vs. frozen sand containing no hydrate is noticeably smaller, not exceeding 70%. However their data were obtained for thermodynamically stable gas hydrate under controlled temperatures and elevated pressures (in the order 5–8 MPa). In our case, thermal conductivity measurements were obtained at atmospheric pressure and freezing temperatures favourable for the self-preservation of pore-space gas hydrate. It is possible that the structural characteristics of sediments containing self-preserved gas hydrate are significantly different than the structural characteristics of sediment containing thermodynamically stable gas hydrate. One plausible explanation may be the formation of numerous microcracks and pinholes within the gas hydrate crystal matrix during partial dissociation of hydrate in the self-preserved condition. The formation of such microcracks in hydrates following depressurization to one atmosphere has been described previously by Ershov et al. (1990). The presence of microcracks in pore-space gas hydrate may result in a substantial reduction of the thermal conductivity of hydrate-bearing sediments, in comparison to frozen samples containing no gas hydrate.

The smallest differences between the thermal conductivity

Table 3. Thermal conductivity for frozen hydrate-saturated sediment samples (*t* = -7 to -8°C).

Type of sediment	Wg, %	Dry density, ρ_s, u.f.	Porosity, ϕ, u.f.	Hv,%	Sh, %.	Si, %	λ_{hyd}, $Wm^{-1}C^{-1}$	λ_{fr} $Wm^{-1}C^{-1}$
Sand	10	1.23	0.55	12	23	6	0.76	1.30
Silty sand	10	1.52	0.42	8	20	23	1.07	1.74
	15	1.51	0.43	13	32	32	0.5	1.9
	17	1.53	0.42	14	40	34	0.46	2.14
	21	1.37	0.48	25	52	18	0.44	2.32
Sandy loam	17	1.55	0.42	22	59	16	1.24	1.93
	17	1.55	0.42	15	34	35	1.59	1.93

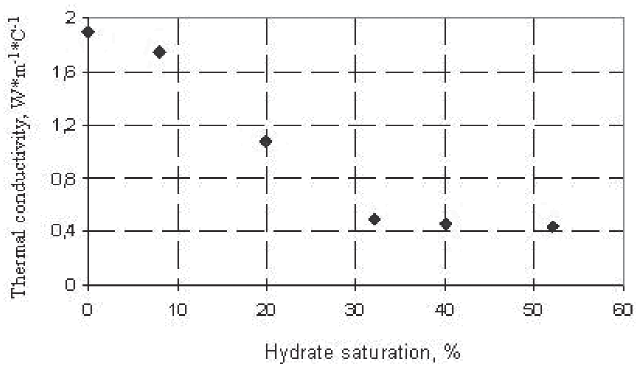

Figure 1. Influence of hydrate saturation on thermal conductivity in frozen silty sand sample (*t* = -7 to -8°C).

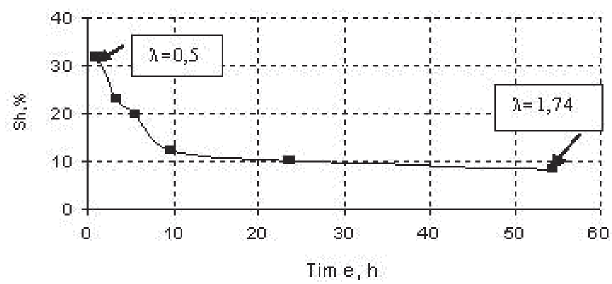

Figure 2. Methane hydrate dissociation kinetic in frozen silty sand sample and thermal conductivity (*t* = -7 to -8°C).

of frozen hydrate-bearing vs. ice-bearing samples (30–50%) were observed in samples of sandy loam (Table 3), characterized by comparatively high dry density (1.55 g/cm^3) and low porosity (~0.42). This result may be explained by the absence of hydrates at contacts between sediment particles, despite the relatively high hydrate content. Comparatively little difference in the thermal conductivity of frozen hydrate-bearing vs. ice-bearing samples was observed for sand having an initial water content of 10%. Note that hydrate saturation of this sample was 2.5 times lower than that of the silty sand having an initial water content of 21%. The large difference between the thermal conductivity of frozen hydrate-bearing and ice-bearing samples representing more dispersed sediments may be associated with structure-textural peculiarities in sediments containing self-preserved pore-space gas hydrate. However, this question requires additional investigation.

Thus, our data indicate that for self-preserved gas hydrate at atmospheric pressure, higher hydrate-saturation is associated with decreased thermal conductivity (Fig. 1).

Additional experiments to measure thermal conductivity during dissociation of pore-space hydrate in silty sand (W_{in}=15%) were conducted at negative temperatures (Fig. 2). Note that the degree of pore saturation with hydrate decreases over time as a result of the slow dissociation of pore hydrate in the self-preserved state, accompanied by an apparent increase in thermal conductivity from 0.5 $Wm^{-1}C^{-1}$ at the beginning of the experiment, to 1.74 $Wm^{-1}C^{-1}$ at the end of the testing period

The observed increase in thermal conductivity at the end of the experiment can be explained by a progressive decrease in the amount of pore-space hydrate and a corresponding increase in the amount of pore ice as dissociation progresses at temperatures below 0°C. Ice is exposed to processes of metamorphism which causes decrease of its porosity. Given that the process of hydrate dissociation in porous media at atmospheric pressure is poorly understood, it is desirable to undertake special micro-morphological studies designed to clarify the specifics of thermal conductivity in frozen hydrate-bearing sediments under non-steady state conditions.

Conclusion

A technique for obtaining rapid measurements of the thermal conductivity of self-preserved hydrate-bearing sediments at atmospheric pressure were was established.
Experimental data confirm that the thermal conductivity of self-preserved hydrate-bearing sediments is considerably lower than that of similar ice-bearing sediments, and that this discrepancy increases with increasing of hydrate saturation and volumetric hydrate content, and with decreasing dry density. This difference is also more apparent in uniform sands than in more dispersed sediments such as sandy loam.

Experimental results show that the thermal conductivity of frozen hydrate-containing soils increases with time because of the pore gas hydrate dissociation at non-equilibrium conditions.

Our results show the possibility of using thermal conductivity to single out frozen hydrate containing layers both in stable and metastable states.

Abstract

In southern Yakutia where permafrost is discontinuous, the numerous taliks on the watershed divide surface provide ideal conditions for groundwater feeding. This groundwater discharges locally in the bottom of valleys. Climate change produces differences in permafrost configuration (geometry). It affects the interaction between underground and fluvial waters through changes in the volume of talik reservoirs. This interaction leads to changes in river discharge, especially in the winter. To describe this interaction, the authors developed an efficient numerical method for solving coupled groundwater flow and phase-change heat transfer problems in porous media. The first results of modeling showed that the watershed divides without permafrost became colder because the descending cold infiltration water is directed toward the ascending heat flow. The developed approach seems to be instrumental in analyzing the peculiarities of discharge dynamics of the Lena River tributaries.

Keywords: climate change; discontinuous permafrost; groundwater flow; numerical modeling; water infiltration.

Introduction

Introduction

The problem of discharge dynamics of the great Siberian rivers and the affect on permafrost conditions is the topic of this paper.

The site of our investigation is located on a plateau with monoclinal bedding of Mesozoic rock in the upper part of the Lena basin. The study area is situated in uplands and mountain foothills where permafrost is the warmest in the region (it is still widespread but discontinuous). This region is between the Aldan and Timpton Rivers (centered at 57°N and 125°E), and, more specifically, within the basin of the Chulman River, right tributary of the Aldan River which is a right tributary of the Lena River. Geologically, this region is located in the central part of the Mesozoic Chulman Depression. This territory is well-studied in geocryological and hydrogeological aspects and is representative in Southern Yakutia as the region with discontinuous permafrost (Chizhov et al. 1975). The water catchment areas are situated predominantly at 850–950 m a.s.l.. The typical depth of valleys is 150–200 m. Locally, the valley depth increases up to 950 m. The density of the river network is very high. The water-collecting areas are flat and have the width of 2–3 km. The steepness of slopes is 10–20º. Permafrost distribution is closely related with different elements of the relief. It exists under slopes and in the valley bottoms. The permafrost thickness varies from ten m to 100–150 m and more. The mean annual permafrost temperatures (MAPT) vary from -0.5 to -2.0ºC rarely to -5.0ºC. The permafrost-free flat surfaces of hilltops are the areas where snowmelt and rain waters percolate into the deeper rock horizons. In these areas the active layer in well-drained coarse sediments, and weathered bedrock is very deep (down to 5 m).

The long-term dynamics of precipitation regime and river discharge demonstrate a tight correlation during most of the year. However, they have opposite tendencies in June and September–October. This fact shows the complexity of water balance within the Southern Yakutia watersheds. Here the groundwater (interpermafrost and subpermafrost) storage and icings are important components of the regional discharge. Recently observed total increase in the annual amount of precipitation goes together with a relatively stable dynamics of evapotranspiration (Berezovskaya et al. 2005).

We suppose the principal factor of river discharge tendencies is an interaction between variable permafrost massifs and underground water-flow intensity. Such assertion has no evident analogs in recent investigation results and requires combined theoretical and field studies.

In this paper, we present some preliminary results of permafrost-hydrosphere interaction modeling.

Methods

Problem definition

We developed a schematization of permafrost-hydrogeological and meteorological conditions and governing pro-

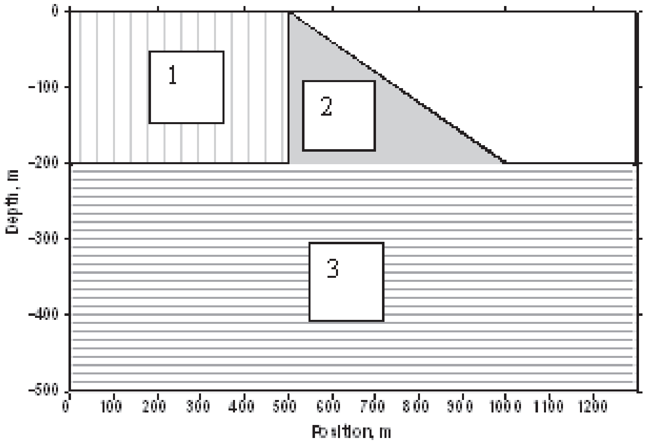

Figure 1. The geometry of the computational domain.

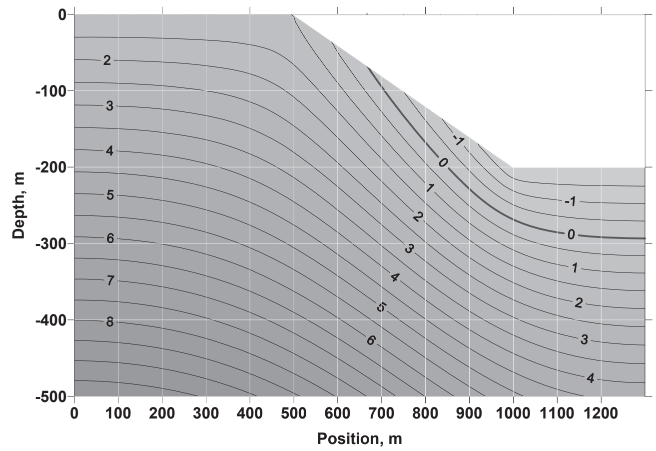

Figure 2. Temperature field without water-flow.

cesses that were used for the formulation of a mathematical model. This model allows the assessment of river discharge dynamics under the influence of permafrost and climate change in the upper part of the Lena River basin.

The hydrogeological setting depends on permafrost conditions. In spring and summer, the feeding of the groundwater takes place due to vapor condensation and percolation of snowmelt and rain waters through the vast watershed taliks situated on the flat hilltops. The vertical zones of air-dry fractured bedrock, periodical saturation, and constant saturation are located within unfrozen massifs of intensively fractured and weathered bedrock. The area and volume of the above-mentioned zones constantly change during the year. In spring, the snowmelt water and atmospheric precipitation start to infiltrate into and through a thick zone of airing (50–150 m and more) and increase the volume of saturation by the groundwater zone. The water movement is very fast and is accompanied by increasing water level in the massif of bedrock and by forming so-called infiltration knolls (reaching up to tens of meters in thickness). Groundwater feeding by atmospheric precipitation stops when the air temperature drops below 0°C in early winter and the active layer freezing starts. Starting from this moment, the gradual decrease of infiltration knolls begins. It is linked with groundwater discharge through open river taliks on the valley bottoms and icing forming. The groundwater transit pass way under the slopes is situated below the bottom of ice-bonded permafrost. This intensive flow of subpermafrost groundwater eventually forms a layer with high water permeability. However, in the lower parts of the slopes, the subpermafrost water head has a level up to 10 m above the permafrost table.

The analysis of available data shows that climate change can affect the groundwater recharge, out-flow, and discharge by the following factors or processes: (1) the expansion or contraction of the area of watershed open taliks; (2) a shift in the duration and timing of seasonal freezing and thawing that controls the time of infiltration and feeding of the groundwater reservoirs; and (3) changes in the amount of atmospheric precipitation.

In an epoch of climate warming and increased precipitation, we should expect the increase in the groundwater discharge in the valleys. There is a very important problem about the time lag of the pressure water waves. They form during the summer under the watershed divides and move toward the valley bottoms during the autumn and early part of the winter.

Research Strategy

The goal of the research presented here is to evaluate the impact of climate and permafrost changes on hydrological dynamics. To achieve this goal, we developed an efficient numerical method for solving coupled fluid flow and the phase-change heat transfer problem in porous media.

Because of the baffling complexity of the problem, the calculations were organized in three stages. *Foremost, we solved the two-dimensional heat transfer problem while taking into account the permanent continuous annual infiltration*. The goal of this stage was the retrieval of equilibrium spatial configuration of permafrost massif under condition of water flow in zones of suspended water and water saturation. In considered conditions, the influence of convective heat transfer on the permafrost develops not only because of the convective transport of the heat, but also because of the redistribution of the direction and intensity of the geothermal heat flow. As a result of this stage, the calculated configuration (geometry) of the permafrost massif in the computational domain was used as the base for the *second stage of modeling, when we are solving the phreatic flow problem with variable infiltration feeding*. In this case, the shape of the ice-bonded permafrost massif was assumed stable because the typical time of its change is much larger than the time scale of changes in the groundwater flow field. The model will allow understanding of the groundwater head level regime within the watershed divide taliks, the transfer of the head wave along the way of water flow under the permafrost, and water discharge dynamics in the valley during the year. Lastly, at *the third stage of modelin,g we plan to investigate the seasonal freezing as well as the full dynamics of the permafrost and taliks-configuration*

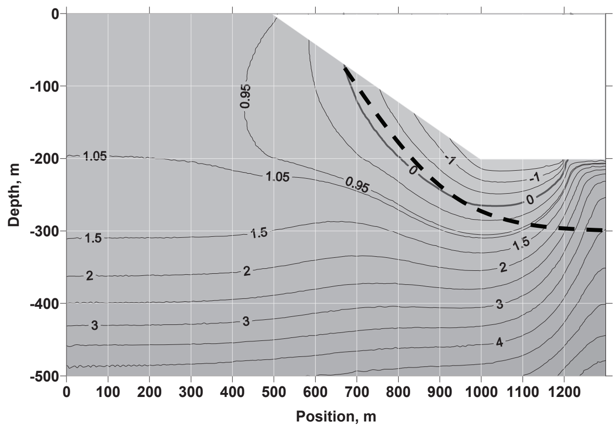

Figure 3.The temperature field in the run with a water-flow. The dashed line shows the zero-temperature isotherm for the run where the convection was not taken into account.

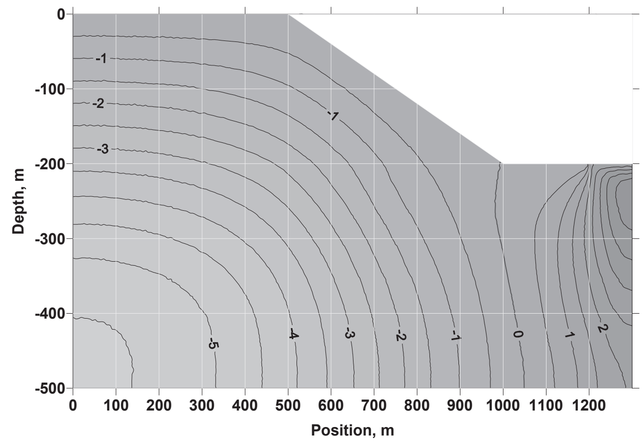

Figure 4. The difference in the temperature between "convective" and "conductive" runs.

development by taking into account the variability of climate and convective heat transfer in the bedrock. The seasonal freezing affects the period, the area, and the patterns of groundwater infiltration. The area of taliks within the watershed divide, and the amount of precipitation controls the volume of groundwater reservoir (storage).

Thus, these three stages of modeling will allow the obtaining of quantitative characteristics of the link between climate change and the hydrological dynamics within a typical site in the southern part of the Lena River basin.

Methods of Modeling and Assumptions

We performed the first stage of the modeling with the following principal simplification to describe the natural conditions. The original numerical model was prepared by G.Tipenko (Sergueev et al. 2003). We assumed that the temperature and water-flow fields can be represented by the two-dimensional vertical section across a river valley because of the elongated shape of the watershed divides. The hydrological and thermal physical properties of sediments and bedrock are sectionally continuous and isotropic.

Because the divide valley is symmetrical, we modeled a fragment between the vertical axis of the watershed divide and the center of an adjacent valley (Fig. 1). The geometry of this area corresponds to a real relief fragment near the town of Chulman in southern Yakutia. The calculation domain contains three blocks (Fig. 1). The width of the flat divide surface is 1000 m (block #1), the horizontal lengths of the slope is 500 m, and the valley depth is 200 m (block #2). The width of the valley's bottom is 600 m. The bottom of the computation area is at 300 m below the bottom of the valley and at 500 m below the top of the divide surface (block #3).

The position of low limit of permeability corresponds to the real data about zone of active water exchange in this region (about 200–300 m).

At the first stage of modeling we use some simplifications of real rules of the water migration. The zone of suspended water is replaced by the zone of full saturation (block #1). Within this zone an effective permeability of rocks was selected to ensure the correspondence to unit value of head gradient as in condition of descending water flow. Thus in condition of flow norm as W_{in} m/year the hydraulic conductivity in the zone of suspended water should be $k_f = W_{in}/365$ m/day (W_{in} is the rate of the infiltration).

The block #2 is water-impermeable because it represents permafrost; therefore there is not any infiltration in the upper part of the valley slope. This assumption explains the absence of the horizontal spread of water from the block #1.

The hydraulic conductivity of the seepage is determined by the reverse calculation from the shape of seepage level surface under the watershed divide under condition of infiltration. We use the value of transmissivity T = 45 m^2/day. This value corresponds to the hydraulic conductivity k_f = 0.15 m/day in condition of seepage thickness at 300 m. It corresponds very well with real mean conductivity of terrigenous rocks in southern Yakutia.

The left- and right-side borders of the computational area are "heat-proof" (zero value of heat flux in the "Second Type" boundary conditions). At the bottom of the computational domain, we set the heat flux q_{dp} = 0.043 W/m^2. At the upper boundary, we prescribed the "First Type" boundary condition as the temperature +1ºC at the hilltop divide surface and some rule of variability of temperature in the valley system. Within the entire bottom of the valley, the surface temperature was set at -2ºC. On the slopes, the temperature has a linear spatial trend from +1ºC on the limit of the hilltop divide surface to -2ºC at the foot of the slope. The chosen initial ground conditions values are theoretically typical for the area (Chizhov et al. 1975).

The surface of the slope and the lower and side limits of the computational domain are hydraulically impermeable. On the top of the divide and at the bottom of the valley we use the "First Type" hydraulic boundary conditions as head values that correspond to the altitude of the relief surface. The permafrost is also impermeable to water-flow in our model.

Results

To describe the influence of infiltration and convective heat transfer on the temperature field dynamics in the thawed zone, we implemented the plain conductive heat transfer computation as the first step of modeling. Here we did not have a riverbed talik in the valley. In this case, we obtained the maximal thickness of the permafrost at 93 m (Fig. 2).

At the second step of modeling, we increased the surface temperature in the 100-m band from the middle part of the river main channel in the valley up to +2ºC. This increase was held for a sufficient time for the occurrence of the riverbed talik as the zone of subpermafrost water discharge and icing formation that exists in reality.

At the third step of modeling, we resolved a coupled groundwater flow and phase-change heat transfer problem in porous media. The surface temperature in the middle part of the valley was +0ºC. The calculation was performed for the 10,000 yr time period to reach the new equilibrium for the temperature field (Fig. 3) and obtain the field of the water head that corresponds to the new geometry of the permafrost massif.

The numerical modeling resulted in following qualitative and quantitative conclusions. Because the descending cold infiltration water is directed toward the ascending heat flow, the watershed divides without permafrost became colder. This cooled area exists not only in the zone of suspended water, but also in water-saturated rock massif up to 200 m below the surface of saturation. This effect is a result of high importance of the vertical component of the water flow in the area between model blocks 1 and 3 where the groundwater flow changes its direction. As a result, a non-gradient temperature field was formed in the zone of suspended water.

The migration of groundwater from cooled divide massif to the valley was accompanied by temperature decrease under the slope and increase in permafrost thickness there. In the valley the convective open talik became stable, and temperature around it increased in comparison with the case without convective heat transfer. This change was not only a consequence of the convective heat flux, but also a result of decrease in the geothermal heat flux from the lower part of the calculation domain because it was shifted from the watershed to the valley.

The influence of the water-flow on the temperature field was illustrated by calculation of the difference between "convective" and "conductive" runs (Fig. 4). The considerable decrease in the temperature in the zone of descending groundwater flow and vertical heat flux from the bottom was obviously noticeable (left part of the figure). On the contrary, in the zone of water discharge into the riverbed talik, the temperature increased (right part of the figure). The separation zone, where the influence of the water-flow on the temperature is insignificant, was located under the lower part of the slope.

Conclusion

The basic conclusion from our numerical modeling is that *even at large depth the temperature distribution and the permafrost configuration (geometry) are sensitive to the percolation of surface water from snowmelt and from liquid precipitation and to amount and pass ways of groundwater infiltration within the thawed zones in sediments and fractured bedrock*. As a result of permafrost degradation related to climate warming, the areas of groundwater feeding and the reservoir capacity of fissured/fractured bedrock increase in size and the river discharge changes.

Considered mechanisms of interaction between permafrost and underground discharge have a regional importance.

We are planning to study these effects during the next stage of modeling. The model must be calibrated using real hydrological and hydrogeological data. A proposed approach could be used to explain the complicated picture of real tendencies in relationships between changes in atmospheric precipitation and river discharge.

Abstract

Current observations show the Seward Peninsula sits on the margin of the continuous/discontinuous permafrost transition in western Alaska, U.S.A. This region of subarctic Alaska could be viewed as a proxy for a warmer Arctic, due to the broad expanses of tussock tundra, invading shrubs, and fragile permafrost. With average annual air temperatures just below freezing and very warm permafrost, the area is susceptible to dramatic change in response to a warming climate. Ground temperatures were estimated using observed meteorological and GCM-simulated forcing of the TTOP soil temperature model, making it possible to investigate the potential rate and mechanisms of change in frozen ground distribution past, present, and future.

Keywords: climate change; IPCC projections; numerical soil temperature model; permafrost; TTOP.

Introduction

The Seward Peninsula of Alaska, USA is located in the western part of the state (Figure 1). As estimated by the International Permafrost Association (2003), the northern part of the peninsula is underlain by continuous permafrost while the southern part, with its higher mean annual air temperatures and a maritime coast, is underlain by discontinuous permafrost.

Villages on the peninsula are located primarily near the coast, but many subsistence activities take place in the interior. Active local economic development includes placer and hard rock gold mining, as well as reindeer herding. Future mining will create a need for a denser road network. With ground underlain by warm permafrost, the economic cost of maintaining current and establishing new infrastructure is expected to rise in a warmer climate due to thawing of permafrost. The economic future of the peninsula is dependent on an accurate projection of permafrost distribution and state.

Permafrost sensitivity is affected by changes in a transitional climate and will shape the economic future on the peninsula. In this paper, permafrost extent is estimated for three periods: the early 20th century, the early 21st century, and the late 21st century using the TTOP numerical model.

Methods

Detailed knowledge about permafrost is difficult to ascertain without extensive research. To develop a better understanding of permafrost distribution on the larger scale we often use models. A model is a way of simplifying the complex natural environment into something more manageable.

In this study, permafrost thermal composition on the Peninsula is estimated using the TTOP numerical model with a spatial resolution of 100 m. The TTOP model is one way of determining the thermal offset between the ground surface and the top of the permafrost table (Smith & Riseborough 1996). TTOP was originally developed by Smith & Riseborough (1996) and is an equilibrium numerical model, which assumes quasi-steady state conditions for each year (Riseborough 2007). The TTOP model was selected because it is numerically efficient so performing calculations over a large domain such as the Seward Peninsula at a relatively high horizontal resolution is not an obstacle. In this study, to reduce the impact of interannual climate variation, several years are averaged together. The three time periods modeled in this study show thermal change over centennial scales. The components of the thermal offset calculation are outlined in Equation 1 below.

$$
\begin{aligned}
T_T &= \frac{n_T k_T I_{AT} - n_F k_F I_{AF}}{k_F P}, T_T < 0 \\
T_T &= \frac{n_T k_T I_{AT} - n_F k_F I_{AF}}{k_T P}, T_T > 0
\end{aligned}
\tag{1}
$$

In Equation 1, T_T is the temperature at the top of the perennially frozen or unfrozen ground (°C). Each variable on the right-hand side of Equation 1 is a function of spatial position except the annual cycle (365 days), P. I_{AT} and I_{AF} are the annual air temperature thawing and freezing indices (°C-days), which are calculated for each time period using another model, MicroMet—a quasi-physically-based program that uses climate forcing to distribute meteorological parameters across a physical domain and will be described in more detail below (Liston & Elder 2006). The annual freezing index is the summation of mean daily air

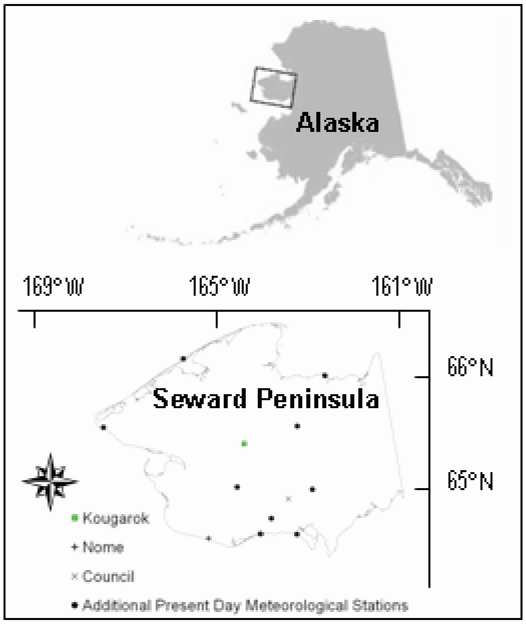

Figure 1 The study area, Seward Peninsula in Western Alaska, USA. Model comparison data are from Kougarok, the square in the interior of the Peninsula. Verification data comes from Kougarok and Council, the *x* symbol in the interior of the peninsula. Nome, the largest community on the peninsula, is the + symbol along the southern coast of the peninsula.

temperatures below freezing at a single point for a one-year period. The annual thawing index is the sum of average daily air temperatures above freezing over the year. N-factors are a way of relating air temperature to soil surface temperature, simplifying the heat transfer relationship between air and the soil surface (Lunardini 1978). N-factors parameterize effects such as radiative heating, evaporative cooling in summer, or snow insulation in winter. For the above freezing and below freezing air-soil surface interface relationship, n-factors are represented as n_T and n_F, respectively (Lunardini 1978). In this study, these two components vary as a function of the primary vegetation group in each cell. In the TTOP equation, thawed and frozen bulk thermal conductivities of the soil in the active layer are represented by k_T and k_F. These two thermal conductivity parameters vary spatially across the peninsula and are based on values from a soil classification map created by the Natural Resources Conservation Service (Van Patten 1990). The next several sections will discuss these components in more detail.

To calculate the annual freezing and thawing air temperature indices across the peninsula (I_{AT} and I_{AF} from Equation 1), the program MicroMet was used. MicroMet is a quasi-physically-based meteorological forcing model (Liston & Elder 2006). MicroMet distributes common meteorological variables, like air temperature, relative humidity, precipitation (solid and liquid), wind speed, and wind direction, across a physical domain. Originally developed for a domain on the North Slope of Alaska, it has been used successfully in other Arctic areas and locations around the world (Liston & Elder 2006). Quasi-physically-based means the point data (e.g., from a meteorological station) are adjusted through physical parameterizations to a common elevation of sea level when appropriate, such as with air temperature. Next, these point data are gridded horizontally across the domain using the Barnes objective distribution scheme (Barnes 1973, Koch et al. 1983). Finally, the interpolated data are adjusted vertically back to a realistic topographic distribution using the model and elevation data from the digital elevation. In this study, MicroMet distributes the meteorological data daily in one-year intervals. At the end of each one-year period the annual freezing and thawing air temperature indices (I_{AF} and I_{AT}) are calculated for each point in the Seward Peninsula domain.

GIS components

When applying the TTOP equations across the Seward Peninsula domain several variables vary spatially. Both MicroMet and TTOP use a Digital Elevation Model (DEM) with the same 100 m horizontal resolution. In addition, a vegetation map is used both by MicroMet (for solid precipitation distribution) and TTOP (the n-factor values are a function of vegetation type). The plant types in this digital map include three types of tundra in varying degrees of wetness, forest, shrub land, water bodies, and barren lands (Thayer-Snyder 2005). The vegetation type in each pixel controls the n-factors (n_t and n_f in Equation 1). Surface n-factor relationships in each vegetation class are primarily calculated using several years of data collected by our established long-term meteorological stations (http://www.uaf.edu/water/projects/atlas/atlas.html) on the peninsula and are supplemented with n-factor values compiled by Lunardini (1978).

The U.S. Natural Resources Conservation Service (NRCS) completed an extensive soil examination covering the Seward Peninsula area (Van Patten 1990). This digital map of peninsula soils serves as the basis for estimating subsurface thermal properties (k_t and k_f in Equation 1). These data are generally qualitative and are divided into 24 landscape groups. In the report, each landscape group has at least one subsurface soil profile typical to that class. To make this map useful in the permafrost extent modeling, quantitative data collected by Ping et al. (2005) was used to estimate thermal conductivity of the mineral soils identified by Van Patten (1990). Using the mineral content of the soil from Ping et al (2005), bulk thermal conductivity over the active layer was estimated using Johansen's method outlined in Farouki (1981). In addition, surface vegetation and subsurface organic layer thermal conductivity were measured by our group during the 2007 field season on the northern part of the peninsula. These values were used for all organic soils mentioned in the typical soil profiles of Van Patten (1990). Frozen organic thermal conductivity is estimated using prior work by Hinzman et al. (1991).

Early 20th century permafrost extent

For the early 20th century permafrost distribution, a single meteorological record from the peninsula (Nome) is available from the National Climate Data Center. Using

MicroMet, annual freezing and thawing air indices for the hydrologic years 1908 to 1918 are calculated. The mean annual air temperature over this period for the Kougarok site is -2.9°C. Since there is just a single point in the domain, MicroMet performs only a vertical temperature adjustment (using the adiabatic lapse rate) across the peninsula. The period 1908 to 1918 was chosen as the earliest continuous segment in the Nome period of record. In summer when sea ice is absent, Nome has a maritime climate rather than the continental climate that is typical of the interior of the peninsula. Temperatures in Nome are also warmer compared to the northern coast of the peninsula. Using only one station observation therefore leaves considerable uncertainties, but it is the only record available for this era.

Present-day permafrost extent

Present-day permafrost extent is estimated using data from significantly more meteorological stations in the region. Data sources include the Natural Resources Conservation Service (NRCS) Snow Telemetry (SNOTEL) sites, Bureau of Land Management (BLM) Remote Automated Weather Stations (RAWS), National Weather Service (NWS) sites, and University of Alaska Fairbanks Water and Environmental Research Center (WERC) sites.

All of these sites record hourly air temperature, relative humidity, wind speed, and wind direction. Additionally, many, but not all, log precipitation. The period of interest is an average of the hydrologic years 2001 to 2004 with the mean annual air temperatures over this period -3.2ºC (Table 2). The recent period was selected because a number of new meteorological stations came online during this time compared to the previous decade.

Late 21st century permafrost extent

Permafrost temperatures at the end of the 21st century are estimated using output from the 13 Intergovernmental Panel on Climate Change (IPCC) fourth assessment report (AR4) General Circulation Models (GCMs) (2007). See Table 1 for a list of the GCMs. These models show considerable variability in their climate projections. For example, at the Kougarok K2 station grid point, the intermodel variation in mean air temperature ranged from -8.7°C (FGOALS 1.0g) to 4.6°C (IPSL CM4). The climate forcing for the GCM output is based on the SRES A1B scenario and encompasses the interval 2092 to 2100 with the exception of the NCAR model, which has an interval of 2092 to 2099. The A1B scenario is driven by technological and economic advancement across the globe with a balanced increase in energy use. Grid points from the GCM output located over the Seward Peninsula are used by MicroMet to downscale meteorological parameters on the peninsula.

For the future distribution experiments, MicroMet is run with data from each GCM individually. An average temperature at the top of the permafrost for each GCM is computed and then averaged over the decade to smooth interannual variability. Finally, a multi-model mean of these late 21st century runs is computed for brevity.

Results

Permafrost temperatures for the early 21st century (2001–2004) are shown in Figure 2. For verification, observed temperature data from two pairs of meteorological stations operated by WERC in Kougarok and Council were compared to the calculated TTOP model results for the present TTOP model output. Kougarok and Council are located in the interior of the peninsula as seen in Figure 1. These four sites are located in three different vegetation types as well as three separate soil classes. A Mann-Whitney *U* test, similar to Student's *t* test but more appropriate for these data, is true at the 0.1 significance level, suggesting good agreement between the calculated TTOP temperature and the observed top of permafrost temperature. With regard to the precision of the modeling results, the mean absolute error is 1.8°C. Site-specific information is shown in Table 2, which is an overview of the climate and permafrost temperatures at one of the Kougarok sites.

In Figure 2, areas with above-freezing TTOP temperatures, which could indicate a talik below the active layer and thawing permafrost or a permafrost-free area, are generally limited to mountains and related features. However, in the south, some areas with a thicker organic base are also estimated to be experiencing thaw.

Table 2. Climate statistics at Kougarok site K2.

K2 Site	Mean Annual Air Temperature	Observed TTOP	Calculated TTOP	Difference (Observed – Calculated)
		Degrees Celsius		
2001	-2.5	-3.7	-3.0	-0.7
2002	-4.4	-2.7	-4.6	1.9
2003	-2.1	-2.5	-3.0	0.4
2004	-3.7	--	-4.6	--

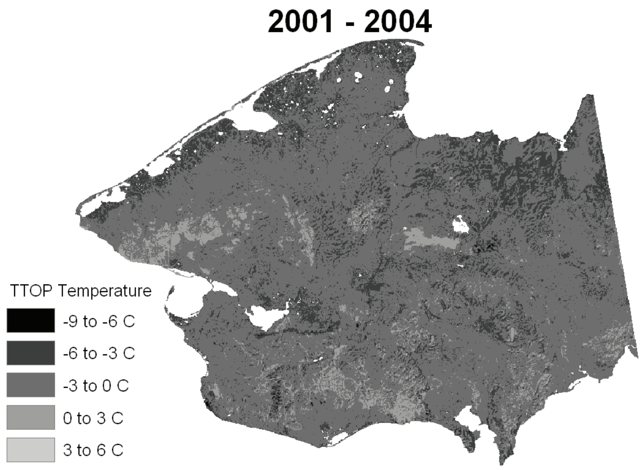

Figure 2. Present-day estimated permafrost temperatures.

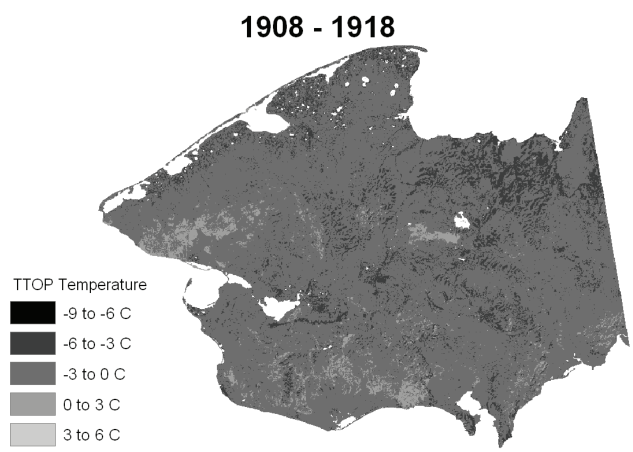

Figure 3. Early twentieth century estimated permafrost temperatures.

One current MicroMet limitation is the lack of an algorithm for calculating wintertime temperature inversions. If included, there would potentially be more land surface estimated as underlain by continuous permafrost in the interior. Winter temperature inversions occur when air temperatures are well below freezing and there has been no wind, which allows air temperatures to stratify vertically with the coldest temperatures at the lowest elevations. Steep thermal gradients develop until the wind mixes the air column again. This is not expected to be a major limitation, as the Seward Peninsula seldom experiences calm winds for extended periods. It is possible that for estimating present

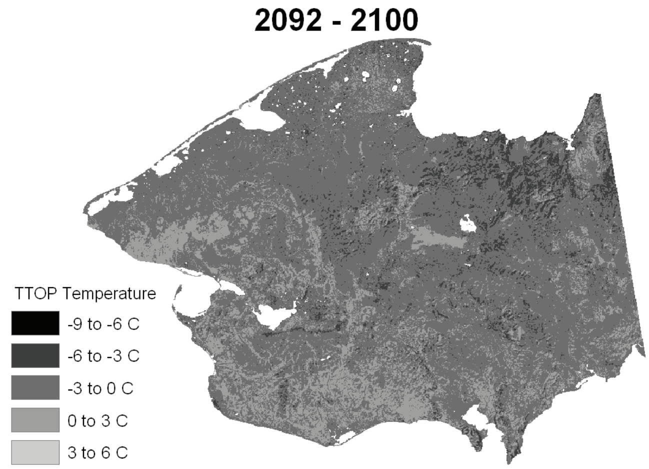

Figure 4. Late 21st century estimated permafrost temperatures.

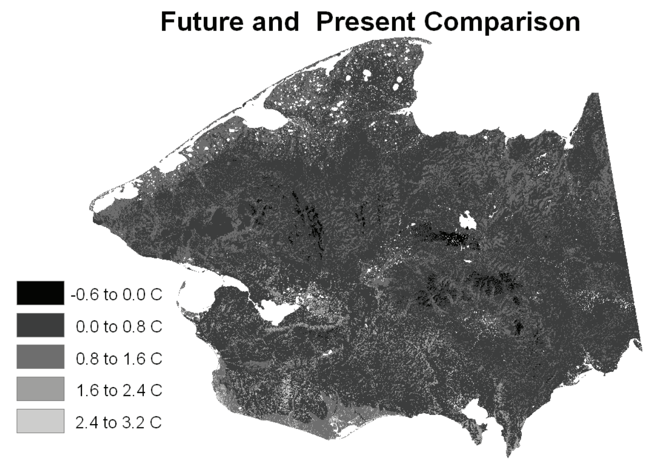

Figure 5. Temperature difference between the future distribution and the present distribution. Higher temperatures represent warmer future conditions.

extent satellite measured ground surface temperatures could allow consideration of winter inversions in future research.

Modeled permafrost temperatures for the early 20th century (1908–1918) displayed in Figure 3 are similar to the present day TTOP results (Fig. 2). In reality the TTOP temperatures for this earlier time should be a bit lower due to using a single weather station in Nome as the only climate forcing point in the domain used by MicroMet. Points further north in the interior would better capture the continental climate for the landscape away from the ocean. Additional experiments are planned to test this hypothesis. Another similarity to the present is that only the mountainous areas, which are dominated by coarse mineral soil, are thawed or thawing. This is probably related to the reduced water content in these coarse soils and the corresponding higher thermal conductivity compared to the valley bottoms, where there is a thick layer of organic mat above the fine-grained mineral soil. About 8% of the area has TTOP temperatures above freezing.

In contrast, permafrost extent for the end of this century (2092–2100) shown in Figure 4 based on the IPCC SRES A1B scenario shows much warmer temperatures across the peninsula. Much of the near-surface landscape in the south and low-lying areas will likely have temperatures at the base of the active layer rise above freezing.

A summary figure comparing the difference between the late 21st century results of the IPCC SRES A1B scenario to the present estimated TTOP temperatures is shown in Figure 5. A plot comparing the early 20th century permafrost temperatures to the present is not shown because the temperatures were similar. In Figure 5, the greatest difference in temperature is concentrated along the coasts. Several small areas in Figure 5 show colder temperatures between the future and the present. These are high in the mountains and are probably skewed by the IAP FGOALS 1.0 g GCM, which predicts future air temperatures 5° colder than the present. Additionally, the increase of thawing landscape between now and the future begins to encompass more of the lower, flatter terrain that is also ice-rich. Charon (1995) estimated permafrost thickness on Cape Espenberg, the northernmost part of the peninsula, to be 158 m. Thus, permafrost is unlikely to thaw completely, but the surface conditions, where there is the highest diversity of plants and organisms, will change.

Conclusion

Permafrost temperatures over the Seward Peninsula of Alaska were modeled over 3 time intervals approximately 80 years apart. Early 20th century simulated permafrost conditions are similar to current estimated permafrost temperatures. When conducting numerical modeling, it is important to start with a simulation that estimates the present conditions well. Comparison of permafrost temperatures modeled with TTOP to observations from four UAF WERC climate stations on the peninsula shows they are statistically similar. In the future, permafrost degradation is likely to accelerate (Fig. 5). This will probably result in additional thermokarst development, because much of the areas predicted to warm are ice-rich valley bottoms. Higher permafrost temperatures and unfrozen talik formation will likely have a mixed effect on local industry, such as mining and reindeer herding, on the peninsula. The logistics of getting to these locations will increase in difficulty, since road maintenance costs are likely to be higher.

Acknowledgments

Support for this research was provided by the U.S. National Science Foundation under the Arctic System Science Programs (Grant Number OPP-0328686 and OPP-0229649). We would like to thank the people of the Seward Peninsula for assisting us in conducting this research. We also acknowledge international modeling groups for providing their data for analysis and the Program for Climate Model Diagnosis and Intercomparison for collecting and archiving the model data.

Soil and Permafrost Properties in the Vicinity of Scott Base, Antarctica

I.B. Campbell

G.G.G.Claridge
Land & Soil Consultancy Services, Nelson, New Zealand

Abstract

The southern tip of Ross Island is the location of two bases: Scott Base and McMurdo Station. The soils in this area are formed from thin volcanic drift over volcanic bedrock materials, and the active layer averages around 30 cm thick. The permafrost is predominantly ground ice, but ice wedges are present and extend into the volcanic bedrock. Extensive ground surface modifications have resulted in loss of permafrost ice, the formation of hummocky and patterned ground, and extensive surface soluble salt precipitation. Low albedo contributes to soil warming and moisture evaporation. Chemically, the soils are influenced by their proximity to the sea. They contain small amounts of soluble salts and are strongly alkaline. They are very little weathered and most of the clay fraction is derived from mechanical rock breakdown. Significant contaminations with heavy metals, wood, metal and fabric materials, and hydrocarbons have resulted from human occupation.

Keywords: Antarctic permafrost; Antarctic soils; human disturbance; Ross Island; Scott Base.

Introduction

Ross Island is a large volcanic island (area approximately 1350 km^2) situated at the southern margin of the Ross Sea and at the edge of the Ross Ice Shelf (Fig. 1). It comprises several extinct volcanoes and the active Mt. Erebus, 3740 m in elevation. Small ice-free areas occur in eastern and northwestern coastal areas (the location of several penguin rookeries), around the central summit crater, and at the southern tip of the island at the end of the narrow Hut Point Peninsula. Permanent research station occupation was established on the southeastern end of Hut Point Peninsula at Scott Base and at McMurdo Station on the southwestern end (some 4 km apart) in 1956/57 but at that time, little consideration was given to the nature of the soils, the permafrost or other environmental issues that are at the forefront today.

Since establishment of these bases, considerable land surface changes have occurred through construction of roads and pipelines, ground surface leveling for building sites and storage of materials, installation of communications, and extensive ground scraping for aggregate requirements, coupled with retreat of snow and ice cover. These have dramatically altered the original permafrost conditions in the modified areas.

The advent of the Antarctic Treaty (1959) and the Protocol on Environmental Protection to the Antarctic Treaty System (1991) have now provided a framework within which environmental management is expected to occur. This report gives an outline of the soil and permafrost conditions observed in the southern Ross Island area to provide a basis for future management considerations. Information and data have been obtained from general observations since the 1970s as well as from experimental, soil sampling, and monitoring activities through the 1990s.

Environmental Background

Ross Island is part of the McMurdo Volcanics Group, the rocks at Hut Point Peninsula being primarily scoriaceous flows and tuffs around 1.5 my old (Kyle 1981). The present hilly topography has been little modified by glacial erosion and is largely inherited from the previous volcanic activity with cones and craters forming distinctive local features. The soil forming material is a patchy thin cover of till, dominated by fragmental volcanic rock with a stony sandy gravel texture that becomes coarser with increasing depth (Table 1). Small partly rounded basaltic clasts are sometimes present, and also some granite and sandstone in the upper horizons. The latter rock materials are believed to be derived from the mainland, some 70 km to the west during the last glacial period (Ross Glaciation, Denton et al. 1971) when ice filled McMurdo Sound and covered Hut Point Peninsula.

The major features of the climate of the Hut Point Peninsula area are a mean annual temperature of -20°C at Scott Base (-18°C at McMurdo) and precipitation equivalent of about 200 mm. Temperatures average from around -30°C in winter months to -4°C in December and January but with occasional days in which summer temperatures may reach +6°C. Precipitation is difficult to assess accurately as much snow accumulates as drift from surrounding sea ice. Periodic summer snowfalls occur, however. Much of the landscape is snow covered in early December with maximum thaw taking place by late December to early January. The December/January thaw period is usually accompanied by small water flows from thawing snow banks, etc., but most of the snow is lost by ablation with only occasional surface soil moistening. Vegetation is restricted to sparse moss and lichen patches.

Soils

The soils of the Hut Point Peninsular area are unweathered and belong to weathering stage I which includes soils less than 50,000 years old (Campbell & Claridge 1975, 1987). They typically have a boulder or pebble pavement of angular scoriaceous basalt which is unweathered apart from a patina or thin varnish that gives upper black coloured clast surfaces a distinct luster. Ventiforms are absent although some clast abrasion is occasionally seen. The undersides of surface clasts commonly have a thin grayish brown calcareous coating and occasionally a thin precipitate of soluble salts. The carbonate was thought to have been derived from wind-deposited dusts originating from the mainland (Blakemore & Swindale 1958) but given the granite erratics that are present and the known fluctuations of the Ross Ice Shelf, the carbonate may have originated from the till materials. Below the stony surface pavement, the soil is grayish brown (10YR 5/2-2.5Y5/2) loose sandy stony gravel with the coarse fraction increasing with depth (Table 1).

Figure 3. Ice wedge formed in tuffaceous volcanic bedrock in a cut section for pipeline construction, near Scott Base.

A weakly-developed vesicular structure, formed as a result of freezing when the soil is moist, may be present in the top few centimeters. The soil passes abruptly into hard ice-cemented and unweathered permafrost. The active layer thickness ranges from near ground surface alongside permanent snow patches to around 60 cm on well-drained windy surfaces that have little snow accumulation. In well-drained sites, the soils have a low moisture content (gravimetric), averaging around 0.5% in the surface horizon and increasing with depth to around 8% above the permafrost.

Permafrost Properties

Physical characteristics

The permafrost in the Hut Point Peninsula region has been observed in the course of a number of investigations including general soils investigation, leaching and contamination studies (Claridge et al. 1999, Sheppard et al. 2000), from experimental disturbance of permafrost (Balks et al. 1995), as part of long-term monitoring studies (Paetzold et al. 2000), and from casual observations during domestic activities.

Examinations from shallow drilling (approximately 1.5 m deep) showed that the average depth of the permafrost table was approximately 30 cm at well-drained sites such as ridge surfaces (Fig. 2). In gullies or nivation cirques where water flows are occasionally present, the active layer thickness averaged 18 cm. At the edge of a permanent snow pack, the permafrost table was at the ground surface but increased to 20 cm some 20 m from the snow pack. The frozen water content (gravimetric) of the permafrost increases from around 10% near the permafrost table to 140% at greater depths with ice layering commonly occurring as ground ice. Our shallow drilling revealed that ground ice was present in the volcanic rock below the cover materials, with ice wedges and sand wedges being observed in the volcanic bedrocks in excavated

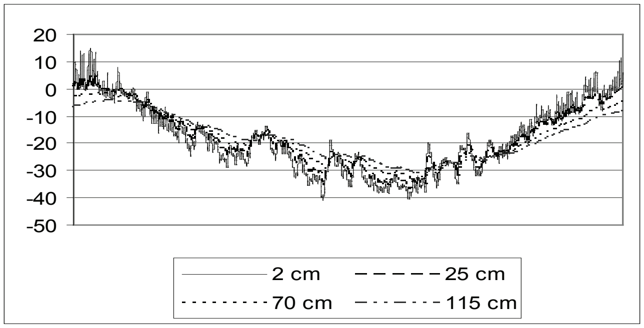

Figure 4. Hourly plots of temperatures (°C) at four depths in 2002 from the CALM site near Scott Base.

roadway sections (Fig. 3). In some places, massive stagnant ice was observed in exposures where regolith removal had given rise to accelerated thaw and ground slumping.

Thermal characteristics

Soil temperature plots from hourly measurements in 2002 at a CALM recording site near Scott Base (Paetzold et al. 2000) are shown in Figure 4. Mean annual soil and permafrost temperatures at four of the depths (2, 25, 70, and 115 cm) from which temperatures were recorded are all similar (approximately -18°C) and are close to the mean annual 1992 air temperature recorded at the site (-19.3°C). The 2 cm depth temperatures range from 14.2°C (January 11) to -40.7°C in mid June. At 115 cm, (approximately 85 cm below the permafrost table, the annual temperature ranged from -4°C to -19°C. At the 2 cm depth, there were 45 freeze/thaw cycles through the period from December 2 to January 31 with soil temperatures remaining above 0°C periodically for 15 days. As soil warming commences after the winter minimum temperatures, the temperature at all depths is briefly isothermal (-23°C) around late August and again in late February when the temperature was -6°C (Fig. 4). In summer months, diurnal temperature changes may reach 16°C while in winter months temperature changes in excess of 20°C occur over short periods due to weather events.

Experimental soil and permafrost disturbance

The moisture content, evaporation rate and soil radiation balance were investigated at an experimental site near Scott Base in January, 1994 (Balks et al. 1995, Campbell et al. 1997). The active layer (approximately 30 cm) was removed from 300 m^2 of eastward-facing, gently-sloping ground and observations were made and compared with those from an undisturbed immediately adjacent similar-sized area.

Observations from neutron probe access tubes to 1.2 m depths in the undisturbed sites showed low moisture contents in the active layer, very high ice contents in the upper part of the permafrost, and decreasing amounts with increasing depth. At the disturbed site, thawing of the permafrost began immediately with some of the thaw water apparently accumulating in the upper permafrost zone, judged by the neutron probe measurements which showed considerably higher moisture/ice contents compared with the undisturbed

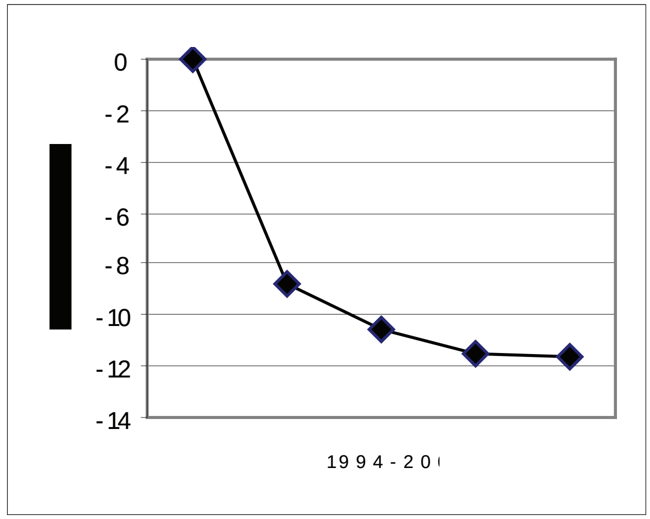

Figure 5. Average ground shrinkage values for 7 tube sites over 6 years at an experimental site near Scott Base.

site. Over the following six years, ice was lost from the disturbed site at a diminishing rate as measured by the amount of ground shrinkage against the access tubes (Fig. 5).

Evaporation rates were measured on undisturbed and the disturbed soil using small lysimeters over six days (Balks et al 1995). For the undisturbed dry soil, the evaporation loss was less than 0.1 mm/day and 1.1 mm/day at a site that was wetted from an adjacent snow melt. For the disturbed soils, initial evaporation rates of 1.5 mm/day and 3 mm/day were measured, but these rates declined as the soil surface became lighter-coloured on drying. These rates are similar to those observed in moist soils in the Dry Valley region (Campbell 2003).

The soil radiation balance was also measured at the disturbed and undisturbed sites (Balks et al. 1995, Campbell et al. 1997) over four days, and albedo measured during the 3-hour period of highest solar angle averaged 0.048 on the undisturbed surface with a similar value on the moist disturbed surface. On the dried disturbed surface, the values averaged 0.112 with more solar radiation being reflected from the disturbed dry surface than the undisturbed and the disturbed moist surface.

Disturbances caused by logistical activities

Soil and permafrost disturbance from logistical activities are widespread in the southern Hut Point Peninsula area and have primarily been caused by ground scraping to provide fill material for construction sites. In some places, only shallow scraping occurred with the active layer being removed but at other sites, repeated ground scraping into the scoria bedrock has removed meters of material. The shallow scraping was observed to result in rapid permafrost thaw with ground shrinkage causing patterned ground to form within three years, due to melting of ice wedges. It was noted that, in places, the ground surface was partly covered with large rock slabs indicating that the ice wedges and ground ice were largely within the volcanic bedrock. A reticular

patterned ground network was present in a few places on the deeply cut surfaces near McMurdo Station suggesting that ice wedges may at times penetrate some depth into the bedrock. At one locality on a ridge that had been scraped, grey quartzofeldspathic sand was noted in a crack that was presumed to be the remains of a sand wedge. Scraping on sloping ground that was underlain by stagnant ice resulted in extensive instability in the early 1980s, with repeated ground slumping and formation of thermokarst terrain (Campbell & Claridge 2003). In most places, ground disturbance is followed by the precipitation of a surface cover of soluble salts.

Examinations of areas in which fill materials have been deposited have not revealed any indications of recent ice accumulation consistent with the reformation of icy permafrost. The gravimetric moisture content was found to vary with depth and probably reflects the moisture content of the materials when deposited.

Soil Chemical Properties

Soil chemistry and mineralogy

The soils at southern Ross Island are very little weathered and contain only small amounts of the fine-earth fraction. Extractable Fe_2O_3, the usual measure of mineral breakdown, and release of iron is also very low, about 0.3% of the fine earth fraction, while clay contents (<2 µm) are around 6%, relatively high for Antarctic soil indicating mechanical breakdown of rock particles, largely the glassy component of the basaltic scoria parent material. The clay fraction of the surface material (Table 2) (0–30 cm) contains mica (illite?), chlorites, and some smectite, as well as clay-size quartz and feldspar, all consistent with much of the clay fraction, apart from the smectite, being derived from materials transported from the mainland, rather than from breakdown of the basaltic rocks. The smectite could have been derived from weathering of the glassy material in the basalt but this has not been investigated.

Within the ice-cemented permafrost, which was accessed by drilling, the clay fraction is dominated (50%) by palagonitic material showing only short-range order and may have been derived from breakdown of glassy material within the basalt.

The soils of the southern Ross Island area are heavily influenced by their proximity to the ocean, in contrast to most of the soils from the Transantarctic Mountains (Campbell & Claridge 1987). They are strongly alkaline, with pH values above 9. They contain moderate amounts of water-soluble salts (Table 3), in contrast to some of the older soils of the Transantarctic Mountains, and the salts are dominantly chlorides of sodium with lesser amounts of calcium and magnesium. The proportion of sulphate ion is very low while nitrate is below the limit of detection.

There is very little difference in the composition of the salts in the active layer of the soil and the salts in the underlying permafrost which was sampled to 1.5 m. At a site where the active layer had been removed and the underlying permafrost had thawed and a new active layer formed, the salts contained within the thawed permafrost had migrated to the surface giving an extensive surface efflorescence of halite. At sites that had not been scraped, only very small efflorescence’s were visible. The ions within the surface efflorescence’s are in the same proportion as those within the soil indicating no differences in mobility of the ions over the distances involved.

It is not clear whether the salts within the permafrost are residual and relate to previous glacial conditions or whether the salts may migrate into the permafrost under current conditions as thin films of concentrated solutions with low melting points as described by Ugolini & Anderson (1973).

Lithium chloride-leaching experiments

In order to assess the potential for salts or contaminants to move within the soils at southern Ross Island, the mobility of lithium chloride, which was added to the soil surface, was studied (Claridge et al. 1999). In this experiment, lithium chloride solution was applied to the soil surface at two sites, one a dry ridge and the other a moist depression, then sampled over several years at and downslope from the application sites, then analysed for lithium.

The results of this experiment showed that at the dry sites, substances added to the soil surface, such as airborne salts or spilt contaminants, will mainly penetrate only a small distance into the soil, related to the particle size and permeability of the soil. A small proportion may penetrate further down by capillary action until the soil temperature reaches freezing point at the permafrost table. Solutions concentrated by freezing and evaporation may also enter the permafrost through cracks and pores as indicated by detectable lithium within the permafrost. At the moist site, lithium was detected several meters downslope after three years indicating that downslope movement of contaminants can occur given sufficient moisture.

Table 4. A 0-2 cm, B 2-10 cm, C 10-20 cm, D 20-30 cm. Con – control site; Sp – contaminated site; THP – total petroleum hydrocarbons (mg/kg);, hyd – hydrocarbon degraders (no./g).

Contaminations of soils around Scott Base

Detailed studies of the contamination of soils around Scott Base were made by Sheppard et al. (2000). Day-to-day activities can result in many kinds of contaminants being added to the soil surface, more especially in the past when management procedures were less concerned with environmental protection. A range of macro-contaminants such as wood, plastic, fibre, metals, etc. as well as odours from fuel spills were detected. The organic carbon content in the soils adjacent to the base was generally higher than at undisturbed sites, indicating the presence of intrusive organic material, which may have ranged from wood fragments to exhaust materials.

Acid extracts of the soils, designed to estimate heavy metal contamination, showed that the soils adjacent to the base were measurably contaminated with Ag, As, Cd, Cu, Pb and Zn, with the highest amounts in sites where materials had been dumped or stored.

The saline, oxidizing, and alkaline environment of the soils and the variations of these conditions within the soil profiles were considered to cause the episodic mobilization and retention of heavy metals in response to freeze-thaw cycles and the movement of water through the soils. Heavy metals can be bound to the surface of the clay particles within the soil, such as the smectites or the short-range order of palagonitic clays, and this may prevent their removal, while the more soluble constituents may be leached out.

Effect of fuel oil spills

Accidental fuel spills can arise from a variety of causes and several spill sites have been noted around Scott Base (Aislabie et al. 2004). The most obvious affect on soil properties is that the soil becomes darker and absorbs more heat, so that soil temperatures may rise by as much as 10°C, possibly causing some thawing of the underlying permafrost. Fuel-affected soils are sometimes weakly hydrophobic with the potential to alter the soil moisture regime and change other soil properties, some of which are shown in Table 4. Hydrocarbon-contaminated sites have slightly lower pH values, especially in the surface layer, increased organic carbon contents, much higher total petroleum hydrocarbons (TPH), and very much larger contents, by five orders of magnitude, of hydrocarbon-degrading bacteria, although total bacterial counts are more or less the same.

If left undisturbed, fuel-contaminated sites have the potential to self-remediate, as the hydrocarbons are used as an energy source by some organisms, as discussed by Aislabie et al. (2004).

Hydrocarbon spills that are sufficiently large may wet the active layer and pond on the ice-cemented permafrost and spread over a much larger area than the surface spill. Liquid hydrocarbons may also penetrate into the permafrost along cracks and fissures filled with unfrozen saline solutions. While no major spills of this sort are known around Scott Base, they have been observed elsewhere in the McMurdo Sound region.

Conclusions

Properties of the soils at southern Ross Island reflect their youthfulness, being exposed to weathering since the retreat of Ross I ice in the late Last Glaciation. The permafrost table is present at a relatively shallow depth compared with that is soils of other coastal locations in the McMurdo Sound region because the combination of low albedo and high moisture availability results in more energy being expended in moisture phase change rather than in soil heating to greater a depth. Variations in depth to the permafrost table are due to differing site moisture availability. Soil disturbance and removal of the active layer soon results in permafrost thawing and ground instability with patterned ground forming where ice wedges have melted and ground slumping where massive stagnant ice is present. Ground ice and ice wedges are common in the volcanic bedrock.

The soils are strongly alkaline because of the marine influence, and salts have penetrated far into the underlying permafrost and are rapidly precipitated at the ground surface after the removal of metres of bedrock permafrost.

As well as the physical and chemical changes resulting from disturbance to the active layer and the permafrost, soils in the region are contaminated from a wide variety of macro-substances, and also by a range of heavy metals and hydrocarbons. Experiments have shown that the movement of contaminants through the soil is small in dry sites but greater in moist sites. The levels of hydrocarbons in the soils can be reduced by biodegrading bacteria.

Abstract

The relationships between vegetation patterns and periglacial features and their underlying ecology are still poorly understood and lack specific investigations in Antarctica. Here we present the preliminary results on vegetation colonization of different types of sorted patterned ground and gelifluction features (stone-banked lobes and terracettes) in two sites at James Ross Island and four sites in Northern Victoria Land. The paper aims to a) understand the relationships between the patterns of vegetation colonization and the investigated periglacial features; b) compare the characteristics of vegetation patterns in similar periglacial features in two geographically remote sites of Maritime and Continental Antarctica; and c) compare the observed patterns of vegetation with those described by literature for the High Arctic. Vegetation relations with the periglacial features show some common patterns between Maritime and Continental Antarctica. Frost creep/gelifluction processes and frost heave are much more effective than grain size as limiting factors for vegetation development.

Keywords: gelifluction features; Continental Antarctica; Maritime Antarctica; patterned ground; vegetation.

Introduction

Periglacial landforms are widespread in the polar regions of both hemispheres (French 2007). While several authors have focused on the relationships between vegetation colonization and the periglacial landforms in the Arctic (i.e., Britton 1957, Billings & Mooney 1959, Jonasson & Sköld 1983, Anderson & Bliss 1998, Matthews et al. 1998, Cannone et al. 2004, Walker et al. 2004), this topic has been poorly addressed in Antarctica (i.e., Heilbronn & Walton 1984). Moreover, to our knowledge, until now there are not specific investigations providing the comparison of the vegetation patterns in relation to periglacial landforms in Maritime and Continental Antarctica.

The aims of this paper are:

1) to understand the relationships between the patterns of vegetation colonization and the type and characteristics of the most widespread periglacial features;

2) to compare the characteristics of the periglacial features and of their related vegetation patterns in geographically remote sites of Maritime and Continental Antarctica: and

3) to compare the patterns observed in Antarctica with those described by literature for the High Arctic.

Study Areas

Two geographically remote areas of Antarctica were selected for this investigation (Fig. 1): James Ross Island, located on the eastern side of the Antarctic Peninsula and used as a template of Maritime Antarctica, and Northern Victoria Land, located at East Antarctica and used as a template of the conditions of Continental Antarctica.

Maritime Antarctica

At James Ross Island, two different sites (about 20 km from each other) were investigated: the Rink Plateau (named Rink in this paper) (63°55′S, 58°10′W) and Lachman Crags (named Lachman in this paper) (63°54′S, 57°35′W).

At James Ross the climate is a cold, dry maritime climate, with a mean annual air temperature of -6.7°C (referred to the period 1996–2004) (Mori et al. 2007) and mean annual precipitation of about 200 mm/yr water equivalent (Strelin & Sone 1998).

Rink site is a relatively high elevation plateau (400 m a.s.l.) delimited by a sharp and almost vertical scarp. This site is characterized by the occurrence of several periglacial features and a small ice cap located in the upper part of the plateau. The outcropping bedrock is composed of Cenozoic lavas and pyroclastites underlain by Cretaceous sedimentary rocks (Strelin & Malagnino 1992, Carrizo et al. 1998).

Lachman site includes different types of environments (i.e., valley bottoms, raised beaches, slopes) at elevations ranging between 0 and 200 m a.s.l. and characterized by a high frequency of periglacial features. The outcropping bedrock is volcanic with the occurrence of different types of deposits ranging from morainic and slope deposits, to raised beaches.

Northern Victoria Land

The climate of Northern Victoria Land is frigid Antarctic, with a mean annual air temperature of -18°C and precipitation, always in the form of snow, between 100 and 200 mm (Grigioni et al. 1992).

Four different sites were selected: Tarn Flat (74°59′S, 162°37′E), Boulderclay (74°44′S, 164°05′E), Gondwana (74°36′S, 164°12′E), and Apostrophe Island (73°30′S, 167°50′E).

All these sites are located along the coast, with the exception of Tarn Flat, at elevations ranging from 20 to 150 m a.s.l. These sites are characterized by the occurrence of different types of periglacial features occurring on different outcropping rock and deposits ranging from gabbro and metamorphic rocks (Apostrophe Island and Gondwana) to granites and morainic deposits (Tarn Flat and Boulderclay).

The vegetation both at James Ross and at Victoria Land is a cryptogamic nonvascular tundra, including different moss- and lichen-dominated associations (Longton 1979). Descriptions of the moss and lichen flora and of the main vegetation communities of Victoria Land have been provided by several authors (Kappen 1985, Castello & Nimis 1995, Seppelt et al. 1995, 1996, Seppelt & Green 1998, Smith 1999, Cannone 2005, 2006).

Methods

Geomorphology

The geomorphological study was performed by field surveys. All the periglacial landforms occurring in each selected study site were recorded and classified. Only in some representative cases, the groups of landforms selected for the vegetation survey were also morphometrically characterized through profiles and visual descriptions. In addition, the thickness of the active layer was measured by frost probing and, where logistical conditions allowed enough time, also by measuring the ground temperature at different depths following the method proposed by Guglielmin (2006).

Trenches were dug into the ground to investigate the internal structure of the features and for sampling.

Vegetation survey

The vegetation was sampled in 50 × 50-cm plots. Two (occasionally three) plots were set up at each of the selected landforms. All of the plots were located in morphologically homogeneous microhabitats within the landforms. All of the moss and lichen species occurring in the plot were recorded and their percentage cover estimated visually. Microtopography and surface-soil texture were assessed visually in each plot. Species nomenclature follows Castello & Nimis (2000), Øvstedal & Smith (2001) and Castello (2003) for lichens, and Ochyra (1998) and Seppelt & Green (1998) for bryophytes.

Results

Maritime Antarctica

At James Ross Island several types of periglacial features were analyzed, including sorted, patterned ground (debris island; sorted polygon; sorted stripes), terracettes, and stone-banked lobes (Rink & Lachman). The geomorphological survey pointed out that, within each site, the high- and low-centered patterned ground shows similar size (Table 1), which is about twofold larger at Lachman than at Rink. The measured frost table depth ranged from 40 cm at Rink and 80 cm at Lachman. In many cases, groundwater flow filled the trenches. The height of the investigated terracettes and of the stone-banked lobes ranges between a few decimeters up to 1.6 m. At Lachman, vegetation colonization shows clear patterns. The average total vegetation coverage is highest on the sorted stripes, decreases to the terracettes, and is lowest on the stone-banked lobes. High-centered and low-centered patterned ground show opposite colonization patterns, with the highest coverage on the border of the low-centered and on the center of the high-centered patterned ground (Table 1). The total vegetation coverage shows differences considering separately the different parts of the landforms (i.e., border and center of sorted patterned ground, tread and riser of both terracettes and stone-banked lobes, fine- and coarse-grained parts of the sorted stripes). As could be expected, the higher values of coverage characterize the elements with finer texture, ranging from the fine part of the sorted stripes (with the highest average coverage recorded >80%), to the treads of the terracettes and the center of sorted high-centered patterned ground (with similar values ranging around 35%), to the treads of stone-banked lobes (c. 25%). In the coarser sediments, vegetation coverage is relatively high on the border of sorted patterned ground (ranging from 14% on high-centered to 48% on low-centered). On the other hand, coverage decreases sharply when considering the coarse part of the sorted stripes and the treads of terracettes, while the riser of stone-banked lobes is devoid of vegetation. In the sorted stripes the vegetation (occurring only on the fine-grained part) is dominated by crustose microlichens with scattered mosses. Similar floristic composition and dominance (crustose microlichens such as *Psoroma*, foliose lichens as *Leptogium* and scattered mosses) characterize the flat part of the terracettes, the center of sorted patterned ground and the flat of stone-banked lobes. The border of sorted patterned ground is mainly colonized by different species of mosses and macrolichens (*Usnea* and *Stereocaulon*).

The high-centered patterned ground shows opposite vegetation colonization patterns between Lachman and Rink, where the stony border shows higher vegetation coverage (60%) than the finer center (1%). At Rink the low-centered patterned ground shows similar patterns to those of Lachman, although with lower vegetation coverage, with higher coverage on the border (21%) than the center (8%). However, the patterns of floristic composition are similar indicating similar environmental and ecological gradients but different intensity of ground disturbance. On the other hand, at Rink the center of all the patterned ground is mainly colonized by crustose microlichens (i.e., *Psoroma*) and mosses, and the vegetation of the borders is composed of mosses (more than 15%) and, only as subdominants, by macrolichens (*Usnea* and *Leptogium*). At Lachman the depressed fine center of the low-centered patterned ground is homogeneously colonized (average coverage 11%) by crustose microlichens (*Psoroma*, *Ochrolechia*) and mosses (*Andreaea*, *Polytrichum*) and by a black crust of *Nostoc*. The border of the low-centered patterned ground shows lower average vegetation coverage (48%) with the prevalence of mosses (*Bryum*, *Andreaea*) and of epilithic foliose and fruticose lichens (*Leptogium*, *Usnea*). Among the rarest periglacial features at Lachman, there are

frost boils, developing on sandy ground close to the raised beach and showing occasionally salt efflorescence. These features are extensively colonized by mosses (*Polytrichum* spp. and *Dicranum* spp.) located on the raised centers.

Continental Antarctica

In Northern Victoria Land in order to achieve a comparable data set, we only considered the same types of periglacial features investigated in Maritime Antarctica. The features that were analyzed were sorted patterned ground (debris island at Boulderclay, high-centered patterned ground at Tarn Flat, Gondwana, Apostrophe Island), terracettes (Tarn Flat, Gondwana, Apostrophe Island), and stone-banked lobes (Gondwana, Apostrophe Island).

From the geomorphological point of view, the absence of low-centered patterned ground and the thinner frost table (from 15 to 50 cm of depth) is remarkable with respect to the values recorded in Maritime Antarctica. No groundwater flow was found in any of the trenches. The height of the investigated terracettes and of the stone-banked lobes is surely much smaller than in Maritime Antarctica, ranging between 10 cm up to 35–40 cm.

In Northern Victoria Land vegetation shows different colonization patterns with higher total vegetation coverage on the tread of terracettes, tread of the stone-banked lobes, and coarse border of high-centered patterned ground and debris island, whereas the riser of stone-banked lobes and terracettes are characterized by a very low total coverage.

Tarn Flat and Gondwana show similar patterns of vegetation colonization both for terracettes and high-centered patterned ground concerning the total coverage and the floristic composition. The tread of terracettes and the center of high-centered patterned ground in these sites are colonized by microcrustose lichens (*Lecidella siplei*), and the slope of terracettes and coarse border of patterned ground are characterized by epilithic foliose lichens (i.e., *Umbilicaria*) and crustose placodioid lichens (i.e., *Buellia frigida* and *Rhizocarpon* spp.). At Apostrophe Island the high-centered patterned ground shows vegetation patterns similar to those observed both at Tarn Flat and Gondwana.

On the contrary, at Apostrophe Island vegetation composition of the gelifluction features is different with the strong ingression of foliose (*Umbilicaria*) and fruticose (*Usnea*) lichens accompanied by crustose lichens (*Buellia frigida*) mainly on the risers of terracettes and on the treads of stone-banked lobes.

(Images from Landsat Image Mosaic of Antarctica, LIMA, International Polar Year 2007–2008 Project by BAS, USGS, NSF).

Discussion and Conclusions

The results obtained in all the investigated sites underline that grain size is not an effective factor in shaping the vegetation distribution patterns in the analyzed features.

The progressive decreasing sequence of vegetation coverage found through the periglacial landforms at Lachman suggest an important role of the frost creep/gelifluction processes as limiting factors for vegetation development. The estimated higher water content within the active layer and the higher height of the frost creep/gelifluction features in Maritime Antarctica than in Victoria Land can suggest that these processes are more intense in the former than in the latter areas. On the other hand, from the fabric of the pebbles in the trenches, the layer involved in the sorting or in the preferential orientation is much thinner (data not shown) than the recorded frost table depth. This pattern is opposite to what was already stressed by Cannone et al. (2004) for the High Arctic, where the substrate disturbance associated with gelifluction landforms does not affect the integrity of the upper soil layer.

Moreover, Northern Victoria Land (Gondwana and Tarn Flat) show similar conditions to what was found at Lachman. The higher vegetation cover of the gelifluction landforms at Apostrophe Island could be related more to the edaphic conditions of the site (high level of nutrients; higher water availability; see Cannone et al., in press) than to the active-layer thickness or to the depth of gelifluction processes.

The similar vegetation patterns at Rink (maritime Antarctica) and in all the selected sites at Northern Victoria Land are contrasting with those of Lachman.

At this site, the frost heave may be weaker than in the other sites not only due to milder conditions, but also due to the high salt content of the ground.

The analyses carried out at Victoria Land (as a template of Continental Antarctica) and at James Ross Island (as a template of Maritime Antarctica) indicate that there are some common patterns between these two geographically remote regions of Antarctica. In particular, the patterns of vegetation distribution (in terms of vegetation coverage, but not for the floristic composition) of the sorted patterned ground of Rink (James Ross Island) are more similar to those of all the investigated locations of Victoria Land than to the other site at James Ross Island (Lachman).

Similar evidences concern the colonization patterns of terracettes, with the patterns observed at Rink being more similar to those of Victoria Land than of Lachman.

On the other hand, the stone-banked lobes show similar trends in all the investigated sites, although at James Ross Island the differences between tread and riser are much more evident than at Northern Victoria Land.

Acknowledgments

Thanks to PNRA for the logistical support in Victoria Land. Thanks to DNA, PNRA and IAA for their logistical support and cooperation in Maritime Antarctica, with special reference to Dr. Jorge Strelin, Dr. Toni Curtosi, and Dr. Rodolfo del Valle. We want to thank also Enrique Serrano and an anonymous reviewer for their precious suggestions and comments.

Rainfall-Runoff Hydrograph Characteristics in a Discontinuous Permafrost Watershed and Their Relation to Ground Thaw

Sean K. Carey
Department of Geography and Environmental Studies, Carleton University, Ottawa, Ontario, Canada K1S 5B6

Chris M. DeBeer
Centre for Hydrology, University of Saskatchewan, Saskatoon, Saskatchewan, Canada S7N 5C8

Abstract

Rainfall-runoff hydrographs were analyzed for 49 rainstorms over 5 years in a 7.6 km^2 alpine discontinuous permafrost watershed to assess the effect of seasonal thawing on hydrograph parameters. Hydrographs were analyzed for 11 common characteristics including runoff ratio, initial abstraction, recession coefficient, and several parameters related to shape of the hydrograph. Runoff ratios varied between 0 and 0.33 (average 0.09) and declined throughout the summer, reflecting increased active layer storage. Hydrograph recessions were steeper immediately post-freshet and flattened as the summer progressed, as flow pathways descended into soils with lower transmissivities. There was no relation between antecedent wetness and timing response, indicating that saturated areas of the catchment exist near the stream throughout the season, facilitating rapid runoff. Results indicate that at this scale, permafrost and active layer depth exert a strong influence on the stormflow hydrograph.

Keywords: discontinuous permafrost; hydrograph analysis; hydrology; recession; runoff.

Introduction

Watersheds underlain with discontinuous permafrost show a high degree of spatial variability in the timing and magnitude of hydrological processes (Carey & Woo 2001a, Spence & Woo 2003). Due to the relatively impermeable nature of permafrost, percolation is restricted and the soil storage capacity reduced, resulting in greater volumes of event water (both meltwater and rain) being conveyed to the stream from perched unconfined aquifers (Quinton & Marsh 1998, Carey & Woo 2001b). Following snowmelt, thaw of seasonally frozen ground increases the thickness of the active layer, enhancing basin storage and altering flow pathways (Bowling et al. 2003, Carey & Quinton 2004). As the ground thaws, the water table descends into deeper soil layers with reduced saturated hydraulic conductivity, stormflow response is dampened. In contrast, catchment areas without permafrost infiltrate and percolate meltwater and rainwater to the deeper regional groundwater table without generating significant lateral flow.

Rainfall-runoff events in permafrost basins are flashy, with accentuated peaks, extended recessions, and low baseflow contributions (Dingman 1973, McNamara et al. 1998). The mechanisms of runoff production in permafrost catchments has emphasized rapid surface and near-surface flow in porous organic soils that are ubiquitous surface cover, preferential flow pathways through interconnected surface depressions, soil conduits, and rills, particularly during the snowmelt period (Hinzman et al. 1993, McNamara et al. 1998, Quinton & Marsh 1999, Carey & Woo 2001a). As the active layer thaws and the saturated layer descends, rapid runoff declines and these runoff pathways become less effective in conveying water to the drainage network. In addition to changes in vertical soil hydraulic properties, the areal extent of runoff generation declines following snowmelt. When the saturated layer resides within near-surface organic soils, water from slopes and upland areas can be conveyed rapidly to the stream and the source area for runoff generation is relatively large and the basin is highly connected. However, as the water table drops into the mineral substrate, hill slopes and areas away from the stream become disconnected, reducing the contributing source area (Carey & Woo 2001b). The total percentage of the basin underlain by permafrost is important as seasonally frozen soils have predominantly vertical water flux throughout the year, and basin comparison studies in zones of discontinuous permafrost reveal significant differences in streamflow properties and hydrochemistry based upon permafrost disposition (McLean et al. 1999, Petrone et al. 2007).

A significant amount of research in discontinuous permafrost environments has investigated runoff mechanisms at the hillslope or plot scale (Carey & Woo 2001b, Spence & Woo 2003). This process information has not been linked to larger scale basin flow attributes. For example, in a continuous permafrost environment, McNamara et al. (1998) studied temporal variations in runoff properties over a cascading range of watershed scales and related hydrograph characteristics to the influence of permafrost. A similar exercise in discontinuous permafrost environments would provide validation that processes operating at small scales are manifested in the streamflow hydrology at the basin scale.

Hydrograph analysis continues to be a widely utilized and practical assessment tool of basin storages and in the calibration of many hydrological models (i.e. Tallaksen 1995, Szilagyi & Parlange 1998). Response times, runoff ratios and recession parameters provide first-order information as to catchment functioning. In this regard, hydrograph analysis remains a useful tool to evaluate whether conceptual and numerical models of runoff generation derived from plot and slope studies are applicable to the entire catchment, which integrates areas of seasonal and permafrost soils. It is the objective of this paper to evaluate five years of summer stormflow data to improve understanding of how heterogeneous discontinuous permafrost basins deliver water to the stream. Hydrograph parameters will be compared with precipitation characteristics and antecedent conditions such as flow and time of year (as a surrogate for ground thaw). The influence of increased basin storage on rainfall-runoff relations will be determined and results compared with knowledge of processes at smaller scales. The snowmelt period will not be considered.

Study Area

The study was conducted within Granger Basin (60º32′N, 135º18′W), a small headwater catchment of the Wolf Creek Research Basin, located approximately 15 km south of Whitehorse, Yukon (Fig. 1). The climate is subarctic continental, which is characterized by a large temperature range, low relative humidity, and low precipitation. Mean annual (1971–2000) temperature at the Whitehorse airport (706 m above sea level) is -0.7ºC, with mean January and July temperatures of -17.7ºC and +14.1ºC, respectively, although winter and summer extremes of -40ºC and 25ºC are not uncommon. Mean annual precipitation is 267.4 mm, of which 145 mm falls as rain.

The drainage area of Granger Basin is approximately 7.6 km^2, and the elevation ranges from 1310 to 2250 m a.s.l. The lower half of the basin and most of the stream channel has a fairly gentle slope (~4°), however the upper portion of the basin is considerably steeper (~15-25°). Throughout the basin there are several small (~0.01 km^2) ponds, and a permanent snowpack near the summit of Mount Granger.

Granger Basin lies within alpine and shrub-tundra ecological zones, with vegetation consisting predominantly of various willow (*Salix spp.*) and birch (*Betula spp.*) shrubs. A significant portion of the upper basin on the slopes of

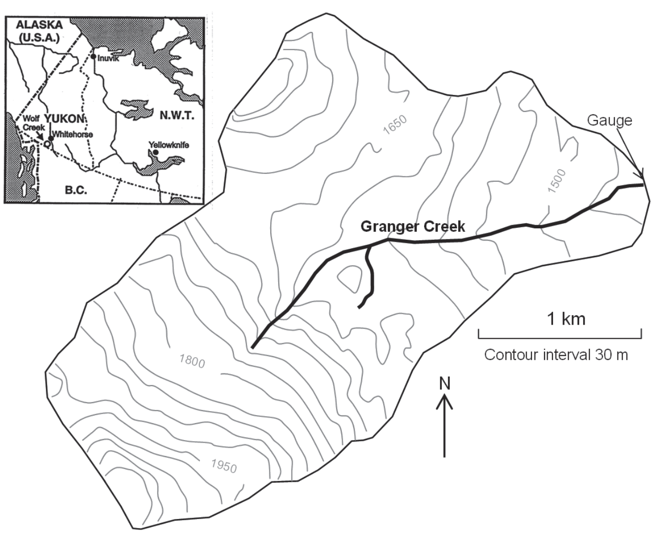

Figure 1. Map of Granger Basin. Inset is location within northwestern North America.

Mount Granger is covered with talus and bedrock outcrops. The lithology of the basin is predominantly sedimentary, comprising limestone, sandstone, shale, and conglomerate. A mantle of glacial till overlies most of the bedrock, ranging up to several meters in thickness. Fine-textured alluvium is found along much of the valley floor where the main channel resides, while colluvial deposits are more common along upper slopes away from the main valley. Soils are primarily orthic eutric brunisols with textures ranging from sandy loam to gravelly sandy loam. These are fairly well-drained soils with coarse parent materials. Surface organic soils range from 0.1 to 0.4 m in thickness, and are deepest in riparian areas and north-facing slopes throughout the basin, becoming thinner and more scattered in higher elevation and south-facing areas. Using the BTS method, it is estimated that approximately 70% of the basin is underlain with permafrost (Lewkowicz & Ednie 2004).

Methodology

Field data

Spring and summer discharge data were collected for Granger Creek over five years from 1999 to 2003 using an electronic stage recorder (Ott) placed inside a stilling well at the basin outlet. Measurements of stage were recorded at 15-minute intervals. A stage-discharge rating curve was developed by manual gauging of the stream at least 10 times per year. Rainfall data were collected using a Texas Instruments tipping bucket rain gauge, part of a nearby meteorology station (Fig. 1), measured rainfall depths in 0.1 mm increments and summed to the total number of these increments of each 30-minute period.

Hydrograph analysis

Hydrographs selected for analysis were taken after the snowmelt period (15 June) to eliminate diurnal fluctuations and mixed runoff signals. Visual inspection of the hydrographs was used to determine which events were suitable for analysis, and the selection criteria was based on distinct and isolated response events. In most cases, only storms >4 mm with one continuous or near continuous (<1 hour of no precipitation) event were chosen. In certain instances, additional precipitation following the peak in discharge prevented the determination of certain response factors. In these cases, the multiple input and flow peaks were treated as a single event to calculate runoff ratios and recession trends. Selected hydrographs were then isolated and analyzed separately.

The separation of stormflow runoff, *R*, and baseflow components was carried out using a straight line drawn from the initial rise in flow to the point of greatest curvature on the recession limb (Fig. 2). The rational for this procedure was that previous research in permafrost environments had justified this method based upon the properties of permafrost soils (McNamara et al. 1998, Carey & Woo 2001b).

Hydrograph parameters were determined as shown in Figure 2. Input starts at time t_{w0} and ends at time t_{we}, and total storm duration, T_w is given by, $T_w = t_{we} - t_{w0}$. Total precipitation

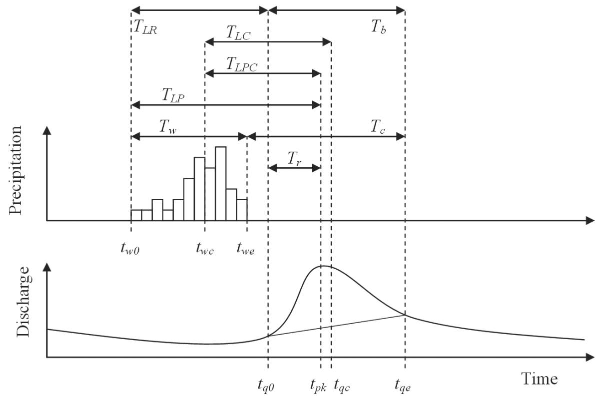

Figure 2. Hydrograph and precipitation parameters measured for analysis. Terms are provided in the text below.

is P_t. Stream response begins at time t_{q0} and ends at time t_{qe}, peaking at time t_{pk}. The time duration of the storm hydrograph is $T_b = t_{qe} - t_{q0}$. The time of rise specifies the period of increasing discharge, or rising limb, and is determined as: $T_r = t_{pk} - t_{q0}$. Time of concentration, T_c, defined as the time required for the water to travel from the most hydraulically distant part of the contributing area to the basin outlet is: $T_c = t_{qe} - t_{we}$. The time between the beginning of input and the initial hydrograph response, known as the response lag is: $T_{LR} = t_{q0} - t_{w0}$. Initial abstraction, P_{abst}, is as precipitation that falls prior to the initial rise in the storm hydrograph. The lag to peak discharge, T_{LP}, measures the time between the beginning of input and the hydrograph peak: $T_{LP} = t_{pk} - t_{w0}$. The center of mass, or centroid, of both input and runoff is useful in characterizing time lags. In determining the centre of mass, or centroid, for the input hyetograph, t_{wc}, the input values, W_i, measured for i = 1, 2, n time periods of equal length as:

$$t_{wc} = \sum_{i=1}^{n} W_i t_i \Big/ \sum_{i=1}^{n} W_i \tag{1}$$

The centroid of the response hydrograph, t_{qc}, is determined in the same fashion, summing the event-discharge-weighted time values for equal length periods, and dividing by the sum of the event discharge values for each period:

$$t_{qc} = \sum_{i=1}^{n} Q_i t_i \Big/ \sum_{i=1}^{n} Q_i \tag{2}$$

The centroid lag is defined as the period of time between the respective center of mass of the input and runoff events: $T_{LC} = t_{qc} - t_{wc}$. The centroid lag to peak is the interval from the input center of mass to the peak discharge: $T_{LPC} = t_{pk} - t_{wc}$.

Hydrograph recessions were analyzed for all of the selected stormflow events. The recession curve conveys information about watershed characteristics and storage properties, as it represents the natural storage that feeds the stream after the input has ceased. Numerous studies have focused attention on this part of the hydrograph, and many models have been develop to describe the decline in streamflow because of the importance in certain areas of hydrological application, including forecasting and water resource planning (see Tallaksen 1995 for review). Additionally, recession analysis has been used widely in permafrost environments (Dingman 1973, McNamara et al. 1998, Carey & Woo 2001b).

The most basic model for describing the recession is the linear-reservoir model of response, where water storage recharge and evaporation are neglected, given as:

$$q = q_0 e^{(-t/t^*)} \tag{3}$$

where q is discharge, q_0 is the discharge at $t = 0$ (the beginning of the recession), t is time, and t^* is the recession parameter, also known as the turnover time, that describes the decay for the draining aquifer. The linear-reservoir model of watershed response has the advantage that it is simple and that t^* is a widely used parameter for inferring watershed characteristics. However, this model is recognized as being valid over a limited range of the recession period (Tallaksen 1995).

Results

Post-freshet hydrographs (15 July to 15 September) are shown above in Figure 3. The interruption in the hydrographs in August 2003 was due to mechanical failure of the logger. Maximum annual flows occurred during snowmelt freshet (not shown) in May and early July when 30 to 50% of the annual precipitation was released over a several-week period. Following freshet, streamflow gradually declined throughout the summer and fall, with rainfall-runoff stormflow events superimposed on the seasonal recession. Discharge rates were typically below 0.4 m^3s^{-1} following snowmelt, and gradually declined to ~0.05 m^3s^{-1} before stream gauging ceased prior to freezing. The 2000 hydrograph shows greater flows than other years, with baseflow rates of ~0.25 m^3s^{-1} in early summer, which later rose to 0.3 m^3s^{-1} triggered by a series of storms in late August. By late September 2000, the flow rate had fallen to ~0.2 m^3s^{-1}.

Rainfall from 15 June to 15 September over the five years was 141, 234, 141, 130, and 129 mm for 1999 to 2003, respectively. In 1999, 2001, and 2002, ~8 rainfall events following the snowmelt period were >4 mm in magnitude, whereas 2000 and 2003 were wetter with 15 and 13 events >4 mm, respectively. The average rainfall for all storms (including those not analyzed) over all years was 8.1 mm with a maximum of 31.8 mm. Rainfall intensities varied from 0.2–2.6 mm hr^{-1}, averaging 0.8 mm hr^{-1}. Storms selected for analysis ranged between 2 and 48 hours with an average of 6 hours.

Hydrograph timing response

During the 5-year study period, 49 rainfall-runoff stormflow events passed the selection criteria and were analyzed for response lags and time durations. A summary of the hydrograph parameters is presented in Table 1. A Spearman rank (Sr) correlation coefficient matrix ($p < 0.05$) of all measured variables was performed to explore relations among hydrograph parameters, rainfall and date (Table 2). Response lags (T_{LR}) ranged between 0 and 11.2 hours, with an average time of 2.4 hours. McNamara et al. (1998) reported a mean response time of 2.15 hours (range 0–6

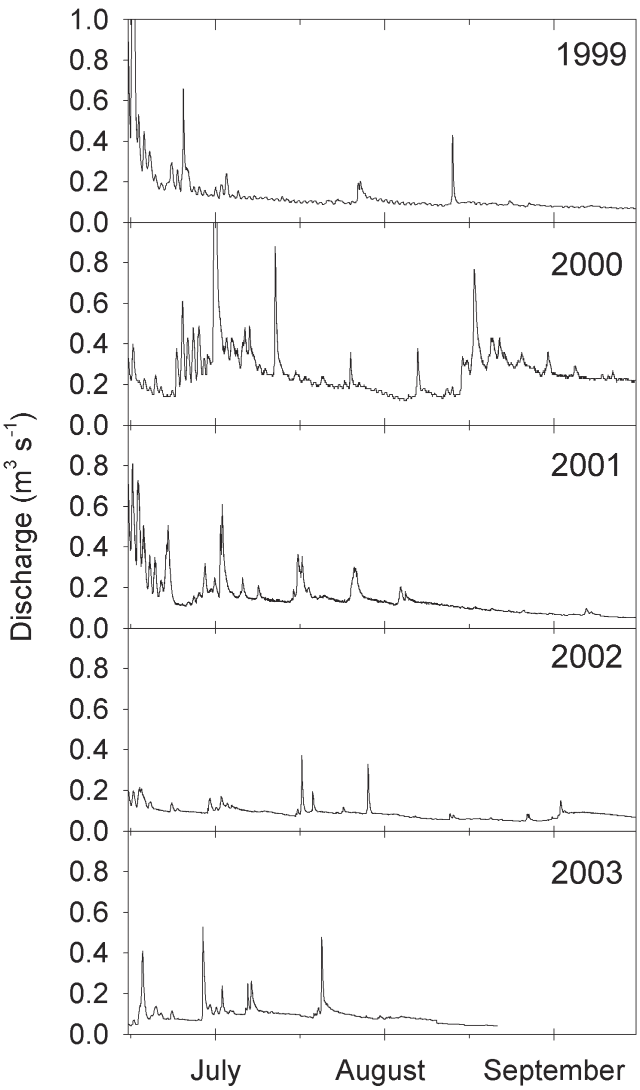

Figure 3. Post-freshet hydrographs (15 June–15 September) for Granger Basin, 1999–2003.

hours) for Imnavait Creek, a continuous permafrost basin (2.2 km²) in northern Alaska. Compared with temperate basins, the average response time was rapid, and the results are consistent with Church (1974) who also reported that rapid response times are a characteristic of northern rivers.

Initial abstractions (P_{abst}) were low, ranging from 0 to 4.1 mm with an average of 1.1 mm. An unexpected significant positive relation existed between P_{abst} and antecedent discharge, (Q_{ant}) (Sr = 0.32), indicating that more water was abstracted when the catchment was wettest. On the other hand, watershed wetness as represented 5-day antecedent rainfall (P_{5day}) showed no relation with P_{abst}. A lack of correlation between P_{abst} and wetness indices has been reported previously for subarctic and arctic watersheds (Dingman 1973, McNamara et al. 1998, Carey & Woo 2001b), and is typically attributed to limited subsurface storage capacity due to the presence of permafrost.

The time of rise (T_R) for most hydrographs was similar to the duration of precipitation (T_W). The lag to peak (T_{LP}), centroid lag to peak (T_{LPC}), and centroid lag (T_{LC}) were short,

Table 1. Summary of hydrograph parameters for 49 storms. Terms are defined in text.

Hydrograph Parameter	Mean	Standard Deviation	Maximum	Minimum
R/P_t	0.09	0.09	0.33	0.00
t^* (h)	41.70	32.20	163.10	7.70
P_{int} (mm)	0.79	0.84	5.20	0.18
P_{abst} (mm)	1.05	0.96	4.10	0.00
P_{5d} (mm)	7.72	6.81	29.30	0.00
T_w (h)	12.19	8.70	46.00	0.50
T_{LR} (h)	2.44	2.72	11.25	0.00
T_r (h)	9.56	6.52	33.50	2.00
T_{LP} (h)	11.83	6.47	34.75	3.50
T_{LPC} (h)	5.80	3.38	18.75	0.36
T_{LC} (h)	8.07	3.15	16.10	1.37
T_b (h)	25.21	13.81	72.50	6.50
T_c (h)	15.29	7.97	45.50	4.00

with averages of 11.8, 5.8, and 8.1 hr, respectively. This is in contrast to values of T_{LP} and T_{LC} of 17.8 and 34.8 hr for Imnavait Creek reported by McNamara et al. (1998). The centroid lag for Granger Basin was closer to the average of 19.5 hr reported by Holtan & Overton (1953) in a study of 40 streams in the conterminous United States, ranging from 76 km² to 3200 km² in basins that are much larger than the study catchment. Both T_{LP} and T_{LC} were positively correlated (Sr = 0.31 and 0.29, respectively) with Q_{ant}.

Runoff ratios (R/P_t) were highly variable, ranging between 0 and 0.33, with an average of 0.1. These values were low when compared with studies from other permafrost basins and hill slopes (Dingman 1971, Slaughter et al. 1983, Woo 1983, McNamara et al. 1998, Carey & Woo 2001b). Seasonally, higher runoff ratios were associated with early periods following melt when the frost and water table was near the surface, and ratios progressively diminished as summer progressed and the active layer thickened (Fig. 4a). A strong negative relationship existed between runoff ratio and Julian Day (Sr = -0.74). Runoff ratio increased with Q_{ant} (Sr = 0.55), yet there was no significant relation between runoff ratio and P_{5day}. Additionally, there was no relation between runoff ratio and total rainfall and rainfall intensity.

Streamflow recessions

Hydrograph recessions were observed to be temporally variable, with steeper recession limbs characteristic of earlier season discharge events that flattened out as summer progressed (Fig. 4b). Values of the t^* parameter ranged between 7.7 and 163.1 hr with an average of 41.7 hr, which compared well with other permafrost and organic-covered permafrost basins of similar area. For example, Dingman (1971) reported an average t^* of 39 hours for Glenn Creek, Alaska, while McNamara et al. (1998) found this value to be 30.2 hours for Imnavait Creek. There was a strong positive relationship between t^* and Julian Day (Sr = 0.69) indicating that as the season progresses and soils thaw, runoff reached the stream through deeper, less conductive soils. As would be expected, t^* increased with decreasing runoff ratio (Sr =

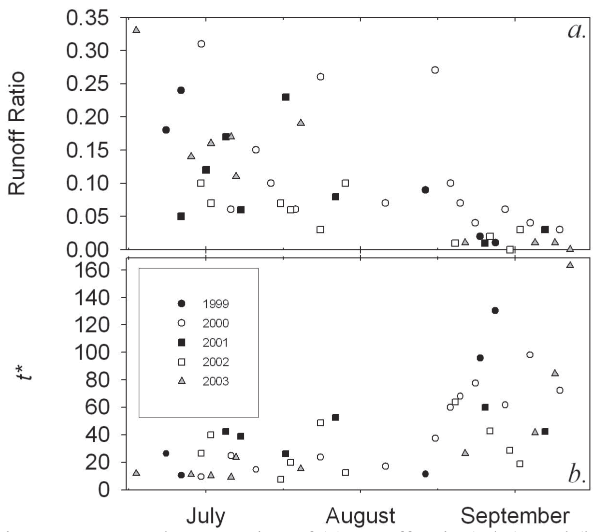

Figure 4. Seasonal progression of (a) runoff ratio (R/P_t), and (b) recession parameter, $t*$, for 49 stormflow events between 1999 and 2003.

-0.66). Recession constants were compared with total rainfall (P_t), antecedent wetness indices (Q_{ant}, P_{5day}), and other storm characteristics to assess for any influence of input volume, intensity, or watershed wetness, yet these relations were poorly defined and not statistically significant at the 95% confidence level.

Discussion and Conclusion

Simple analysis of stormflow hydrographs provide useful insight into the dynamics of runoff generation as permafrost-underlain catchments, unlike more temperate catchments, undergo significant physical changes throughout the summer due to ground thaw. For example, the decline in runoff ratio implies a widespread increase in soil storage capacity as the active layer becomes thicker and soils dry. Large rainfall events late in the summer must overcome significant storage deficits to generate even small volumes of runoff. Increasing $t*$ indicates water inputs take progressively longer to reach the stream due the gradual deepening of the flow pathways into less transmissive soil layers. Results from Granger Basin compare well with others reported in permafrost regions (Dingman 1973, Slaughter et al. 1983, McNamara et al. 1998) and support conceptual models of runoff generation being controlled by the relation between frost and water table positions for this environment (Carey & Woo 2001b).

Hydrograph lag-time indices had little correspondence with time of year or wetness, implying at the basin scale, these variables were not controlled explicitly by permafrost-related processes, but rather to other catchment characteristics (which may be affected by the presence of permafrost). The lack of correlation between response lags (T_{LR}), initial abstractions (P_{abst}), and measures of basin wetness such as antecedent discharge (Q_{ant}) and 5-day rainfall (P_{5day}) indicate that certain areas of the basin (footslopes of permafrost-underlain slopes and riparian areas) remain wet, contributing water rapidly to the stream after rainfall begins. The spatial extent of these wet areas expands and contracts away from the stream based on time of year and basin wetness, which is reflected by the declining trend in runoff ratios (R/P_t) throughout the summer. This process is similar to that reported by Quinton & Marsh (1998) and Carey & Woo (2001b), whereby hill slopes become effectively disconnected from the stream as the season progresses.

The recession coefficient, $t*$, was strongly related to time of year and runoff ratio, yet had no relationship with precipitation characteristics. Shallow thaw depths in the early summer lead to rapid drainage of the slopes through near-surface organic soils and preferential pathways that are well-linked. As the active layer deepens, the water table descends atop the frost table, and rainfall is able to percolate into deeper, less permeable, mineral soils. The hydraulic conductivity of mineral soils is typically orders of magnitude less than organic soils (Carey & Woo 2001b), resulting in increased transmission times to the stream and larger $t*$.

Hydrograph parameters investigated in Granger Basin, a discontinuous permafrost alpine basin, indicate that at the headwater scale, streamflow response reflects the influence of permafrost throughout the post-freshet season. Hydrological models that use these parameters in calibration must consider their temporal dependent nature.

Abstract

Under global warming scenarios, the traditional method of simply increasing the thermal resistance by raising the embankment height and using insulating materials has been proven ineffective in warm and ice-rich permafrost areas and, therefore, could not be used in the Qinghai-Tibet Railway engineering. Instead, an alternative "cooled-roadbed" approach was developed and used to lower the ground temperature in order to maintain a perennially frozen subgrade. The concept that local and site-specific factors play an important role in the occurrence and disappearance of permafrost has helped us to devise a number of measures to cool down the roadbed. For example, we can adjust and control heat transfer by using different embankment configurations and fill materials. The Qinghai-Tibet Railway project demonstrates that a series of alternative roadbed-cooling methods can be used to lower the temperature of permafrost beneath the embankment and to stabilize the roadbed. These methods include solar radiation control using shading boards, heat convection control using ventilation ducts, thermosyphons, air-cooled embankments, and heat conduction control using "thermal semi-conductor" materials, as well as combinations of the above-mentioned three control measures. This roadbed-cooling approach provides not only a solution for engineering construction in sensitive permafrost areas, but also a countermeasure against possible global warming.

Keywords: cooled roadbed; global warming; Qinghai-Tibet Railway; warm permafrost.

Introduction

The Qinghai-Tibet Railway, 1142 km from Golmud to Lhasa, crosses 632 km of permafrost terrain of which 275 km is warm permafrost (mean annual ground temperature between 0 and -1°C) and 221 km is ice-rich permafrost (ice content >20% by volume). The section that is underlain by both warm and ice-rich permafrost is 134 km in distance (Wu et al. 2002). At the beginning of the Qinghai-Tibet Railway project, Chinese scientists and engineers were confronted with two unfavorable factors: the "warm" nature of the plateau permafrost and scenarios of global warming. Finding a solution for building the railway and keeping it operational and stable under such conditions became one of the greatest challenges (Cheng & Wu 2007). Observations along the Qinghai-Tibet Highway indicate that, after the road surface was paved with asphalt, talik pockets developed in 60% of the paved sections due to increased thawing. All that happened in warm permafrost areas. Approximately 85% of the damage to highway embankments is caused by thaw settlement of ice-rich permafrost (Wu et al. 2002). The performance of the Qinghai-Tibet Highway and other engineering structures in permafrost areas indicates that the traditional design method of simply increasing the thermal resistance by raising the embankment height and using insulating materials can no longer meet operational and safety needs. An alternative "cooled-roadbed" approach was developed and used to lower the underlying ground temperature, especially in areas of warm and ice-rich permafrost. Otherwise, it is difficult to maintain a stable roadbed (Cheng 2004a, 2005a). It has long been known that local and site-specific factors (e.g., slope aspect, soil type, etc.) have a significant impact on the occurrence and disappearance of permafrost. With the same concept, we devised and used a number of measures to cool down the roadbed for the Qinghai-Tibet Railway. These methods include adjusting and controlling the amount of solar radiation, heat convection, and heat conduction, as well as combinations of the above-mentioned measurements, by using different embankment configurations and fill materials (Cheng 2004b, 2005b).

Controlling Solar Radiation

The combination of low latitude and high altitude makes solar radiation on the Qinghai-Tibet Plateau one of the strongest in the world. Shading the surface from solar radiation can effectively lower the ground temperature (Kondratyev 1996). Feng et al. (2006) investigated the effect of awnings and measured the ground surface temperature at 14:00 over the course of a one-year period at the Fenghuoshan area. The surface temperature was 8–15°C lower inside the awnings than outside, and the maximum temperature difference can reach 24°C. But awnings are not suited on the plateau due to the strong wind. Consequently, shading boards were

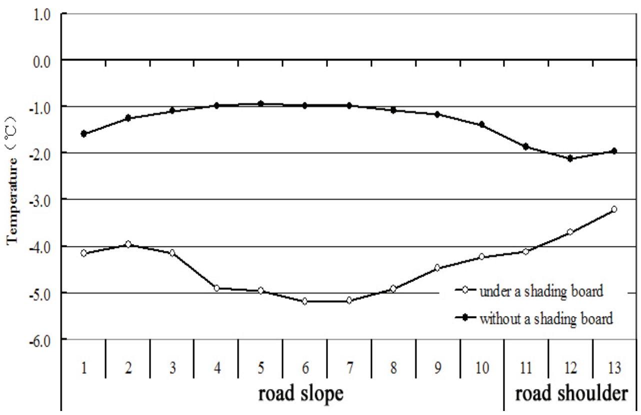

Figure 1. The variation of soil temperature under a shading board.

installed on embankment side slopes at Beiluhe to study the cooling effect. Observations show that the mean annual slope-surface temperature under the board was 3.2°C lower than that outside the board (Fig. 1) and 1.5°C lower than that of the natural ground surface (Yu et al. 2007a).

The original embankment fill may become loose and weak after undergoing repeated freeze–thaw cycles. Shading boards can reduce the number of these cycles and can also protect the embankment from the impact of wind action and erosion caused by the rain.

Altering Convection Patterns

Crushed rocks, ventilation ducts, and thermosyphons (or thermal tubes) were used in the Qinghai-Tibet Railway engineering to adjust and control convection patterns within embankments (Fig. 2).

Crushed rocks

On the Qinghai-Tibet Plateau, crushed rocks over permafrost act as "thermal semi-conductor" materials. In winter, the air is colder than permafrost; this induces R-B convection within the crushed rocks. As a result, permafrost releases heat into the air. In summer, the air is warmer than permafrost. Since the cold air is heavier and sinks to the bottom, no convective heat transfer takes place, and heat exchange is mainly in the form of conduction. Because of the small contact areas between the crushed rock and the low thermal conductivity of the air, the crushed rocks act as thermal insulators and reduce the amount of heat gained by the underlying permafrost from the air. The imbalance of increased heat releases in winter and reduced heat gains in summer produces a net heat release over the course of one year and thus lowers the underlying ground temperature (Cheng & Tong 1978, Goering & Kumar 1996, Goering 2003, Cheng et al. 2007a). When crushed rocks are placed on sloping surfaces, the chimney effect develops if the slope angle is sufficiently big. This chimney effect also lowers the underlying ground temperature (Cheng et al. 2007a).

On the Qinghai-Tibet Plateau, wind speeds are stronger in winter than in summer; 75% of the strong winds occur in winter. Therefore, wind-forced convection in crushed rocks

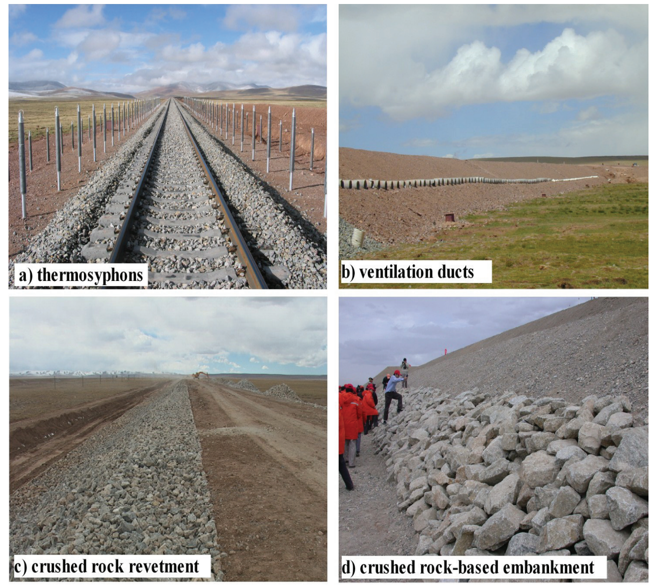

Figure 2. Measures adjusting and controlling convection.

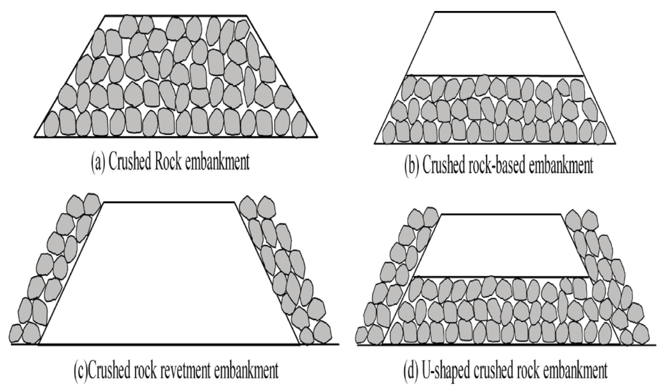

Figure 3. Different types of crushed-rock embankment.

is greater in winter than in summer, causing a cooling effect in the underlying ground (Cheng et al. 2007b).

The use of crushed rocks in embankments during the Qinghai-Tibet Railway construction took several different forms and configurations: crushed-rock embankment, crushed rock-based embankments, crushed-rock revetments embankments, and U-shaped crushed-rock embankments (Fig. 3).

Crushed rock-based embankments

The railway design standard in China requires that the soil layer beneath the railroad tracks be at least 2.5 m thick. A rock layer is often placed at the base of the embankment, so a crushed-rock embankment (Fig. 3a) is changed into a crushed rock-based embankment (Fig. 3b). This type of embankment covers 130 km of the Qinghai-Tibet Railway. The base of the embankment is usually between 1.0 and 1.2 m thick and consists of crushed rocks of 20–30 cm in diameter. The overlying soil layer ranges in thickness from 2.5 to 10 m.

Ground temperature monitoring was carried out on rock-based embankments at seven sites. Monitoring data

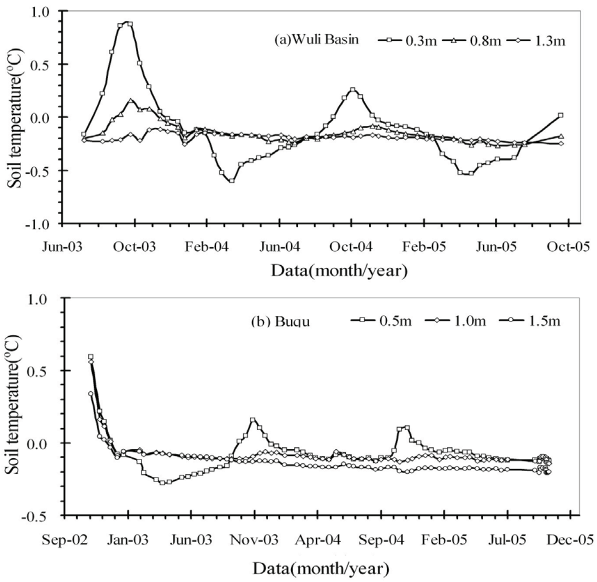

Figure 4. The variation of soil temperature under crushed rock-based embankment in warm permafrost areas.

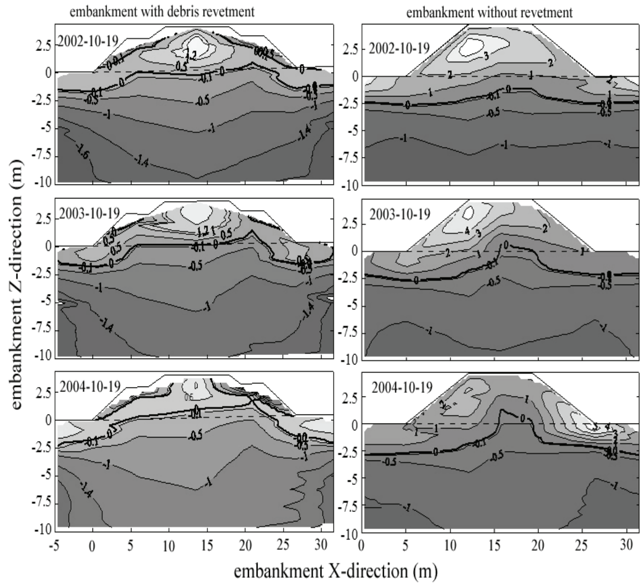

Figure 5. Comparison of soil temperatures under embankment with and without crushed-rock revetment.

indicates that the permafrost table beneath the embankment had raised at most sites by as much as between 1.8 and 2.6 m. Ground temperature near the permafrost table showed a cooling trend. However, at Wuli Basin and the Buqu River, where the mean annual ground temperature is warmer than -0.5°C, the ground temperature near the permafrost table did not show a clear cooling trend (Wu et al. 2006a) (Fig. 4), indicating that the cooling effect of crushed rocks is greatly reduced due to the overlying soil layer. Therefore, we cannot rely on the rock-based embankment alone to ensure a stable roadbed; additional cooling techniques are required.

A comparison study was made on the cooling effect of open and closed crushed rock-based embankment at Beiluhe. *Closed* means that the crushed rocks on the embankment side slopes are covered with a soil layer of 20 cm thick. *Open* means that the crushed rocks are not covered by a soil layer and are exposed to the air on either side of the embankment. At Beiluhe, the crushed-rock layer at the base is 1.2 m thick, consists of crushed rocks of 20–30 cm in diameter, and is overlain by a 2.5 m thick soil layer. At this site, wind speeds are also much higher in winter than in summer. For example, the average wind speed in winter is 5–8 m/s and is mainly from the east-northeast, roughly perpendicular to the embankment. The average wind speed in summer is 2–3 m/s and is mainly from the north-northwest. Observations indicate that, due to the overlying soil layer, natural convection in the closed rock layer is weak. On the other hand, the wind-forced convection dominates and is strong in the open crushed-rock layer. In the open crushed-rock layer, natural convection takes place in winter only when the wind speeds are low. Wu et al. (2006b, 2007) conclude that open crushed-rock layers at the base of the embankment have a greater cooling effect than its closed counterparts, because the ground temperature beneath open rock layers is 2–4°C lower than that beneath closed rock layers.

Crushed-rock revetments embankment

Crushed rocks are placed on embankment side slopes to cool down the roadbed (Fig. 3c). Approximately 37 km of the embankment along the Qinghai-Tibet Railway is covered with crushed-rock revetments. The revetment is 80–100 cm thick and is made up of crushed rocks of two different sizes: 8–10 cm and 20–30 cm in diameter.

A comparison is made between embankments with and without crushed-rock revetments at Beiluhe on the Tibet Plateau. At this site, the mean annual air temperature is -3.8°C, and the mean annual ground temperature is between -1.4 and -1.6°C. Two different rock sizes are used in the revetment. The side slopes of one section of the embankment are covered with rocks 5–8 cm in diameter. The revetment is 80 cm in thickness and is 4.1 m in height. A neighboring section is covered with rocks of 40–50 cm in diameter. The revetment is also 80 cm in thickness and is 4.8 m in height. The height of the traditional embankment (without a crushed-rock revetment) is 4.5 m. Temperature readings were taken from the 10 cm depth below the crushed-rock surface. The results show that summer temperature in the crushed-rock (5–8 cm in size) revetments, regardless of their aspect, is lower than that of the unrevetted counterparts, due to the insulating action of crushed rocks. In winter, the opposite is true, indicating the development of air convection in rock revetments (Saboundjian & Goering 2003). Temperature measurements from boreholes drilled at the center of the general and crushed-rock (5–8 cm in size) revetment embankments indicate that the magnitude of temperature decrease in the revetment embankment is greater than that in the general embankment. The temperature within 2 m of the surface is still decreasing under the revetment embankment, displaying a greater cooling effect (Fig. 5). Three years after completion of the above embankments, the permafrost table had risen slightly into the unrevetted embankment.

In contrast, the permafrost table had moved well into the embankment fill for most of the embankments with crushed-rock (40–50 cm in size) revetments. The overall temperature in the crushed-rock revetment embankment is lower than that in the general embankment. This demonstrates the cooling effect of crushed-rock (40–50 cm in diameter) revetments (Sun 2006).

Laboratory models and field data indicate that placing rock revetments of different thicknesses on embankment side slopes can reduce the differential thaw depth. This may help prevent differential thaw settlement and longitudinal cracking in the embankment (Yu 2006).

U-shaped crushed-rock embankments

As the cooling effect of crushed rocks is reduced due to the overlying soil layer, crushed rocks are placed on side slopes of rock-based embankments to form U-shaped crushed-rock embankments (Fig. 3d) in order to strengthen the thermal stability. Although it is too early to draw any conclusions, preliminary results show that it has an even greater cooling effect than both the rock-based and rock-revetted embankments (Ma et al. 2007).

Zhang et al. (2005, Niu et al 2006) completed a numerical simulation on three different embankments: the traditional embankment with ballasts, the rock-based embankment, and the U-shaped crushed-rock embankment. The objective was to evaluate the impact of future climatic warming on the embankment thermal regime. The model assumes an increase of 2.6°C in mean annual air temperature over the next 50 years. The initial mean annual air temperature used in the model is -4.0°C. The embankment height is 5.0 m; crushed rocks are 10 cm in size; the crushed-rock layer at the base is 1.5 m thick; the overlying soil layer is 3.5 m thick; the rock revetment is 1.6 m thick. The model shows that in 50 years, the permafrost table under the traditional embankment will be lowered to a depth of 7.4 m, and this will reduce the stability of the embankment due to the thaw settlement and subsidence. The permafrost table under the rock-based embankment will be very close to the natural ground surface, but its overall temperature will be warm and close to 0°C. For the U-shaped rock embankment, the permafrost table will be above the natural ground surface and in the base layers of crushed rocks. The overall temperature will be 0.25–0.3°C lower than the rock-based embankment, improving the thermal stability.

The crushed rocks layer used in the Qinghai-Tibet Railway engineering have a cooling impact on the underlying ground, but they are not as effective as theoretically predicted. This may have been caused by fine soil grains within the crushed rocks layer. These soil grains reduce the porosity of the rock layer and thus decrease the cooling effect. Fine-grained soils can find their way into the crushed-rock openings during the construction; wind can also blow them into the openings. Necessary measures should be taken in the future to prevent this from happening.

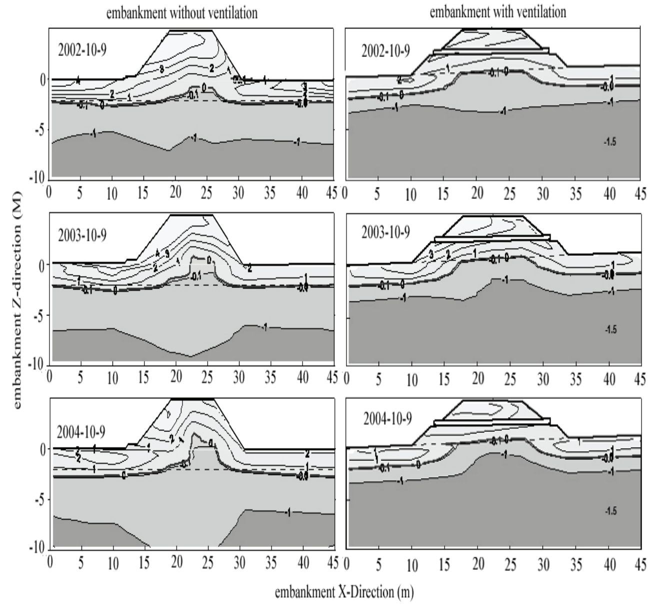

Figure 6. Comparison of soil temperature under embankment with and without ventilation ducts.

Ventilation ducts

Field experiments on ventilation ducts were carried out using PVC and concrete ducts at Beiluhe (Fig. 2b). These ducts are either 30 cm or 40 cm in diameter; the distance between two neighboring ducts is 2 times the duct diameter. They are buried into the embankment 0.5–0.7 m from the original ground surface.

The mean annual air temperature on the Tibet Plateau is, on average, about 3°C colder than the mean annual ground surface temperature. Consequently, embedding air ducts in embankments can effectively lower the underlying ground temperature. Field observations show that air ducts do lower ground temperatures. Ventilation ducts buried below and near the original ground surface have a greater cooling impact than those buried in higher positions (Niu et al. 2006). For embankments with ducts buried below and close to the original ground surface, the permafrost table moved up to the same level as the original ground surface three years after embankment construction (Fig. 6). The -1°C isotherm continued to rise, showing a clear cooling trend (Fig. 5). Temperature data indicate that the air temperature within the ventilation ducts is just 1.6–1.8°C higher than the air temperature, while the embankment surface temperature is 45°C higher, and the natural ground surface temperature is 2.5°C higher than the air temperature (Niu et al. 2007).

Air ducts increase the heat loss of the underlying soil during winter; they also increase the heat absorbed by the underlying soil in summer. To enhance the cooling effect of air ducts, an experiment was conducted to investigate the impact of a temperature-controlled ventilation system where one or both ends of the air ducts are installed with shutters that open and close automatically with changes in air temperature. The shutter has a temperature sensor and a control unit. It closes when the ambient air temperature is higher than a pre-set value. The temperature data measured from the inner walls of the ventilation ducts indicate that ducts with shutters are 1°C colder than those without. The mean annual ground temperature measured at a depth of 3.5 m beneath the embankment with shuttered air ducts is 0.45°C lower than that beneath the embankment installed with normal air ducts (Yu et al. 2007b).

To further improve the cooling effect, an experiment was carried out on an embankment ventilated by perforated air ducts at Beiluhe. Because of the holes in the duct wall, the heat exchange between the air inside the duct and surrounding soils is greatly increased, and the cooling effect is improved (Hu et al. 2004).

Thermosyphons

Thermosyphons were installed in over 34 km of the Qinghai-Tibet Railway embankment (Fig. 2a). Based upon the embankment height, thermosyphons of different length (7 m, 9 m, and 12 m) were inserted either vertically or at an angle into the shoulder or the foot of side slopes. The lower end is usually 2–3 m below the permafrost table.

Experiments on actual embankments at Qingshuihe show that thermosyphons do lower the ground temperature and make the permafrost table move upwards. As the "radius of influence" of a thermosyphon is about 1.8 m, the suggested distance between the thermosyphons is 3 m (Pan et al. 2003). Numerical modeling suggests that the cooling effect both in the embankment and at the foot of side slopes is greatest when the incline angle of the thermosyphons (installed at the foot of side slopes) is 25–30° (Yang et al. 2006).

Altering Heat Conduction

When water is frozen, its thermal conductivity increases by 4 times, from 0.45 to 2.2 W/m·K. This characteristic of water can be used to manufacture a material with a much greater thermal conductivity in the frozen state than in the thawed state. The material, similar to a "thermal semi-conductor" will lower the ground temperature by increasing heat loss in winter and decreasing heat gain in summer. Yu (2006) completed a laboratory experiment by placing layers of a water-absorbing material, separated by layers of air, in a sealed container. Water was added to the container. The result indicates that, when the material froze, its thermal conductivity changed from 0.11 W/m·K to 1.2 W/m·K, an increase of about 10 times. So far, this study has not been applied to cold regions engineering.

Combined Control Measures

The three different measures (e.g., adjusting radiation, adjusting convection, and adjusting conduction) can be combined in engineering practices to improve the cooling effect.

Dry bridges

Dry bridges totaling 125 km in length were built in ice-rich and extremely unstable permafrost sections along the Qinghai-Tibet Railway. Piles 1.2 m in diameter were buried 25–30 m into the ground to form a solid foundation. Since the dry bridges became operational, the deformation has been less than 2 mm on average, with a maximum of 5 mm.

Dry bridges can lower the ground temperature, as they can shade the ground from the sun; the air can freely flow through it. They possess good mechanical stability and can support heavy loads. They are effective means of ensuring the stability of roadbeds in ice-rich and sensitive permafrost. Dry bridges can also provide a migration route across the railroad for wild animals on the plateau. A numerical simulation on the dry bridge at Qingshuihe shows that the bridge has a cooling effect because the mean annual permafrost temperature under the bridge is lower than that without the bridge (Xiao et al. 2004).

Combining shading boards and crushed-rock revetments

Li et al. (2007) studied a different embankment configuration by combining shading boards with crushed-rock revetments. This configuration not only can shade the embankment from the sun but also can make good use of natural convection in crushed rocks to lower the ground temperature. The shading boards can also reduce the amount of fine-grained soil getting into the openings of crushed rocks. A numerical model was developed for this combined configuration to calculate the optimum values for the shading board height, for the thickness of rock revetments, for the embankment height, and for the size of crushed rocks. Li et al. (2007) proposed an optimum design for this type of embankment configuration.

Combining thermosyphons and insulating board

Wen et al. (2005) numerically simulated another embankment configuration that combines insulating board with thermosyphons. The board is embedded near the base of the embankment (0.5 m above the original ground surface). The model indicates that, assuming a mean annual air temperature of -3.5°C and a 2°C increase in air temperature on the plateau over the next 50 years, the stability of all three types of embankments (e.g., normal embankments, embankments installed with thermosyphons, and embankments with insulating boards) will without exception be compromised. However, if thermosyphons are combined with insulating board, the embankments will have a greater resistance to global warming and will remain stable.

Combining crushed-rock revetments and insulating board

Zhang et al. (2005) studied the effect when insulating board is embedded at a 0.8 m depth beneath the surface of rock-reveted embankments. The numerical model indicates that the temperature measured from the middle portions of the embankment is lower when insulating boards are used.

Conclusions

Under the global warming scenario, the "cooled roadbed" approach must be used for road design and construction in "warm" and ice-rich permafrost. This approach changes the design philosophy from traditional insulation to alternative cooling to better deal with possible global warming.

Combining solar radiation control, heat convection control, and heat conduction control can achieve a better cooling effect on the roadbed. Shading boards, crushed rocks, ventilation ducts, thermosyphons, and dry bridges were all used in the Qinghai-Tibet Railway engineering and have proven successful in lowering the ground temperature and in ensuring the roadbed stability.

Further studies are necessary to quantify and to optimize various measures employed in the Qinghai-Tibet Railway project.

Does Permafrost Deserve Attention in Comprehensive Climate Models?

Abstract

Traditionally, from a climate modeling perspective, permafrost is looked upon as a phenomenon impacted by climate change. However, it is well recognized that thawing permafrost may create climate feedback loops via changes in greenhouse gas emissions and surface hydrology. Only recently, these effects are being introduced in comprehensive climate models. The thermal properties of permanently frozen regions on the other hand have not been much explored in this context, mainly because models rarely resolve soil layers deeper than a few meters. One reason comes from the still rather poor ability of climate models to simulate realistic snowpack behavior, which is vital to allowing for a realistic depiction of below-surface properties. Here, we stress the sensitivities of near-surface atmospheric temperatures to inadequacies in the description of soil processes including retreat of permafrost to deeper layers under warming conditions.

Keywords: global climate; permafrost modeling; regional climate change; systematic errors.

Introduction

A major effort in the development of comprehensive climate models is devoted towards a reduction in systematic errors. In general, the better a model can reproduce in a satisfactory manner observed climate statistics, the higher its credibility in simulating climate change. But the demand for accurate representation of climate variables is changing steadily as the application of models for climate change research and demand for realistic climate projections increase. Efforts in the 1990s were concentrated on getting a realistic energy balance at the top of the atmosphere energy balance, along with a realistic annual cycle in mean climate variables such as mean sea level pressure, temperature, and precipitation. The field has moved forward, and focus is now set on other aspects of the climate system, including the ocean, sea ice, and land-surface processes. Furthermore, higher moments of climate variables are being assessed. This includes, for example, the ability to reproduce observed trends or the entire spectrum of daily precipitation intensities and temperature variables. The understanding of models' ability to reproduce these features has become the cornerstone in identifying model shortcomings and gives a clear hint to the modeler on where to improve model descriptions (e.g., IPCC 2007).

Despite the ongoing improvement of models and the associated enhanced credibility in climate change projections, the deficiencies in the models are still limiting their ability to provide detailed regional projections where systematic errors are indisputable. Examples are errors in the ability to capture the overall distribution of sea ice, the seasonality of snow cover, and more complex inefficiencies due to erroneous atmospheric or oceanic circulation. In applying such models to investigate the influence of anthropogenic climate changes, it becomes vital to keep in mind these model deficiencies as they may leave an imprint on the resulting climate projections. Here we discuss the complexity of such errors and how they may be interpreted. We focus on the role of permafrost as a key to improvement of model behavior in the Arctic and, hence, add to an improved understanding of the future behavior of permafrost in a warming world.

Understanding Modeled Climate Change

Global climate change in the Arctic

The ability to simulate present-day climate conditions by a climate model is well depicted by characteristics of the dynamics of the atmosphere. Hence, if the position of the storm tracks is erroneous, the details of the simulated climate cannot be accurate and must be erroneous even if the model validates well with statistical properties of temperature and precipitation, for example. To a certain extent, it simply must be an artifact of the way the model is constructed and less due to a correct depiction of the physical processes. Thus the ability to simulate aspects of the North Atlantic Oscillation (NAO) and atmospheric blocking events becomes of particular relevance for the Arctic. According to the recent Intergovernmental Panel on Climate Change (IPCC 2007), models have continued to improve in their ability to represent some of the main observed NAO-related characteristics. However, there are still major discrepancies in their ability to represent blocking frequency. The implications of this will tend to manifest themselves in inadequate depictions of precipitation and temperature patterns, but these may be obscured by the presence of other systematic errors, resulting in error cancellations, that may not easily be depicted from model validation analyses.

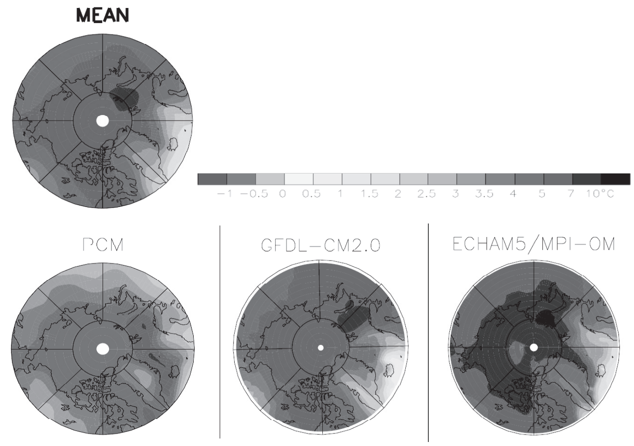

Figure 1. Maps of composite (based on 21 models) and 3 individual model simulated annual mean temperature change (2080–2099 vs. 1980–1999) for the IPCC A1B SRES scenario. From IPCC (2007).

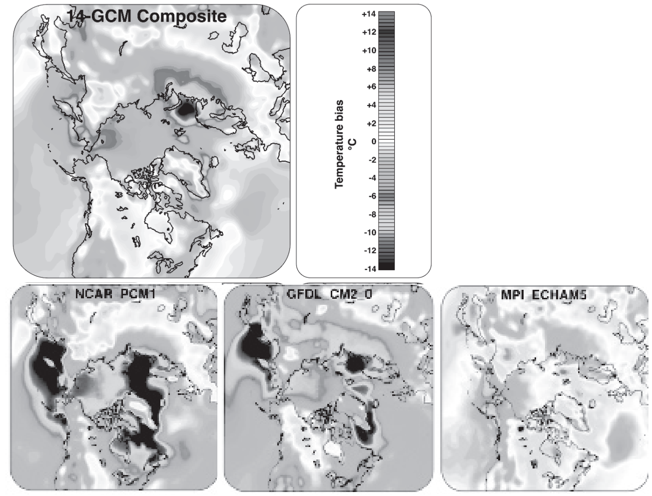

Figure 2. Maps of composite (based on 14 models) and 3 individual model temperature biases for winter (1958–2000). From Walsh et al. (2007).

Changes in temperature and sea ice

In IPCC (2007), the temperature within the Arctic is assessed to increase at a higher rate than globally, confirming results from previous IPCC reports and ACIA (2005). For the IPCC SRES A1B scenario, the annual mean Arctic temperature increase by the end of the 21st century is projected to be about twice that of the global mean (5°C–7°C vs. 2.5°C–3.5°C) (IPCC 2007, Christensen et al. 2007). Figure 1 shows an extract of an evaluation of 21 model simulations of global change under the A1B scenario (from Christensen et al. 2007), highlighting 3 models—the NCAR PCM, GFDL CM2.0, and MPI ECHAM5—as well as the 21-model mean. It is evident that these 3 individual models qualitatively show the same climate change response, but the magnitude of the change differs by several °C, with the PCM model exhibiting the lowest degree of warming, and the ECHAM5, the highest degree of warming, while the GFDL CM2.0 model is close to the ensemble mean.

It is interesting to note, however, that the projected climate signals to some degree are caused by quite different mechanisms. Figure 2 shows an extract of an analysis of the performance of 14 model simulations for the period 1958–2000 from Walsh et al. (2007). Again the ensemble mean behavior is shown along with the same 3 individual models. A common feature for most of the models, reflected by the ensemble mean, is a clear cold bias in the Barents Sea due to a tendency to simulate too much sea ice, with the MPI model being a clear exception. At the same time, the greatest warming by the end of the century is simulated exactly over this region in the ensemble mean as well as by the individual models. In the NCAR and GFDL models, this is partly reflecting the bias in present-day sea ice conditions, while in the MPI model this apparently cannot be the case. Note also that, in general, the largest warming occurs in the area with too much ice (strong cold bias) under present-day conditions, and in the NCAR model in particular, even though we here compare winter with annual mean. Thus, to some extent, the results are at the regional scale clearly subject to the systematic errors in the present-day simulations. Using an ensemble of models masks this deficiency.

Therefore, maps of warming must be carefully analyzed, and data cannot be used in a region with nonlinear feed backs such as the presence and absence of sea ice without further analysis.

Changes in snow conditions

Snow cover presents a challenge to models, and the issue is further complicated by a rather incomplete verification database. Apart from very few sites, the information available is only snow cover extent. While this is a similar challenge as for sea ice, there is much less constraint on the temperature below the snow seal. In the ocean, temperatures are well approximated by -1.7°C under sea ice, while soil temperatures can go well below -10°C in some places. Therefore, the ability to simulate snow cover realistically is essential.

According to the IPCC (2007), models are now more consistent in their simulation of snow cover than previously. Problems remain, however, and Roesch (2006) showed that the recent models predict excessive snow water equivalent in spring, likely because of excessive winter precipitation. The magnitude of these model errors is large enough to affect continental water balances. Snow cover area is well captured by the recent models, but interannual variability is too low during melt. Moreover, many models are able to reproduce the observed decline in annual snow cover area for the period 1979 to 1995, and most models capture the observed decadal-scale variability over the 20th century. Despite this, some of the models still exaggerate snow covered areas in spring and summer. This has obvious consequences for any analysis on permafrost-related properties using such models.

Implications for changes in permafrost

Re-inspection of Figure 1 reveals that the largest warming, apart from that occurring over the Arctic Ocean, is seen

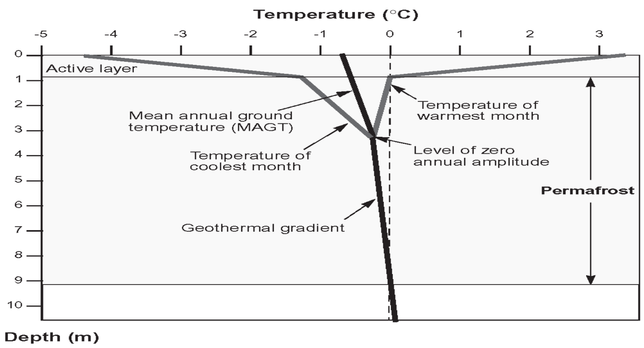

Figure 3. Schematics of temperature profiles at a permafrost site. Fat horizontal stippled line indicates an arbitrarily chosen lowest soil model level as typically represented in a climate model.

over the northern-most part of the continents, for several reasons. Firstly, the warming associated with the reduced sea ice cover simulated by all models has an impact mainly in spring and autumn. During these periods, relatively warm and moist air is more likely to influence these regions due to the lack of sea ice cover in a longer period, while in summer and winter the atmospheric conditions in this aspect will be more like present day. Thus the largest signal in the warming comes from the change in the seasonality of the sea ice. This in turn has implications for the poleward advection of heat in the shoulder seasons as well, leading to enhanced warming. But the albedo feedback from reduced snow cover from the return of sun light in spring to late autumn is also likely to contribute to the enhanced warming. Any bias in the seasonality of sea ice or snow cover will strongly impact this warming signal. This immediately implies that simulated permafrost properties are impacted by a model's ability to capture the present-day conditions as well as respond to increased greenhouse forcing in an adequate way.

Figure 3 illustrates the classical depiction of temperature profiles at a site underlain by permafrost. This schematic picture also shows how the typical representation of the soils in a GCM is handled. The lowest layer in the soil is located somewhere above the level with zero annual amplitude. Typically, GCMs adopt a zero heat flux adjustment at the lowest level in order to avoid an artificial energy source or sink. This implies that instead of allowing for heat penetration into the deeper soils, heat accumulates near the lowest level if the general model behavior reflects a warming, as indeed is the case unanimously in the Arctic under global warming. Therefore, in the model, once the possible nonlinear jump due to changes in snow cover conditions (earlier melt and later reoccurrence) has expressed itself at a grid point underlain by permafrost, heat can start to accumulate in the shallow soils, starting from below. This in turn will show up as a faster warm-up and, subsequently, thaw of the permafrost conditions than should be expected if the excess heat were allowed to propagate into greater depth. Recently, it has been demonstrated that indeed such behavior is found using the CLM land surface scheme (Alexeev et al. 2007, Nicolsky et al. 2007). Therefore, these authors proposed a procedure to parameterize the existence of deeper soil layers. In their idealized case study, the CLM was driven off-line with observations from one winter season, and the authors were able to show how heat was effectively transported to further depth, avoiding a pile-up of excess heat near the deepest model levels. The implications are important not only for the depiction of soil temperature behavior. Once a region experiences strong warming due to modified snow-cover insulation conditions, permafrost erroneously warms up too fast below the active layer, implying excess heat capacity during the cold season which in turn may lead to too-warm conditions close to the surface as well. Thus a feedback mechanism is initiated that may induce further warming, which at least partly is induced by the imperfect lower-boundary condition. The implications for the interpretation of direct GCM model-based soil temperatures are therefore severe; the induced warming and subsequent thawing of permafrost will take place too quickly. Moreover, when more advanced permafrost models are used to provide detailed information about changes in permafrost conditions, the simulated permafrost properties will be impacted by the biased precipitation, snow, and near-surface temperature provided to it by the GCM.

Conclusion

Here we have highlighted some of the well-known deficiencies of most state-of-the-art climate models. It is also clear, however, that some models appear to be less prone to some of the errors we have discussed here. In particular, a few of today's models are capable of reproducing crucial aspects of the climate system in the Arctic. In order to provide reliable climate change scenarios in areas underlain by permafrost, we have illustrated the need to single out some of today's GCMs that are representing with reasonable accuracy the atmospheric circulation, sea ice distribution, and general aspects of snow cover for the present climate Furthermore, we have demonstrated that there is a need to introduce a more sophisticated treatment of soil processes which includes information about soil thermal development even at considerable depth, as this has the potential to further improve the ability of climate models to simulate arctic climate, hence increasing credibility of arctic climate change projections.

Finally, the importance of permafrost in high-latitude climate change implies a need for accurate representations of the soil vertical profiles of conductivity, porosity, and other parameters affecting soil temperature and moisture content.

Abstract

Trace gas fluxes in tundra regions have attracted substantial attention in recent years because of the large quantity of carbon stored in tundra soils and the associated feedbacks to climate change. Major international assessments (e.g., ACIA, IPCC) have not been able to come up with a conclusive answer as to trace gas budgets of the Arctic. Here we find that the Circumpolar North is roughly in balance with respect to carbon dioxide exchanges, with some regions showing signs of current losses and others showing sings of current carbon sinks. Taking into account methane emissions over a decadal timescale, however, the Circumpolar North is considered a current source of radiative forcing. Whether this source functioning will continue or increase into the future is uncertain and depends on the fate of permafrost, soil moisture, and surface hydrology.

Keywords: Arctic tundra; carbon dioxide (CO_2); methane (CH_4); permafrost regions; trace gas flux.

Introduction

Arctic terrestrial ecosystems have attracted major attention in the context of global carbon cycling in recent years (ACIA 2005, Millenium Ecosystem Assessment 2005, McGuire et al. 2007). A reason for this is that Arctic terrestrial ecosystems store a significant proportion of the global stock of soil organic carbon (C). In the arctic tundra proper, some 121-191 Gt of C are stored, or approximately 12-16% of the estimated world total (McKane et al. 1997, Tarnocai et al. 2003). Arctic permafrost regions are predicted to undergo significant changes due to anthropogenic climate impacts (Kittel et al. 2000, IPCC 2001, Wookey 2002, ACIA 2005, Lawrence and Slater 2005). These changes and the feedbacks they engender could change the climatic conditions that have allowed the development of such large soil C stocks in the Arctic (Gorham 1991, Shaver et al. 1992, McKane et al. 1997, Hobbie et al. 2000). Extensive regions of the High Arctic that lack substantial C stocks and currently have very limited rates of atmospheric exchange could develop dynamic C cycles. Climate driven changes in plant community structure, specifically shifts from herbaceous and cryptogamous dominance to systems dominated by ericaceous and woody species, are also likely to change ecosystem C dynamics and balance.

Arctic soils are often wet and, when waterlogged, become anoxic. Anoxic soils often accumulate C in the form of peat (Gorham 1991, Clymo et al. 1998) and release methane (CH_4), a radiatively important trace gas (Matthews and Fung 1987, Joabsson and Christensen 2001, Öquist and Svensson 2002). Methane flux is rarely a quantitatively important component in the ecosystem C balance but it can play a disproportionately important role in terms of greenhouse gas forcing (gram for gram methane in the atmosphere has 23 times the radiative forcing potential of CO_2).

Permafrost environments are very dynamic with respect to trace gas exchanges and there are important interactions between permafrost dynamics and, in particular methane emissions both in terrestrial (Christensen et al. 2004) and thaw lake ecosystems (Walter et al. 2006). Here we briefly review the current state of budgets for the northern permafrost regions with respect to observational data on seasonal and annual CO_2 and CH_4 fluxes.

Mechanisms

Processes controlling trace gas budgets in arctic ecosystems vary across a continuum of space (plot to region) and time (minutes to decades), and varying classes of biological complexity (e.g. from individual species, through trophic interactions, to whole ecosystems). Thus, determining an accurate C budget for the Arctic requires an extensive and sustained observational capacity, which incorporates measurements and instrumentation that are sensitive to processes influencing C uptake, storage and loss. The latter is arguably the greatest source of current scientific uncertainty due to significant uncertainties remaining in the mechanistic understanding of processes controlling C losses, whereas accurate scaling across space and time is perhaps more constrained by logistical and funding limitations. Here, we discuss the importance of several crucial processes controlling C uptake, loss and storage in arctic tundra. Factors that are important for scaling process studies across space and time are considered below.

There are a finite number of basic processes involved in controlling CO_2 exchange. Net ecosystem production (NEP) of organic carbon is the net product of two independent processes that drive the uptake and release of C; gross primary production (GPP) and respiration (both autotrophic and heterotrophic, CO_2 as well as CH_4; Fig. 1). The net

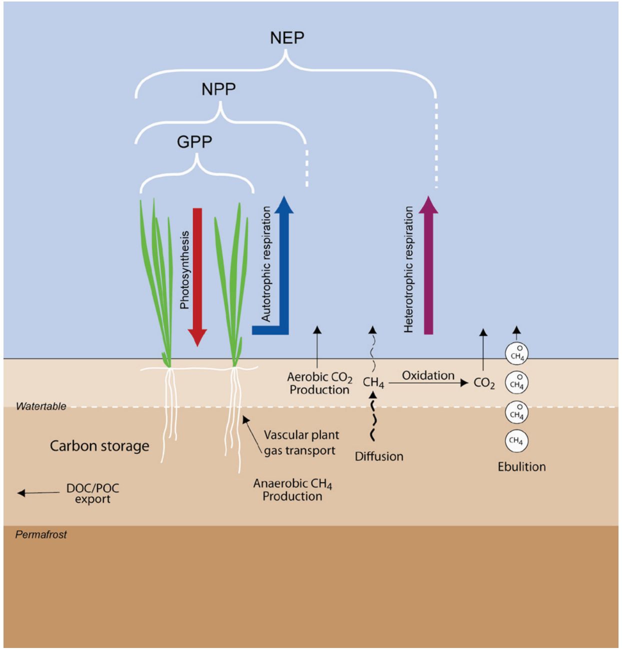

Figure 1. Schematic diagram of the processes governing the net balance of CO_2 and CH_4 fluxes in typical permafrost regions.

annual C budget of a given ecosystem is also affected by export of dissolved and particulate organic C in ground and streamwater flows (Michaelson et al. 1998, Tipping et al. 1999, Cole et al. 2002, Judd and Kling 2002), which are relatively unknown for the Arctic. In addition to the capacity for C transport in Arctic soils and streams (Kling et al. 1991, Judd and Kling 2002) there are minor releases of volatile organic compounds (Kesselmaier et al. 2002) contributing to a full C budget. The net annual C balance or budget is, hence, the result of both independent and coupled (e.g., Boone et al. 1998, Högberg et al. 2001) processes that often respond differentially to the same abiotic forcing factors which makes interpretation and prediction of their quantitative impact a major challenge.

The net emission of CH_4 from a given ecosystem is also the result of a complex set of independent processes that regulate production, oxidation and transport (Fig. 1). Controls on these processes include soil temperature, plant species composition (and functional type), and factors that influence the redox potential (Eh) of the soil environment (e.g. the position of the water table) (Moore and Knowles 1989, Christensen 1993, Funk et al. 1994, Yavitt et al. 1997, Bellisario et al. 1999, Christensen et al. 1999, 2000, Joabsson and Christensen 2001, Öquist and Svensson 2002, Sjögersten and Wookey 2002, Blodau and Moore 2003, Ström et al. 2005). Also, as is the case for CO_2 exchange, the temporal dynamics of net CH_4 fluxes between a given landscape and the atmosphere can be highly variable due to contrasting processes controlling exchange at different times of the year. Permafrost dynamics impact all these factors (Fig. 1) in arctic, subarctic and some boreal ecosystems. Thus, changes in the permafrost regime (Christensen et al. 2004, Lawrence and Slater 2005, Walter et al. 2006) will have fundamental consequences for CO_2 and CH_4 fluxes in the Arctic.

Seasonal Flux Dynamics

Figure 2 illustrates critical components controlling the seasonal dynamics of C exchange in a simplified arctic tundra ecosystem. Within the four seasons (I-IV in Figure 2) there are important, and at times very different, processes acting which are resulting in the net effect of the individual seasons on the annual budget. Critical facets of early-season conditions - such as a substantial C loss during spring melt and early summer due to release of trapped CO_2, and possibly a hindered onset of photosynthesis due to dry early summer conditions - can seriously affect the annual budget.

In midsummer again water deficit can be important as a limiting factor for photosynthesis, while a very warm summer has the potential to stimulate respiration (including root respiration) more than photosynthesis (in particular in dry years) so these effects together can be very important for the annual budget (Crawford et al. 1993, Marchand et al. 2005, Kwon et al. 2006). In the third season, a mild autumn followed by the delayed appearance of a consistent snowcover could be critical for processes involved in C fluxes. Usually photosynthesis will decline regardless of warm "Indian" summer conditions that will stimulate respiration for as long as the soils remain unfrozen (or contain free water). So a mild autumn may also be a very important triggering factor for C losses on an annual basis (Jackovitz-Korchinsky et al. in prep.). The critical factors for determining the annual carbon budget of a simplified arctic tundra are summarized in Table 1, which includes examples of factors that can affect seasonal processes (δa, δb, δc, δd) occurring in season I (spring), II (summer), III (autumn) and IV (winter) and, therefore estimation of annual budgets. The annual budget can then be summarised as Equation 1 (below) where k is a site specific productivity factor and δ represents seasonal factors that indicate the positive or negative effects that each season is having on the net annual balance.

$$C_{annual} = k * (\delta a + \delta b + \delta c + \delta d) \quad (1)$$

Importantly, there may be several complications associated with this very simplified model. For example, an early freeze-up in season III, which would tend to increase net C uptake in a given year through preventing respiratory C losses in a lengthy autumn, may act very differently during the subsequent year depending upon whether or not the soil is underlain by permafrost. In a permafrost free setting, where there are still unfrozen conditions and substantial microbial activity beneath the freezing front, there is the chance for a substantial winter-time build-up of CO_2 below the frozen ice and soil layer, which in turn may affect the δa in the subsequent year through a substantial and potentially pulsed release of trapped CO_2. In continuous permafrost this hand-over effect from one year to the next may be less apparent.

Nonetheless, Equation 1 may be useful for comparing annual budgets between ecosystems, studies and sites to determine factors controlling not only intra-site inter-annual variability but also for comparing why different sites appear with different annual budgets. The discussion on estimates of annual fluxes below rationalizes why such differences in annual budgets can be found both within and between sites.

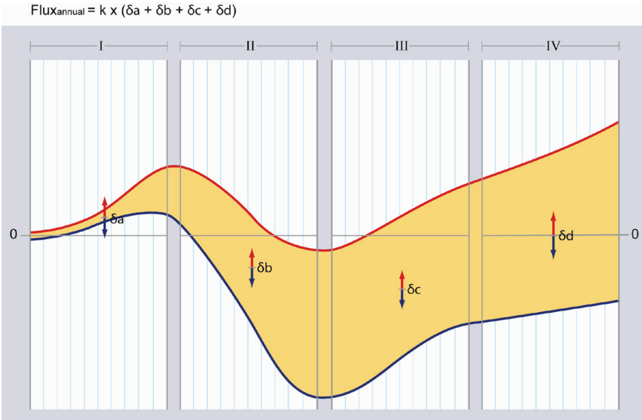

Figure 2. Conceptual model for the seasonal dynamics of accumulated carbon exchange with the atmosphere in a tundra ecosystem. The four different seasons determining the annual balance are indicated starting with the Spring (I) defined as the time from snowmelt until the carbon balance turns negative. The reverse point defines the end of the following period defined as Summer (II). Autumn is from the turning point of the carbon balance to the onset of permanent snowcover (III) and winter is the permanent snow covered period (IV). Examples of critical parameters for the annual total budget outcome in these individual parts of the season are shown in table inserted below.

Table 1. Examples of requirements for δx (Fig. 2) to be:

	Positive	Negative
δa	Short (little snow);	Long and cold;
	Soil moisture limitation;	Little trapped CO_2
	Lots of trapped CO_2	
δb	Short and warm.	Long and cold.
	Moisture limitations on	No moisture deficit for GPP
	GPP; Insect outbreaks	
δc	Long and dry	Short; Early freeze-up
δd	(snowcover) long	(snowcover) short

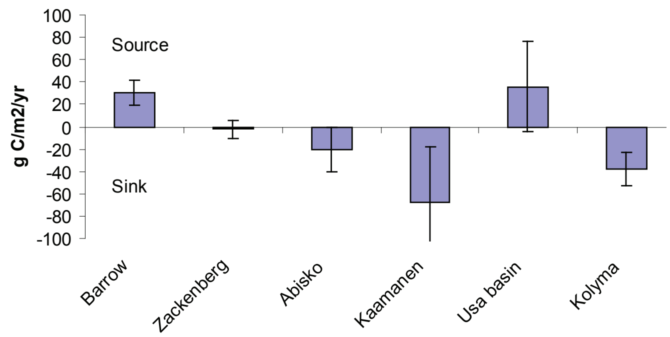

Figure 3. A compilation of annual C budgets based on measurements at sites ranging from Alaska over Greenland, northern Scandinavia and north-eastern European Russia to NE Siberia. (Data from Oechel et al. 2000, Nordstroem et al. 2001, Soegaard et al. 2000, Christensen et al. 2000, Aurila et al. 2004, Jackovitz-Korchinsky et al. in prep, Heikkinen et al. 2003 and Corradi et al. 2005.)

Trace Gas Budgets

Annual estimates

Due to the natural interannual variability determined by the factors discussed above it is extremely difficult to ascertain the C budget status of any tundra ecosystem from single year or even 2-3 year studies. The degree of variability between years is generally quite high. The longest series of annual C balance estimates for tundra ecosystems is from N Alaska, where chamber flux measurements in the 1970's and 1980's, and eddy correlation measurements in more recent years, have indicated a shift from sink to source by the early 1990's, after which there was a tendency for the system to tend towards sink status despite remaining a net source (Oechel et al. 2001). Regardless of these rather dramatic fluctuations in annual budgets over decadal time scales, tundra sites in northern Alaska have also shown relatively stable summertime uptake rates of 40 to 70 g C m^{-2} $season^{-1}$ (Spring to Fall) in recent years (Kwon et al. 2006), emphasising the importance of the shoulder season for determining the variability between years.

Other sites where full annual budgets have been monitored include Stordalen in northern Sweden (Jackovitz-Korchinsky et al. in prep.) and Kaamanen in northern Finland (Aurela et al. 2002, 2004). From NE Greenland there are several years of full seasonal flux observations available both from wet tundra fen and dry heath sites and annual budgets have been estimated at an overall balance close to zero (Soegaard et al. 2000, Nordstroem et al. 2001, Groendahl et al. 2006). In Siberia an annual sink estimate of 38 g C m^{-2} $year^{-1}$ was measured in tussock tundra in NE Siberia (Corradi et al. 2005).

The status of C exchange in the Circumpolar North based on the few actually observed annual C budgets indicate that Arctic terrestrial ecosystems are functioning with significant spatial and temporal heterogeneity with some regions being sources of carbon to the atmosphere (mostly dry and mesic ecosystems) and some regions sinks (mostly wet tundra) (Fig. 3).

From the available circumpolar data it is very difficult to provide a straight answer to the question of whether the Arctic tundra is a source or a sink of atmospheric carbon. There was a time in the 1990s where there was a tendency for the studies and sites that represented the larger areas of tundra to show source activity (northern Alaska and European Russia, Figure 3) but this pattern has changed since the vast NE Siberian tundra became represented by Corradi et al.'s (2005) study (Fig. 3). Taking into account the error bars also shown in Figure 3 it is impossible, given the currently available measured annual carbon budgets, to say for certain that the overall carbon balance of the Circumpolar North should be different from equilibrium.

Greenhouse gas budgeting

Few of the annual budgets referred to above include observations of CH_4 emissions. Where such combined measurements are available on an annual basis, i.e. at Stordalen (Sweden), Kaamanen (Finland) and Kolyma (NE Siberia), the contribution of CH_4 to the actual net annual carbon exchanges (NEP, Figure 2) amounts to 10-25% of the heterotrophic respiration (Jackovitz-Korchinsky et al. in prep, Corradi et al. 2005).

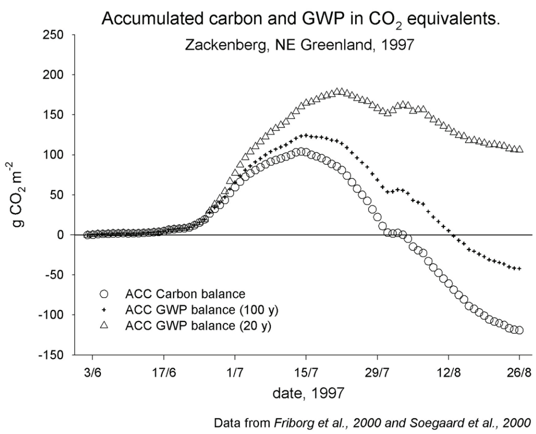

Figure 4. An accumulated greenhouse gas budget (CO_2 and CH_4 as CO_2 equivalents) for a northern wet tundra site versus one of CO_2 only (from ACIA, 2005 based on data in Soegaard et al. 2000 and Friborg et al. 2000).

Since CH_4 is a greenhouse gas with a radiative forcing potential 23 times greater (expressed as gram per gram) than that of CO_2 (in a 100 yr time perspective), the emissions of methane from wet tundra ecosystems, in particular, must be taken into account in any attempt to document the radiative forcing capacity of arctic landscapes (Johansson et al. 2006). For tundra ecosystems where a third commonly studied greenhouse gas, nitrous oxide (N_2O), is assumed to be rarely exchanged with the atmosphere due to nutrient limitations, estimates of total greenhouse gas fluxes are usually confined to the combined effects of CO_2 and CH_4 exchange. Here a complicating factor is time. Most tundra ecosystems have accumulated carbon over many thousands of years. Over such a period the accumulated and reduced radiative forcing potential of CO_2 uptake is a stronger factor than that of accumulated CH_4 emissions (Frolking et al. 2006). However, in most greenhouse gas budgets, focus is generally directed to the immediate emissions and possible changes that may occur and what impact these will have on climate as this responds to change over the coming decades. Over decadal time scales, most wet tundra CH_4 emissions will be a stronger greenhouse forcing factor acting on climate than the CO_2 uptake. Typical calculations of such a total GHG budget may look like that illustrated in Figure 4, which has been derived for the Zackenberg eddy tower site in NE Greenland by applying two typical CH_4 greenhouse warming potentials of 63 for a 20 yr time perspective and 23 for a 100 yr time perspective respectively (Friborg et al. 2004, ACIA 2005).

Many dry/mesic tundra ecosystems have minimal CH_4 emissions, if any, and CO_2 budgets are balanced around zero or are actual sources of C to the atmosphere, However, we conclude that arctic tundra regions should currently be considered a net contributor to greenhouse warming because wet tundra ecosystems are likely to be sources of climate warming over the next few decades due to strong CH_4 emissions. Whether this source functioning will continue into the future without acclimation is uncertain. In all likelihood, this may depend on the response of permafrost that appears to be warming, soil moisture status that appears to be variable with moisture levels increasing in some regions and drying in other regions. A further factor is the future state and carbon fixing potential of the High Arctic.

Current research infrastructure, monitoring and international and scientific coordination will not be sufficient to answer such questions. To further understand the significance of arctic environmental change for global greenhouse warming potential, new and concerted efforts need to be sustained to investigate further and adequately measure processes modulating C flux in arctic tundra and how C fluxes in arctic landscapes vary across multiple scales of space and time.

Conclusions

Throughout the Holocene, most tundra in the Arctic has been a net sink for carbon due to low rates of decomposition and loss relative to rates of uptake. Based on the few observed annual carbon budgets in the Circumpolar North, the current status of carbon exchanges indicates that Arctic terrestrial ecosystems are dynamic and heterogeneous, with some regions being sources of carbon to the atmosphere (mostly dry and mesic ecosystems) and some regions being sinks (mostly wet tundra). If the measurements from sites in N America and North Eurasia are assumed representative for these vast regions, then source and sink areas are roughly balanced.

Current global and regional climate modeling of predicted future states of arctic precipitation dynamics and hydrological balance are highly uncertain (ACIA, 2005). The models must be better parameterized and validated in order to constrain predictions of future soil hydrological states that will determine the magnitude and of C efflux from arctic tundra and the dynamics and the composition (CO_2, CH_4, VOCs etc.) of that exchange (Sitch et al. 2007).

Many dry/mesic tundra ecosystems have minor CH_4 emissions if any, and CO_2 budgets are balanced around zero or are actual sources. However, wet tundra ecosystems are likely to enhance radiative forcing over decadal time scales through the emission of CH_4. As such, arctic tundra and small lake regions should be concluded to currently be acting as a source of greenhouse warming. Whether this source functioning will continue or increase into the future is uncertain and will depend on the fate of permafrost, soil moisture and surface hydrology and the future state of ecosystem structure and function in the high arctic. To decrease uncertainty and improve our fundamental understanding of carbon balance at high northern latitudes new novel and concerted research and monitoring efforts need to focus over decadal time scales.

Institute of Geoscience, University of Oslo, P.O. Box 1041 Blindern, 0316 Oslo, Norway
The University Centre in Svalbard, UNIS, P.O. Box 156, 9171 Longyearbyen, Norway

Abstract

Long-term monitoring of active layer thickness and top permafrost thermal state has been ongoing since the year 2000 in the UNISCALM site on a loess-covered terrace in Adventdalen, central Svalbard. The site has proved to be excellent for studying the effects of meteorological variables such as air temperature and cloud cover on active layer thickness. The active layer thickness varied from 74 to 105 cm in the UNISCALM site since 2000. This fairly-large interannual active layer thickness variation reflects extremely shallow thaw in 2005. The top permafrost is warm, and no two-sided freezing occurs. This makes the site susceptible to the meteorological variations with MAAT variations, with MAAT variations between -1.7ºC and -6.1ºC recorded over the 2000 to 2007 monitoring period.

Keywords: active layer; CALM; interannual variations; monitoring, permafrost temperature; Svalbard.

Introduction

Svalbard is located in a high arctic maritime setting, exposed to significant interannual meteorological variations similar in magnitude to modeled climatic changes during the 21st century. Permafrost is classified as continuous (Humlum et al. 2003), and several characteristic periglacial landforms, such as rock glaciers, ice-wedges, and pingos, all show widespread permafrost existence. The mean annual air temperature (MAAT) at sea level has varied, however, between -1.7ºC and -6.1ºC in the period 2000–2006, measured at the official meteorological station at Longyearbyen airport (www.met.no).

MAAT for the year 2006 was 4.4ºC above the average for the entire period of meteorological measurements in Svalbard, but the warming mainly occurred in winter, with the summer average temperature 6.3ºC (June, July, and August) closer to the average of 4.4ºC (1912–2007 summers), but still warmer than ever recorded before. The 2007 summer temperature was higher still, at 6.4ºC. As ground thaw progression measurements exist since 2000, we can study how much and how quickly the active layer responded to the recent warm years.

Circumpolar Active Layer Monitoring (CALM) network sites exist in Svalbard, mainly along the west coast (Brown et al. 2000). The UNISCALM site, located in the most continental central part of Svalbard, is probed regularly during the thawing season from May to September to follow the thaw progression. Inside the UNISCALM site, active layer and top permafrost temperatures are measured directly in the sediment. This combination of measurements enables a good understanding of how the active layer has responded to recent meteorological variations.

The UNISCALM site

Adventdalen is one of several large valleys that dissect the mountainous landscape in central Svalbard. The UNISCALM site is located at 10 m a.s.l. in the central lower part of Adventdalen at 78º12′N, 15º45′, on a Late Holocene loess-covered terrace. The upper 1.3 m of sediment consists of horizontally layered silt-dominated sediments (Christiansen et al. in prep).

UNISCALM extends over a 100 x 100 m grid, with 10 m grid size spacing. It was established in mid-summer of 2000. It is being measured by physical probing of all 121 grid points from 8 to 15 times during the thawing season from May–September each year to follow the seasonal thaw progression and record the active layer thickness (ALT). As the grid was established in July 2000, only four measurements were carried out that year. The location of the grid is marked by small wooden pegs extending 5 cm above ground. The repetitive seasonal measurements are taking place in the same hole each summer to follow thaw progression in each grid point. Each year the location of the probe hole is moved slightly from the year before, to avoid measuring into earlier years' sites. Three persons have done the measurements in the eight-year period, usually by only one person during each season.

To investigate spatial variability within the UNISCALM site over the eight-year period, a normalized variability index (Iv) was calculated for each grid node (Hinkel & Nelson 2003) for the ALT measurements in late summer. If Iv varies only slightly between years, the interannual node variability (INV) is small (Hinkel & Nelsen 2003), indicating a high degree of consistency in thaw depths over the eight-year period. If Iv varies much between years, local factors may have a large influence on ALT.

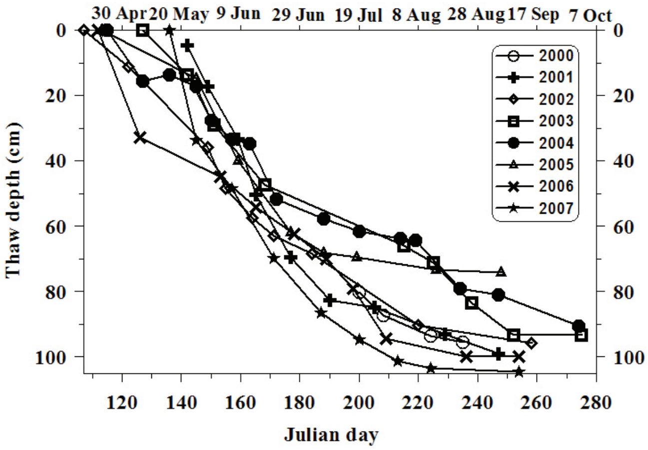

Figure 1. Thaw progression in the UNISCALM site calculated as the average from all 121 grid points at each date.

Active layer temperatures have been measured at the centre on the UNISCALM grid since it was established in summer 2000. Data are obtained by miniature dataloggers of the Tinytag type, with external sensors inserted horizontally directly into the ground at 0, 10, 20, 50, and 110 cm depths in the active layer and one was placed vertically into the top permafrost by drilling. Air temperature at 20 cm above ground is also measured by a Tinytag datalogger with an external sensor, also located at the site of the ground thermal profile, but built into a well-ventilated cairn of rocks. The resolution of the Tinytags is ±0.1ºC and the recording interval is one hour. Snow depths are measured manually on a regular basis during winters at the site of the active layer ground temperature profile.

Meteorology

The nearest official meteorological station to the UNISCALM site is the Longyearbyen airport, 9 km to the west, at the mouth of Adventdalen. It is situated at 28 m a.s.l. but closer to the sea than UNISCALM. This station has operated since 1975, but older data exist from nearby stations, and a homogenized data series exists for the entire period since the first meteorological records in 1912 (Førland et al. 1997).

Mean annual air temperatures (MAAT) has varied from -12ºC to -1.7ºC in the 1912–2006 recording period (www.met.no), partly because of warming since the Little Ice Age, but also because of large interannual temperature variations, which are natural in the maritime setting of Svalbard. The average MAAT for the entire period of measurements is -6.1ºC (www.met.no). The interannual variations are largest during winter, while summer temperatures vary significantly less. This causes a somewhat reduced meteorological influence on ALT, as summer temperatures typically exert large meteorological control.

The annual precipitation varies from 100–200 mm (www.met.no). It is evenly distributed throughout the year, but shows large interannual variation. During the winter, most precipitation falls as snow. Wind activity causes exposed areas at the UNISCALM site in the flat valley bottom to have only a shallow snow cover. This allows good energy exchange between atmosphere and ground.

Table 1. UNISCALM data and statistics based on data from the Longyearbyen airport meteorological station.

	2000	2001	2002	2003	2004	2005	2006	2007

Results

Thaw progression

Thawing degree-days (TDD) start when continuous positive air temperatures start in the spring. TDD thaw end is the date of the UNISCALM active layer measurement. TDD to thaw end is the amount of TDD during the recorded active layer thawing period, calculated from average daily temperature values. TDD total is for the entire year from the beginning of continuous daily positive air temperatures to the last day of the year. TDD at thaw end is the % TDD recorded at the time when the active layer measurement was done. Rain is the amount of precipitation falling during the month of June, July and August. Cloud cover (% of the sky with cloud cover) and wind speed are the means for the TDD thawing period. In 2007 TDD total and TDD at thaw end could not be calculated as the year was not over at the time of paper submission.

The average ALT recorded in the UNISCALM site was 94 cm for the 2000–2007 period with large interannual variations; the minimum was 74 cm in 2005, while 105 cm was the maximum in 2007. Thawing started as early as the end of April (2002 and 2006), and as late as end of May 2001 and 2007 (Fig. 1 and Table 1). The largest interannual variation in thaw progression occurred in the uppermost 40 cm (Fig. 1). These large differences are mainly controlled by the timing of snowmelt. No thawing is recorded until the surface is snow-free. In a year with very early thaw, such as in 2006 when continuous positive air temperatures were recorded from April 8 with a few subsequent short cold periods, thawing was very early. In contrast, in 2005 thawing was very slow for the first month because of a more protracted snowmelt period. The 50 cm thaw depth was reached in the same period June 4–19 in all years. Below this depth, some interannual variation exists, but with maximum thaw depths reaching 90–100 cm in most years. In 2005 the active layer, however, only reached down to 74 cm as late as September 5. In 2000, the active layer was already 95 cm by August 22. There is generally a correlation between the ALT and the TDD at the time of the active layer recording, but 2005 was clearly anomalous (Fig. 2).

Summer air temperatures (June, July, and August) exhibited less variability than other months, in the entire study period. The coldest summer was 2000, and the warmest summer was 2007. The active layer was 4.7 cm thicker in 2007 than in 2006, although the summer air temperature was only 0.1ºC higher in 2007, and TDD at the end of thaw (Table 1) was higher in 2006 than in 2007, because thawing had already started by April of 2006. The low correlation between ALT and summer air temperature (Fig. 2) largely reflects the influence of the anomalous years in 2000 and 2005. This means that something other than air temperature can have significant influence on ALT in some years. The difference cannot be explained by bad timing of the active layer measurements, as 94% of the annual TTD (Table 1) had occurred at the time of active layer recording in 2005. Only 70% of the annual TDD had occurred in 2000 at the time of active layer recording, so most likely the active layer was somewhat deeper this year, which most likely would locate it closer to most of the other years. In all other years, the ALT was recorded when around 85–98% of the TDD had occurred, indicating that normally the active layer develops in early to mid September.

Precipitation in the form of rain could affect ground thawing. Although there is rather large interannual variation in the amount of summer rain in the study period (Table 1), there is no correlation between the amounts of summer rain and the active layer depths (Fig. 2). Actually, the 2007 summer with only 31.3 mm rain had the deepest thaw of 104.6 cm.

The mean cloud cover in the entire thaw season varied on average from 68–78% and had the best correlation with ALT. ALT decreased when the cloud cover increased (Fig. 2). This indicates that increasing amounts of direct radiation increase thawing in this valley-bottom site. Increasing mean wind speeds over the summer generally increase the ALT, but again this correlation becomes low when including the year 2005.

Spatial variation

The UNISCALM site has a characteristic spatial thaw pattern (Fig. 3) with the deepest active layer in the southern

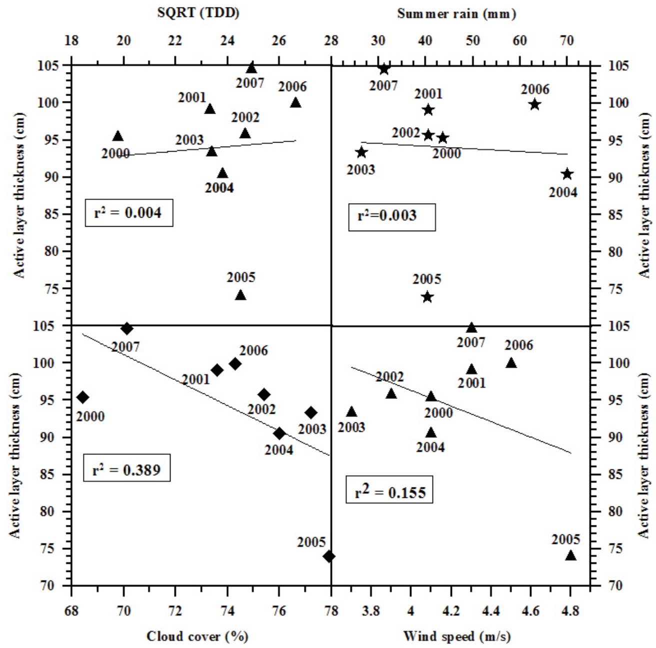

Figure 2. UNISCALM active layer thickness correlated to meteorological parameters in the 2000–2007 period. Correlations include data from all years 2000–2007.

and northeastern part, while the northwestern corner consistently had the thinnest active layer. The maximum grid node point ALT was as deep as 92–121 cm (Table 1)—all in the southern part of the grid during the 2000–2007 period (Fig. 3). The spatial thaw pattern is reproduced in all years except in 2005, where thawing in the southern part was particularly shallow: only 60–70 cm in several areas consisting of more points. The entire southern part of the grid had shallower thaw in 2005 than in all other years. This year, thawing was thinnest in the southern part of the grid, while it was deeper and not far from the depths recorded in the other years in the northern part of the grid.

The average interannual grid node variability (INV) is 18.5% for the entire site, with a maximum of 46% and a minimum of 3.3% for the individual grid nodes. The areas with high INV (Fig. 4) are exactly the areas with relatively shallow thaw in summer 2005. Otherwise, the INV values are fairly low, showing little interannual thaw variability and a generally consistent thaw pattern.

Temperature in the active layer

Active layer and top permafrost thermal monitoring was continuous, except for two summer breaks in the ground surface temperature in the summers of 2001 and 2004. Data from a borehole 100 m away, also on the loess-covered terrace, were used to substitute the missing values in 2004, while data from another flat ground surface site 2.5 km further up the Adventdalen were used in the 2001 period. The air temperature recording was first established in October 2000, so data from the Adventdalen site was also used in the first months.

The annual ground temperature distribution is presented from September 1–August 31 in the following year for all

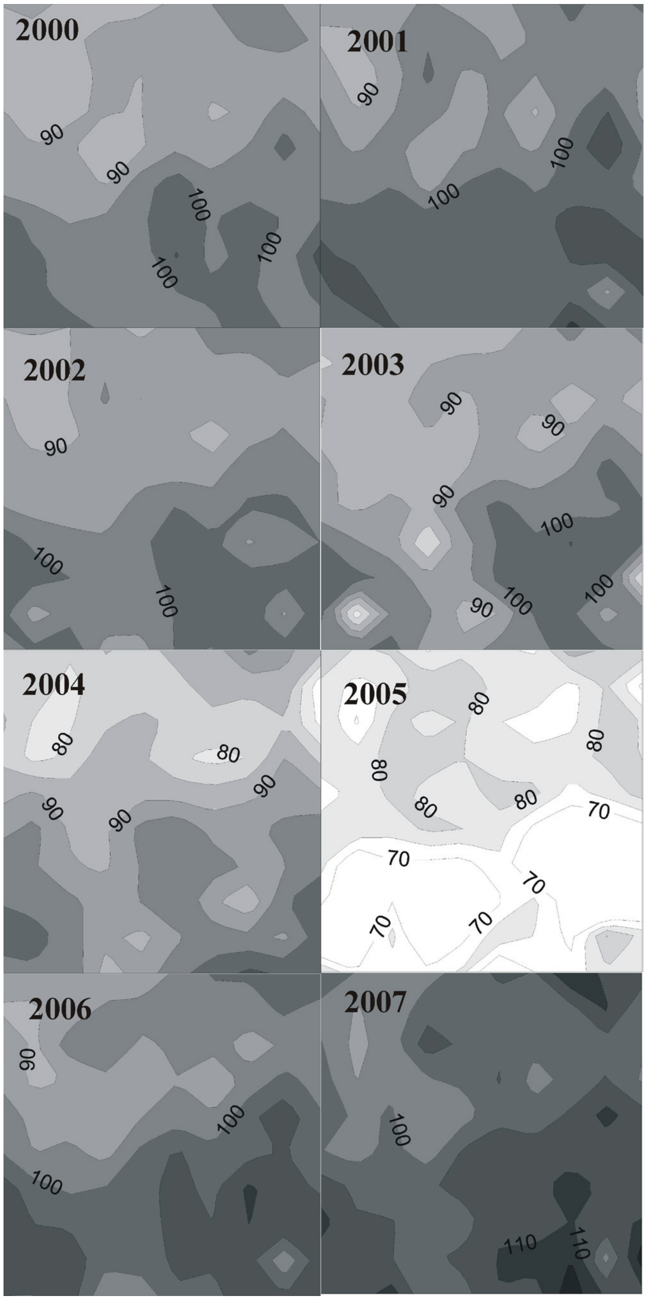

Figure 3. Spatial distribution of the active layer thickness in the UNISCALM site, mapped using the kriging interpolation method (Golden Software, 2002), and a grid spacing of 11 m, based on the 10 m grid node measurements. N is towards the top.

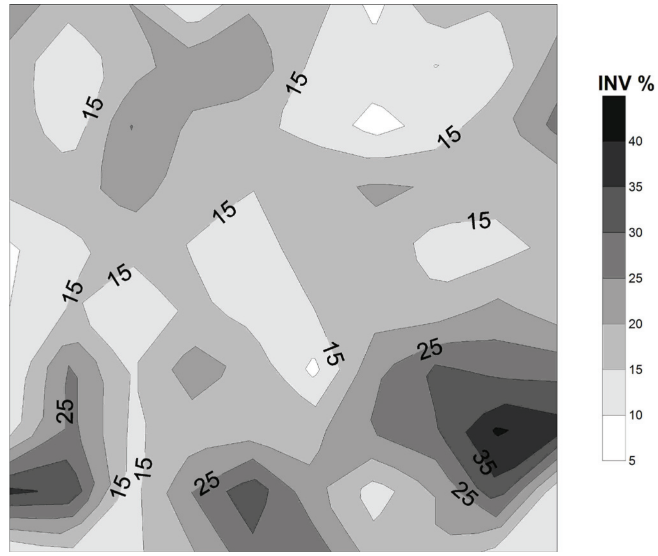

Figure 4. Interannual grid node variability (INV) for the period from 2000–2007. The mean for the entire grid is 18.5%. Based on the kriging interpolation method (Golden Software, 2002), with a grid spacing of 11 m of the 10 m grid node measurements.

years (Fig. 5). There is large interannual variation especially in the winter ground temperatures, while the summer temperatures have much less variation between the years, as for the air temperature conditions. The thermal conditions in the summer of 2005 are not significantly different from the other summers (Fig. 4). The phase change during freezing in autumn occurs mainly from the top down, so that the zero curtain is much shorter in the top than at the bottom of the active layer. The difference is up to 2 months before the bottom of the active layer is completely frozen and further cooling can occur. It is mainly the top 70–50 cm of the active layer that experiences significant cooling with temperatures below -10ºC, whereas the lower part of the active layer and top permafrost, especially in the last two years, have not reached temperatures below -10ºC. Also, in the last 3 winters, relatively longer periods of warming of the ground have occurred with ground temperatures as high as -4ºC in almost the entire active layer (Fig. 5).

Figure 3. Spatial distribution of the active layer thickness in the UNISCALM site, mapped using the kriging interpolation method (Golden Software, 2002), and a grid spacing of 11 m, based on the 10 m grid node measurements. N is towards the top.

MAAT varied from -6.2°C to -3.2°C in the study period, while MAGST varied from -5.7°C to -2.2°C and MAGT at 110 cm, in the top permafrost, varied from -5.8°C to -3.6°C (Fig. 6).

Thus, the largest annual variation was at the ground surface, and it occurred in just three consecutive years. The highest mean annual ground temperature was found at 10 cm depth in three of the seven years; thus the theoretical ground temperature profile (Smith & Riseborough 2002) did not occur in all years. There is very large interannual variation in the mean annual ground temperature conditions.

The almost vegetation-free UNISCALM site at the exposed valley-bottom terrace has a generally thin snow cover from late September or October to April or May, with a maximum of 20–30 cm snow depth. Despite the shallow snow, annual surface offsets (Smith & Riseborough 2002) from 2.0–0.4ºC occurred. The n-factor (Carlson 1952) varied from 0.57–0.93 despite the shallow snow cover. The annual thermal offsets (Smith & Riseborough 2002) varied from 2.0–0.1 ºC.

Annual ALT was calculated from the interpolated ground thermal data by locating the lowest position of the 0ºC isotherm in Figure 5. This shows active layer values from 98–105 cm, which is comparable to the UNISCALM-

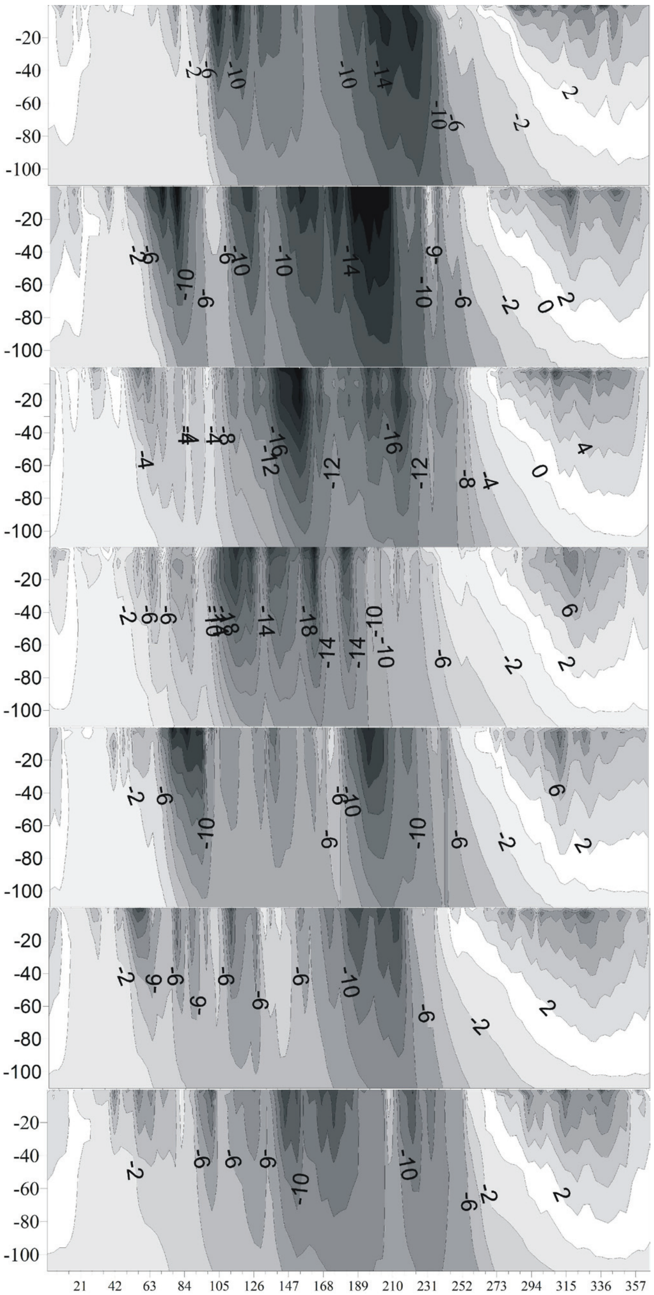

Figure 5. Active layer and top permafrost temperatures in the UNISCALM site measured by miniature loggers with temperature sensors at 0, 10, 20, 50, and 110 cm depths. The annual ground temperature distribution is presented from September 1–August 31 in the following year, and the units on the x-axis are therefore days after September 1. The upper plot is 2000–2001, while the lowermost is 2006–2007.

measured average values, but with less interannual variation. This is especially true in 2005 when the calculated active layer was 102 cm, and thus not as shallow as the clear minimum in the UNISCALM data. The timing of the calculated active layer is much earlier than the measured values in UNISCALM—up to 2 months, but typically one to four weeks.

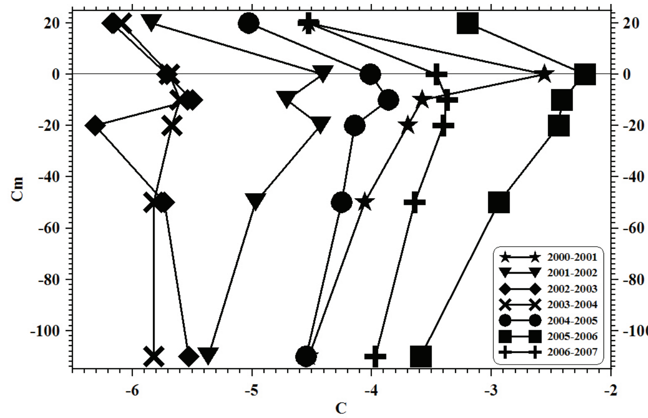

Figure 6. Annual mean temperature distribution from 20 cm above ground down through the active layer and into the top permafrost in the UNISCALM site. Data is from Tinytag miniature dataloggers.

Discussion and Conclusions

In the fine-grained UNISCALM loess site in the Adventdalen valley bottom setting, the active layer varied from 0.74–1.04 m in the 2000–2007 period. Fourteen km further into Adventdalen on the exposed Janssonhaugen sandstone bedrock hill, the active layer varied from 1.5–1.8 m in the 2000–2006 period (Harris et al. submitted).

Sediments are often assumed to experience less interannual active layer variation due to the effect of ice-rich conditions in the transient layer between the active layer and permafrost top (Shur et al. 2005). The active layer monitoring data from bedrock and sediment in Adventdalen, however, show variation of the same size. Therefore the transient layer is presumably not ice-rich in the UNISCALM site, enabling large interannual fluctuations in ALT.

The recorded 30 cm interannual ALT variation in the UNISCALM seems to be mainly controlled by meteorological conditions. However, there is not only a simple correlation between TDD and ALT, but most likely also the cloud cover influences ALT, as this parameter has the highest correlation with ALT for the entire 2000–2007 study period (Fig 3). Thus direct solar radiation seems to affect ALT at this site. This seems most likely due to the relatively low water vapor and dust content in the High Arctic atmosphere in combination with a dark-colored sediment surface with very little vegetation, which will have a low albedo. This combination promotes ground heating during direct radiation in summer. Also the water content in the site is fairly low during most of the summer, as only a little summer rain falls, as stressed by the missing correlation between summer rain and ALT. Finally the UNISCALM site is dry due to the local topography, without drainage from surrounding areas, which further supports it being most likely relatively ice-poor in the top permafrost. Water contents of only 10–18% of the dry soil weights were measured in summer 200 0, with the largest values down through the active layer (Oht 2002).

It is mainly the relatively shallow thaw depths from the end of the 2005 summer that cause large INV in the southern end of the UNISCALM site. We do not think that these values represent bad probing, as the thaw progression curve is consistent through the summer with no significant jumps. Comparing the calculated active layer depth of 102 cm from the temperature profile in the middle of the UNISCALM site to the entire UNISCALM average ALT of 74 cm, and studying the typical annual distribution of ALT in the entire UNISCALM site in 2005, show that the southern part experienced significantly reduced thawing this summer.

In the UNISCALM site, the ALT is largely controlled by the air temperature and radiation, with the warmest conditions occurring in the last two warm years. ALT increased 21 cm from 2005–2007 according to the average UNISCALM data (Fig. 4), but only 3 cm according to the ground thermal data (Fig. 5). This large difference between the two methods must lead to precautions when interpreting the direct effect of climatic variations on the ALT.

The significant surface offsets existing every year of the study period show that the winter influence of even a shallow snow cover of 20–30 cm significantly reduces the ground cooling. Also, there is a clear thermal offset causing the top permafrost in the UNISCALM site to be a relatively warm, 0 to -2ºC, during summer with no significant two-sided freezing in autumn. These conditions and the generally low assumed ice content in the top permafrost make the UNISCALM site very susceptible to meteorological variations, as it has experienced in the last 8-year period. This first overall data analysis from the UNISCALM site shows that this site is a good monitoring site for recording the response of climatic variations to the state of the top permafrost and active layer, but also that several factors affect the atmosphere and ground interaction in the maritime Svalbard setting, such as the Adventdalen site.

The UNISCALM site experienced much larger interannual variations than what is recorded in another flat High Arctic sediment CALM site, the ZEROCALM-1 site in northeast Greenland (Christiansen 2004). This is most likely due to the much-more maritime setting of Svalbard compared to the Zackenberg area in northeast Greenland.

Acknowledgments

Several persons have been our field assistants during the UNISCALM measurements. We extend our thanks to all of them for patiently writing down numbers. A special thanks to Sigurd D. Nerhus, who conducted the UNISCALM measurements in 2006 and 2007. The University Centre in Svalbard, UNIS, is thanked for providing funding for the equipment used to operate the UNISCALM site. The measurements from 2007 are part of the International Polar Year project "Permafrost Observatory Project: A Contribution to the Thermal State of Permafrost in Norway and Svalbard," supported by the Research Council of Norway, grant no. 176033/S30. Thanks to the two anonymous reviewers and the review editor for constructive comments. Thanks to our colleague Doug Benn for improving the English of the paper.

Experimental Study of the Self-Preservation Effect of Gas Hydrates in Frozen Sediments

O.M. Guryeva
Department of Geocryology, Geological Faculty, Moscow State University, Russia

Abstract

Gases released from shallow frozen sediments may include methane from the dissociation of relict gas hydrate maintained by self-preservation. A series of experiments to substantiate this possibility were conducted. This research involved artificial formation of methane hydrate in frozen sediments, including samples recovered from gas shows in permafrost horizons, and studying the effect of self-preservation of gas hydrates in frozen soil samples at decreased pressure. The experiments show that self-preservation of gas hydrates in frozen sediments is enhanced by low formation temperatures, high ice content, and low sediment gas permeability.

Keywords: dissociation; gas hydrate; self-preservation.

Introduction

The presence of gas hydrate in permafrost has been confirmed by hydrate found in core samples and by indirect evidence in various regions of the world (e.g., Canadian Arctic, Alaska, and northern Siberia). Hydrate-containing samples have been recovered from permafrost and subpermafrost layers in the Mackenzie Delta (Dallimore & Collett 1995, Dallimore et al. 1999). In addition, there is evidence that self-preservation of relict methane hydrate, made possible by the continual frozen nature of the sediment, occurred in the upper permafrost layers (Dallimore et al. 1996).

Numerous hydrate shows were also indirectly found in Russia above a depth of 200 m in northwest Siberia and other regions containing permafrost (Are 1998, Chuvilin et al. 1998, Skorobogatov et al. 1998, Yakushev & Chuvilin 2000). These "relict" gas hydrates may have formed during glacial periods. Subsequently, glacial retreat induced metastable preservation of the hydrate by self-preservation (Ershov et al. 1991, Stern et al. 2001, Istomin et al. 2006).

Gas hydrate self-preservation phenomenon can be defined as a very slow decomposition of gas hydrates when the external pressure drops below a three-phase equilibrium pressure of the gas-ice-hydrate system at sub-zero (below -3 to -2°C) temperature as a result of thin ice film emergence on the gas hydrate surface (Istomin et al. 2006).

This effect was initially discovered and described in detail between 1986 and 1992, by researches from Canada (Ottawa National R&D Center) and Russia (VNIIGAZ and Moscow State University) (Davidson et al. 1986, Handa 1988, Ershov et al. 1989, 1991). The term "gas hydrate self-preservation" was introduced by Russian researches after several laboratory experiments revealed that gas hydrate decomposition came to a virtual halt when hydrate particles became covered by a thin ice shell at the initial decomposition stage.

Japanese scientists from Hokkaido Institute (HNIRI) studied methane hydrate decomposition kinetics and the self-preservation effect using X-ray diffraction. They showed that at temperatures above -84°C there are two stages in methane hydrate dissociation. Initially, hydrate dissociates rapidly (during first 10 minutes) then the rate of hydrate decomposition abruptly decreases due to the formation of an ice film on the surface of hydrate. The slow rate of decomposition is controlled by the conditions of methane diffusion through the pores or boundary of ice crystals (Takeya et al. 2002).

Research on the kinetics of gas hydrate decomposition at temperatures below 0°C revealed irregularly low rates of methane hydrate dissociation at temperatures between -31°C and -2°C, which was termed "anomalous preservation" of gas hydrates (Stern et al. 2001).

German scientists studied anomalous preservation of CH_4 and CO_2 hydrates and structural transformation of ice at low temperatures using neutronography and scanning electron microscopy (Kuhs et al. 2004). They determined that the lower temperature boundary of methane hydrate self-preservation occurs at -33°C; at temperatures below this threshold the ice structure does not inhibit gas diffusion, while gas diffusion becomes hindered as the ice structure changes at -33°C.

Using field data from gas shows in shallow permafrost and laboratory research of gas hydrate behavior at negative temperatures, we can identify the so-called metastable zone of gas hydrates. This zone is located above the stability zone of gas hydrates where the temperature conditions are favorable for the self-preservation effect (Fig. 1).

These self-preserved shallow-depth gas hydrates are presently under non-equilibrium conditions and pose a serious geological hazard to drilling exploration in these regions. The dissociation of shallow metastable methane hydrate may also contribute to global warming by adding significant amounts of methane, a greenhouse gas, to the atmosphere.

Since relict gas hydrates are poorly understood, experimental research on the self-preservation effect of gas hydrates in frozen sediments under non-equilibrium conditions is of significant importance.

Methods

Experiments on the self-preservation of gas hydrate in frozen sediments under non-equilibrium conditions were conducted on natural samples from Vorkuta, Russia, located 160 km beyond the Arctic Circle. Cores were collected from permafrost horizons exhibiting gas release at the Yamburg gas field (dust sand, depth: 63 m) and the Bovanenkovo gas field (light loam, depth: 65 m) (Table 1). The initial sediment water contents ranged from 10 to 20%.

The experimental technique is based on physical modeling of water phase transitions and frozen methane hydrate-saturated samples in pressure chambers (Chuvilin & Kozlova 2005a). Methane (99.98% pure) was used to form hydrate at temperatures between ~0.5 and 2.0°C in two partially water saturated 9-cm long sediment samples with 4.6 cm and 6.8 cm diameters. The pressure chambers were filled to 6-7 MPa. After hydrate formation stopped, the pressure chamber containing the test sample was cooled to -8°C freezing any remaining free water and pushing the hydrate deeper into

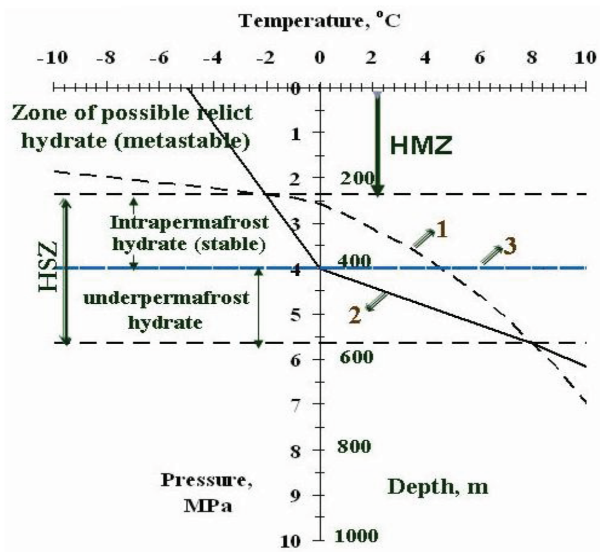

Figure 1. Conditions of gas hydrate occurrence in permafrost environments. **1** - Equilibrium curve of methane-hydrate stability in water-gas medium; **2** – Ground temperature profile; **3** - Permafrost boundary; **HSZ** - Hydrate stability zone; **HMZ** – Hydrate metastability zone.

the stability field. The experimental technique is described in detail in Chuvilin et al. (2003).

The hydrate content and hydrate coefficient (share of water which has transformed in hydrate) were determined from changes in thermobaric conditions incorporating compressibility according to Mendeleyev-Clapeyron equation:

$$m_G = \frac{P_i \cdot V \cdot M}{R \cdot T_i \cdot z},$$

where P_i is pressure at a point in time i (MPa); V is free volume of the pressure chamber (cm^3); M is molar mass of gas (g/mol); R is absolute gas constant (N·m/K ·mol); T_i is temperature at a point in time i (K); z is gas compressibility.

After chamber pressure was vented to atmosphere, the chamber was opened in a cold room at -8°C. Detailed petrophysical analyses were performed on the frozen hydrate within 30 minutes of it being taken out of the chamber. Petrophysical analyses included macro- and micromorphological observations, calculation of water content, density, gas and hydrate content, porosity, hydrate coefficient, degrees of hydrate, and ice pore saturation. Gas content was measured by thawing in a solution of NaCl. Quantification of methane hydrate dissociation assumed a hydrate number of 5.9.

Remaining frozen hydrate-bearing sediment samples were stored on weighing devices for extended periods of time at freezing temperatures. Sublimation of the ice was reduced by a thin ice coating on the samples. Samples were monitored for over a month, during which time volumetric hydrate content Hv (Hv =VH·100% /Vsamp where VH is volume of hydrate, Vsamp is volume of the sample), hydrate saturation Sh (Sh = Hv /ϕ, % where Hv is volumetric hydrate content, and ϕ is sample porosity); ice saturation Si (Si = Iv /ϕ, % where Iv is volumetric ice content) and hydrate coefficient K_h (share of pore water which has transformed in hydrate) were calculated.

Experimental Results

In general, the test samples were characterized by homogeneous sediment structure and uniform distribution of hydrate and ice in the pore space resulting from an initial uniform water distribution (Chuvilin & Kozlova 2005b). The samples were also characterized by massive cryohydrates.

Table 1. Characteristics of soils.

Type of sediment	Particle size distribution, %			Particle density, ρ_s, g/cm^3	Plastic limit, W_p, %	Liquid limit, W_l, %	Salinity, %
	1-0.05 mm	0.05-0.001mm	<0.001 mm

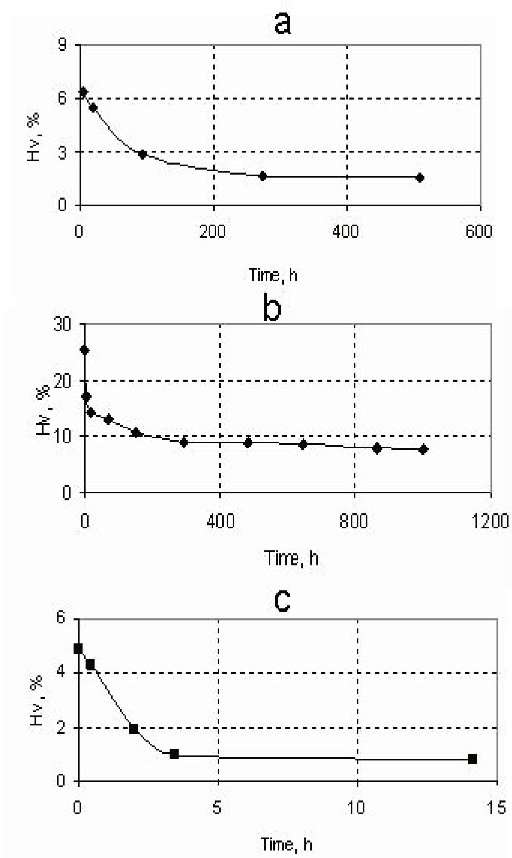

Figure 2. Methane hydrate dissociation kinetics in hydrate saturated frozen sediment after release of pressure to 0.1 MPa (atmospheric pressure).
a - sandy loam (W_g= 18%, t = -7.0°C);
b - silty sand (W_g= 18%, t = -6.5°C);
c - light loam (W_g= 20%,t = -5.0°C).

The sample properties are presented in Table 2. The porosity of the artificially hydrate-saturated sediment samples ranged from 0.41 to 0.47. The proportion of water incorporated into hydrate (K_h) in the silty sand sample (W_g=18%) (under equilibrium condition prior to pressure release) was 0.74, with a hydrate pore saturation (S_h) of 50%. 30-minutes after pressure release K_h and S_h decreased to 0.66 and 42% respectively. The light loam sample (W_g = 20%) had a K_h of 0.12 and S_h of 11% under equilibrium conditions. These values decreased to 0.11 and 10% respectively after pressure release. Thus, hydrate distribution in the finer-grained sediments was more dispersed and the pore saturation was lower. After pressure release, there is an intense decomposition of pore-space hydrate, followed by a more gradual decomposition (Fig. 2).

Our experimental data show that self-preservation reduces decomposition of pore-space hydrate in all samples. The self-preservation effect forms a thin ice film around particles of dissociating gas hydrate at temperatures below 0°C. As a result of this effect, hydrate can remain in a metastable condition for a long time.

As hydrate saturation decreases, ice content (S_i) increases (Fig. 3). At the beginning of the experiment (before gas release) hydrate saturation was 50%, and ice saturation was 8% in the silty sand sample. After 845 hours, gas hydrate saturation decreased to 13%, and ice saturation increased to 43%.

Self-preservation of gas hydrate in frozen sediment depends on many factors such as thermobaric conditions, hydrate and ice saturation, gas permeability, structure of organic-mineral skeleton of sediment, pore water salinity, and structure of hydrate, including micromorphology.

Ice formed during freezing of residual pore water which has not transformed into hydrate plays a special role in the self-preservation of gas hydrates. Occurrence of this ice promotes gas hydrate stability in a porous medium. As a rule, samples of frozen hydrate with greater ice content after pressure release are more prone to self-preservation. The presence of clay particles increases gas hydrate dispersion and reduces, but does not eliminate, the self-preservation

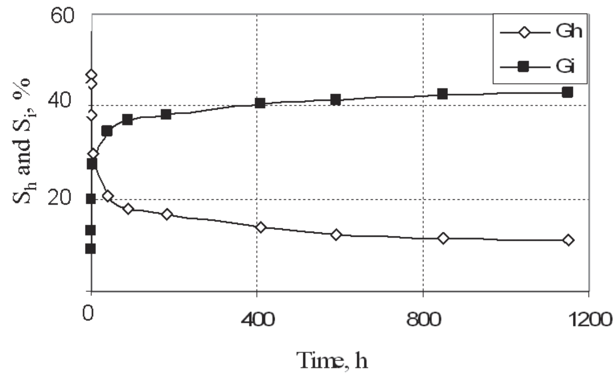

Figure 3. Change in methane hydrate saturation (S_h) and ice saturation (S_i) in hydrate-saturated silty sand (W_g=18%, t = -6.5 °C) after pressure release to 0.1 MPa.

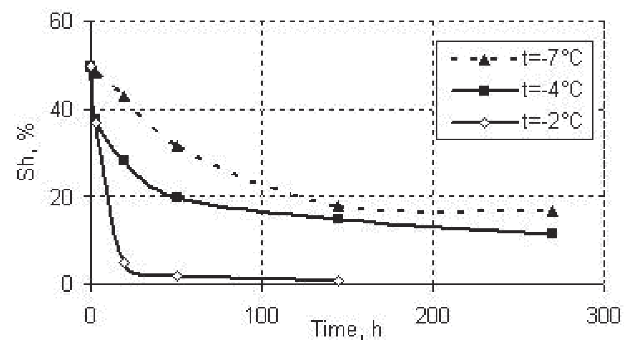

Figure 4. Methane hydrate dissociation kinetics in artificially hydrate-saturated frozen silty sand (W_g=14%) after pressure release to 0.1 MPa.

effect even in loamy deposits. Presence of salt in hydrate containing sediments also reduces the self-preservation effect. Thus, in light loam the intensive reduction of hydrate content after pressure release can be connected with the higher salinity (to compare to other samples) (Table 1, Fig. 2).

Results of experiments on sand and loam samples show that the intensity of pore gas hydrate dissociation sharply decreases with lower temperatures. In the silty sand sample (W_g=14%, initially about 45% hydrate saturation at all temperatures) hydrate saturation after pressure release decreased to 5% at -2°C in 20 hours, 28% at -4°C, and 43% at -7°C (Fig. 4). After 150 hours at -2°C, little hydrate remained, however, at -4°C and -7°C decomposition was sharply decreased.

Pore-hydrate dissociation practically ceases at lower temperatures. Because experimental temperatures compare favorably to natural temperatures (-5°C to -7°C) for permafrost sediments at the Yamburg and Bovanenkovo gas fields, it is possible for *in situ* gas hydrate to remain in a metastable condition for long periods of time.

In addition, the weight of overburden and high ice content of sediments provide additional stability to the metastable hydrate.

Conclusions

Experiments were conducted on kinetics of gas hydrate dissociation. Our experiments conducted on core samples confirm the self-preservation of natural pore-space gas hydrates. The conditions promoting self-preservation of natural gas hydrates are: low temperature, high ice content, low gas permeability, and overburden pressure. However, increased sediment temperature and pore water salinity, and gas hydrate dispersion in fine-grained sediment reduce the self-preservation effect.

Acknowledgments

This research was funded by the Russian Foundation Basic Research Program No 05-05-39019 and 06-05-91573. We thank the anonymous referees for various suggestions to improve the manuscript.

Effects of Recent Climate Change on High Mountains of Western North America

John J. Clague
Simon Fraser University

Abstract

Pronounced step-wise atmospheric warming during the 20th century reduced ice cover in mountains by 25–50 percent. Net changes in average annual and mean summer temperatures responsible for this remarkable deglacierization are less than 2°C, a small fraction of the warming that occurred at the end of the Pleistocene. Yet the effects of these changes on mountain landscapes have been profound. Alpine permafrost, which expanded during the Little Ice Age, now appears to be thinning and disappearing in many areas. Loss of alpine permafrost and glacier downwasting appear to be partly responsible for accelerated mass wasting and catastrophic rock-slope failures in high mountains. New lakes appeared during the Little Ice Age when glaciers advanced across streams and rivers and blocked drainage. Most of these lakes drained one or more times during the 20th century, producing catastrophic floods orders of magnitude larger than normal nival or rainfall floods. In some instances, lakes have appeared upvalley of former, drained ones as glaciers have continued to retreat under a warming climate. Lakes also formed behind Little Ice Age end moraines when glaciers retreated in the early 20th century. Moraine dams are vulnerable to failure because they are steep-sided and consist of loose sediment. Outburst floods from lakes dammed by glaciers and moraines erode, transport, and deposit huge amounts of sediment over distances tens of kilometers. They broaden flood plains, destroy pre-flood channels, and create a new braided planform. The changes can persist for decades after the flood.

Keywords: climate change; deglacierization; jökulhlaup; landslides; Little Ice Age; permafrost thaw.

Introduction

Alpine glaciers in the Northern Hemisphere achieved their greatest extent of the Holocene during the "Little Ice Age" (AD 1200–1900; Holzhauser 1985, Grove 1988, Wiles et al. 1999, Luckman 2000, Luckman & Villalba 2001). Although Earth's climate was highly variable during this period, alpine glaciers grew episodically but progressively larger, culminating with the maximum advances of the Little Ice Age in the late 17th to mid 19th centuries.

Climate variability during the Little Ice Age (Moberg et al. 2005) probably was caused by a combination of forcing mechanisms (Mann et al. 1998). Explosive volcanism has contributed to Northern Hemisphere temperature changes during the past 600 years (Bradley & Jones 1993, Briffa et al. 1998), and some glacier advances coincided with intervals of elevated volcanic aerosols in the atmosphere (Porter 1986). Some researchers have argued that solar activity influenced the climate of the past millennium (Lean et al. 1995, Crowley & Kim 1996, Crowley 2000); indeed, periods of late-Little Ice Age moraine formation generally coincide with solar minima (Lawrence 1950, Wiles et al. 2004, Luckman & Wilson 2005). In addition, ocean-atmosphere interactions influenced atmospheric circulation and thus glacier behavior during the past millennium (Hendy et al. 2002, Nesje & Dahl 2003, Lewis & Smith 2004*,* Mann et al. 2005). Ruddiman (2003) suggested that widespread farm abandonment during the Black Death plagues and attendant reforestation may explain the cool phases of the Little Ice Age by changing concentrations of atmospheric carbon dioxide and methane.

The Little Ice Age ended about 100 years ago when climate around the world began to warm. Glaciers in most mountain ranges in the Northern Hemisphere, including those in western North America, receded during the first two decades of the 20th century. Some glaciers advanced in the 1920s but underwent rapid and extensive recession over the next three decades. Most glaciers advanced small distances between the 1950s and early 1980s but since then have retreated. Today most glaciers are 25% to 50% smaller than at the end of the Little Ice Age.

Net changes in average annual and mean summer temperatures responsible for glacier and climate change during and following the Little Ice Age are less than 2°C (Mann et al. 1998). This amount is a small fraction of the total warming that occurred during the demise of Northern Hemisphere ice sheets at the end of the Pleistocene. Corresponding changes in mean and seasonal precipitation in most areas also are relatively small. Yet these changes have had significant effects on high mountain environments and on rivers flowing from these mountains. This paper summarizes and discusses these effects.

Permafrost Thaw and Deglacierization

An increase in large landslides in northern British Columbia during the 20th century (Geertsema et al. 2006) may be related to warming or thaw of alpine permafrost and deglacierization. Permafrost expanded in high mountains during the Little Ice Age but now appears to be thinning and disappearing there (Zhang et al. 2006). Alpine permafrost has a complex and patchy distribution that is controlled mainly by altitude, material properties, snow cover, and topography. A rough estimate can be made of changes in the extent of permafrost in high mountains of North America using independently determined temperature changes, bearing in mind that permafrost distribution is affected by more than

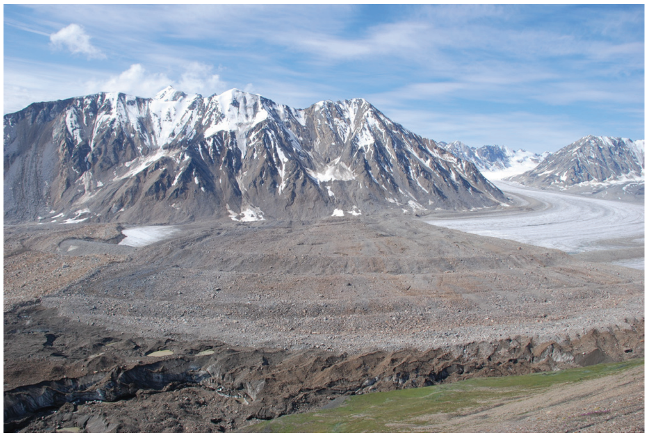

Figure 1. Landslide deposit on Black Rapids Glacier, Alaska. The rock avalanche was triggered by a large earthquake in November 2002, but loss of glacier ice on the source slope may have contributed to the failure. The landslide scarp is indicated by an arrow.

just temperature. Using a range of mean annual temperature of 2°C on timescales of decades and an adiabatic lapse rate of 4°C/km–6°C/km, the limit of permafrost shifted vertically 300–500 m during the Little Ice Age. The average rise in the limit of alpine permafrost in the 20th century, during which climate warmed 0.6°C–0.8°C, may have been 100–200 m. These values may not seem significant, but even greater reductions in permafrost can be expected through the remainder of this century. Even 20th century warming and loss of permafrost have been implicated by recent instability of slopes in some mountain ranges (Watanabe et al. 2000, Gruber et al. 2004). Further, permafrost warming alone, without thaw, may increase the likelihood that rock slopes will fail (Davies et al. 2001, Harris et al. 2001). Sediments may mobilize as debris flows when their interstitial ice thaws (e.g., Bovis & Jakob 2000), and masses of rock may fail, generating rockslides and rock avalanches when ice within the fractures undergoes repeated thawing and freezing.

Another consequence of increased thaw of permafrost in high mountains is that many active rock glaciers will cease moving. Evidence has been reported that formerly active rock glaciers became less active or even fossil landforms in the 20th century (McCarroll et al. 2001, Baroni et al. 2004).

Glacier downwasting and retreat appear to be partly responsible for some catastrophic rock-slope failures in high mountains (Evans & Clague 1994, Evans & Clague 1999, Holm et al. 2004). Many marginally stable slopes that were buttressed by glacier ice during the Little Ice Age failed after they became deglaciated in the 20th century (Fig. 1). A factor that possibly has contributed to such failures is steepening of rock slopes by cirque and valley glaciers during the Little Ice Age.

These effects are most pronounced in mountain ranges with the largest ice cover, because it is there that ice losses in the 20th century have been greatest. An extreme example is Glacier Bay, which until the end of the 18th century was covered by glacier ice. Since then, Glacier Bay has become deglaciated with the loss of over 1000 km^2 of ice in 200 years. This amount of ice lost is so great that the land is rising due to isostatic rebound (Larson et al. 2005).

Figure 2. Summit Lake, located in the northern Coast Mountains of British Columbia. The lake is impounded by Salmon Glacier (background) and has drained and refilled more than 40 times over the past 47 years.

Outburst Floods

New lakes appeared in the mountains of western North America when glaciers advanced across streams and blocked drainage during the Little Ice Age (Fig. 2). The histories of these lakes are poorly known except in the 20th century when most of them drained one or more times, producing catastrophic floods (jökulhlaups) orders of magnitude larger than normal nival or rainfall floods (Fig. 3, Costa & Schuster 1988, Clague & Evans 1994, and references therein). These floods have occurred during a period of warming climate due to progressive wastage of the glacier dam and the formation of subglacial, supraglacial, or ice-marginal channels. Lakes may also form during rapid glacier advances ("surges").

New lakes also formed behind Little Ice Age end moraines as glaciers retreated in the late 19th and early 20th century (Fig. 4; Costa & Schuster 1988, O'Connor & Costa 1993, Clague & Evans 1994, Clague & Evans 2000). Moraine dams are vulnerable to failure because they are steep-sided and consist of loose sediment. Irreversible rapid incision of the dam may be caused by a large overflow triggered by an ice avalanche or rockfall. Other failure mechanisms include earthquakes, slow thaw of ice within the moraine, and removal ("piping") of fine sediment from the moraine. "Outburst floods" from lakes dammed by glaciers and moraines erode, transport, and deposit huge amounts of sediment over distances tens of kilometers (Fig. 5).

Outburst floods from glacier- and moraine-dammed lakes display an exponential increase in discharge, followed by a gradual or abrupt decrease to background levels as the water supply is exhausted. Peak discharges are controlled by lake volume, dam height and width, the material properties of the

Figure 3. Jökulhlaup caused by the sudden drainage of Summit Lake, north of Hyder, Alaska.

dam, failure mechanism, and downstream topography and sediment availability. Floods from glacier-dammed lakes tend to have lower peak discharges than those from moraine-dammed lakes of similar size. This is because enlargement of tunnels within ice is a slower process than overtopping and incision of sediment dams.

Floods resulting from failures of glacier and moraine dams may transform into debris flows as they travel down steep valleys. Such flows can only form and be sustained on slopes greater than 10°–15°, and only where there is an abundant supply of sediment in the valley below the dam. Entrainment of sediment and woody plant debris by floodwaters may cause peak discharge to increase down valley, which has important implications for hazard appraisal.

Outburst floods from lakes dammed by moraines and glaciers commonly alter river flood plains tens of kilometers from the flood source (Fig. 5). The floodwaters erode, transport, and deposit huge amounts of sediment. They commonly broaden flood plains, destroy pre-flood channels, and create a new multi-channel, braided planform. The changes can persist for decades after the flood, although rivers quickly reestablish their pre-flood grades by incising the flood deposits.

Climate is an important determinant of the stability of moraine and glacier dams. Most moraine-dammed lakes formed in the last century as glaciers retreated from bulky end moraines constructed during the Little Ice Age. The lakes soon began to fail as climate warmed. With continued warming and glacier retreat, the supply of moraine-dammed lakes susceptible to failure will be exhausted, and the threat they pose will diminish (Clague & Evans 2000). Glacier-dammed lakes typically have gone through a period of cyclic or sporadic outburst activity, lasting up to several decades, since climate began to warm in the late nineteenth century. The cycle of outburst of floods from any one lake ended when the glacier dam weakened to the point that it could no longer trap water behind it. However, with continued glacier retreat, the locus of outburst activity may, in some cases, shift up-glacier to sites where new lakes develop in areas that are becoming deglaciated (Geertsema & Clague 2005).

Changes to Streams

Fluctuations of glacier margins on timescales of decades and centuries can mobilize sequestered glaciogenic sediment. During glacier advance, initial incision due to increased competence of meltwater streams is quickly followed by aggradation as sediment supply increases (Maizels 1979). Sediment stored within and beneath glaciers is delivered at an increasing rate to fluvial systems as glaciers advance (Karlén 1976, Maizels 1979, Leonard 1986, Leonard 1997, Karlén & Matthews 1992, Lamoureux 2000). Similarly, subglacial erosion increases during glacier advance, and meltwater may carry more sediment into river valleys than at times when glaciers are more restricted. Paraglacial sediment pulses may propagate rapidly downstream in narrow mountain valleys when glaciers advance to maximum positions and, subsequently, as they begin to retreat. Glacier retreat typically exposes large areas of unstable, poorly vegetated sediment that is easily transferred to the fluvial system, causing valley-wide aggradation and complex changes in channel planform (Church 1983, Desloges & Church 1987, Gottesfeld & Johnson-Gottesfeld 1990, Brooks 1994, Ashmore & Church 2001, Clague et al. 2003, Wilkie 2006).

Increased glacial erosion and sediment production during glacier advance, coupled with climatically induced changes in discharge and sediment yield, can cause rivers to aggrade their beds. Sediment delivery to streams in the Coast Mountains of British Columbia, for example, increased during the Little Ice Age, and the streams responded by aggrading their channels and braiding over distances up to tens of kilometers down valley from glaciers (Church 1983, Gottesfeld & Johnson-Gottesfeld 1990, Wilkie 2006). Subsequently, during the 20th century, the streams incised their Little Ice Age deposits and reestablished single-thread channels characteristic of periods of lower sediment flux.

Conclusion

Climate warming during the 20th century and the first decade of the present century has caused changes in the pace of geomorphic processes in mountains in western North America and elsewhere. Rapid, large-scale deglacierization and thaw of alpine permafrost have increased the incidence of landslides and debris flows in mountains. Lakes that formed against retreating glaciers and end moraines have drained suddenly, catastrophically altering valley bottoms far downstream. Changes in sediment delivery to streams have altered local base level and channel planform in mountain valleys. If the forecasts of climate modelers are correct, loss of glacier ice and alpine permafrost will continue and perhaps accelerate through the remainder of this century.

A Model of Permafrost Distribution and Disturbance Sensitivity for Denali National Park, Using Soil-Ecological Site Inventory Information

Mark H. Clark
USDA-Natural Resources Conservation Service, Palmer, Alaska, USA

Abstract

A soil-ecological site survey of Denali National Park and Preserve (Denali) completed in 2004 by the Natural Resources Conservation Service is used to provide a map of Gelisols, soils with permafrost within 2 m of the surface, and their sensitivity to disturbance. Three sensitivity classes are assigned, based on similarities in the degree and rapidity of change to soil properties and plant communities following disturbance, as well as return interval to the pre-disturbance condition. The model aggregates ecological sites into groups with similar plant community structure and species richness, two elements useful in evaluating wildlife habitat. Dynamic soil properties, such as thickness of organic mat, depth to water table, and permafrost, may also be estimated for the various ecological states identified for each sensitivity class. This information is useful for estimating transient carbon budgets in soils and hydrologic functions, as well as indicating soils that are likely to be impacted by climate change. Gelisols considered highly sensitive to disturbance comprise 118,185 ha, or about 4% of Denali. Moderately sensitive Gelisols comprise 445,192 ha, or 18% of Denali. Gelisols considered low in sensitivity include 391,760 ha, or about 16% of Denali.

Keywords: ecological site inventory; Gelisols; permafrost; soil survey.

Introduction

The northern region of Denali includes areas lying north of the Alaska Range summit. This represents a subset of the Polar Domain described by Bailey (1994) and lies within the zone of discontinuous permafrost (Péwé 1975). The "Interior" climate of the northern part of Denali is continental, with long cold winters and short warm summers, relatively low precipitation, with a significant moisture deficit during the growing season (Patric & Black 1965).

Gelisols, soils with permafrost within 2 m of the surface (Soil Survey Staff 2006), are widely distributed within the northern part of Denali and generally absent in the remainder of the Denali south of the Alaska Range summit (Fig. 1). Gelisols are common to gently sloping, infrequently flooded surfaces throughout the boreal forest biome and lower elevations of the alpine life zone (Fig. 1) Gelisols are defined as having permafrost. However, extensive areas alternate between a poorly-drained, ice-rich condition, and a well-drained, permafrost-free state due to disturbance such as fire and post-disturbance plant succession. In this application, the definition of Gelisols includes those soils that have permafrost within 2 m of the soil surface under potential natural vegetation. Soils that are permafrost-free, with early to mid-succession communities and soil morphological properties that suggest that permafrost is present under potential native vegetation, are also considered Gelisols.

Variable rates of thaw, recession of water tables, and return intervals to the pre-burn condition are common to Gelisols following disturbance (Dyrness 1982). These differences are documented in the Ecological Site or Landtype (Bailey 1994) descriptions for each Gelisol soil component provided in the soil-ecological site survey of Denali National Park and Preserve (Denali) (Clark & Duffy 2004). The purpose of this poster is to provide a distribution map of Gelisols in Denali and present a model of sensitivity of Gelisols to disturbance based on ecological Landtypes.

Methods

The sensitivity of Gelisols to disturbance and lowering or loss of permafrost is modeled using a two-step process. The first step includes deriving a map of the distribution of Gelisols in Denali. This is accomplished using the soil-ecological survey database (Clark & Duffy 2004) to develop criteria and the spatial data to illustrate the map and provide associated statistics. Map units consisting of at least 15% Gelisols are aggregated into a map for consideration in the development of the disturbances sensitivity model (Fig. 1). The second step includes assigning map units into three sensitivity classes based on similar response to disturbance as defined in the ecological landtype descriptions. Significant soil properties associated with each disturbance class are then derived from the ecological landtype database.

Both static and dynamic site and soil properties are determined as useful to the model. Soil texture and overall thickness of the surface mineral layer are important static soil properties useful in determining sensitivity. A soil's ability to conduct heat increases as particle sizes increase (Jury et al. 1991). Soils with a low sand and rock fragment content conduct heat less effectively than soils with high sand or rock fragment content. Soils with high silt content have lower thermal conductivity and are most likely to experience a slower rate of permafrost recession and more rapid return to pre-burn condition than coarse textured soils. Soils with high sand and rock fragment content are less likely to have the potential for permafrost, because the high thermal conductivity promotes summer warming and prevents frost from persisting through the summer months. Dynamic soil and site properties for each ecological landtype are useful to document transitional states between the non-permafrost and permafrost condition and provide a time-line for change between each pathway element. Dynamic soil properties important to the model include organic mat thickness, depth to permafrost, and depth to water table perched above the permafrost.

Fire is the only major disturbance factor available for use in the criteria. Anthropogenic disturbance in Denali is minimal, and flooding and landslide activity is primarily limited to soils other than Gelisols. The criteria assumes that a level of fire intensity common to the boreal biome and alpine life zone has occurred, including a mosaic pattern of scorched and unburned ground, and only partial incineration of the surface organic mat where burned. Fire disturbance is infrequent on soils with permafrost within the alpine life zone. The assignment of sensitivity classes to Gelisols within the alpine life zone are based on similar soils from within the boreal biome. Criteria used to assign three categories of sensitivity are outlined below.

Gelisols that are highly sensitive to disturbance, are rarely or non-flooded, and have a surface mineral soil layer consisting of 50 to 100 cm of silt loam, or stratified fine sand and silt with few rock fragments over sandy and gravelly alluvium with variable rock fragment content. Soil properties and plant communities associated with this sensitivity class are represented by ecological landtype Loamy Frozen Terraces-131B_104 (Clark & Duffy 2004). Thermal conductivity properties of the silt or stratified surface mineral soil layer are relatively low ranging, from about 0.25 to 1.4 cal $cm^{-1}s^{-1}$ $^{o}C^{-1}$ (Jury 1991). However, the thin nature of the surface mantle does not significantly retard surface warming following disturbance, and subsequent recession of permafrost is relatively fast. The high thermal conductivity of the underlying sand and gravel is estimated at 4.5 cal $cm^{-1}s^{-1}$ $^{o}C^{-1}$ (Jury 1991), and the porous nature of these coarse texture materials likely contributes to rapid warming and recession of permafrost in these soils. Landforms associated with the highly sensitive class include stream terraces, alluvial fans, and high positions on flood plains (Fig. 2). Climax plant communities from this class include shrub birch (*Betula glandulosa*)-bog blueberry (*Vaccinium uliginosum*)/moss scrub within the alpine life zone; and black spruce (*Picea mariana*)-tamarack (*Larix laricina*)/Labrador tea (*Ledum groenlandicum*) woodland within the boreal biome. Soils included in this class include Typic Historthels, Ruptic-Histic Aquiturbels, Fluvaquentic Historthels, and Typic Aquiturbels subgroups of US Soil Taxonomy (Soil Survey Staff 2004).

Gelisols that are moderately sensitive to disturbance are loamy throughout the soil profile, with 15 to 40% rock fragments in the upper 100 cm of soil. Soil properties and plant communities associated with this sensitivity class are represented by ecological landtype Gravelly Frozen Slopes, M135A_180 (Clark & Duffy 2004). These soils have intermediate levels of thermal conductivity related to the moderate level of rock fragments and loamy soil matrix, which overall exchange heat at a slower rate than soils of the first class. Landforms associated with this sensitivity class include till plains, all positions on glaciated low mountains, and on lower mountain slopes of non-glaciated mountains (Fig. 3). This class mostly consists of gelisols within the alpine life zone, commonly with a climax plant community of shrub birch-mixed ericaceous shrub/sedge (*Carex spp*.) scrub. Soils in this sensitivity class include Typic Historthels and Glacic Folistels subgroups of US Soil Taxonomy (Soil Survey Staff 2004).

Soils with permafrost that are considered to have a low sensitivity to disturbance (Fig. 4) are rock-free with silt or stratified fine sand and silt textures over 100 cm thick and have soils with near-surface water tables associated with cottongrass (*Eriophorum spp.*) tussock late succession communities. Soil properties and plant communities associated with this sensitivity class are represented by ecological landtype: Loamy Frozen Slopes, Wet-131B_402 (Clark & Duffy 2004). This group has soil texture of silt loam, loam, or stratified loamy surface layers with relatively low thermal conductivity properties ranging from 0.25 to 1.4 cal $cm^{-1}s^{-1}$ $^{o}C^{-1}$ (Jury 1991). Landforms associated with the low sensitivity class include loess covered plains, hills, and stream terraces (Fig. 4). Climax plant communities include black spruce-tamarack/tussock cottongrass woodland within the boreal biome and tussock cottongrass/mixed ericaceous shrub meadow in the alpine life zone. Soils in this sensitivity class include Typic Histoturbels, Typic Historthels, and Typic Umbrothels subgroups of US Soil Taxonomy (Soil Survey Staff 2004).

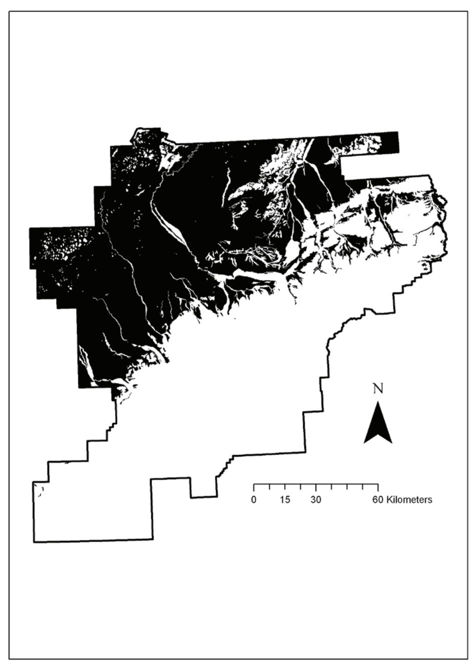

Figure 1. Distribution of soil map units consisting of at least 15% Gelisols in Denali.

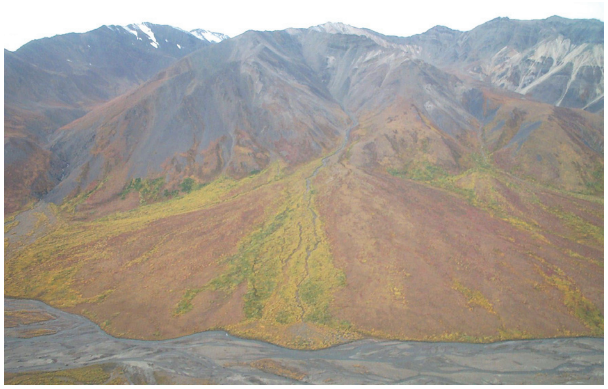

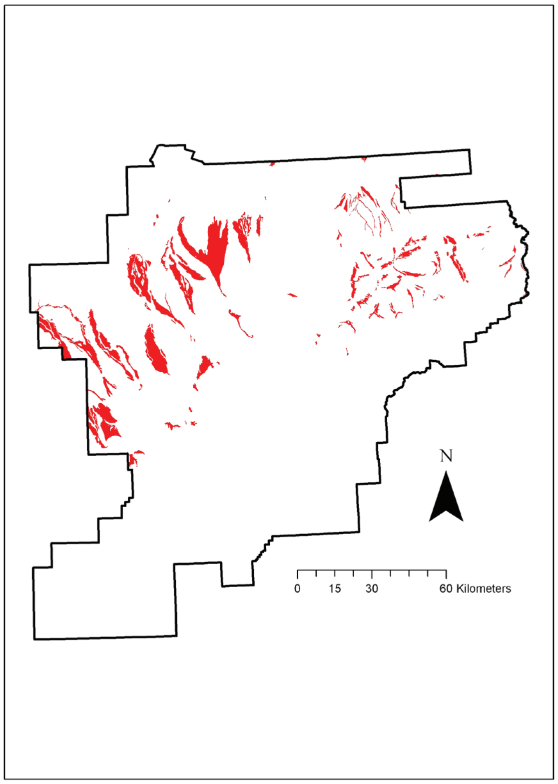

Figure 2. Upper: Alluvial fan with Gelisols illustrated in the foreground with shrub birch-bog blueberry/moss scrub typical of a Gelisol sensitive to disturbance. Lower: Gelisols highly sensitive to disturbance or temperature change are represented in black and total 118,185 ha, or about 4% of Denali.

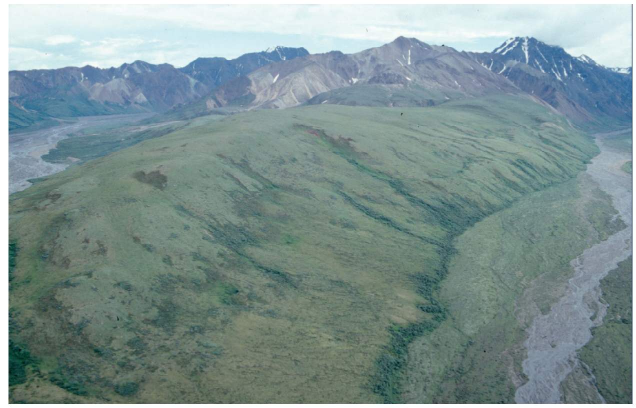

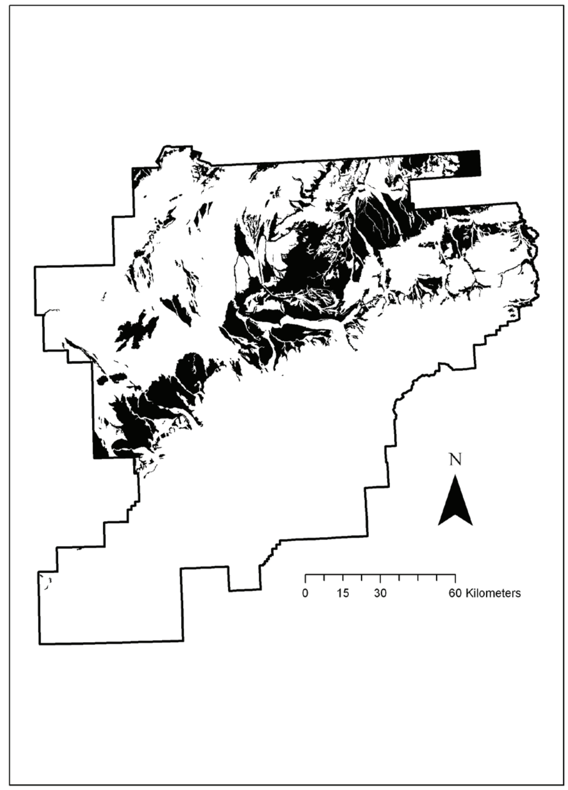

Figure 3. Upper: Glaciated mountains with shrub birch-mixed ericaceous shrub/sedge scrub illustrated in the light tonal areas of the foreground. Soils are primarily Gelisols that are moderately sensitive to disturbance. Lower: Gelisols moderately sensitive to disturbance are represented in black and total 445,192 ha, or 18% of Denali.

Results

Distribution of soil map units with Gelisols in Denali is provided in Figure 1. This illustrates map units containing soil components with permafrost that comprise 15% or more of the map unit. The total distribution of map units that meet these criteria encompasses 931,000 ha, or about 38% of the park. Soil map units with Gelisols highly sensitive to disturbance or temperature change are represented in black, and total 118,185 ha, or about 4%, of Denali (Fig. 2). The high thermal conductivity property of soils is considered an important factor in the high sensitivity of these soils to change following disturbance Permafrost is observed to drop rapidly to below 200 cm of the ground surface within one to three years following fire in this class. Return to the pre-burn condition in the black spruce type in Interior Alaska is suggested as 50 to 70 years Foote (1976) and Viereck (1973). However, based on tree core observations in Denali, a return interval of 100 to 150 years is estimated for this sensitivity category. Gelisols within the boreal biome that are included within this class have a single climax and two distinctive transitional plant communities, suggesting that significant changes in dynamic soil properties following disturbance are associated with a diverse array of wildlife habitat types, especially within the boreal biome.

Soil map units with Gelisols moderately sensitive to

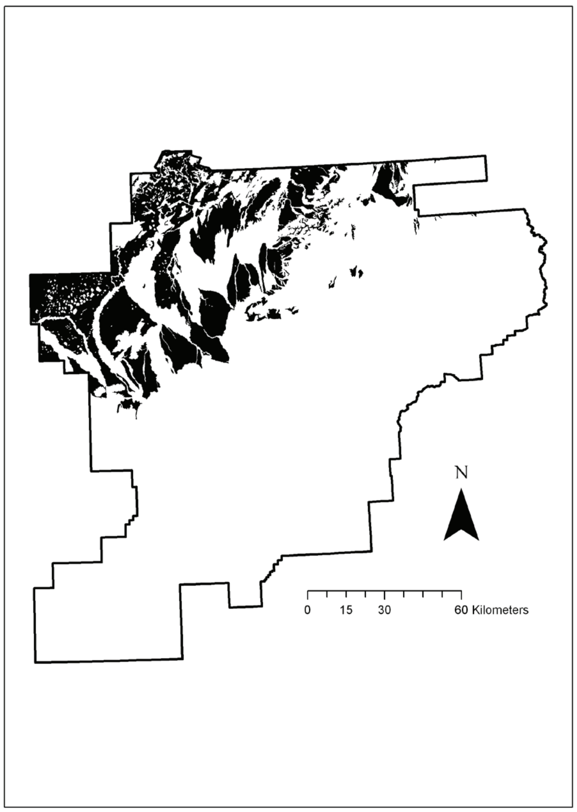

Figure 4. Upper: An extensive loess plain with black spruce/ericaceous shrub woodland and Gelisols with low sensitivity to disturbance. Lower: Gelisols with low sensitivity to disturbance are represented in black and total 391,760 ha or about 16% of Denali.

disturbance or temperature change are represented in black in Figure 5 and total 445,192 ha, or 18% of Denali. The moderate thermal conductivity property of soils is considered an important factor of change in this class. Loss of permafrost to depths below 200 cm is observed at three to five years following fire, and is significantly longer than that observed for the previous class. However, the return to the pre-burn condition is similar to that of the highly sensitive soils: about 130 years. A single climax plant community consisting of shrub birch-mixed ericaceous shrub/sedge scrub has been identified, suggesting a moderately low level of diversity in terms of habitat types.

Soil map units with Gelisols that have low sensitivity to disturbance are represented in black in Figure 7 and total 391,760 ha, or about 16% of Denali. The relatively low thermal conductivity property of soils is attributed to the minimal change on these soils following disturbance. Gelisols within this sensitivity class are observed to experience only slight lowering in depth to permafrost, rarely exceeding 200 cm depth unless associated with localized massive ice degradation. Site and soil characteristics typically return to the pre-burned condition within 25 years, based on tree core observations. Several ecological landtypes are included in this sensitivity class, each with unique climax vegetation and seral communities. Black spruce woodlands with various understory including ericaceous shrub, cottongrass tussock are common late succession communities within the boreal biome and tussock cottongrass/mixed ericaceous shrub meadow in the alpine life zone. Several community types are identified for this sensitivity class. However, most types are similar in terms of species composition, with only subtle differences apparent between succession states.

Abstract

Imperial College London is researching with BP some potential impacts of future climate change. BP has a significant number of facilities in cold high-latitude regions, where global climate models predict significant rises in air and ground surface temperature. This could impact on the state and extent of permafrost, potentially posing risks to facilities, infrastructure, and operations (ACIA 2005). The paper reviews the research, focusing on an exemplar study region in eastern Siberia. The key elements included: (1) Developing an approach to provide a best estimate of future climate change. (2) An engineering geological appraisal of the ground conditions in the study region. (3) Performing a parametric study of geothermal conditions in the study region using finite element thermal analyses. (4) Developing a Thermal-Hydraulic-Mechanical modeling approach for assessment of climate change impact on specific engineering facilities. (5) Developing a methodology for incorporating potential climate change considerations into engineering decision-making and design.

Keywords: climate change; engineering adaptation; engineering geology; GCM modeling; Siberia; thermal modeling.

Introduction

This paper describes research by Imperial College London commissioned by BP Research. The objective was to provide BP with a process for assessing the likely effects of climate change on the integrity of its engineered facilities. The original brief was to:

- Describe the potential impact of changes in local climatic conditions on BP's current operations between now and the 2050s.
- Determine the potential vulnerability of new projects should existing design parameters remain unchanged.
- Provide a process to evaluate BP's exposure to damaging or beneficial effects of climate variability.
- Provide guidelines for the design of structures and infrastructure that anticipate potential future climactic changes in the region of interest.

A generic process has been developed to assess the potential exposure of future projects to climate change, but it became clear during the early parts of study that the outputs of General Circulation Models (GCM) used to predict climate change are not easily converted into data that can be used for engineering design. It was therefore decided to focus particular attention on the possible engineering consequences of air warming on the temperature profiles of frozen ground, the potential effects of permafrost thawing, and the difficulties of operating facilities in permafrost areas. This required the development of new modeling techniques for the assessment of climate change-induced effects on pipelines, foundations, and slopes in regions of existing permafrost.

An area of eastern Siberia was chosen as a relevant example, in order to validate the process,and to demonstrate the potential importance of climate change to BP operations.

Climate Modeling as a Geotechnical Input

The climate data used in this study is based on the predictions of seventeen coupled Atmosphere Ocean General Circulation Models (AOGCM) included in the IPCC Fourth Assessment Report (IPCC 2007), whose data is available from the Coupled Model Intercomparison Project (see URL: https://esg.llnl.gov:8443). These models were chosen because they have provided climate predictions under the conditions of the SRES A2 emissions scenario (Nakicenovic et al. 2000) adopted in this study, which is a standard pessimistic projection of greenhouse gas emission.

Coupled AOGCMs are the most sophisticated tools available for modeling current and future climate. All models used in this study have produced simulations of 20th Century climate that have been validated against appropriate contemporary observations. Climate models perform better at large spatial scales (such as global mean predictions), than at regional or local level, but there is nevertheless reasonably good agreement between modeled and observed temperature trends in Siberia and other cold regions. Careful statistical assessments indicate that the most reliable predictions are made by averaging the results of all available models to form a multi-model ensemble mean.

The multi-model ensemble mean air temperature (defined as the temperature at 2 m above the ground surface) was compared with the corresponding European Centre for Medium-Range Weather Forecasts 40 Year Re-analysis (ERA-40) observational dataset (Simmons & Gibson 2000) for each study area over the 1958–1998 period. Corrections were applied to the entire 1940–2059 time-series based on the difference between modeled and observed 40–year monthly mean temperature from 1958–1998, in an attempt to eliminate model bias as far as possible. The same process was applied to the corresponding multi-model mean time-series for snow depth. Each model time-series was then considered to correspond to the relevant 2.5° x 2.5° ERA-40 grid cell, which is equivalent to an area of approximately 150 km (east-west) by 280 km (north-south) in the study region. In all cases, the processed time-series represents a significantly larger area than would ideally be required for the thermal ground modeling, but further improvements in resolution would require better coverage of local station data than is currently available. An example of the model output is included in Figure 4, along with the predictions for changes in the ground thermal regime discussed below.

Height corrections were applied to produce both air temperature and snow depth time-series for different elevations. Temperature was adjusted based on mean monthly lapse rates derived from linear regression of the corresponding ERA-40 temperature, available for six elevations between 0 and 3000 m above sea level (m a.s.l.). Snow depth was adjusted in the accumulation phase based on a simple model describing orographic enhancement of precipitation (Roe et al. 2002), for which mean slope and wind speed data were taken from ERA-40. In the melting phase, snow depth was adjusted based on a combination of air temperature and solar radiation (Cazorzi & Fontana 1996), the former being dependent on the height correction applied to the temperature time-series. The final predicted mean monthly time-series were validated against local data and appear to be consistent with conditions in the study areas.

Project Geotechnical Strategy

The strategy developed for assessing the impact of climate change in cold regions has involved geotechnical research and development in four main areas:

1. Assessing the regional engineering geology and geomorphology of the study region, including identification of potential geohazards.
2. Reviews of present conventional frozen ground engineering practice.
3. Developing rigorous geothermal analytical tools and applying these on a regional basis.
4. Exploring and developing the potential of THM modeling in cold region engineering applications.

This work has led to a practical process for assessing geotechnical impact of climate change in cold regions that involves a hierarchy of risk assessment activities. The level of sophistication adopted for the risk assessment reflects the severity of potential adverse effects to BP's infrastructure and operations. The consequence assessment is carried out at a regional scale and incorporates consideration of the local ground conditions (identification of geohazards), the climate modeling outputs (sensitivity of hazard to climate change) and the inventory of BP's infrastructure (exposure and vulnerability).

The following three-level approach is recommended:

- Low-consequence hazards addressed through check-lists combined with simple accepted empirical methods.
- Intermediate-level cases to be tackled through regional (or site-specific) uncoupled geothermal modeling predictions combined with well-established conventional geocryological engineering approaches.
- Potentially high-consequence hazards to be addressed by advanced site-specific THM modeling.

The results obtained from any one of these approaches should confirm or challenge the initial assessment and could lead to a higher level of investigation.

Engineering Geology and Geomorphology

A region of eastern Siberia around Lake Baikal (Fig. 1) was chosen as the main focus for investigating the geotechnical impacts of climate change in an area of variable permafrost. The local geological, geographical, and climatic setting was assessed through an extensive review of published data, including geological and geocryological maps, consulting reports as well as interviews with local and international specialists. A brief reconnaissance field trip was also undertaken. The work was limited by the remote, undeveloped nature of the region. The data availability to western parties was also limited by a combination of material sensitivity, geographic location of resources, and translation requirements. A good data set is crucial to the recommended process and, to progress this study, the current assessment was augmented by reference to data from analogous geological and geocryological settings around the world.

Data requirements

The inputs needed to assess the geotechnical impact of climate change on permafrost are driven by the requirements of the geothermal modeling analyses discussed below. The key data requirements are:

- Comprehensive local climate records.
- Geographical and geomorphological information.

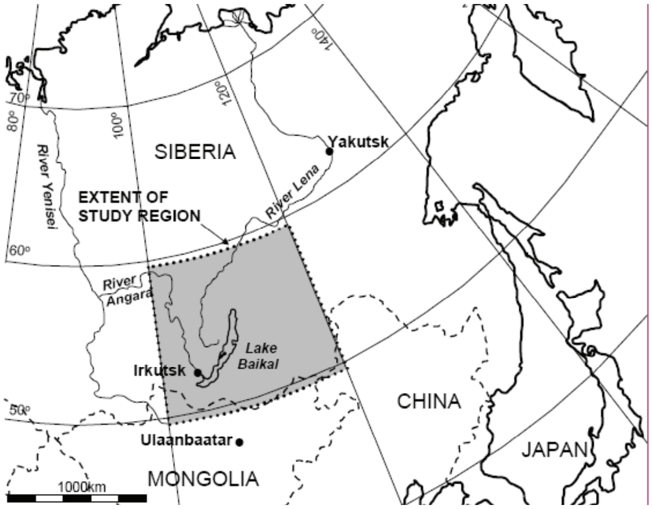

Figure 1. Study region and vicinity map.

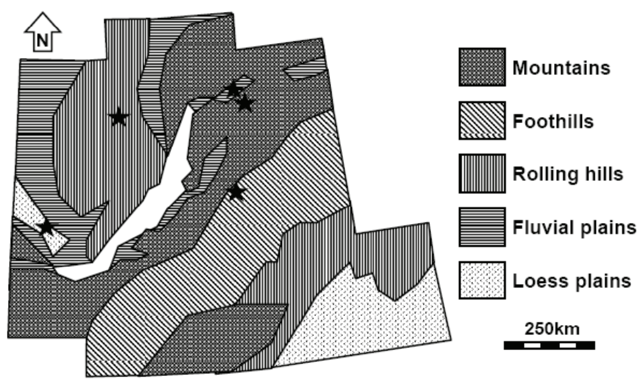

Figure 2. Classification into five geomorphological units. Black stars show location of "exemplar" study areas.

- Surface and deeper geology.
- Geocryology, including ground thermal regime and geothermal material properties.
- Land use and forest fire records.
- Inventory of relevant infrastructure.

Regional setting of study area

Ground conditions vary considerably over the area selected for detailed study, which is outlined in Figure 1 and measures approximately 1300 km east-west and 1100 km north-south. The topography ranges from high-relief mountains (Baikal, Patoma, and Khamar Daban ranges) to low-lying fluvial plains towards Mongolia and along the Angara River valley. The geology varies from relatively flat-lying undisturbed sedimentary rocks of the Siberian platform, to much older highly deformed and metamorphosed rocks along the active Baikal rift zone. The significant variation in relief has a profound effect on the observed climatic conditions, the vegetation, drainage characteristics, and hence the permafrost distribution within the region, which varies from being absent to continuous.

Geomorphological units and expected ground conditions

In order to assess the ground conditions across the study region, five geomorphological units were defined, which encompass broadly similar physical characteristics, as shown in Figure 2.

Once these geomorphological units were defined, five "exemplar" study areas were selected (Fig. 2), which provided representative settings for the associated climate modeling, geothermal ground modeling and engineering geological terrain analysis.

Remote sensing data (Shuttle Radar Topography Mission [SRTM] topographic survey data) was used to produce a Digital Elevation Model (DEM), allowing detailed assessment of elevation, slope angle, slope aspect, and drainage characteristics within each study area. This terrain analysis could be further enhanced in future applications by incorporating higher resolution datasets.

Geological, geocryological, and geotechnical characteristics were interpreted for each study area, based on literature review and field reconnaissance, assigning data where necessary from other global analogues. The latter included representative vegetation and ground void ratio profiles for each study area, which provided best-estimate, lower-bound, and upper-bound parameters for geothermal numerical modeling in each setting.

Although this investigation has included a thorough review of all of the readily available data, there is significant uncertainty associated with the age, provenance, and hence accuracy of some of the available information. The current review is considered adequate for a preliminary research study, which could be compared with the feasibility or possibly appraisal stage of a large civil engineering project. However, detailed site-specific information and further analysis would be essential before progressing to any preliminary design stage.

Geocryological Engineering

Civil engineering activity in the North American cold regions prompted rapid development from the 1960s of specialist geotechnical tools, analyses and practices, as detailed in Andersland & Ladyanyi (2004), for example. Similar work was undertaken from an earlier date in the Former Soviet Union, although much of the output was published in Russian and is less well known in the West. The paradigms, practices, and design codes applied in North America and the Former Soviet Union are substantially different.

Some of the practical geocryological engineering topics that are important to the proposed risk assessment and design processes are highlighted below.

Geocryological analysis: elements, options, and strategy

Geocryological engineering analysis involves many elements; the relative significance of which depends on the nature of the engineering problem of interest. For example, thermal (T), hydraulic (H), and potentially chemical (C) elements are more important than the mechanical (M) element in water discharge or contaminant transport problems. However, it is essential to address the mechanical element when assessing the viability, stability, and serviceability of facilities, pipelines and slopes.

Checklists, definitions, and indices

The essential precursor for all rational geocryological analyses is the information gathering and data access. Geothermal modeling is only possible when adequate climate, geology, and ground temperature data exist, including the local air-to-ground temperature conversion factors, which are influenced by local vegetation, soil types, topography, and weather patterns.

Ground behaviour associated with thermal regime changes

Engineering activities and climate change trends are both likely to modify the ground's thermal regime. Significant deterioration of the engineering properties of frozen soil is expected as temperatures increase, potentially leading to difficulties with embedded structural elements such as foundations and pipelines. Potentially severe phenomena may be encountered in soils or rocks that become unstable as they thaw. It is also well known that frozen soils show very strongly time-dependent behaviour: creep movements can be large in the field and field strengths may be far lower than are seen in laboratory loading tests.

Furthermore, the thawing of frozen open ground can lead to substantial settlements and large transient pore-water pressures. In cold regions, slope stability is dominated by thermal effects. Slopes sited in permafrost areas experience annual cycles of thawing and freezing in their active layers, experiencing seasonal downslope creep. Large-scale instabilities can also occur as a result of changes in ground surface conditions or sub-surface hydrology.

Construction itself may generate more significant thermal changes in foundation soils and rocks than those expected from climate change alone. Insulation elements, air ducts, or active cooling systems are often designed and installed to improve foundation behaviour, and these could be required more extensively to cope with climate change.

A key issue in pipeline engineering is the effect on the ground thermal regime of heat flow to or from the pipeline and its products. Thawing induced by running warm oil in pipelines buried in frozen ground can induce melting, settlement, strength loss, and even floatation. Elevated sections may be utilised, but these require piled foundations that can cope with the possible geotechnical consequences of climate change. On the other hand, ice migration and growth caused by running chilled gas in buried unfrozen ground can cause serious differential heave in pipelines installed in discontinuous permafrost regions. It is therefore vital to consider all potential damage processes within the risk assessment process.

Thermal Modeling and Permafrost Mapping

In order to make reasonable assessments of how slopes, foundations and pipelines may respond to climate change, it is necessary to be able to reliably predict how ground temperatures and properties will react over tens of metres of depth. GCM models incorporate sophisticated formulations that address temperature variations within the atmosphere and oceans, and offer projections as to how the climate may change in the future. However, the near-surface temperature of the ground is usually considered in a simplistic manner, for example, by assuming a constant ratio between air and ground temperature changes, and little attention is given to what may happen at greater depths. The GCMs therefore fail to predict the considerable time lag between climate change and ground response, potentially resulting in gross overestimates of the depth of permafrost melting expected by any given date, the degree of ground warming, and, therefore, of permafrost degradation and infrastructure distress.

Simple models have been proposed to relate air and ground temperatures; however, the Authors' work has shown that the thermal conductivity is complex and nonlinear in permafrost, and a fundamental analytical treatment is necessary to predict the variations with time of the thermal regime, extending tens of metres beneath the ground surface. A fundamentally formulated regional approach has been developed for the present study. A new Finite Element Code (FEM FATALE, Nishimura 2007a) was written to perform rigorous thermal analyses efficiently for multiple vertical profiles. The code can also be applied to any other specific site, for which detailed information is available.

The model is based on non-linear heat conduction theory, with material properties that effectively vary with unfrozen water content and hence temperature. The thermal properties of water, ice, and the soil minerals are fixed, and the global properties at any point in the ground profile depend on the ground's porosity profile (which is input on the basis of the engineering geology assessment described above) and a specific function that relates the degree of ice saturation to temperature. The code also incorporates latent heat effects. The effects of the seasonally-variable snowcover are modeled explicitly. The surface energy transfer is modeled using the n-factor approach (Lunardini 1978), making careful distinctions between summer values and times when the ground is snow-covered, when n is taken as unity. These purely thermal regional analyses do not consider pore fluid migration or ground deformations; these features are covered by the more sophisticated, fully-coupled THM approach reported later.

The purely thermal approach has been applied on a regional basis by considering multiple analyses of the development of permafrost in the circum-Baikal region, covering the period 1940 to 2059. Climate predictions have been applied to stereotypical ground profiles that were selected to encompass the range of geological/geotechnical conditions that might reasonably be expected within the five geomorphological units in the study region. An extensive parametric study has been performed with FEM FATALE to produce time-series predictions for ground temperature and ice content profiles from ground level to 100 m depth, considering the effects of different surface elevations, porosity profiles, snow cover, and natural geothermal gradients; the output data providing the basis of a large-scale risk assessment process for climate change-induced hazards. Examples of some predictions are shown in Figures 3 and 4; substantial warming and thawing is indicated over the next 50 years within

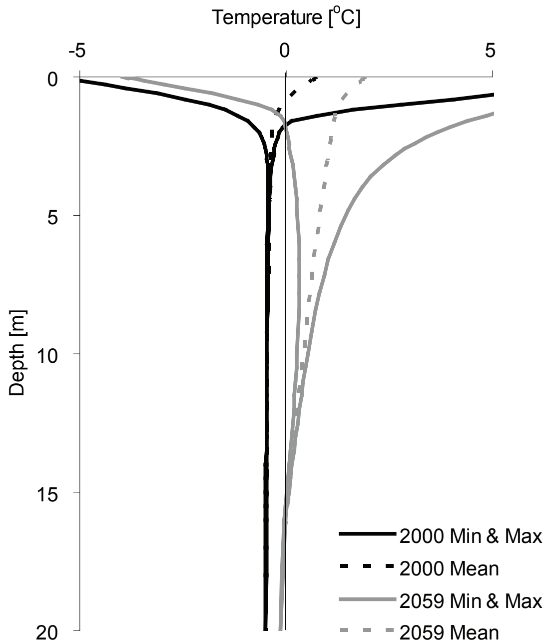

Figure 3. Example of simulated geothermal curves: case of stratigraphy with 1 m colluvial soil (assumed porosity, ∅ = 0.4) and 9 m weathered rock (∅ reducing from 0.4 to 0.04 with depth) overlying base rock (∅ = 0.04) in the rolling hills study area, 643 m a.s.l. (assuming air-surface thawing index, n_t = 0.6).

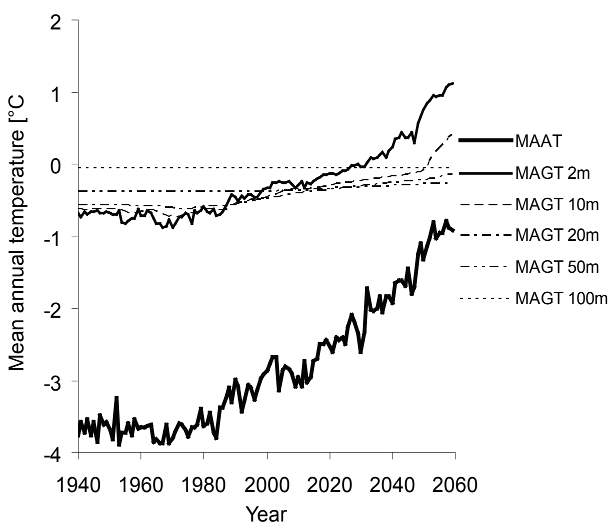

Figure 4. Predicted time-series of temperature at different depths, for example shown in Figure 3.

the top 20 m that would have a considerable negative impact on foundations, pipelines, and slopes.

In addition, a new method has been developed for correlating, synthesising, and presenting the time-dependent evolution of geocryological conditions in a series of layered maps. The approach interfaces data from DEM and GCM sources with the FEM FATALE thermal analyses. The approach has been used to successfully predict, from first principles (i.e., “Type A” prediction, Lambe 1973), the current and historical extent of permafrost in each geological study area, and can be used to produce maps of future distribution of permafrost and its thermal characteristics. Engineering geocryological analyses may be performed based on these data to predict the geotechnical impact for a particular facility or area.

Fully-Coupled Finite Element Analysis

In cases where the consequences of the expected ground temperature changes are sufficiently significant, more rigorous THM analyses of the interconnected thermal (T), hydraulic (H) and mechanical (M) processes may be deemed necessary. THM analyses incorporate predictions for ground movements, soil stresses, and changes in state, along with possible ground failure and soil-structure interaction. While THM models offer potentially powerful tools for assessing climate change impact, they are rarely conducted in practice: their complexity, incompletely developed formulation, and long computational run times limit their current appeal. Assessing, developing, and demonstrating THM applications in cold region geotechnical engineering was an important aspect of the present study, even though THM analyses are likely to be reserved for high-consequence cases.

THM-analysis has been developed intensively for high-temperature problems, particularly related to nuclear waste disposal. However, its application to frozen soils has concentrated on frost heave, and its potential use in permafrost problems has only been noted recently. The group collaborated with colleagues at UPC Barcelona for this purpose, running and developing with them their sophisticated THM programme CODE-BRIGHT (Olivella et al. 1996, Gens 2008). The main aims of the THM component of the study, and the achievements made, were:

- An assessment of the difficulties in applying THM-analysis to permafrost problems. Potential problems have been identified and solutions found that will enable a wider range of applications.
- Developing a robust overall THM modeling framework capable of embracing future sub-model developments. The formulation requires additional features that are important in ice-rich permafrost, including the development of large creep strains under load and the potential for extreme pore pressure generation during thawing.
- A new framework of describing stresses in frozen soils. This development has opened a way for recently developed soil model elaborations to be directly applied in frozen ground modeling.
- Successful back analyses of practical pipeline frost heave problems, which demonstrate the potential for THM analysis in cold region engineering applications.

Freezing ground water migration problems such as frost heaving around chilled pipelines can be simulated with reasonable accuracy by the CODE-BRIGHT model in its current state; the case study outlined below is provided as an illustration. THM analyses undertaken with the code for this project provide good predictions of the frost heave measured in a carefully controlled, long-term field test involving chilled gas running in a frost susceptible unfrozen silty soil (Slusarchuk et al. 1978). Figure

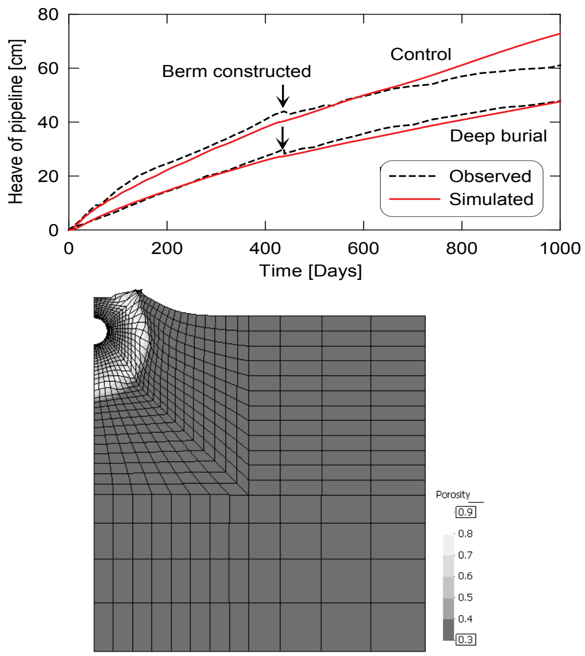

Figure 5. Top: Comparison between observed and measured heave of pipeline buried at two different depths. Bottom: Deformed mesh showing simulated pipeline heave and porosity contours in "Control" case at day 1000.

5 shows the generally good agreement between the observed and simulated heave of pipelines buried at two different depths; 'Control' and 'Deep burial' (Nishimura 2007b).

The THM model's fully-coupled treatment allows far more generalised situations to be considered than conventional engineering geocryological methods. Three-dimensional soil-structure interaction in discontinuous permafrost can be considered, in principle, without many additional modifications.

Conclusions

- A multi-disciplinary approach has been developed to assess the impact of climate change on infrastructure; this has been applied in an exemplar cold region of eastern Siberia.
- The effect of air temperature change on ground temperature profiles has been identified as being of critical significance to facilities and ground conditions in areas of variable or discontinuous permafrost.
- An integrated regional assessment approach has been developed that combines climate modeling data, engineering geology assessments, remote sensing data, and geocryological engineering methodologies to produce regional ground condition predictions.
- More advanced fully-coupled THM approaches have also been explored for site-specific application in critical cases. Key development targets have been identified for future THM modeling research.
- The research predicts that climate change will have a considerable impact on ground conditions in the study region over the next 50 years. However, the effects will be less severe than might be anticipated from studies that do not model the ground response with the same level of sophistication.

Acknowledgments

The Authors thank BP for their permission to publish and acknowledge the modeling groups for providing their data for analysis, PCMDI for collecting and archiving model output, and the JSC/CLIVAR Working Group on Coupled Modeling for organizing model data analysis activity. The multi-model data archive is supported by the Office of Science, U.S. Department of Energy. ERA-40 data have been obtained from the ECMWF data server. We would also like to acknowledge assistance from Arup Geotechnics London with the SRTM processing and terrain analysis.

Abstract

Following 26 years of successful mining, the tailings facility at the Nanisivik Mine site was reclaimed between 2004 and 2005. The objective of the reclamation plan for the tailings facility was to use the cold environmental conditions to encapsulate the tailings in permafrost, thereby limiting the potential for negative environmental impacts over the long term. During reclamation planning, a talik was identified within the tailings deposit. The talik was studied in detail due to its unknown effect on the stability of the adjacent tailings retention dike and the effect of freezeback on surface water quality, and to assess the time required for freezeback to occur. This paper summarizes the studies undertaken to characterize the talik and assess freezeback, ,and includes performance monitoring undertaken to date.

Keywords: cryoconcentration; freezeback; Nanisivik; pingo; tailings; talik.

Introduction

Nanisivik Mine is located at the northern end of Baffin Island in the Territory of Nunavut in the Canadian Arctic. The mine operated from 1976 to 2002, during which time sulphide ore was mined to produce lead and zinc concentrates. The tailings generated during the mining process were initially deposited directly into West Twin Lake (WTL). However, as additional mining reserves were identified, the West Twin Lake reached its storage capacity, and it became necessary to identify further storage options to keep the mine in production. Construction of a frozen tailings retention dike permitted the continued use of the West Twin Lake area until closure of the mine in 2002. During tailings deposition in the West Twin Disposal Area (WTDA), a partial water cover was maintained over most of the tailings. In areas where the tailings were aerially exposed, or where only a thin water cover was maintained, permafrost aggraded into the tailings. In areas where a deeper water cover was maintained, the tailings remained in a thawed state. As such, a talik, a zone of thawed materials surrounded by permafrost, formed within the tailings deposit.

Between 2002 and 2004, development of the Final Closure and Reclamation Plan (FCRP) for the West Twin Disposal Area was undertaken. This included characterization and delineation of the talik and an assessment of the potential effects of freezeback of the talik anticipated during closure. The talik delineation and characterization program was undertaken by conducting a detailed geotechnical drilling investigation which included installation of several types of monitoring instrumentation. Freezeback assessment of the talik included geothermal modeling to predict the rate of talik freezeback and assessing the potential for pingo growth, frost-heave and generation of high pore pressures within the center of the talik and its effect on the stability of the adjacent dike.

Figure 1. Regional location map – Nanisivik Mine.

Between 2004 and 2005, the reclamation plan for the West Twin Disposal Area was implemented. The partial water cover was removed from the tailings pond and a permafrost aggradation cover was constructed over the tailings to promote the freezeback of the talik. Additional instrumentation was installed after construction of the cover to monitor ground temperatures, pore pressures, and water quality in the talik during freezeback. This paper provides a summary of the talik characterization and assessment work that was completed and a summary of the monitoring data collected during the initial years of talik freezeback.

Background

Location and climate

The Nanisivik Mine Site is located on the northern end of Baffin Island in the Canadian Arctic, as shown on Figure 1.

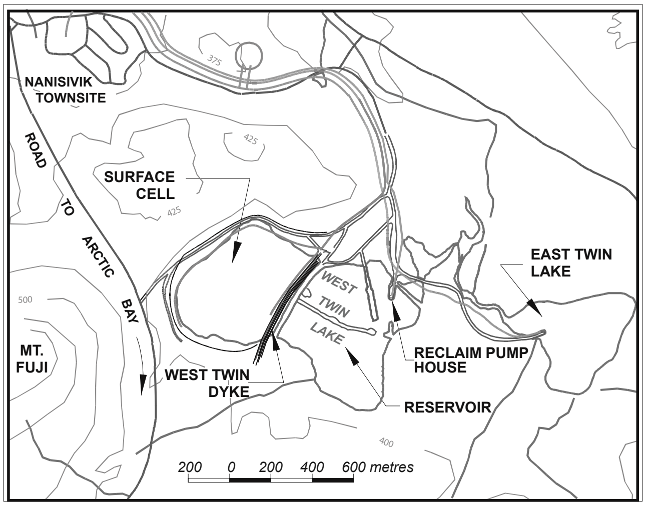

Figure 2. West Twin Disposal Area.

Based on the available climate record from the Nanisivik airport (1971–2006) the mean annual air temperature (MAAT) is approximately -14.8°C and the mean annual precipitation is 282 mm/yr.

Permafrost

Nanisivik is located in the region of continuous permafrost. Permafrost has been observed to extend to a depth of at least 430 m, as observed in a borehole drilled from the underground workings. Ground conditions in the area have been characterized by NRC (1995) as having the potential for medium amounts of ground ice (as high as 20%) and mean annual ground temperatures colder than -10°C. This has been verified by ground temperature measurements at various locations around the mine site as cold as -13°C at depth. The depth of the active layer in natural ground has been observed to average between 1 m to 2 m below ground surface.

Tailings deposition practices

Tailings were initially deposited sub-aqueously into WTL beginning in 1977. Based on the known mine reserves at the time, WTL had sufficient tailings storage capacity for the life of the mine. Mine reserves, however, continued to expand each year and by the mid 1980s, it was apparent that continued production would exceed the storage capacity of WTL. In 1988, an approval was received from the Northwest Territories Water Board to begin surface deposition of tailings at Nanisivik. To accommodate this, WTL was divided into two sections using an earthen dike, as shown on Figure 2. The dike was constructed using a north/south trending causeway that was developed by beaching of tailings in the lake as a foundation. The eastern portion of the lake, the Reservoir, retained its original lake level and was used as a stand-by when surface disposal was not practical (i.e. during annual dike construction periods). The western part of the lake, the Surface Cell, became the main deposition area for the tailings and accommodated sub-aerial tailings.

On-land deposition of tailings in the Surface Cell commenced on August 27, 1990. Tailings discharge in the Surface Cell continued throughout the 1990s, permitted by annual raises of the West Twin Dike in 2 m increments. Tailings continued to be discharged mainly from the northwest corner of the Surface Cell with a deeper section of the pond in the southeast corner for water reclamation and mineral processing purposes. In total, it is estimated that 6.5 million m^3 of tailings were deposited into the Surface Cell between 1978 and 2002.

It should be noted that tailings were deposited subaqueously into the area later known as the Reservoir between 1976 and 1990. The discharge of tailings generally took place near the current location of the West Twin Dike resulting in the aggradation of the tailings deposit in a southeasterly direction into the Reservoir. Tailings deposition along an east-west trending line from the centrer of the West Twin Dike resulted in exposure of a tailings causeway in the Reservoir by 1988. This causeway eventually became the foundation for the east/west arm of the Test Cell Dike. Tailings deposition along a northwest-southeast trending line resulted in a second tailings causeway near the reclaim water pumphouse, which was exposed by 1992. This causeway eventually became the foundation for the north/south arm of the Test Cell Dike. The Test Cell Dike was constructed in 2000 and 2001, increasing the storage capacity of the Test Cell thereby allowing for the additional placement of tailings into the Test Cell. Deposition of tailings at the base of the West Twin Dike in 2000 resulted in aerial exposure of tailings in the Reservoir and Test Cell. In total, it is estimated that 3.5 million m^3 of tailings have been deposited into the Reservoir and Test Cell since 1978.

Talik Characterization and Delineation

Geotechnical drilling investigation

In 2002 and 2003, a total of 44 boreholes were drilled in the Surface Cell, Test Cell Dike, and at the base of the West Twin Dike. The drilling was completed using a diamond drill coring rig and chilled brine was used as a drilling fluid to enable core recovery of frozen tailings. The following points summarize the significant observations recorded during the geotechnical drilling investigation:

- The maximum thickness of tailings contained within the Surface Cell was approximately 34 m.
- The maximum thickness of tailings contained within the Test Cell was 20 m.
- During the drilling investigation, thawed tailings were encountered in both the Surface Cell and Test Cell.
- Artesian pore pressures were encountered in the Surface Cell talik.
- The frozen tailings were generally observed to be ice-poor. However, some ice lenses were observed in the frozen tailings. It was unclear if the ice formed in-situ or was encapsulated during deposition.

Select samples collected during the drilling process were forwarded for geotechnical testing. The following points summarize the geotechnical characteristics of the tailings:

- The grain size distribution was variable ranging from 95% sand-sized particles to 95% silt-sized particles.
- Specific gravity ranged from 3.9 to 4.5.
- The tailings generally had a saturation value of greater than 90%.
- The frozen bulk density of the tailings ranged from 2100 to 3500 kg/m^3, with the lowest values associated with samples containing visible ground ice.
- The thermal conductivity of the tailings was measured to be approximately 1.9 W/(m·°C) at room temperature and 3.2 W/(m °C) at -15°C.

A number of monitoring instruments were installed during the geotechnical investigation to further characterize the subsurface conditions. Thermistors and thermocouples were installed to assess geothermal conditions and vibrating wire piezometers were installed to monitor pore pressures within the thawed tailings. Monitoring wells were also installed to assess the pore water quality in the taliks.

Geothermal monitoring data indicated near 0°C temperatures within the talik. Ground temperatures within the thawed zones were observed to be as cool as -0.2°C, indicating freezing point depression. Piezometers installed in the Surface Cell talik indicated artesian pore pressures 3 m to 4 m above ground surface.

The results of the geotechnical investigation and the available historical information on tailings deposition was used to estimate the size of the Surface Cell and Test Cell taliks. Based on the analysis, it was estimated that the Surface Cell and Test Cell taliks contained approximately 2,000,000 m^3 and 1,000,000 m^3 of thawed tailings, respectively, which was approximately 30% of the tailings contained within the facility.

Technical Analyses

Due to the unknown effect of the freezeback of the taliks on the stability of the West Twin Dike, the surface of the reclamation covers or the water quality of the entire system, a number of technical analyses were undertaken. The following sections summarize the objectives and results of each analysis.

Geothermal modeling

Geothermal modeling of the Surface Cell talik was completed to predict the rate of permafrost aggradation into the talik. The results of the modeling were to be used to direct future monitoring efforts and to estimate the time required to achieve various benchmarks during closure.

The geothermal modeling was completed using the commercially available software Temp/W produced by GeoSlope International. The model was calibrated using the geothermal data collected in an area of recently deposited tailings, and by comparing the predicted freezeback thermal regime to the observed freezeback thermal regime over a one year period.

Once the model was calibrated, several analyses were conducted to assess the variability and sensitivity of the results to initial thermal conditions, global warming, snow cover, and the placement of the shale as a cover material. Additionally, an envelope of freezeback times was developed, based on the results of the parametric analyses.

The following is a list of the principal conclusions derived from the geothermal analysis of the Surface Cell talik:

1. There is minimal sensitivity in the predicted depth of permafrost aggradation of the various parameters in the initial 5 years.
2. Permafrost aggradation reaches a depth of 17 m (the base of the West Twin dike) between 7 and 8 years after the initial winter following completion of reclamation activities.
3. Permafrost aggradation reaches an elevation of 365 m, a depth of approximately 23 m, between 13 and 15 years after the initial winter.
4. Depending on the modeled scenario, permafrost aggradation reaches an elevation of 353 m, a depth of approximately 35 m, between 27 and 32 years after the initial winter.
5. The results were not sensitive to assumed global warming values.

Effect of high pore pressures on dike stability

The effect of high pore pressures in the Surface Cell talik on the stability of the West Twin dike were assessed due to the artesian piezometric conditions encountered during the geotechnical investigation.

The artesian pore pressures are thought to be attributed to the process of pore water expulsion that occurs during freezing of saturated soils. McRoberts and Morgenstern (1975) attributes the pore water expulsion process to the fact that when the ice-water interface progresses through a freezing saturated soil, water may be expelled from the ice interface, depending upon soil type and stress level. If no drainage of the excess pore pressures is permitted, then the system is considered closed. If drainage is allowed, the system is considered open.

Useful information can be found on the topic of pore pressures generated by pore water expulsion through the study of pingos. Pingos are intrapermafrost ice-cored hills, typically conical in shape, that grow and persist only in a permafrost environment (Mackay 1998). Many pingos form in the bottoms of old lakes that drained rapidly. They form in response to the development of excessive pore water pressures and differential permafrost thickness. Mackay et al. (1972) suggests that pore pressures generated by pore water expulsion in growing pingos can exceed 80% of the total overburden pressure, even beneath permafrost 40 m thick. Additionally, Mackay (1978) notes that pressure transducers installed in one sub-pingo water lens measured a hydrostatic head of 22 m above lake bottom.

Due to the fact that no evidence of hydraulic connectivity between the Surface Cell talik and the Reservoir was defined during the geotechnical investigation, the Surface Cell talik is considered to be a closed system. As such, the pore pressures within the Surface Cell talik are expected to continue to rise

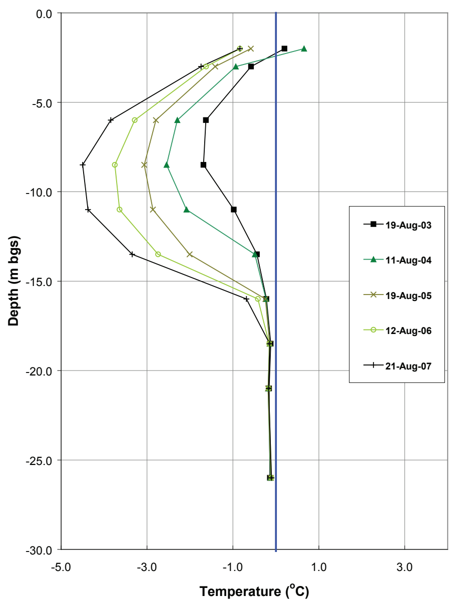

Figure 3. Geothermal monitoring data from edge of Surface Cell talik (BGC03-09).

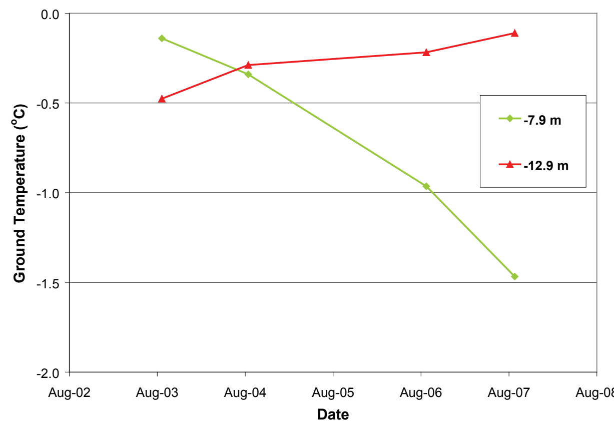

Figure 4. Geothermal data from center of Surface Cell talik (BGC03-10).

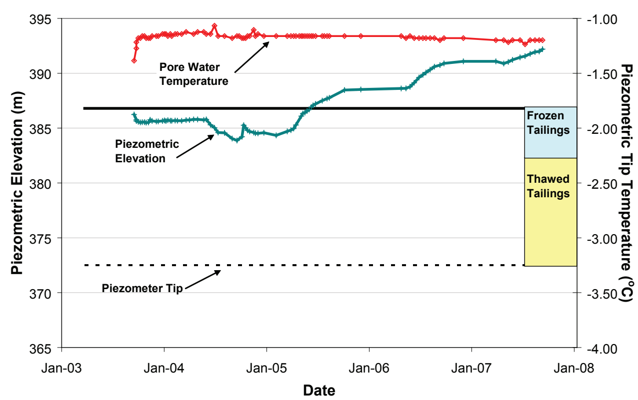

Figure 5. Piezometric monitoring data from Surface Cell (BGC03-35).

as freezeback of the talik progresses. Conversely, due to the presence of a hydraulic connection between the Test Cell alik and the Reservoir, the Test Cell talik is considered an open system. However, the flow path is lengthened by the permafrost aggradation which has occurred beneath the Test Cell Dike. As such, the pore pressures within the Test Cell talik may continue to rise as freezeback progresses, however at a much slower rate than they are anticipated to increase in the Surface Cell talik.

Since the West Twin Dike would remain in place during closure, it was important to determine the effect of the high pore pressures on the long term stability of the dike. As such, a stability analysis was completed assuming a portion of the talik extended beneath the base of the dike, which was considered a conservative assumption. A variety of pore pressure conditions were applied to the thawed zone and the effect of these pore pressures on the stability of the dike were noted. The analysis suggested that pore pressures corresponding to 12 m of artesian head would be required to reduce the Factor of Safety against sliding to 1.0. However it should be noted that the results were sensitive to the configuration of the talik. For example, if the pore pressures were confined deeper beneath the base of the dike, it was found that higher pore pressures could be experienced without affecting the stability of the dike.

Pingo growth potential

The potential for pingo growth was assessed due to the potential deformation it could cause to the physical integrity, and the overall effectiveness, of the surface reclamation cover.

Based on the extensive research by Mackay and others, there are several occurrences required to initiate the growth of a pingo, as summarized below from Mackay (1998):

1. A lake, sufficiently deep to form an underlying talik, must drain, allowing permafrost to aggrade into the underlying talik.

2. If there is at least one large and relatively deep residual pond without any permafrost directly beneath it, then expelled pore water can discharge into the unfrozen basin that underlies the residual pond and a pingo is unlikely to grow.

3. If at least one residual pond of sufficient size and critical depth exists so that the bottom sediments gradually freeze downward, the pressure exerted by the groundwater flow from the large lake bottom area of aggrading permafrost acts like an hydraulic jack (Gasanov 1978) on the much smaller area of the frozen bottom of the residual pond to dome it up and so to initiate pingo growth.

As can be inferred from the research, pingo formation results from a very delicate balance of gradual permafrost aggradation, pore water expulsion, and resultant overburden heaving, in combination with the differential in-situ conditions from the residual pond area to the perimeter lake bottom area. For the case of drained lakes that do not lead to the formation of a pingo, the expelled pore water must either report to the surficial pond (through some vertically oriented talik) or a cryopeg must form at depth below the frozen lake bottom.

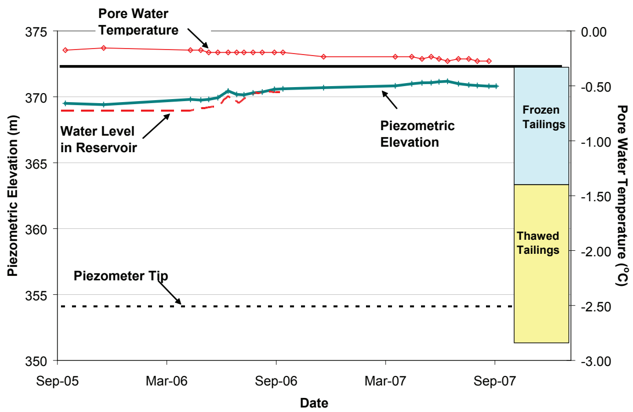

Figure 6. Piezometric monitoring data from Test Cell talik.

In comparison to the pingos formed in the Mackenzie Delta area, the following differences are suggested with respect to the Surface Cell and Test Cell taliks:

1. The remnant pond on the surface of the tailings has been completely removed and the cover has been sufficiently graded such that no residual pond can be formed.
2. Since the pond was completely removed, permafrost aggradation has been quite rapid, as inferred from the geothermal monitoring data collected to date. Due to the rapid aggradation of permafrost, and the high specific gravity of the tailings, the overburden pressure acting on top of the talik was expected to increase soon after completion of the cover.
3. Since there is no remnant pond, there is limited differential in the permafrost aggradation conditions from the previously existing pond area to the surrounding tailings surface.

As a result, instead of a pingo forming, it was considered more likely that a cryopeg would form at depth in the Surface Cell. Based on the monitoring data collected to date, this appears to be the case as no surficial indications of pingo growth have been observed while the pore pressures within the talik continue to increase.

Hydraulic fracturing

Hydraulic fractures occur in frozen ground whenever the fluid pressure exceeds the tensile strength of the enclosing frozen material plus the least compressive principal total stress (Mackay 1998). Hydraulic fractures are of significance significant with respect to reclamation of the WTDA because they could result in the release of pore water from the taliks at surface.

Hydraulic fracturing was thought to be possible in two scenarios during freezeback of the taliks. One area is a hydraulic fracture propagating vertically from the talik to the surface of the Surface Cell. The second is at the base of the West Twin Dike where the fracture could propagate upwards from the talik near the foundation of the dike to surface. Since the freezeback of the top 4 to 5 m of tailings was expected to occur rapidly during the first winter, the water pressure would have to exceed 110 kPa to 135 kPa (the approximate overburden pressure) plus the tensile strength of the frozen tailings for the first scenario to occur. Additionally, the overburden pressure in the area of the talik that underlies the dike is estimated to be approximately 400 kPa. For hydraulic fracture propagation to be initiated, this overburden pressure plus the tensile strength of the frozen tailings must be exceeded.

Table 1. Water quality testing Surface Cell talik.

Instrument	Year	pH	*Total Zinc Concentration*
BGC05-11	2005	10.9	*0.01*
	2006	11.3	*0.08*
	2007	10.5	*0.09*
BGC05-12	2005	10.3	*0.54*
	2006	10.3	*0.29*
	2007	*9.7*	*0.17*

Considering the rapid permafrost aggradation rate into the talik, it was considered unlikely that extremely high pore pressures would develop during the initial freezing period. By the time the pore pressures increased to the values required for fracturing, a frozen layer of sufficient thickness, and of significant frozen density, would likely be in place. Therefore, it was considered unlikely that hydraulic fracturing would occur.

To date, no observations of hydraulic fracturing have been noted. Although, the pore pressures have been observed to be somewhat cyclical potentially indicating that the pore pressures are relieved by some means, at certain times of the year.

Talik Freezeback Monitoring

Instrumentation and monitoring program

After completion of the reclamation covers, an additional twenty instruments were installed to monitor the freezeback of the talik. Thermistors were installed to monitor ground temperatures, vibrating wire piezometers were installed to monitor pore pressures within the talik, and monitoring wells were installed to monitor changes in pore water quality within the talik.

The instrumentation has been monitored regularly since installation. Monitoring is undertaken by site staff on a bi-weekly basis from May through October, and two to three additional times throughout the winter months.

Geothermal monitoring

The thermistors in the Surface Cell monitored since 2003 provide an excellent record of freezeback of the talik. The data from one instrument, BGC03-09, is provided in Figure 3.

Only the data from mid-August of each year is illustrated to provide a clear indication of progression of the freezing front into the talik. As can be seen, the -1°C isotherm has progressed from approximately 11 m below ground surface (bgs) in 2003 to approximately 16 m bgs in 2007. This compares favorably with the predictions made during the geothermal modeling analysis which was predicted for this location. Additional geothermal monitoring data is presented in Figure 4.

The data on Figure 4 is derived from thermistor BGC03-10 which was installed near the center of the talik. As can be seen, nodes within 10 m of the surface are cooling with time, as expected. However, nodes below 10 m have experienced a small degree of warming over the monitoring period. This suggests that heat flow from the surrounding tailings, which are actively freezing, is towards the centrecenter of the talik.

Piezometric monitoring

The piezometers in the Surface Cell monitored since 2003 provide an excellent record of pore pressure in response to freezeback of the talik. The data from one instrument, BGC03-35, is provided in Figure 5.

As can be seen, the pore pressures were not artesian when monitoring began in 2003. This was due to the proximity of the instrument to the former location of the retained pond that used to be contained in the Surface Cell. As the water was removed form the Surface Cell during reclamation activities, the pore pressures in this part of the talik initially reduced. During the first winter after the pond was removed, the pore pressures began to rise in response to freezeback of the talik. This rise in pore pressures suggests that that the system is closed and that pore pressures are not being relieved. Additionally, the vibrating wire piezometers are equipped with a thermistor node at the tip of the instrument. The data collected from this thermistor node suggests the pore water temperature is approximately -1.2°C, indicating a freezing point depression of at least this amount in the centrer of the talik. In contrast, piezometric monitoring data from the Test Cell talik is provided on Figure 6.

As can be seen, the pore pressures in the Test Cell talik are not artesian and tend to mirror the water level in the nearby Reservoir. This suggests hydraulic connectivity between the Test Cell talik and the Reservoir, as was anticipated. Also of note, the pore water temperature measured in the Test Cell talik was approximately -0.2°C, indicating only a slight amount of freezing point depression.

Pore-water quality monitoring

Water samples have been collected from the Surface Cell and Test Cell taliks once a year since completion of the surface reclamation covers in 2005. The data is summarized in Table 1.

The main conclusion drawn from the data is that metals concentrations are highest in the centrer of the talik (BGC05-12) compared to the edge of the talik (BGC05-11). Since the degree of freezing point depression is related to solute concentration, the data suggests that a higher degree of freezing point depression can be expected in the centrer of the talik. This is verified by the monitoring data reviewed earlier which suggested a freezing point depression of at least -1.5°C near the centrer of the talik, compared to -0.2°C along the edge of the talik.

Summary

The freezeback of the tailings at the Nanisivik Mine is a unique process which required detailed study, assessment, and ongoing monitoring to understand the significance with respect to reclamation and long term environmental impacts. Monitoring undertaken to date has supported the conclusions of many of the technical studies undertaken during the development of the reclamation plan.

Geologic Controls on the Occurrence of Permafrost-Associated Natural Gas Hydrates

Timothy S. Collett
U.S. Geological Survey, Denver, Colorado, USA

Abstract

With an increasing number of highly successful gas hydrate field studies, significant progress has been made in addressing some of the key issues on the formation, occurrence, and stability of gas hydrates in nature. The concept of a gas hydrate geologic system as a subcomponent of a conventional oil and gas petroleum system is gaining acceptance. The primary goal of this report is to compare and contrast several permafrost-related gas hydrate systems in order to better understand the geologic controls on the formation and occurrence of gas hydrates. This report focuses on the results of the recently completed BP Exploration Mount Elbert project, which successfully cored, logged, and tested a gas hydrate accumulation on the North Slope of Alaska in the spring of 2007. The Mount Elbert Test, along with the Canadian Mallik 2002 project, have for the first time allowed the rational assessment of the physical response of permafrost-associated gas hydrate occurrences to production.

Keywords: Alaska; Arctic; Canada; gas hydrate; resources.

Introduction

Gas hydrates are naturally occurring 'ice-like' combinations of natural gas and water that have the potential to provide an immense resource of natural gas from the world's oceans and polar regions. Gas hydrates are known to be widespread in permafrost regions and beneath the sea in sediments of outer continental margins. The amount of natural gas contained in the world's gas hydrate accumulations is enormous, but these estimates are speculative and range over three orders-of-magnitude, from about 2,800 to 8,000,000 trillion cubic meters of gas. Milkov et al. (2003) recently reported that the volume of gas trapped in global gas hydrate accumulations was actually in the range of 3,000 to 5,000 trillion cubic meters, which is 1/7 to 1/4 of some of the more widely cited estimates. By comparison, conventional natural gas accumulations (reserves and technically recoverable undiscovered resources) for the world are estimated at approximately 440 trillion cubic meters as reported by Ahlbrandt (2002). Despite the enormous range in reported gas hydrate volumetric estimates, even the lowest reported estimates seem to indicate that gas hydrates are a much greater resource of natural gas than conventional accumulations. However, it is important to note that none of these assessments has predicted how much gas could actually be produced from the world's gas hydrate accumulations.

Arctic Gas Hydrate Accumulations

Gas hydrate in onshore arctic environments is typically closely associated with permafrost. It is generally believed that thermal conditions conducive to the formation of permafrost and gas hydrate have persisted in the Arctic since the end of the Pliocene (about 1.88 Ma). Maps of present day permafrost reveal that about 20 percent of the land area of the northern hemisphere is underlain by permafrost (Fig. 1). Geologic studies (Molochushkin 1978) and thermal modeling of subsea conditions (Osterkamp & Fei 1993) also indicate that permafrost and gas hydrate may exist within the continental shelf of the Arctic Ocean. Subaerial emergence of portions of the Arctic continental shelf to current water depths of 120 m (Bard & Fairbanks 1990), during repeated Pleistocene glaciations, subjected the exposed shelf to temperature conditions favorable to the formation of permafrost and gas hydrate. Thus, it is speculated that 'relic' permafrost and gas hydrate may exist on the continental shelf of the Arctic Ocean to present water depths of 120 m. In practical terms, onshore and nearshore gas hydrate can only exist in close association with permafrost, therefore, the map in Figure 1 that depicts the distribution of onshore continuous permafrost and the potential extent of "relic" sub-sea permafrost also depicts the potential limit of onshore and nearshore gas hydrate.

This paper deals with the assessment of the geologic factors that control the occurrence of gas hydrates. This assessment will be conducted mainly though the examination of several relatively well-characterized gas hydrate accumulations in northern Canada and the United States.

Mackenzie Delta, Canada – Mallik gas hydrate accumulation

Assessment of gas hydrate occurrences in the Mackenzie Delta-Beaufort Sea area have been made mainly on the basis of data obtained during the course of hydrocarbon exploration conducted over the past three decades (Dallimore et al. 1999). Prior to the more recently completed Mallik gas hydrate research drilling programs (Dallimore & Collett 1995, 2005, Dallimore et al. 1999), the most extensively studied gas hydrate occurrences in the Mackenzie Delta-Beaufort Sea region were those drilled in the onshore Mallik L-38 and Ivik J-26 wells (Bily & Dick 1974) and those in the offshore Nerlerk M-98, Koakoak O-22, Ukalerk C-50, and Kopanoar M-13 wells (Weaver & Stewart 1982). On

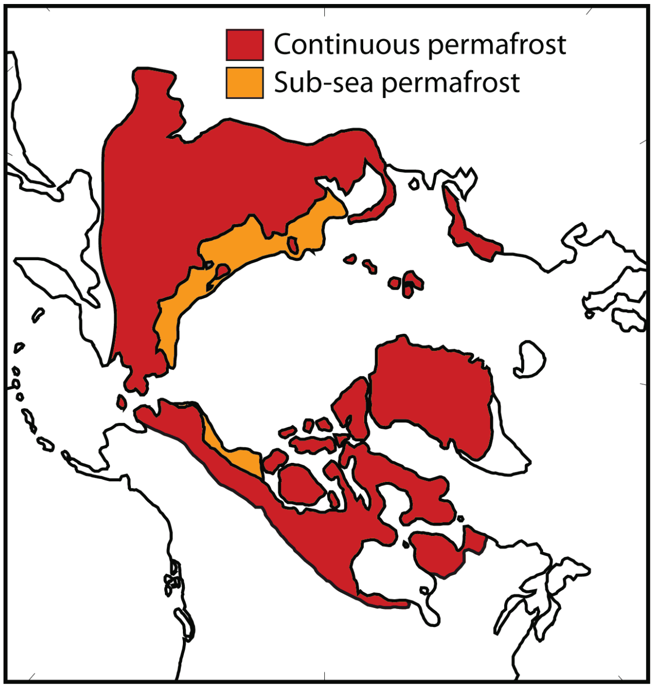

Figure 1. Distribution of permafrost in the Northern Hemisphere.

the basis of open-hole well log evaluation, it is estimated that Mallik L-38 encountered about 100 m of gas-hydrate-bearing sandstone, and Ivik J-26 penetrated about 25 m of gas hydrate. Analyses of open-hole well logs and mud-gas logs indicate that the offshore Nerlerk M-98 well penetrated about 170 m of gas-hydrate-bearing sediments, while the Koakoak O-22, Ukalerk C-50, and Kopanoar M-13 wells drilled approximately 40 m, 100 m, and 250 m of gas hydrate respectively. In all four cases, the well-log inferred gas hydrate occurs in fine-grained sandstone rock units.

During a permafrost-coring program in the Taglu area on Richards Island in the outer Mackenzie Delta, ice-bearing cores containing visible gas hydrate and possible pore-space gas hydrate were recovered (Dallimore & Collett 1995). The visible gas hydrate occurred at a depth of about 330 to 335 m and appeared as thin ice-like layers that released methane upon recovery.

Estimates of the amount of gas in the gas hydrate accumulations of the Mackenzie Delta-Beaufort Sea region vary from 9.3 to 27 trillion cubic meters (Smith & Judge 1995, Majorowicz & Osadetz 1999, 2001); however, these estimates are generally poorly constrained. A more detailed study by Osadetz and Chen (2005) resulted in an estimate that is within the same bounds given by Majorowicz and Osadetz (2001) and range between 1.0 to 10 trillion cubic meters of gas within the permafrost associated gas hydrate accumulations of the Beaufort Sea-Mackenzie Delta region.

The JAPEX/JNOC/GSC Mallik 2L-38 gas hydrate research well, drilled in 1998 near the site of the Mallik L-38 well (Fig. 2), included extensive scientific studies designed to investigate the occurrence of in situ natural gas hydrate in the Mallik field area (Dallimore et al. 1999). Approximately 37 m of core were recovered from the gas hydrate interval

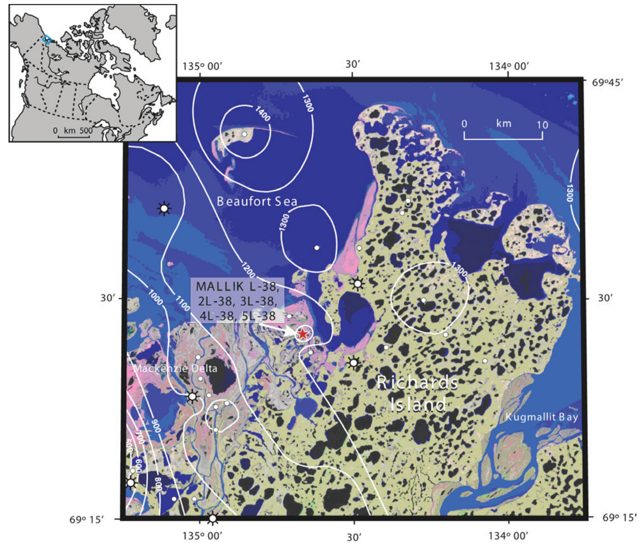

Figure 2. Location of the JAPEX/JNOC/GSC et al. Mallik 3L-38, 4L-38, and 5L-38 gas hydrate production research wells, Mackenzie Delta, Northwest Territories. Base map is a false-color mosaic constructed from a Landsat V image taken July 8, 2002. Contours indicate depth to the base of the gas hydrate stability zone in meters. Symbols include small circles as well locations, larger circles with ticks are wells containing gas hydrate (Dallimore & Collett 2005)

(878–944 m) in the Mallik 2L-38 well. Pore-space gas hydrate and several forms of visible gas hydrate were observed in a variety of unconsolidated sands and gravels interbedded with non-hydrate bearing silts. The cored and downhole logged gas hydrate occurrences in the Mallik 2L-38 well exhibit both high electrical resistivities and rapid acoustic velocities. In total, the gas hydrate-bearing strata was approximately 150 m thick within the depth interval from 889 to 1101 m.

Because of the success of the 1998 Mallik 2L-38 gas hydrate research well program, the Mallik site has been elevated as an important gas hydrate production test site with the execution of two additional gas hydrate production research programs: (1) The Mallik 2002 Gas Hydrate Production Research Well Program, and (2) 2006–2008 JOGMEC/NRCan Mallik Gas Hydrate Production Research Program.

In June of 2005, the partners in the Mallik 2002 Gas Hydrate Production Research Well Program publicly released the results of the first modern, fully integrated field study and production test of a natural gas hydrate accumulation (Dallimore & Collett 2005). From December 25, 2001 through March 15, 2002 the Mallik 2002 Gas Hydrate Production Research Well Program drilled three wells (the JAPEX/JNOC/GSC et al. Mallik 3L-38 and 4L-38 observation wells and Mallik 5L-38 gas hydrate production test well) in the Mallik Gas Hydrate Field on Richard's Island in the Mackenzie Delta, Northwest Territories, Canada.

The Mallik 5L-38 well cored and recovered gas hydrates and associated sediments from an interval between 880-1150 m depth (Fig. 3). These cores were the subject of intensive examination by members of the Mallik research team. Detailed information on the geology, geochemistry, geotechnical, and microbiological properties of gas hydrate bearing sediments was complemented by an extensive research geophysics program, which included both surface seismic surveys and downhole logging studies. Downhole measurements allowed for direct estimates of in situ permeability, gas hydrate content, and investigations of the occurrence of natural fractures.

Rather than carry out long term production testing during the Mallik 2002 effort, a decision was made to conduct carefully controlled production experiments. The response of gas hydrates to heating and depressurization was evaluated with careful attention to accurately measure both input conditions and reservoir responses. The overall goal was to combine the science and production program to allow for calibration and refinement of reservoir simulation models capable of predicting long-term reservoir response. Pressure draw down experiments were designed to study the response of gas hydrate to a reduction in formation pressure conditions. The results of three short duration gas hydrate tests demonstrate that gas can be produced from gas hydrates with different concentrations and characteristics, exclusively through pressure stimulation. The data supports the interpretation that the gas hydrates are much more permeable and conducive to flow from pressure stimulation than previously thought. Thermal stimulation experiments were designed to destabilize gas hydrates by using circulated hot water to increase the in situ temperature. A five-day experiment was undertaken within a 17-m-thick section of highly concentrated gas-hydrate-bearing strata. Gas was continuously produced throughout the test at varying rates with maximum flow rate reaching 1500 cubic meters per day. The total volume of gas produced was small, reflecting that the test was a controlled production experiment rather than a long duration well test.

The Mallik 2002 production research well program proved for the first time that gas production from gas hydrates is technically feasible. The Mallik 2002 thermal and depressurization production data have allowed the calibration of several reservoir models used to simulate the thermal and depressurization tests. Part of the calibration process has been the recognition that gas hydrate deposits are much more permeable than previously thought. The Mallik data allowed for the rational assessment of the production response of a gas hydrate accumulation if the various tests were extended far into the future. These studies show that among the possible techniques for production of natural gas from in situ gas hydrates, depressurization will produce more gas than just heating the formation. However, the combination of heating and depressurizing the gas hydrate at the same time will produce the greatest amount of gas. Project-supported gas hydrate computer production simulations, including those performed by Lawrence Berkeley National Laboratory, have shown that under certain geologic conditions gas can be produced from gas hydrates at very high rates, exceeding several million cubic feet of gas per day.

The following discussion dealing with the 2006–2008 JOGMEC/NRCan Mallik Gas Hydrate Production Research Program has been taken almost entirely from a news article appearing in the Spring/Summer 2007, U.S. Department of Energy, Office of Fossil Energy, National Energy Technology Laboratory, Fire in the Ice, Methane hydrate newsletter (available at http://www.netl.doe.gov/tech nologies/oilgas/publications/Hydrates/Newsletter/HMNewsSpringSummer07optmiized.pdf; viewed August 16, 2007). The 2006–2008 JOGMEC/NRCan Mallik Gas Hydrate Production Research Program is being conducted to mainly monitor long term production behavior of gas hydrates. The Japan Oil, Gas, and Metals National Corporation (JOGMEC) and NRCan are leading this research program. Aurora College/Aurora Research Institute is acting as the operator for the field program. The primary objective of the winter 2007 field activities was to install equipment and instruments to allow for long term production testing of several gas hydrate intervals during the winter of 2007–2008. Drilling rigs were used to re-enter and deepen the Mallik 2L-38 and Mallik 3L-38 wells (Fig. 3). Each well was also logged with various tools to establish formation properties prior to testing. After completing operations in the Mallik 2L-38 and 3L-38 wells, a short pressure draw down production test was conducted to evaluate equipment

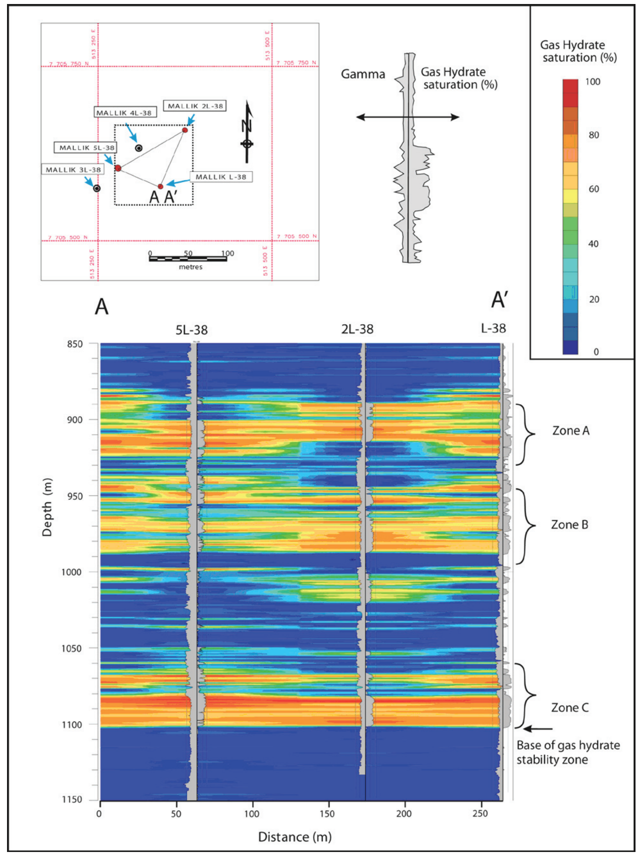

Figure 3. Fence diagram showing well-log-derived gas hydrate concentrations and natural gamma-ray logs for Imperial Oil Ltd. Mallik L-38, JAPEX/JNOC/GSC Mallik 2L-38, and JAPEX/JNOC/GSC et al. Mallik 5L-38 wells. The well locations are shown on the location map (Dallimore & Collett 2005).

performance and short term producibility of the gas-hydrate-bearing section. A 12-m-thick gas hydrate interval near the base of the gas hydrate stability zone was tested for 60 hours. The test results were described as 'encouraging', documenting "robust" gas flow rates. Important observations were also made in terms of produced water and the sediment response to production. The JOGMEC/NRCan Mallik gas hydrate production research program is currently planning operations for the 2007–2008 winter program.

North Slope, Alaska, USA – Eileen gas hydrate accumulation

On the North Slope, the subsurface temperature data, needed to assess the distribution of the gas hydrate stability zone, comes from high-resolution, equilibrated well-bore surveys in 46 wells and from well log estimates of the base of ice-bearing permafrost in 102 other wells (Collett 1993). The methane-hydrate stability zone in northern Alaska, as mapped in Figure 4, covers most of the North Slope. The offshore extent of the gas-hydrate stability zone is not well established; however, 'relic' permafrost is known to exist on the Beaufort Sea continental shelf to a present water depth of 90 m (Osterkamp & Fei 1993).

Before the recently completed coring and downhole logging operations in the BP Exploration (Alaska) Mount Elbert well in Milne Point, the only direct confirmation of gas hydrate on the North Slope was obtained in 1972 with data from the Northwest Eileen State-2 well located in the northwest part of the Prudhoe Bay Field. Studies of pressurized core samples, downhole logs, and the results of formation production testing have confirmed the occurrence of three gas-hydrate-bearing stratigraphic units in the Northwest Eileen State-2 well (Collett 1993). Gas hydrates are also inferred to occur in an additional 50 exploratory and production wells in northern Alaska based on downhole log responses calibrated to the known gas hydrate occurrences in the Northwest Eileen State-2 well. Many of these wells have multiple gas-hydrate-bearing units, with individual occurrences ranging from 3- to 30-m-thick. Most of the well-log inferred gas hydrates occur in six laterally continuous sandstone and conglomerate units; all are geographically restricted to the area overlying the eastern part of the Kuparuk River Field and the western part of the Prudhoe Bay Field

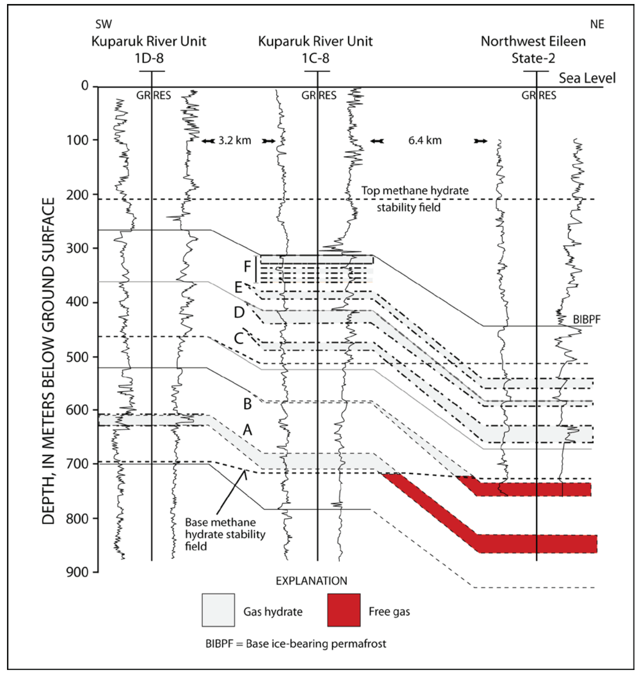

Figure 5. Cross section showing the lateral and vertical extent of gas hydrates and underlying free-gas occurrences in the Prudhoe Bay-Kuparuk River area in northern Alaska. See Figure 6 for location of cross section. The gas-hydrate-bearing units are identified with the reference letters A through F (Collett 1993).

(Figs. 5, 6). The six gas-hydrate-bearing sedimentary units have each been assigned a reference letter, Units A through F, with Unit A being the stratigraphically deepest (Fig. 5). Three-dimensional seismic surveys and downhole logs from wells in the western part of the Prudhoe Bay Field indicate the presence of several large free-gas accumulations trapped stratigraphically down-dip below four of the log-inferred gas hydrate units (Figs. 5, 6 Units A through D). The total mapped area of all six gas hydrate occurrences is about 1643 km^2; the areal extent of the individual units ranges from 3 to 404 km^2. The volume of gas within the gas hydrates of the Prudhoe Bay-Kuparuk River area, which has come to be known as the Eileen Gas Hydrate Accumulation, is estimated to be about 1.0 to 1.2 trillion cubic meters, or about twice the volume of known conventional gas in the Prudhoe Bay Field (Collett 1993).

The 1995 National Oil and Gas Resource Assessment, conducted by the U.S. Geological Survey, focused on assessing the undiscovered conventional and unconventional resources of crude oil and natural gas in the United States. This assessment included for the first time a systematic resource appraisal of the *in-place* natural gas hydrate resources of the United States onshore and offshore regions (Collett 1995). The onshore portion of the assessment dealt with most of northern Alaska, in which it was estimated that there may be as much as 590 trillion cubic feet of in-place gas trapped in gas hydrates.

Under the Methane Hydrate Research and Development Act of 2000 (renewed in 2005), the U.S. Department of Energy (DOE) funds laboratory and field research on both

Arctic and marine gas hydrates. Among the current Arctic studies, BP Exploration (Alaska), Inc. and the DOE have undertaken a project to characterize, quantify, and determine the commercial viability of gas hydrates and associated free gas resources in the Prudhoe Bay, Kuparuk River, and Milne Point field areas on the Alaska North Slope. Ultimately, this project could determine if gas hydrates can become a part of the Alaska North Slope gas-resource portfolio.

The following discussion dealing with the BP Exploration (Alaska) Inc. (BPXA) Mount Elbert Gas Hydrate Stratigraphic Test Well has been taken almost entirely from a news article appearing in the Winter 2007, U.S. Department of Energy, Office of Fossil Energy, National Energy Technology Laboratory, Fire in the Ice, Methane hydrate newsletter (available at http://www.netl.doe.gov /technologies/oilgas/publications/Hydrates/Newsletter/HMNewsWinter07.pdf; viewed August 16, 2007). On February 18, 2007, a team of scientists concluded an extensive data collection program in the Mount Elbert Gas Hydrate Stratigraphic Test Well drilled in the Milne Point area on the Alaska North Slope; it yielded one of the most comprehensive datasets yet compiled on naturally-occurring gas hydrates. This project began in earnest in 2002, following BPXA's response to a DOE request for proposals to evaluate the gas hydrate resources on the North Slope. Over the following three years, the project team conducted regional geological, engineering, and production modeling studies through collaborations with the University of Alaska (Fairbanks), the University of Arizona, and Ryder-Scott Company. In 2005, extensive analysis of BPXA's proprietary 3-D seismic data and integration of that data with existing well log data (enabled by collaborations with the U.S. Geological Survey, the Bureau of Land Management, and Interpretation Services, Inc.), resulted in the identification of more than a dozen discrete and mapable gas hydrate accumulations within the Milne Point area. Because the most favorable of those targets was a previously undrilled, fault-bounded accumulation (Fig. 7), BPXA and the DOE decided to drill a vertical stratigraphic test well at that location (named the 'Mount Elbert' prospect) to acquire critical reservoir data needed to develop a longer-term production testing program.

The Mount Elbert gas hydrate stratigraphic test well was designed as a 22-day program with the planned acquisition of cores, well-logs, and downhole production test data. A surface hole was first drilled and cased to a depth of 595 m. The well was then continuously cored to a depth of 760 m with chilled oil-based drilling fluid using the wireline-retrievable coring system. This core system delivered 85% recovery through 154 m of gas hydrate and water-bearing sandstone and shale. The coring team processed these cores on site and collected subsamples for analyses of pore water geochemistry, microbiology, gas chemistry, petrophysical properties, and thermal and physical properties. Core samples were also stored in liquid nitrogen or transferred to pressure vessels for future study of the preserved gas hydrates. After coring, the well was reamed and deepened to a depth of 915 m, and the well was surveyed with a research-level wireline logging program including magnetic resonance and dipole acoustic logging, resistivity scanning, borehole electrical imaging, and advanced geochemistry logging. Following logging, Schlumberger Modular Dynamic Testing (MDT) was conducted at four open-hole stations in two sandstone reservoirs. Each test consisted of flow and shut-in periods of varying lengths, with one lasting for more than 13 hours. Gas was produced from the gas hydrates in each of the tests.

Gas hydrates were expected and found in two stratigraphic sections. An upper zone, (Unit D) contained ~14 m of gas hydrate-bearing reservoir-quality sandstone. A lower zone, (Unit C), contained ~16 m of gas hydrate-bearing reservoir. Both zones displayed gas hydrate saturations that varied with reservoir quality as expected, with typical values between 60% and 75%. Presently, the project research partners are in the process of fully analyzing and integrating all the data collected from the Mount Elbert test well, including re-calibration of the initial geological and seismic models for the site.

Conclusion

Despite the apparent obstacles to the development of gas hydrate resources, it is important to remember that extraordinary technological developments in the petroleum industry—three-dimensional seismic techniques, secondary recovery methods, and horizontal drilling, for example—have allowed the extraction of resources once thought to be unavailable. Natural gas hydrates may also become economically extractable. On-shore Canada and Alaska are proven exploration targets for gas hydrates. The first commercial production of gas hydrates is likely to occur in either northern Alaska or Canada, where gas from gas hydrates will either support local oil and gas field operations or be available for commercial sale, if and when suitable gas pipelines are constructed. It is important to highlight that on the North Slope of Alaska, critical drilling and transportation infrastructure exists, which will allow gas hydrate prospects to be drilled and produced from existing installations.

Abstract

Small gullies observed on Mars could be formed by groundwater seepage from underground aquifers or may result from the melting of near-surface ground ice at high obliquity. To test these different hypotheses, a laboratory simulation has been performed. An experimental slope was designed to simulate debris flows over sand dunes with various slope angles, different granulometry, and permafrost characteristics. Preliminary results suggest that the typical morphology of gullies observed on Mars can be best explained by the formation of linear debris flows related to the melting of near-surface ground ice with silty materials. This physical modeling highlights the role of the active layer during debris flow formation.

Keywords: debris flows; gullies; Mars; physical modeling.

Introduction

The recent discovery of groundwater seepage and surface runoff on Mars suggests the local occurrence of subsurface liquid water at mid and high latitudes during recent periods. They have been proposed to result from subsurface seepage of water (Malin & Edgett 2000), brines (Andersen et al. 2002), near-surface ice melting at recent periods of high obliquity (Costard et al. 2002), snowmelt in more recent periods (Christensen 2003), geothermal heating (Mellon & Phillips 2001), or liquid CO_2 breakout (Musselwhite et al. 2001). Among this large variety of surface runoff features, an unusual example of debris flows over sand dunes retains our attention. These debris flows are characterized by (1) their localisation over sand dunes, (2) a typical morphology with long and narrow channels, and (3) the development of networks made of long, parallel down-dip flows (Fig. 1). The exact process of their formation still remains speculative. This study focuses on the formation of that typical morphology by means of various laboratory simulations within a cold room. According to these experiments, we discuss the possibility of explaining these gullies over sand dunes as a consequence of surface and near-surface melt of volatile-rich material. In this study, we describe how the depth of the active layer helps us to understand better the formation of Martian linear gullies observed in the Russell Crater. Such interpretation has important consequences in terms of recent climate change on Mars. We show that the characteristics of these typical linear Martian gullies are consistent with some external processes triggered by seasonal melting at high obliquity.

Gullies on Mars

Morphological characteristics

The observation of small gullies on Mars was one of the more unexpected discoveries of the Mars Observer Camera (MOC) aboard the Mars Global Surveyor spacecraft (Malin & Edgett 2000). *Debris flow* is the term used by Malin and Edgett (2000) to describe a downslope flow of debris mixed with a significant amount of water within the walls of impact craters. They mostly occur in a latitudinal band higher than 30°, with preferential pole-facing gullies in the southern mid-latitudes (Balme et al. 2006). A large majority are sited on the inner walls of impact craters and are occasionally found on central peaks of impact craters (Balme et al. 2006). They often become narrower and shallower downslope, are often slightly sinuous, and sometimes display complex morphologies such as levees, tributaries and streamlining around obstacles.

The upper part of most debris flows has a steeper slope that is dissected by channels, often sinuous, whereas thick accumulations of debris cover the bases of escarpments. The upper part of the slopes (mostly south-facing slopes in the Southern Hemisphere) exhibits alcoves. They are also characterized by their distinct V-shaped channels with well-defined levees. Individual channels exhibit low sinuosity and deep erosion down to the fans that bury the lower parts of the crater walls.

Most of the gullies observed on Mars are preferentially located at latitude higher than 30°. Therefore, they are located in regions where the Martian permafrost is supposed to contain ground ice in the near subsurface (Mellon & Phillips 2001).

Perched aquifer

Various mechanisms have been proposed for the formation of gullies by water. According to Malin and Edgett (2000), debris flows would result from springs fed by shallow aquifers. Water usually emerges from the lower part of the slope producing springs. According to that hypothesis, however, under hydrostatic pressure, springs may occur in the upper part of hills or slopes. The sources of this water can freeze on the surface. When the hydrostatic pressure oversteps the lithostatic pressure, the discharge can occur. The main problem is the difficulty for a shallow aquifer

Figure 1. Linear gullies over sand dune in the inner part of the Russell Crater on Mars. One can note the presence of sinuosity near the crest rim. HIRISE image PSP_002904_1255 (25 cm/pixel). Width of the image: 5 km. Light from the left. Credit: NASA/JPL/University of Arizona.

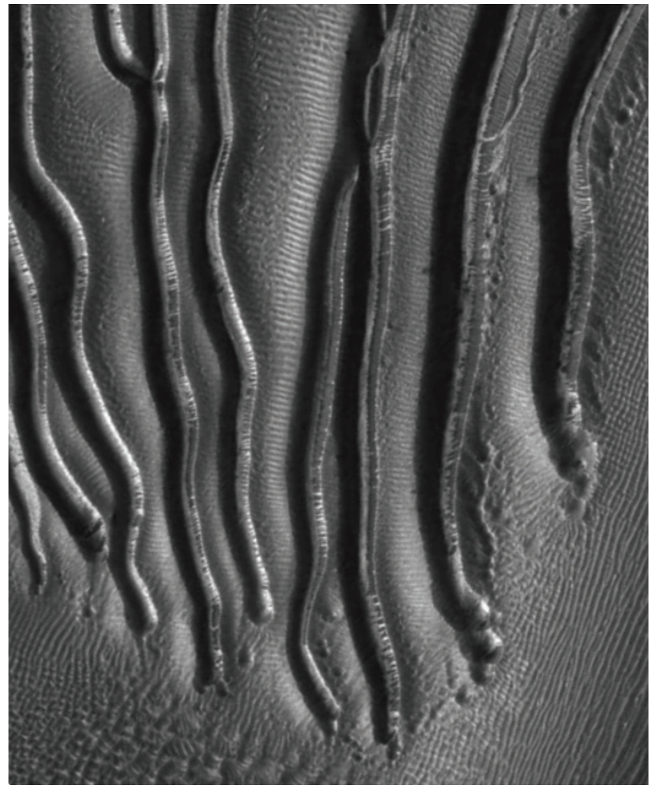

Figure 2. Close-up over the terminal part of gullies on the megadune. HIRISE image PSP_002904_1255 (25 cm/pixel). Width of the image: 1 km. Light from the left. Credit: NASA/JPL/University of Arizona.

to survive in equilibrium at such shallow depths under the cold ambient conditions. One possibility is to suppose a concentration of brines within the aquifer (Mellon et al. 2001).

CO_2 frost cover

Current seasonal defrosting has been proposed to explain gullies on hill slopes (Bridges et al. 2001) or over dunes (Reiss & Jaumann 2002). Recent HIRISE images clearly show a blanketing of CO_2 frost covering the south flank of dunes. Dark spots observed on the top of the dunes are attributed to the sublimation of CO_2 (Mangold et al. 2003). The possibility of snowmelt is not excluded (Lee et al. 2001; Christensen 2003).

Ice-rich deposit and obliquity scenario

This ground ice may represent one source of liquid water for the debris flows. However, this conclusion is contradictory with the usual consideration that liquid water cannot exist at the surface because of the low pressure and temperatures. This implies either that the ice-water is not pure or that climatic conditions were warmer in the recent past.

Ice-water doped with salts or CO_2 clathrates has been reported in different ways (Hoffman 2000, Ishii & Sasaki 2004). At least, it could explain gullies of the south polar regions, at 70°S, where temperatures are very cold; that is, 190 K of mean annual temperatures. According to terrestrial analogs in periglacial regions, Costard et al. (2002) have discussed the possibility of explaining some of these landforms by debris flows only due to surface and near-surface (<10 m) melt of volatile-rich material at high obliquities. Recent climatic changes may be possible considering the large pseudo-cyclic variations of the obliquity of the planet (Laskar et al. 2004). Variations of the orbital parameters are probably required to generate a subsurface melting of the supposed ice-rich permafrost or seasonal frost in these regions, thus allowing other processes to occur such as transient melting of ice-water (Costard et al. 2002).

Terrestrial analogs

On Earth, debris flows occur in periglacial environments when soils begin to be heavily saturated with water after the melting of the snow cover and/or the ground ice (Coussot et al. 1998). The initiation process of flow is still not fully understood. This initiation can be either due to water saturation by a peak intensity of rainfall events or to a rapid snowmelt (or melting of ground ice) with subsequent saturation or to a seismic event. Field observations indicate that snow cover plays an important role in the dynamic of debris flows. The duration of these debris flows is extremely variable and may occur as single or multiple waves. The deposition occurs along the narrow channel in levees of very coarse materials with boulders.

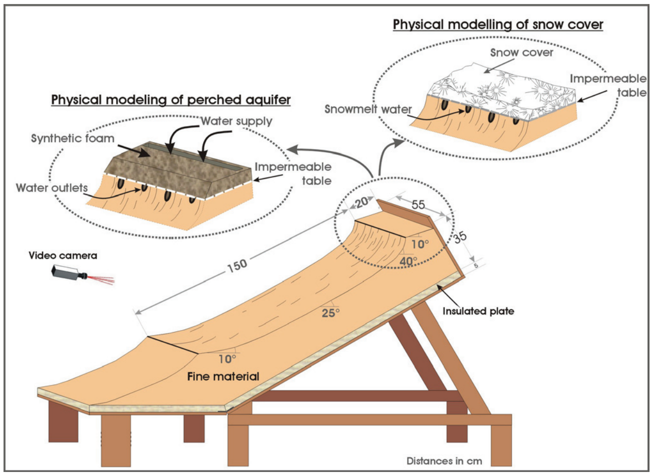

Figure 3. Global overview of the experimental setup and experimental configurations for two types of water supply (perched aquifer and snow cover).

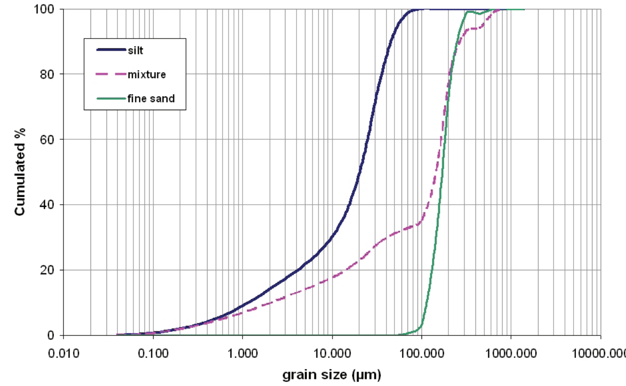

Figure 4. Grain size distribution of materials used for the experiment.

Gullies Over Sand Dunes

Russell Crater, a 200 km large crater located at 55°S and 347°W, exhibits various dune fields. One of them is relatively high (500 m) and covered by relatively low albedo volcanic sands. The SW flank of the megadune exhibits a few hundred long and narrow linear gullies, first discovered by Mangold et al. (2003). Gullies are about 2.5 km in length, and their mean slope is 10°. They start from regularly spaced small alcoves just under the crest of the dune, which is the steepest part of the dune (Fig. 1). Individual gullies exhibit linear and narrow channels with a loose pattern of connections.

Levees are observed on both sides of these channels as continuous and narrow ridges. These levees characterize a flow with a yield strength (Coussot et al. 1998) that corresponds to the minimal shear strength before flow. They are typically associated with flows containing 50% to 90% solid particles (silt to pebble size).

Relatively small distal-lobes are found lower down at the end of the channels at the foot of hill slopes. But gullies without terminal deposits are especially visible on the flank of dunes in the Russell Crater (Fig. 2). From a high-resolution HIRISE image (Fig. 2), most of the terminal deposits do not exhibit terminal lobes, but rather a concentration of small pits of unknown origin (thermokarst process ?).

These dune gullies present sinuosity and connections with a geometry that allows the calculation of flow properties, like the velocity and the viscosity (Mangold et al. 2003). The exact process of their formation over sand dunes, however, still remains speculative.

Terrestrial analogs for these typical linear gullies are unknown, justifying the use of laboratory experiments to try to understand the processes and conditions of the formation of these gullies.

Laboratory Simulations

Many factors work simultaneously in the triggering of debris flow, and their interdependence makes their analysis very difficult. High-resolution images are not completely appropriate in assessing the main parameters affecting the dynamic of debris flow. Laboratory simulation studies provide an opportunity for more detailed monitoring than can be done from imagery. The purpose of the study is to test qualitatively the influence of different parameters on the formation of linear gullies.

Methodology

Physical modeling has been developed in order to simulate the development of some typical gullies observed over Martian sand dunes in the Russell Crater. The major purpose of the experiment was to examine the respective effects of slope angle, material, and permafrost. To simulate a periglacial environment, these experiments require a cold room wide enough to receive an experimental slope (Fig. 3). We used the facility at the University of Caen/CNRS, France in a laboratory dedicated to physical modeling in geomorphology (Font et al. 2006).

Experimental setup

Our small-scale experiment was composed of a rectangular box of 2.5 m by 0.55 m wide and 0.50 m depth in which reconstituted debris from fine sand or silt materials was saturated with water (Figs. 3, 5). Morphologies are tested, with a median slope gradient of 15°, whereas the top and bottom slope gradients are constant (8° and 50° respectively). In order to simulate the periglacial environment, the slope was frozen from the surface, and permafrost was created at depth (0.50 m) with a temperature of -10°C.

The experiment procedure allowed the simulation of natural water supply for the debris flow formation. Two types of water supply were tested (Fig. 3):

1. To simulate perched aquifer, solid and porous synthetic foam was placed on the top of the rim crest. Then during thawing, a controlled water supply was injected into the foam.

2. Inflowing snowmelt water during thawing was simulated using fine particles of ice (<1 mm) covering all of the upper part of the slope.

Figure 5. Close-up of the apparatus used in the physical modeling of debris flows.

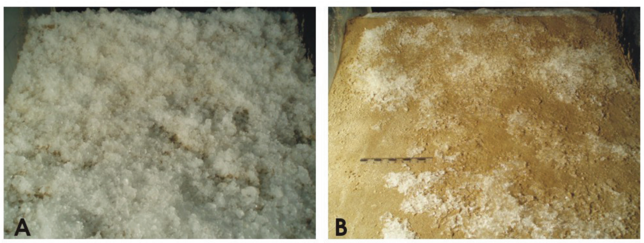

Figure 6. Experimental slope before (A) and after (B) snowmelt. In the laboratory simulation, the snow blanket is covering all of the slope. In that typical situation, no debris flows are observed probably because the snow blanket has a too wide-spread effect during the melting.

Ice-rich permafrost and control of the active layer

For each experiment, the material was initially saturated just before freezing. The thermal stability of the experiment was controlled by using 10 thermocouples at various depths. After freezing, the surface of the frozen soil is then progressively (and naturally) warmed to induce a controlled active layer formation. Thawing of the upper few mm of permafrost was done with an average air temperature of 18°C, giving rise to an active layer of 1 mm to 1 cm thick. Figures 3 and 5 outline the experiment.

Here, we assumed that liquid water was stable on the surface of Mars. The Martian gravity was not taken into account, and we assumed that the scale effect was not a limited factor. Our cold room is not a climatic chamber, so we do not control the atmospheric pressure and the thermodynamic aspect of the debris flow process. Here, the objective was mainly to simulate linear gullies as those observed on Mars in order to evaluate the respective influence of different parameters in terms of the efficiency of different parameters on the formation of these typical linear gullies.

Results

We carried out 42 experiments over two years. Data from a few tens of experimental gullies formation are presented here. They attest to the efficiency of periglacial processes

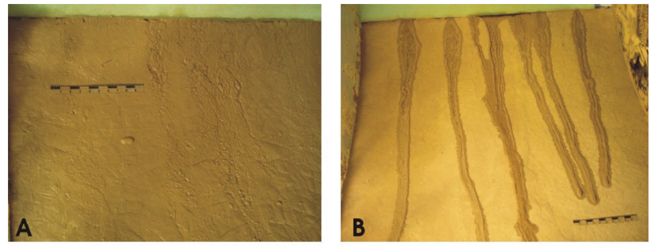

Figure 7. Effect of active layer thickness in a permafrost environment. A: diffused flow on surface with an active layer up to 10 mm. B: localized debris flows with an active layer of 1 mm thick. A relatively thin active layer strongly favors the formation of long and narrow linear gullies like those observed on Mars. Here, narrow gullies are preferentially formed by the water supply in the debris from the progressive thawing of the ice-rich permafrost, which occurs along a significant length of the flow.

that control both erosion and changes in gully morphology: (1) near-surface permafrost leads to a rather low sinuosity of the channel; (2) effects of silty material lead to increase the length/width ratio of the channel.

Blanket of snow or effect of the active layer?

From the experiment, the melting of the snow and the interstitial ice leads to the saturation level being reached within the layer of weathered debris. The decrease of the shear strength of the debris by water saturation is probably responsible for repeated debris flow episodes. According to the Christensen hypothesis (2003), gullies were created by trickling water from melting snowpacks, not by underground springs or pressurized flows. We did several simulations with a blanket of snow on the slope. The subsequent melting of snow deposits all over the slope has no effect on gully formation (Fig. 6B). However, underground springs or pressurized flows (either by a simulated perched aquifer or by inflowing snowmelt water from the rim crest, Fig. 3), both induced the melting of near-surface permafrost and the subsequent formation of linear gullies (Fig. 7B). To obtain such linear gullies, we need a clean pulse of water; the melting of the blanket of snow has a too wide-spread effect to trigger this kind of pulse.

Longitudinal variation and width/length ratio of gullies

According to Johnson (1970), debris flow deposits exhibit a variation of their morphologies in agreement with successive waves of debris. A plan view of the experiment (Fig. 8) shows the supposed waves and deposits formed by successive waves of debris. Figure 9 shows a comparative study between a terminal lobe from our laboratory simulation and a high-resolution image of the terminal lobe of two gullies on the megadune.

From various experiments with both silt and fine sand frozen material, carried out with the same volume of water supply and similar active layer thickness, it appears that silt material strongly favours the total length of debris flows (Table 1). The implication for Mars is to suppose that Martian dunes in the Russell Crater are made of silty materials. This interpretation is in agreement with the low

Figure 8. Narrow gullies with lateral levees and relatively small terminal lobes. The morphological characteristics of these gullies on sand are similar to those found on Mars in the Russell Crater. On the top: sinuous channels on the rim crest (like those observed on Mars). In the middle: connections between gullies and variation of their growth by successive wave of debris due to several pulses of water from the rim crest. The analogy with Figures 1 and 2 is striking.

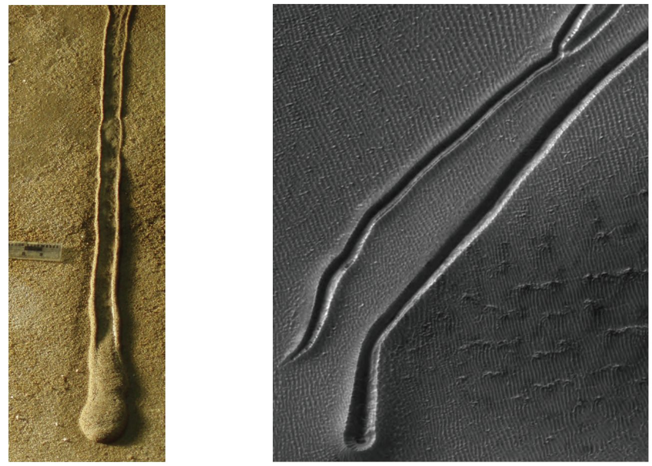

Figure 9. Comparative study of the development of lateral levees and terminal lobe between our experiment (left) and on Mars (right: HIRISE image PSP_002904_1255 (25 cm/pixel). Width of the image: 500 m. Light from the left. Credit: NASA/JPL/University of Arizona.

Table 1. Morphological properties of experimental debris flows obtained by the thaw of the ice-rich permafrost (protocol using synthetic foam).

Material	Lenght/width	% of length incised	% of levees
Sand	23	34	26
Sand/silt mixture	41	34	48
Silt	86	32	66

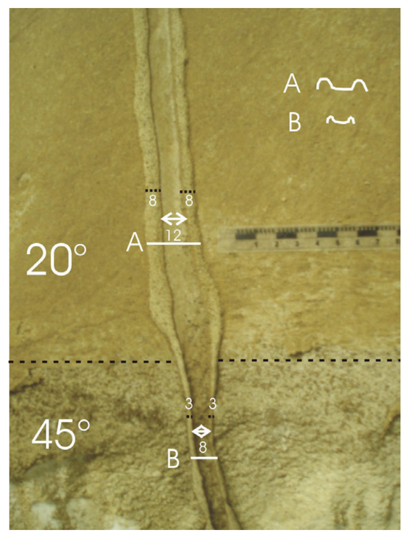

Figure 10. Variations of levees width in relation to slope angle. As on Martian gullies, levees are larger on the lowest slope. Laboratory simulation with fine sand.

albedo, which should be volcanic sands. The composition of these debris flows over sand dunes supposes finer particles than usual terrestrial debris flows (Mangold et al. 2003). In our experiment, the existence of linear gullies implies the incorporation of meltwater in the debris. This is only possible if thawing of the ground occurs along a significant length of the flow.

Levees and channel connections

Figure 9 shows a comparative study between a terminal lobe from our laboratory simulation and a high-resolution image of the terminal lobe of two gullies on the megadune.

The morphological change of the levees (Fig. 10) is related to the variation of velocities which results from the small change in slope gradient. This observation is in agreement both with characteristics of Martian gullies (Mangold et al. 2003) and rheological properties of terrestrial debris flows (Johnson & Rodine 1984).

Conclusion

Laboratory experiments have been undertaken to explore processes involved in gully formation over a sand dune in the Russell Crater. Debris flows over dunes involve either water formation from external processes (Mangold et al. 2003) or subsurface aquifers. The comparison between Martian and laboratory simulations leads to the conclusion that a periglacial environment could explain many of the described features in the Russell Crater. More than 40 laboratory simulations have been proposed in order to understand the formation of gullies over sand dunes on Mars. We used various materials (sand, silt), different slope angles, and different depths of active layers.

Our experiments suggest that the morphology of gullies found on Mars implies the presence of ice-rich permafrost with a relatively thin active layer. In any case (whatever the origin of the water—melting of snow, perched aquifer, or melting of permafrost), the active layer, together with the permafrost, controls the typical morphology of these linear gullies

The best analogy was observed with experimental permafrost made of silty materials with a very thin active layer (higher length/width ratio and percent of total length limited by levees: Table 1).

This preliminary work shows that a periglacial environment and the presence of near-surface permafrost could explain the formation of the Martian gullies. This hypothesis is consistent with some external process triggered by seasonal melting at high obliquity.

In the near future, we plan to test other debris flow formations with lower slope angle in agreement with both slopes from Russell Crater and Martian gravity.

Modeling the Erosion of Ice-Rich Deposits Along the Yukon Coastal Plain

Nicole J. Couture

Wayne H. Pollard
Geography Department, McGill University, Montreal, Canada

Abstract

The Yukon Coastal Plain is an area of ice-rich deposits along the Canadian Beaufort Sea and has been identified as highly vulnerable to the effects of sea-level rise and climate warming. Erosion is a function of the composition and morphology of coastal features, as well as wave energy. This paper outlines a simple model that considers these factors. Variations in ground ice contents and onshore and nearshore morphology are examined, as is their effect on the coastal dynamics of the region. Ice volumes are variable, ranging 52% to 84% by volume. A wave climate for the region is hindcast from historical climate records with offshore significant wave heights averaging between 0.32 and 0.45 m. Modeled wave energy shows that cross-shore energy is up to four times greater than longshore. Net longshore sediment transport is westward at all sites although the magnitude varies. Potential erosion is appraised.

Keywords: Beaufort Sea; coastal erosion; erosion model; ground ice; wave climate; Yukon Coastal Plain.

Introduction

Climate changes in the Arctic will have profound impacts on the permafrost coastline of Canada's Beaufort Sea. In addition to warmer air and sea temperatures, changes are expected in several other primary environmental forcings on permafrost coastal systems such as relative sea level (RSL), storminess, and the duration and extent of the open water season. The Yukon Coastal Plain is considered to be in a submergent area (Forbes 1980), with current rates of RSL rise estimated to be approximately 3.5mm/a (Manson et al. 2002). These increases in sea level will be magnified by oceanic thermal expansion which will contribute to the region's sensitivity to erosion (Shaw et al. 1998). Lambert (1995) suggested an increase in the frequency of storms under a warming climate and Solomon et al. (1994) have shown that there is a strong correlation between storm intensity and coastal erosion along the Beaufort Sea. The coast of the Beaufort Sea is micro-tidal with astronomical tide heights less than 0.5 m, so waves play a strong role in coastal change. This is particularly true during the open water season, when sea ice does not dampen wave development. Impacts of climate change along the Yukon Coastal Plain go beyond a physical response. The oil and gas industry are concerned about the effect of shoreline changes on infrastructure and exploration activities. Erosion and changes in the nearshore ecology also have the potential to directly affect local communities since hunting, fishing, and trapping are economic and cultural mainstays for many aboriginal communities along the coast. Numerous historical and archeological sites in the region have already been destroyed by erosion and a number of others are threatened.

The goal of this paper is to outline a simple erosion model to predict how ice-rich coastlines along the Beaufort Sea will respond to changes in climate. A wave climate is hindcast-based on historical climate data and is then used to calculate the potential wave energy available for erosion and sediment transport. The properties of the coastal bluffs are considered in determining spatial variability in erosion potential. The future susceptibility of the different coastline types is considered, based on predicted changes in environmental forcings for the region.

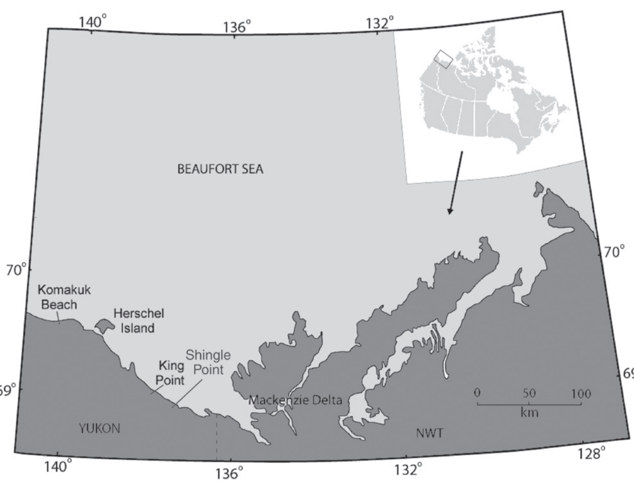

Figure 1. Location map showing the study region and sites along Canada's Yukon Coastal Plain.

Study Area

Canada's Yukon Coastal Plain, located along the Beaufort Sea west of the Mackenzie Delta (Fig. 1), is a lowland of dissected and hilly tundra about 250 km long and 10–30 km wide. Offshore, the continental shelf slopes gently to the shelf break located at about 80 m water depth (Hill et al. 1991). The shelf is relatively narrow, ranging from 40 km wide and sites in the western area to over 150 km wide at the Mackenzie

Delta. This region is classified as having a low arctic climate, with a mean annual temperature of -11°C and mean annual precipitation between 200 and 300 mm. The coastal plain is largely an erosion surface cut into Tertiary sandstone and shale. Most of it was covered by a lobe of the Laurentide ice sheet known as the Buckland Glaciation in the early Wisconsin, as well as by a later stillstand or re-advance known as the Sabine Phase. Surficial deposits reflect this history, with the coast east of Herschel Island being covered by glacial outwash plains and fans, moraines, and fine-grained lacustrine sediment. Moraines make up ice-pushed ridges or else blanket rolling to hummocky topography likely resulting from thermokarst activity (Rampton 1982). West of Herschel Island, the plain was unaffected by the Buckland Glaciation and is made up of coastal lagoons, coalesced deltas, and alluvial fans (Rampton 1982). Most of the flat or gently sloping landscape is covered by organic deposits and peat beds are common, particularly in lacustrine basins (Rampton 1982). Beaches along the coast are generally narrow and are backed by coastal bluffs that can be up to 90 m high. Permafrost along the Yukon coast is continuous and reaches depths of approximately 300 m (Smith & Burgess 2000). The ice content of these soils is high due to the presence of pore ice and thin ice lenses, abundant ice wedges, and beds of massive ice. Subsea ice-bonded permafrost is present below the Beaufort Sea in water depths up to 100 m (Mackay 1972, Dallimore et al. 1988, Dyke 1991). Three sites along the coastal plain were selected for study: Komakuk Beach, King Point, and Shingle Point.

Methods

Coastal composition and morphology

The presence of ground ice in coastal soils constrains the sediment content and influences the coast's susceptibility to erosion. To assess ice content along the Yukon Coastal Plain, a morphological model was developed based on a method first presented by Pollard & Couture (1999). The model calculates the total volume of ground ice for different terrain units along the coast by determining how much of each different type of ground ice is contained within that segment. Three types of ground ice are considered in the calculations: 1) pore ice and thin lenses of segregated ice, 2) wedge ice, and 3) beds of massive ice. As part of the Arctic Coastal Dynamics (ACD) project, a detailed segmentation of the Canadian Beaufort Sea coastline was conducted based on predominant landforms, surficial materials, permafrost conditions, and coastal processes. This initial segmentation was then refined using direct field observations, as well as data from Rampton (1982), Wolfe et al. (2001), and Harper et al. (1985). The percentage of ice content for each type of ground ice was first established, then the volume of each ice type in a terrain unit is determined. Finally, the percentages of total ice content by volume for each terrain unit are calculated.

Wave hindcasting

Meteorological data was obtained from Environment Canada weather observing stations at Komakuk Beach and Shingle Point and from a Campbell Scientific automatic weather station set up at King Point in 2004. Average hourly wind speed and direction were considered for the open water period for the years 2004–2006. The open water period is based on normals of median sea-ice concentration data from the Canadian Ice Service for the period 1971–2000. For the Yukon coast, ice concentrations fall below 5/10 during the last week of June, and open water lasts until the first week of October. Data from the King Point observing station was first adjusted to the 10 m level. Wind speed measurements from the three overland stations were then converted to overwater values to account for differences in roughness between the two surfaces, using commonly used empirical coefficients (Resio & Vincent 1977, cited in Kamphuis). The wind data were then used to model deepwater waves, following the JONSWAP method:

$$H_s = \frac{\lambda u^2}{g} \qquad (1)$$

where H_s = significant wave height for a fully developed sea (m), λ = dimensionless coefficient (approximately equal to 0.243), u = wind speed (m/s), and g = gravitational acceleration (9.8 m/s^2).

In the above calculations, shoreline orientation at each site was accounted for, and only offshore winds were considered to be capable of wave generation; winds blowing from a landward direction were set to 0. The waves are not considered to be fetch-limited, so the values are for a fully developed sea. Although only local winds are used to derive the offshore wave climates characteristics, the JONSWAP method considers the entire wave spectrum, so low frequency swell waves, which may be generated a great distance from the area of interest, are included in the calculated outputs. Nevertheless, swell waves are rare in the study region and are low when they are seen (Forbes 1997).

Wave energy and material transport

As waves approach shore, the bottom of the wave begins to interact with the seabed and shoaling begins. The wave is slowed, the wavelength becomes shorter, successive waves begin to pile up, and the heights of the waves increase until they steepen to the point that they break on the shore. The energy they contain is thereby liberated to effect sediment transport and erosion. If a wave approaches the shore at an angle, the portion of the wave closer to shore will slow first, while the deeper portion remains unaffected. As a result, the wave is refracted, or bent, so that the wave crest more closely parallels the shore. Standard equations based on linear wave theory were used to convert the deepwater waves to nearshore ones and determine the height of the breaking wave. Wave energy was then calculated based on the following equation:

$$E = \frac{\rho g H_b^2}{8} \quad (2)$$

where E = energy per area (N/m^2), ρ = density of seawater (1025 kg/m^3), g is as noted above, and H_b = breaking wave height.

The energy term was separated into its component vectors to give longshore and cross-shore values. Sediment transport in the longshore direction is given by the CERC expression (Kamphuis 2000):

$$Q = 330 H_b^{5/2} \sin 2\alpha_b \quad (3)$$

where Q = volume of transported material (m^3/h) and α_b = the incident angle of breaking wave.

Results

Wind data for the three-year period under consideration are shown in Figure 2. The importance of using site- specific wind data has been noted by earlier studies (Pinchin &and Nairn 1987), and is highlighted here by the differences between the stations examined. The coastal plain is narrowest in the west, and at Komakuk Beach, the close proximity of the British Mountains contribute to channeling the winds in an east-west direction. Offshore waves were hindcast from these winds producing average significant wave heights ranging up to approximately 0.5 m. Details of the significant wave heights for the three sites are given in Table 1.

The breaking wave heights are used to generate wave energy for each modeled wave, which is then broken down into a crossshore component (X) and a longshore one (Y) (Table 2). The proportion of energy going into each component is dependent on the incident angle of the nearshore wave which is, in turn, a factor of the original wind direction and the degree of wave refraction that occurs. This angle also governs which direction the longshore current will take (overall east or west, in the cases examined here). Net annual longshore energy is obtained by subtracting the total longshore in one direction from the total in the opposite direction. Using Equation 3, the potential net volume of sediment transported by the longshore wave energy can be calculated for the three-year period examined (Table 3). Although these calculations indicate potential transport of several thousands of cubic metres of sediment, the amount transported at Shingle Point is nevertheless not considered to be significant, if one considers that the uncertainty of the method is on the order of 10–-20%.

In order to assess how this potential sediment transport might affect coastal retreat at the study sites, the actual volume of material in the bluff needs to be considered. At Komakuk Beach, coastal bluffs are approximately 3 m high and consist of fine-grained lacustrine material. Ground ice comprises 61% by volume of the coastline. At King Point, cliffs up to 30 m high are made up of morainic material. The presence of beds of massive ice contributes to a very high ice content of 84%. At Shingle Point, the 10 m high bluffs are also morainic in origin, but their ice content is only 52%.

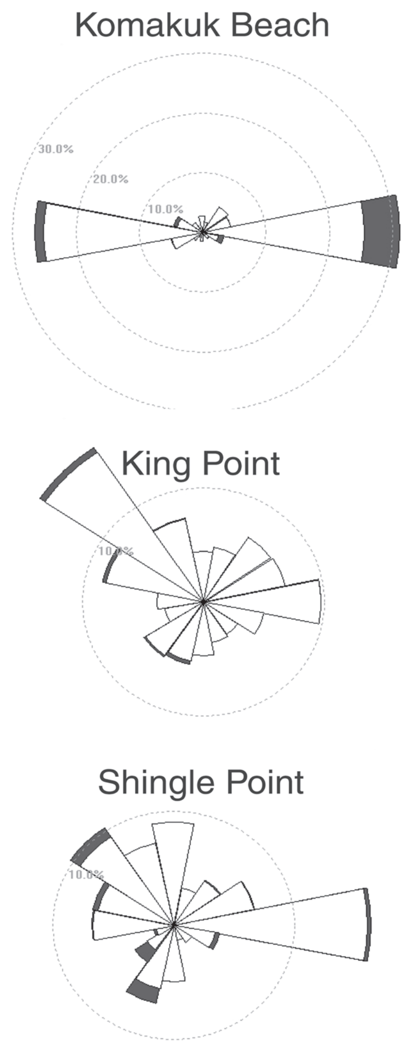

Figure 2. Wind roses showing frequency and magnitude of winds. Shaded areas indicate winds in excess of 37 km/hr, a common criteria for storm winds.

Figure 3 provides an indication of how these values compare to other sites along the Yukon coast.

Based on cliff heights and the percentage of ice they contain, the volume of sediment for a section of the coast extending 1 m inland can be calculated for each segment of coastline under study:

$$V = lh(1 - PIV) \quad (4)$$

where V = volume of sediment in a homogeneous coastline segment based on ACD project criteria (m^3),
l = length of the coastline segment (m),
h = height of the coastal bluff, and
PIV = percentage of ice from all sources of ground ice.

Entire segments of coastline are used to account for the fact that not all sediment being transported alongshore at any one point is necessarily sediment eroded from the coastline at that particular point. Rather, some of it has been supplied from further up the coast and is simply in transit. It

Table 2. Cross shore (X) and longshore (Y) components of modeled wave energy.

Site	Total X (N/m^2)	Total Y (N/m^2)	Eastward Y* (N/m^2)	Westward Y* (N/m^2)	Ratio X/Y
Komakuk	15.7 X 10^5	5.2 X 10^5	0.7 X 10^5	4.6 X 10^5	3.0
King Pt.	13.4	3.4 X 10^5	1.3 X 10^5	2.1 X 10^5	4.0
Shingle Pt.	16.0	4.5 X 10^5	2.2 X 10^5	2.2 X 10^5	3.6

* These represent only general direction of Y component. Actual movement of material is parallel to the shore at each site.

Table 3. Modeled longshore sediment transport for 2004–06.

Site	Q (m^3)
Komakuk	3.2 X 10^5 towards the west
King Pt.	0.5 X 10^5 towards the west
Shingle Pt.	0.1 X 10^5 towards the west (not significant)

Table 4. Volume of sediments and erosion rates for the different coastline segments in this study.

Site	Segment length (m)	Volume of sediments (m^3)	Annual sediment transport (m^3)	Potential retreat (m/yr)
Komakuk	6020	0.70 X 10^4	10.6 X 10^4	15.1
King Pt.	2990	1.43 X 10^4	1.8 X 10^4	1.3
Shingle Pt	8850	4.23 X 10^4	0.3 X 10^4	0

is therefore more realistic to integrate erosion over a longer length of homogeneous coastline. Total sediment transport for the 3-year period of study was averaged to arrive at a potential annual rate of transport. Assuming that this volume of sediment is being removed from the segment of coastline under consideration, then based on the volume of the sediments in the segment, a potential rate of annual coastline retreat is calculated (Table 4).

Discussion and Conclusions

This study examines nearshore wave energy generated through hindcasting. Previous studies have modeled potential erosion through wave climate analysis (Solomon et al. 1994, Hequette & Barnes 1990), but used offshore waves only so the results cannot be directly compared. Different techniques for nearshore wave transformation produce varying results (Pinchin & Nairn 1987) and the results of this study will need to be validated using measured nearshore waves. Previous work usually considers only storm winds and waves in their evaluation of erosion. We chose to examine all waves because several processes unique to arctic coasts can provide material for erosion between storms. Figure 4 shows two types of failures along coastal bluffs—retrogressive thaw slumps and block failures—that are common in ice-rich environments such as the Yukon Coastal Plain. In both cases, material is available close to the waterline and so is potentially subject to erosion by even moderate wave action. The erosion of the sediment from such failures may not result in any immediate retreat in the shoreline position, but once that material is removed, the toe of the bluff is not longer protected from direct wave action and subsequent shoreline retreat can proceed more rapidly. This study only examines three years of data and so does not necessarily reflect the

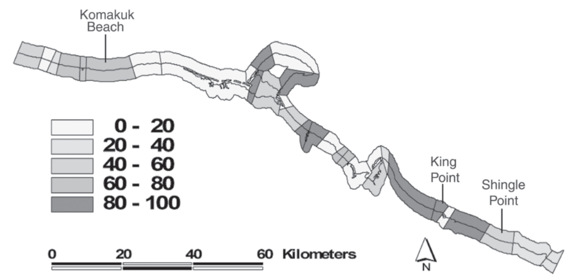

Figure 3. Ground ice volumes (by percentage) for different terrain units along the Yukon Coastal Plain.

longer term retreat rates resulting from these types of slopes failures

The modeled results can be considered acceptable given that the annual erosion rates are of the same order of magnitude as measured rates for the region (e.g., Harper 1990, Solomon 2005). Although the rate for Komakuk Beach shown here is higher than ones reported in earlier studies (0.76 m/a in Forbes 1997), this may be due to the fact that, rather than contributing to active erosion, the majority of the wave energy is devoted to transporting the high sediment loads being input from two rivers to the east of the site..

The simple erosion model in this study provides a first approximation of the influence of wave energy on coastal retreat rates. However, this model can only hope to explain some of the lower- level coastal landscape features. Coastal dynamics are extremely complex and are also influenced by currents, wave refraction around major features such as Herschel Island, river inputs of sediment, shoreface profiles, and ice-push events. The larger landscape structures like spits and barrier islands are likely controlled by major storm events. This is underscored by the fact that even though sediment transport at Shingle Point is shown to be not significant, a major spit does exist at this site. Improvements to the model presented here can be made by extending the length of the data set (preferably to at least 15 years), by validating the hindcast wave climate, and by incorporating grain size into the sediment transport equation since the one used for this study assumes that all transported material is sand. Fetch length was considered to be unlimited as soon as ice concentrations fell below 5/10, but its variability with time and direction should be part of future work. An examination of crossshore sediment transport is also planned. 4a) Ab) Episodic events such as these deliver sediments to the beach that can be subsequently removed by even moderate wave activity. The model could be used to examine future erosion rates, but several factors would need to be considered including changes to sea ice extent.

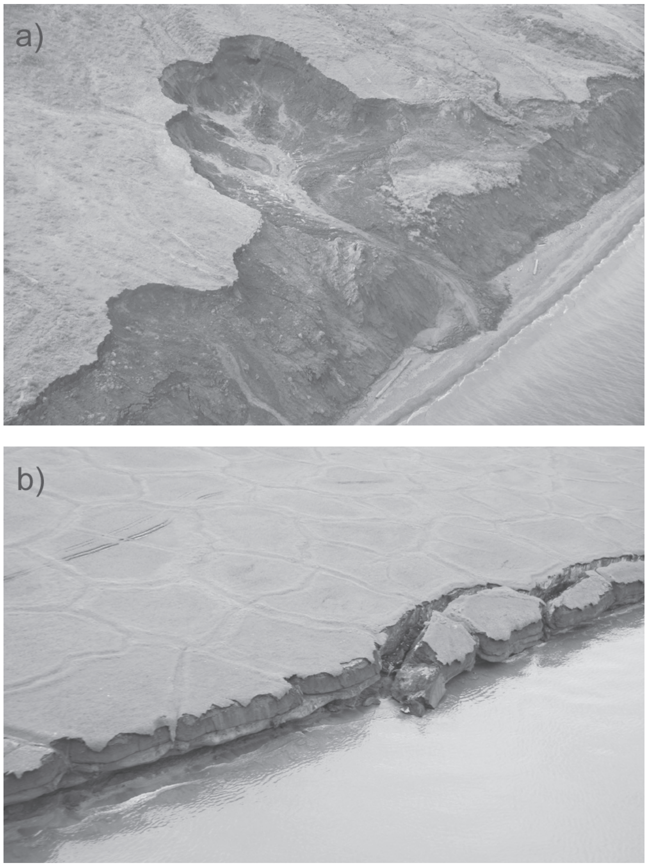

Figure 4. a) A retrogressive thaw slump near King Point and b) a block failure near Komakuk Beach. . Episodic events such as these deliver sediments to the beach that can be subsequently removed by even moderate wave activity.

Dynamics of Patterned Ground Evolution

James G.A. Croll
University College London, London, England WC1 E 6BT

Abstract

New dynamic mechanisms for the formation of a number of different forms of patterned ground are postulated to result from alternations of solar energy reaching the ground surface. Extensions of the thermo-mechanical processes widely believed to power the growth of ice wedge polygons are suggested to contribute to the dynamic evolution of many patterned ground features, such as sorted and unsorted stone circles, polygons, nets, stripes and steps. hummocks, frost mounds, palsas, and pingos. For each, fluctuations in solar energy at various temporal scales are argued to provide at least part of the dynamic driving force in what might be referred to as thermo-mechanical ratchet processes. While these ratchet models appear to be supported by past field observation, new field data are clearly needed if they are to be adequately assessed as to whether they might better explain the formation of many forms of patterned ground.

Keywords: contraction; cracking; expansion; patterned ground; periglacial morphologies; ratchet; thermal loading.

Introduction

Many forms of patterned ground within periglacial environments have been the subject of long-standing fascination. From the formation of geometrically patterned ground, to the sometimes distinctive mounds developing out of otherwise flat areas of permafrost, to the hummocks and other regular geometric patterns observed over ground subject to seasonal freeze-thaw cycles, much has been written as to their possible causes. Understanding of the processes responsible for their initiation and growth is of significance in relation to the interpretation of past climatic conditions through the observation of the relic geomorphic features remaining long after previous permafrost has receded. It is therefore not surprising that the processes which might have been responsible for the growth of these various forms of patterned ground have occupied considerable research attention. In many cases there is widespread agreement on the processes involved in these formations while in others there remains considerable uncertainty.

This paper approaches the subject of the mechanical causes of these various features from a somewhat different perspective. It postulates dynamic mechanisms that are in some form the result of alternations of solar energy reaching the ground surface. It suggests that these alternations of solar energy produce warming periods when the frost layer, or permafrost where it is present, is subject to horizontal compressive forces arising from the restrained, lateral, thermal expansion. During subsequent cooling, tension forces will accompany the restrained thermal contraction. Because of differential mechanical properties exhibited by ice and ice-rich ground at high and low temperatures, or under compression and tension, certain forms of deformation will accumulate to form morphological features through processes that might be generically referred to as thermal ratchets. Of particular interest here is how these processes might be at work in the development of patterned ground and as such is intended to complement earlier work dealing with the development of various forms of surface mound (Croll 2004, 2007b).

Ice wedges and ice wedge polygons are widely accepted to be the result of a form of this thermo-mechanical ratchet process. This was recognised by Lachenbruch (1964) and further elaborated from the field observations of Mackay (1974, 2000) and Mackay & Burn (2002). In this model of the formation of ice wedges and ice wedge polygons, the thermal ratchet process relies upon the cyclic compressive and tensile energies being dissipated through two very different processes. During seasonal warming, the compression phase, the release of stored energy is through an outward shoving of ground material, particularly within the active layer, giving rise to upward shearing and folding into the typical forms of rampart either side of the ice wedge. During seasonal cooling, the tensile phase, the dissipation of energy is the result of brittle tensile fracture, preferentially accumulating in the growing ice wedge. Over many such cycles the outward and upward movement of permafrost and active layer material compensates the growth in volume of the peripheral ice wedges. Yet surprisingly, the elegant logic of this seasonally driven thermal ratchet model process has not been transferred into efforts to better understand other periglacial phenomena occurring at possibly different spatial and temporal scales. As the following suggests, a related from of thermal ratchet model may also be responsible for the development of some of the many patterned ground features so eloquently described by Washburn (1979).

Stone Circles and Polygons

While reasons have in the past been proposed for the horizontal movements needed to form such curious features as the sorted stone circles of Figure 1(a), or polygons of Figure 1(b), etc, none of them appear to be entirely convincing or able to account for all such features. Encouraged by field measurements showing clear patterns of outward radial movements of the surface materials, from the centres of well formed stone circles (see e.g., Hallet et al. 1986), there have been many attempts to explain the formation of stone circles in terms of the development of convection motions within the active layer. Indeed, during the 1980s the convective cell model seems to have become the dominant explanation for the growth of stone circles (Gleason et al. 1986, Ray et al. 1983).

There are, however, fundamental problems with these models based as they are upon density differences largely resulting from variations in moisture content of the soil. First, the forces required to not just power the outward radial surface motion of the fines, but also shift the considerable weight of the border stones to allow the surface layers to be subducted beneath, would seem to be very much higher than any generated by the relatively small changes in soil density,and this does not even include the very considerable forces needed to visco-plastically distort the soil layers. Just as the density differences due to thermal gradients were held to be insufficient to drive a convection cell at the scale required for stone circles (Morgenstern 1932), it would appear that the forces due to density differences are also inadequate. Even the measurements of outward deformations of the soil surface do not appear to support the hypothesis of buoyancy driven convection. Accurate readings taken in western Spitzbergen clearly show radial deformation rates increasing away from the centre of the monitored stone circles (see Fig. 5, Hallet et al. 1986). Were the driving mechanism to be convection, very simple considerations of mass conservation would predict that the outward deformation rates would decrease with radial distance form the centres.

There appear to be similar problems with some of the more recent hypotheses for the development of stone circles and ice wedge polygons, even though results from computer generated models appear to support them (Kessler et al. 2003, Plug et al. 2002). Space does not allow fuller discussion. While it is likely that no single explanation will be able to account for all motions involved in the formation of periglacial morphologies, the following would appear a feasible explanation for at least some of the features outlined in classic texts such as Washburn (1979) and French (1996).

Role of thermal ratchetting

To illustrate how thermal-mechanical ratchet processes could be at work in the horizontal motions of both top soil and stones, consider a typical stone lying at surface level a distance h from the centre of a stone circle having radius r that is in the process of forming, as depicted in Figure 2. Here “circle” will be assumed to cover the case where the circular diameters are such that they would overlap were it not for the development of interacting polygons, nets, etc. Putting aside for the moment the question of what governs the characteristic dimensions of the stone circles, of current concern is the process that continues to drive the outward movement of the stones and surface material once the basic geometric patterns have been defined. In early autumn the seasonally unfrozen ground will start to refreeze. Initially this surface freezing and thawing would be governed by

Figure 1 (a). Examples of sorted stone circles.

Figure 1 (b). Examples of stone polygons.

circadian periodicities, for which the temperatures would follow a pattern similar to that shown in Figure 2(a). Each night the typical stone will be locked into the downwardly propagating freezing layer as suggested at time (1) in Figure 2(b). With the frozen layer being grounded within the stone boundary rampart, a drop in surface temperatures will develop tensile stresses in the frozen surface layer, as a result of the constrained contraction – time (2). Desiccation and even discrete cracks, associated with the development of the tensile stress, will attract moisture that at the low temperatures will turn to ice – time (3) in a similar way to ice wedge polygons. When temperatures begin to increase towards morning, the frozen ground will start to develop compressive stress as a consequence of the restraint to the expansion that would otherwise occur. Because the frozen layer of soil is likely to have fairly high compressive strength the overall radial forces being developed will be in certain ground conditions sufficiently high to dislodge the stone and cause it to move outward – time (4). At least in early autumn and spring the nocturnal frozen layer will completely thaw during the high diurnal warmth, leaving the stone and adjacent soil permanently moved out a small distance, δu, as shown at time (5). And so the process will continue with the radial distances moved increasing as the circadian fluctuations in temperature are increased.

To provide an indication of the levels of radial deformation and force developed during a typical circadian period, consider a nocturnally frozen layer of thickness 10 mm, having a coefficient of linear thermal expansion α = 50x10^{-6}/°C, subject to an increase in temperature ΔT = 10°C during

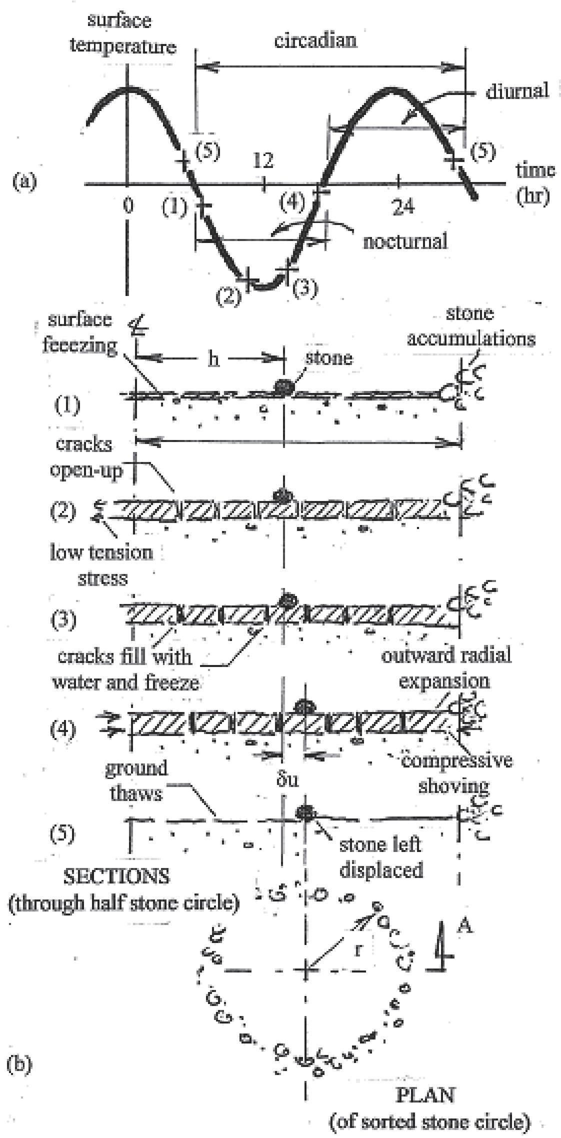

Figure 2. Schematic representation of (a) typical autumnal circadian thermal cycle acting on a stone circle, showing (b) typical half cross sections taken at times indicated.

the diurnal warming and prior to any melting. If there were no radial restraint, the outward radial deformation of a stone at a distance of, say, h = 1500 mm from the circle centre, would be $\delta u = \alpha \, \Delta T \, h$ = 1.3 mm/d. These rates of outward deformation are consistent with those recorded by Hallet et al. (1986). In that they are predicted to increase linearly with the distance from the centre of the stone circle, the deformation profiles are, in contrast with those predicted from the convection cell model, also in accord with those recorded by Hallet et al. (1986). If the outward radial deformation was to be fully restrained by the stone boundary, the radial stress σ_r developed in the frozen soil, assumed to have a modulus of elasticity E = 1 GPa, would be $\sigma_r = \alpha \, \Delta T \, E$ = 0.5 MPa. With the frozen layer of thickness 10 mm, a single stone of diameter 50 mm would attract a radial force of 250 N, or nearly 60 lbf, enough to dislodge even the most recalcitrant of stones. While it is difficult to conceive of soil convection developing force levels of this magnitude, the above scoping calculations suggest that a combination of thermal expansion and contraction is well capable of providing the driving force for the development of stone circles.

Even when the frozen layer ceases to completely thaw and starts to propagate downward, there may be short, daily or possibly longer, timescales over which a surface melt allows the stone to be ratcheted out a little further in much the same way as that described above. Under these circumstances the mechanism discussed in Figure 2 would operate in the diurnally thawed layer above the seasonal, downwardly-propagating frozen layer. Longer period thermal cycles could also be operating in the seasonally frozen ground in much the same way as they do in the growth of ice wedge polygons. As discussed below, these longer-term thermal cycles could play an important part in the determination of the characteristic dimensions of the rock or stone circles.

Controls of characteristic dimensions

While the above appears to provide a very plausible mechanism for driving the development of stone circles, it does not directly explain the mechanics whereby the stone circles are formed in the first instance and what it is that determines for a particular set of circumstances the characteristic radii for the rock circles, polygons, etc. In a given location and within a particular set of thermal climatic conditions, the characteristic dimensions of any stone circles appear to be fairly robust. If the forcing mechanism derives from a ratchet process driven by fluctuations in thermal loading, like that described above, then the nature of the mechanics involved but at longer timescales could also determine the characteristic dimensions that can be achieved. There are a number of mechanical processes that could be controlling these characteristic dimensions.

At annual timescales the depth of the thermal wave would determine not just the thickness of the frozen ground but also the depth and the spacing of any cracks connecting up to form crack-wedge polygons. This form of tensile energy relief could influence the typical dimensions of the eventual stone polygons, in much the same way as they control the characteristic dimensions of the ice wedge polygons within the deeper permafrost.

Another potentially controlling factor could be the shear capacity between the frozen layer and the underlying unfrozen ground. For a given set of ground conditions, the total shear capacity resisting an outward radial expansion would increase linearly with increasing radius of the stone circle. For a given range of thermal loading, which for a fully restrained expansion would control the maximum compressive force developed, the radius of accumulating stones would be increased until such time as the thermally dependent compressive force just equilibrates the shear resistance inhibiting radial movement. The most extreme thermal loading could be controlled by relatively short term thermal cycles, with moderately large temperature fluctuations but for which the frozen ground might be expected to retain high stiffness, or it could be the longer-term, annual seasonal, thermal cycles involving much larger average temperature fluctuations but for which the visco-plastic response would imply that the frozen ground has a lower effective stiffness to thermal straining. Whichever exerts the most extreme compressive loading will control, for a given set of prevailing underlying shear strength properties, the maximum or characteristic radius of the stone circle – or polygon where these start to overlap. The stone ramparts could be caused by shoving actions similar to the processes responsible for the formation of ramparts at the edges of expanding lake ice (Gilbert 1890, Hobbs 1911, Scott 1927).

Another possible mechanical condition that could control the characteristic radii would be the development of a form of upheaval buckling of the frozen layer, similar to the process recently described for the possible formation of pingos (Croll 2004, 2007a,b). Depending upon the thickness of the frozen layer and the thermal compression developed when during the spring its average temperature is increased, it is possible that the characteristic radius could be controlled by thermal uplift buckling. While such an upward doming would likely be recovered when the frozen ground thaws, the sloping sides and the surface melt in spring prior to this recovery might also contribute to the outward movement of any surface material to the lower edges of the buckled dome.

Development of differential frost heave

Once sorting of the type described above has taken place, there will be spatial inhomogeneity in the thermal conductivity of the surface layers. Peripheral stone or rock mounds with air voids will be likely to have a lower than average thermal conductivity with the result that downward growth of the circadian, seasonal or other periodicity growth of the frozen layer will be retarded around the periphery. The more rapid downward propagation over the central regions would induce greater rates of frost heave in these areas. If sufficiently large, this form of differential frost heave could elevate the central regions sufficiently that gravity might also lead to larger stones and rocks being moved towards the outer periphery. Even if the slopes are not sufficient to induce purely gravity-related sliding of the larger particles, a form of Moseley-Davidson thermal ratchet, similar to that described by Croll (2006) and believed to be the cause of insolation creep (Moseley 1855, Davison 1888), could be operating. However, on this basis the differential frost heave would be the result of the sorting not its cause.

Sorting through erosion

The thermal ratchet model described above would also account for the finer soil particles also being gradually shoved out to form peripheral edge ramparts, like those shown in Figure 1. Why these fines do not remain could be accounted for by subsequent differential surface erosion. Surface runoff from the elevated edge ramparts and selective erosion of the fines within these peripheral accumulations would wash back into the lower central regions of the circle/polygon. In certain circumstances it is likely that summer surface water or wind action could see the accumulated finer soil at the outer edges being eroded back to fill the fissures and pores left by the melting of ice from the previous winter's cracking action. This additional form of mass movement would accentuate the process of soil sorting whereby the centres of the circle are gradually colonised by finer particles and the outer edges by those of larger dimension.

High-centred stone circles

It is interesting to speculate as to why in seemingly more restrictive circumstances the larger stones accumulate not at the outer boundaries but at the centres of the graded stone circles, polygons, etc. It seems plausible, as suggested by Washburn (1979), that these stone accumulations may be an advanced form of the stone polygon. The corner nodes of the polygonal array may eventually attract, through a process similar to that described above, the accumulations previously occurring at the edges of the polygon. These nodes would then become the centres of arrays of essentially high-centred triangles, the triangular array representing the congugate of the original polygonal array. High-centred, sorted, or unsorted circles may either be the result of collapse of the underlying ice wedges at the boundaries, or in active permafrost be the result of a compression failure at the centre of the circle. Such failures might involve a process of upheaval buckling similar to that described recently in relation to the development of hummocks, frost mounds, palsas, and pingos (Croll 2007a,b).

Other Permafrost Features

Descriptions of many periglacial geomorphic features are consistent with the role of thermal ratchet processes like those described above being ubiquitous. Stone nets, stripes, and steps appear to be driven by mechanisms similar to those described above, but with the intervention of gravity the geometric patterns become orientationally distorted. Stone pavements and string bogs appear to have many features in common with the process described above for the formation ice wedge polygons. High-centred polygons seem to share a close resemblance to and possible similarity in origin to the pingo. As observed by Washburn (1979, p. 135) "some ice-wedge polygons enclose small pingo-like ice cored mounds."

Mention should also be made of frost-creep in the context of ratchetting processes. In this case the ratchet mechanism within currently accepted models is somewhat different, and thought to involve a combination of frost-heave occurring normal to the slope, followed by a thaw that results in a stone or other object settling vertically under the action of gravity. The result is a gradual downward motion accompanying each freeze-thaw cycle. Space does not permit consideration of the extent to which those phenomena, explained in terms of solifluction and gelifluction, might also have contributions from the thermo-mechanical ratchet processes outlined above.

In all of these surface motions, it is possible to construct models that could be complementing the processes currently considered to provide the driving force.

Some Closing Remarks

One of the purposes of this paper has been to suggest a form of dynamic mechanisms that may be contributing to the initiation and development of various forms of patterned ground. Thermo-mechanical ratchet processes, derived from fluctuations in the levels of solar radiation reaching the earth's surface, are suggested to contribute to the formation of rather more periglacial processes than currently accepted. The dynamic mechanism for the formation of various forms of patterned ground is postulated to result from alternations of solar energy reaching the ground surface. Extensions of the thermo-mechanical processes widely believed to power the growth of ice wedge polygons have been postulated to contribute to the dynamic evolution of many patterned ground features, such as sorted and unsorted stone circles, polygons, nets, stripes, and steps. Simple calculations have demonstrated that outward radial displacements of the frozen surface soil are consistent with previous field measurements. They also show that the levels of force generated when the expansions are restrained are large enough to account for the outward shoving of the stone ramparts.

Similar processes have recently been discussed (Croll 2007a,b) for the development of hummocks, frost mounds, palsas, and pingos. For each, fluctuations in solar energy at various temporal scales are argued to provide at least part of the dynamic driving forces in what might be referred to as thermo-mechanical ratchet processes.

While these ratchet models appear to be supported by past field observation, new field data are clearly needed if they are to be adequately assessed as to whether they might better explain the formation of many forms of patterned ground. Field tests would need to be devised that would allow, for example, the radial displacement rates to be correlated with the thermal conditions and especially temperature alternations. To be adequate, these measure-ments would need to be recorded continuously over full circadian cycles at the times of the year when motions are at their greatest. They would need to monitor variations in both the thickness and temperature gradients through the thickness of the frozen layer at circadian and other periodicities. If such data are to be adequately interpreted, it will be important to measure the site-specific coefficient of thermal expansion, modulus of elasticity, and other thermo-mechanical properties of the frozen soil.

As is becoming clear in evidence from recent planetary probes, many of the surface features being observed on the other planets and their satellites (see e.g., Kuzmin 2002, Yoshikawa 2002) would appear to have close relationships with similar features on Earth. Improved understanding of the mechanics responsible for developing these features will be essential if these observations are to allow better understanding the origins of the solar system, including a more complete appreciation of the nature and influences of present and past climatic conditions.

It is also becoming clear that closely related morphological features exist at very small scale in the behaviour of asphalt (Croll 2005a, 2006, 2007c). In these analogous cases similar forms of thermo-mechanical ratchet processes would appear to be responsible. Again, better understanding of the mechanics will be essential if future design and maintenance strategies can be expected to reduce the currently high maintenance costs for asphalt pavements. To capture all these phenomena, account must be taken of the relationships linking the thermal periodicities and the spatial scales.

Fluctuations in levels of solar energy and the operation of various forms of thermo-mechanical ratchet process seem to be rather more common in the shaping of environments, including periglacial environments, than is currently recognised. This paper represents a small start towards suggesting for patterned ground a new classification based upon the form of the thermo-mechanical ratchet processes that might be at work in their formation.

Acknowledgments

Financial support to cover attendance at the 2008 NIPC has been provided by a fellowship from the Leverhulme Foundation, whose support is gratefully acknowledged. Being relatively new to this fascinating field, I have relied heavily upon the excellent descriptions in books by French (1996) and Washburn (1979) and the impressive series of papers by Mackay. I have also benefited from private correspondence with Professors Mackay and Burn, whose efforts to correct many misunderstandings and provide references that might put me on a more correct path are gratefully acknowledged. In preparing this revised version of the original paper, I have also benefited from the comments of two anonymous referees, whose perceptive and helpful comments I hope to have at least partially addressed.

Yuri Shur
University of Alaska Fairbanks, Department of Civil and Environmental Engineering, Fairbanks, Alaska, USA

Abstract

One of the most extensive frozen ground engineering studies in the world was started in Alaska in 1945. It was led by the U.S. Army Corps of Engineers and has remained the most ambitious project in frozen ground engineering research. The name of the project was "Investigation of airfield construction in arctic and subarctic regions." This paper presents a review of some parts of this project, which paved the way for numerous further studies.

Keywords: aerial photographs interpretation; foundations design and construction; n-factor; permafrost; thermal conductivity.

Introduction

One of the most extensive frozen ground engineering research programs was conducted 60 years ago in Alaska. It was led by the St. Paul District of the U.S. Army Corps of Engineers and was a most ambitious project in frozen ground engineering research. The purpose of the program was "to determine design methods and procedures to be used in military construction in arctic and subarctic regions" (U.S. Army 1950). This goal was achieved, and results of the studies were widely used in military manuals for arctic and subarctic construction. The results have also contributed to contemporary knowledge on permafrost, and some of these became a starting point for numerous later studies.

The program integrated direct frozen ground engineering with supplementary studies. The direct frozen ground engineering studies consisted of the construction of sections of runways, with different types of embankments, insulation, and surfaces, and buildings with different types of foundations. These construction sections were conducted at Fairbanks Research Area with "the purpose of providing an opportunity to observe various types of structures erected on permafrost under conditions that would be known and recorded from the beginning to the conclusions of operations" (U.S. Army 1950). The study also included the monitoring of existing runways and buildings, and their impact on permafrost. These existing facilities were at the Northway Airfield, Eielson Air Force Base (near Fairbanks), and Ladd Air Force Base (Fort Wainwright).

The supplementary studies included development of methods for aerial photographic reconnaissance in permafrost regions, applicability of geophysical methods to permafrost investigations, thermal properties of frozen and unfrozen soils, and literature research.

In this paper, we describe the most notable studies and their results, which were presented in 1950 within the comprehensive report (U.S. Army 1950) by the Corps of Engineers and in several reports on the supplementary studies.

Design and Construction Studies at Fairbanks Research Area

Numerous experiments were conducted at the Fairbanks Research Area. They included the evaluation of terrain modifications (Area No. 1), different types of runways (Area No. 2), and different building foundations (Area No. 3) in the permafrost region.

Area No. 1 included three 61 m by 61 m sections of different surface conditions. Section A was an undisturbed area with natural vegetation. In Section B, trees and bushes were removed, but the surface vegetation cover was left. In Section C, all vegetation was removed with the top 40 cm of soil. Then another 10 m by 30 m section, Section D, had all the vegetation removed with the top 30 cm of soil. This section was then backfilled with sand to the original ground line and paved with 15 cm of concrete. Then the section was divided in three equal sections where two were colored white and black, and the third was left its natural gray color.

Monitoring of permafrost conditions in Area No. 1 included observations of the ground temperature to a depth of 10 m, the supra-permafrost ground water level, the vertical movement of the soil surface, probing to the permafrost table, and testing of the soil moisture content and density.

The report presents mean monthly soil temperature data for Sections A, B, and C from July 1946 to November 1948, and the positions of the permafrost table in 1947 and 1948. The studies in Area No. 1 are well-known from Linell (1973), who presented 17 years of observations of the positions of the permafrost table in Sections A, B, and C. Recent positions of the permafrost table are evaluated by Douglas et al. (in these proceedings).

The soil temperature data for Section D covered only one year of observations. At the end of summer 1948, the depth to the permafrost table under each part of Section D was about 2.5 m. The authors of the report concluded that "concrete surface color whether black, gray or white under the test conditions has no appreciable effect on depth of thaw" (U.S. Army 1950). It seems to us that the period of observation was too short for such conclusion.

Area No. 2 included 26 runway test sections of approximately 250 m by 60 m each. The natural vegetation was removed from the site, and the upper soil was stripped to various depths from 0.3 m to 1.2 m. The thicknesses of embankment of test sections varied from 0.6 m to 3.6 m, with 1.2 m thickness for most sections. Two sections had gravel surfaces, while the others had asphalt or concrete surfaces. Some sections were insulated with 7.5 cm and 15 cm thick foamglas, 15 cm and 30 cm thick cell concrete, and 15 cm thick compacted moss. Fifteen sections were not insulated.

The data presented in the report on ground temperatures and soil freezing and thawing in the runway test sections cover only one year of monitoring and are of very limited value. However, one conclusion is worth mentioning: it was found that "the ground temperature below the insulation is cooler in summer and warmer in winter than if the insulation were not present. The net effect is that the mean annual ground temperature is about the same, whether or not insulation is used" (U.S. Army 1950). This conclusion has not appealed to many arctic engineers, and thermal insulation is still often considered as a trusted measure of permafrost protection under roads and airfields in any permafrost area. Nidowicz and Shur (1998) analyzed data presented in several works from Alaska, Canada, and Russia which also show that thermal insulation has either no effect or increases the mean annual soil temperature. Thermal insulation is effective in areas of cold permafrost because it decreases the depth of seasonal thawing and protects upper ice-rich permafrost, while at the same time, the increase in permafrost temperature does not impact the integrity of structures in these areas. In the discontinuous permafrost zone, thermal insulation does not protect permafrost from degradation. The permafrost protective effect of thermal insulation in any permafrost area is greatly increased with the addition of a soil cooling system, such as heat pipes or ventilated ducts. These cooling systems make the soil colder under thermal insulation in the winter, and thermal insulation decreases heat flow into the soil in the summer.

Eleven buildings were built in 1946–1947 in Area No. 3 to study the stability of different types of foundations. Five of them were built on gravel pads where the thickness ranged from 0.6 m to 1.8 m, with concrete or insulated wood floors placed on the ground. Two buildings had 60 cm high crawl spaces, where one of them had wood skirting. One building had an open crawl space that was 1.2 m high.

Building No. 11 was constructed on a gravel pad of 1.5 m thickness. It was based on a 48 cm thick concrete slab containing a layer of continuous hollow tile that was open to air on both sides. Ventilation of the foundation was not sufficient, and the permafrost thawed to a depth of 3.2 m under the center of the building in 1948. The monitoring data of the settlement of building corners in 1948 to 1964 were presented by Linell and Lobacz (1980). The maximum thaw settlement from 1948 to 1964 reached 75 cm. The buildings, also, were left unheated from 1957 to 1964 which did not stop the thaw settlement during this period.

Building No. 10 was built on piles with an open crawl space of 1.2 m. One pile at the southwest corner did not refreeze and frost jacked 18 cm during 1947–1957. Posts supporting two porches were installed in the active layer and frost jacked 40 cm in the same period (Linell & Lobacz 1980).

During initial observations covered by the report, it was found that seasonal vertical movement depends on the thickness of the gravel pads for buildings with floors placed on the ground. Movement was less than 2 cm for Building No. 4 constructed on a 1.8 m thick pad and more than 12 cm movement for Building No. 8 which was constructed on the natural surface. Data show this dependence greatly decreases when the thickness of the pad reaches 1.2 m.

Lobacz and Quinn (1966) analyzed the performance of buildings from their construction in 1946 until 1954, and found that the gravel pads did not protect the buildings from permafrost degradation and had "appreciable amounts of vertical settlement" (Lobacz & Quinn 1966). The thermal insulation of the floors slightly improved the foundations' integrity. They also found that buildings on piles with open crawl spaces performed well when "piles are firmly bonded in permafrost" (Lobacz & Quinn 1966).

The special project on the Navy monotube test piling was not successful. A steel pile of 18 m length and another steel pile of 12 m length were installed by steam thawing of the permafrost during November 13–20, 1947. The loading was concluded on December 12, 1947. It is possible that the method of pile installation was chosen because of the contemporary belief that "Piles cannot be driven into permafrost by the usual methods. It is therefore necessary to resort to a preliminary thawing of the ground by steam points" (Muller 1947). But the same source warned that "at a depth of 5 or 6 meters below the permafrost table the freezing of a pile to permafrost takes about a month and a half to 2 months. Only after that time can the pile be loaded with the calculated weight of the projected structure" (Muller 1947). Both statements do not specify the permafrost conditions for which they are applicable. At the test site, freezeback did not occur, and the piles experienced rapidly accelerating settlement, even after a part of the load was taken away.

The permafrost temperature at the site was close to 0°C, and only lack of experience can explain the chosen method of pile installation in warm permafrost and the pile loading shortly after the pile's installation. Even six months later, in June 1948, soil temperature was above 0°C throughout the length of both piles (U.S. Army 1950). The experiment did produce one interesting result, where thermistors were installed in the pipes attached to the piles showed an increase in soil temperature during the settlement of the piles.

The full history of the Fairbanks Research Area was recently briefly described by Henry and Bjella (2006).

N-Factor

One of the long-lasting results of the studies at the Fairbanks Research Area is the way of correlating air and surface temperatures. "Since air temperatures are generally available and surface temperatures are not, a study has been made of data from Fairbanks, Alaska to determine the relation between a thawing or freezing index calculated from air temperature and indexes calculated from the temperatures of different types of surfaces with the thermocouples so installed that they were partially embedded in the surfaces" (U.S. Army 1950, Carlson 1952). As a result of the Corps of Engineers studies, the correlation factor, which is now known as the n-factor, was proposed to evaluate a surface thawing or freezing index from the known air thawing of freezing index. With time, the n-factor approach became a very powerful tool in arctic engineering and permafrost studies.

The set of data for the correlation factors (n-factors) for different types of surfaces was developed on the basis of surface temperature measurements at the Fairbanks Research Area and air temperature measurements at the Weeks Airfield in 1947 and 1948. The correlation factors founded in the study were later included in countless works. We highly value this part of the study, as well, because it had a great impact on the development of engineering methods of the evaluation of soil freezing and thawing and permafrost methodology. We should observe that the air and surface temperature measurements were taken at two separate sites, which could have compromised the data, especially for winter conditions. The Fairbanks Research Area is on a gentle south-facing slope, and the Weeks Airfield was located on the flat surface of a low terrace of the Chena River. The distance between sites was 5 km, and the difference in elevation was about 10 m. This elevation difference in Fairbanks, which is famous for winter inversions, can partly explain why the winter n-factors for concrete and asphalt surfaces without snow were as low as 0.7. We also suspect that the snow was not completely plowed from the thermistor locations to protect them from damage.

Permafrost Existence and Thermal Offset

In the Russian book, *General Permafrost Studies,* by Sumgin et al (1940), the authors of the report identified the following equation as "a definite contribution" which describes "the conditions necessary for the existence of permafrost" (Main Report 1950):

$$k_f T_f \tau_f > k_u T_u \tau_u, \tag{1}$$

f = factors in the equation during freezing
u = factors during thawing
k = coefficient of thermal conductivity
T = average temperature of the ground at depth h
τ = time during freezing or thawing.

The equation (1) was found by Krylov (1934) from the Stephan equation for soil freezing and thawing, with an assumption that permafrost exists if freezing is greater than thawing.

$$\sqrt{\frac{2k_f(T-T_f)\tau_f}{L}} > \sqrt{\frac{2k_u(T-T_f)\tau_u}{L}} \tag{2}$$

At sites where the bottom of the active layer merges with the permafrost table, the depth of the seasonal freezing is equal to the depth of the active layer defined by seasonal thawing. Kudriavtsev (1954) named the freezing associated with the left part of the equation (1) as the potential freezing. The authors of the comprehensive report finally presented the equation (3) in the following form (U.S. Army 1950, Carlson 1952):

$$\frac{k_f}{k_u} > \frac{I}{F} \tag{3}$$

I = thawing index at the soil surface,
F = freezing index at the soil surface.

The authors of the report noticed that the ratio in the left part of equation (3) is greater than one, if the thermal conductivity of soil in the frozen state is greater than its thermal conductivity in the unfrozen state. They concluded that "permafrost can exist even though the thawing index is greater than the freezing index" (U.S. Army 1950).

The greater the thermal conductivity of the frozen soil than the unfrozen soil also leads to the decrease of the soil mean temperature at the bottom of the active layer in comparison with the temperature at the soil surface. Kudriavtsev (1954) used the Russian term *temperaturnaya sdvizhka* to describe this effect. Burn (1988) and, Romanovskiy & Osterkamp (1995) use the term *thermal offset*, and Shur & Jorgenson (2007) literally translated the Russian term as *the thermal shift*. Kersten (see below) showed that the thermal conductivity of coarse well-drained soils in the frozen state can be smaller than their thermal conductivity in the thawed state. In this case, the disparity (3) should be rewritten as

$$\frac{k_f}{k_u} < \frac{I}{F} \tag{4}$$

From (4) we can conclude that permafrost can be absent even though the freezing index of the soil surface is greater than the thawing index. In this case, the thermal offset (thermal shift) has the opposite sign. To be consistent, we should consider the negative thermal offset (which is usually referred to as the thermal offset) and the positive thermal offset.

Thermal Properties of Frozen and Unfrozen Soils

The Corps of Engineers contracted the research of the thermal properties of soil, with objectives "to determine under varying conditions of temperature, moisture, bulk density, and composition the thermal properties of representative soils and organic material from Alaska" (Kersten 1949). The study was conducted at the Oak Street Laboratories of the Engineering Experimental Station of the University of Minnesota. Miles S. Kersten, Associate Professor of Civil Engineering, was in immediate charge of the investigation. Procedures and results were presented in a report (Kersten 1949) and numerous publications since then.

Soils from Alaska included Chena River gravel, sand, silty clay loam, silt loam, and peat from Fairbanks; sand and silt loam from Northway; and clay from Healy. To cover a wider range of soil properties, some soils from other regions were also studied.

Soil was placed in a hollow cylinder for thermal conductivity tests. Boundary conditions at the inside face of a hollow soil cylinder were kept at a constant heat flow. Constant temperature was the boundary condition on the outside face. Temperature was measured at two points in the inside face and two points at the outside face. To evaluate the coefficient of thermal conductivity the following equation was used:

$$q = \frac{\dfrac{k(A_2 - A_1)}{\ln(A_2 / A_1)}(T_1 - T_2)}{r_2 - r_1} \quad (5)$$

where:
q = measured rate of heat flow,
k = coefficient of thermal conductivity,
A_2 = area of outside face of soil cylinder,
A_1 = area of inside face of soil cylinder,
T_1 = temperature at inside face,
T_2 = temperature at outside face,
r_2 = outside radius,
r_1 = inside radius.

This equation can be transformed into the commonly used equation, written for one unit of length:

$$q = \frac{2\pi k(T_1 - T_2)}{\ln(r_2 / r_1)} \quad (6)$$

The equations define steady-state heat flow between two cylindrical surfaces having constant temperatures consequently T_1 and T_2. This is not the case for the test conditions dealing with a composed hollow cylinder with prescribed heat flux at one surface and prescribed temperature at the other. To satisfy the boundary conditions expected in equations (5) and (6), the heat flow (voltage and amperage of the heater) at the inner face was manually adjusted to reach the desired temperature at this face of the hollow cylinder filled with soil. Measurements were taken when temperature variations were less than 1% during a five-hour period.

The thermal conductivity of soils was studied using a wide range of soil densities and water contents at average temperatures of 70, 40, 25, and 20°F. The temperature difference between sides of the soil cylinder was 10°F. This means that for the average temperature of 25°F, it was 30°F on the hot face of the soil cylinder and 20°F on the cold face.

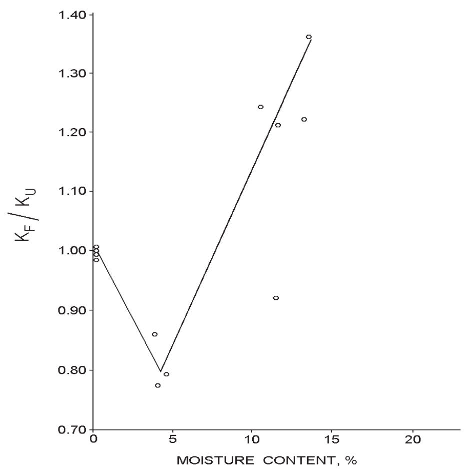

Figure 1. Ratio of soil thermal conductivity in frozen state to thermal conductivity in unfrozen state (from Kersten 1949).

After the tests, the moisture content of sandy soils at the cold side of the specimens was greater by a few percentages than on the warm side, and some mass transfer occurred during the tests. This could be driven by extremely high temperature gradients which were about 6°C over 5 cm.

Experimental data show that over a wide range of soil moisture content, the ratio of soil thermal conductivity in a frozen state is greater than the thermal conductivity of the same soil in an unfrozen state. This is because the thermal conductivity of ice is four times greater than the thermal conductivity of water. This rule is practically always applicable to fine soils. Kersten also found that, at low water content, the thermal conductivity of unfrozen soil is greater than the thermal conductivity of frozen soil, and the ratio k_f/k_{un} is less than one (Fig. 1). This was because of the separation of soil particles and the disturbance of thermal contacts between particles by ice during freezing, and an increase in soil porosity (Gavriliev 2004). It is a very rare situation for fine soils, but it is a common one for well-drained coarse soils.

Thermal conductivity of a few soils were compared (Kersten 1949) with limited data obtained by the Corps of Engineers New England Division, Boston, by a different method on the same soils. Values found by the University of Minnesota are less than those of the Boston study, but the difference does not exceed 10%.

Kersten did not test the frozen soils in their natural state. Soils from Alaska were remolded, and different water contents were assigned that were limited by saturation. In natural conditions, permafrost soils often have water content sufficiently greater than soils studied by Kersten. This limitation was later overcome by Slusarchuk and Watson (1975). Extensive research of thermal conductivity of surface covers was done by Gavriliev (2004).

Aerial Photo Interpretation for Permafrost Identification

As a part of the research, the U.S. Army Corps of Engineers funded and provided field support of the studies

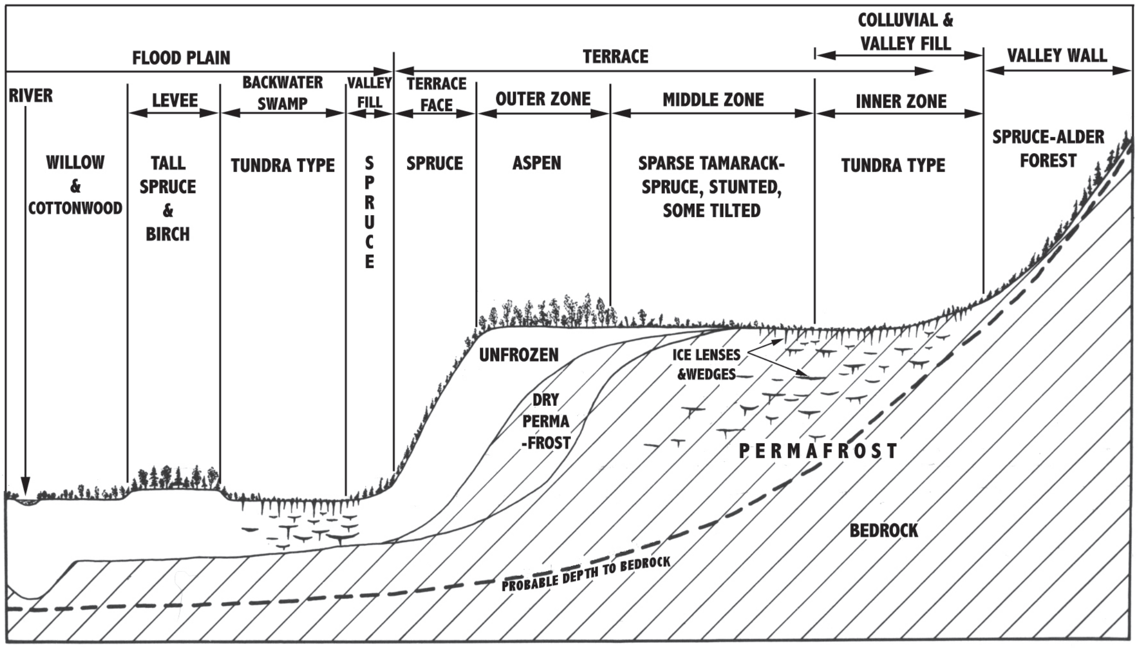

Figure 2. Possibly the first permafrost-relief-vegetation sequence (from Frost 1950).

by Purdue University. The purpose was to evaluate soils and permafrost conditions in Alaska by means of aerial photographs. Colonel Yoder, one of the leaders of the project, described expectations in the following words: “In relatively undeveloped regions, such as in the Territory of Alaska, aerial photographs can be used to great advantage in locating airports, highways, railroads, bases, etc. In a few hours’ time, a general engineering soil map can be produced which will show the good, poor, and intermediate soil areas evaluated on the basis of anticipated performance of engineering structure. Thus, the poor soil areas can be eliminated almost entirely by study of the aerial photographs, and the field investigation can be concentrated on those areas best suited to construction” (Frost 1950).

Scientists from Purdue University spent five summers in Alaska, gathering information which helped to develop techniques of aerial photograph interpretation. Field work was conducted in Interior Alaska, Seward Peninsula, Yukon-Kuskokwim Delta, Arctic Slope, and Arctic Coastal Plain. “When possible, such studies were made by ‘on the spot’ sampling with the aerial photographs in hand” (Frost 1950). As a result of the field studies and analysis of the field data, aerial photo patterns related to permafrost conditions were developed. They include vegetation, topography, drainage, erosion, and some direct indicators of permafrost conditions. With the information from the aerial photographs and ground reconnaissance, engineering soils maps can be made for finding suitable construction sites. These maps can shorten the preliminary investigation and eliminate the need for costly, extensive preliminary drilling (Frost 1950). This work became widely known from the extensive paper presented by R.E. Frost in a symposium, *Frost Action in Soils,* and published in the proceedings of this symposium (Frost 1952).

The report compiled by Frost (1950) for the Corps of Engineers consists of several examples of aerial photographs and descriptions of land forms and vegetation in relation to permafrost in Alaska. Figure 2, from the report, presents the typical profile through a river valley in the discontinuous permafrost zone showing patterns of permafrost existence and absence in relation to relief and vegetation. It is possible that this figure is the first permafrost profile of such kind in permafrost literature.

Frost’s report outlines a comprehensive approach to applications of aerial photography to permafrost studies. It stimulated similar studies in Russia (Protas’eva 1967) and Canada (Brown 1964, 1966). It was also the first step in the series of studies which led to the effective application of terrain unit analysis to permafrost investigations for the Trans-Alaska Pipeline. Kreig and Rigert (1982) improved and effectively applied aerial photo interpretation and application of the terrain analysis to geotechnical investigations for the pipeline, with the acknowledgement Frost’s report. Roger Brown (1970) in his book, *Permafrost in Canada*, also acknowledged the pioneering studies by Purdue University in Alaska and later in Canada, which “justified the belief in the applicability of airphoto interpretation methods for preliminary site surveys in permafrost areas” (Brown 1970). The method, which was initially solicited for engineering investigations for airfields in the Arctic, finally became an interdisciplinary tool of arctic and subarctic scientific studies and applied investigations of different scales and for multiple purposes.

Stoeckeler, who worked with the Purdue University team, studied a relationship between permafrost and vegetation. He found that vegetation is not a good indicator of permafrost presence in areas where the permafrost table is lower. “The presence of the permafrost table at a depth of 6 feet or more from the ground surface has little or no deleterious effect on tree growth, with the possible exception to deep rooted trees like balsam poplar, cottonwood, and jack pine. Therefore, vegetation alone can be employed only as an indicator of soil conditions to a relatively shallow depth" (Stoeckeler 1949). This message, from 1949, still remains relevant to permafrost and many other studies in the discontinuous permafrost zone.

Conclusions

In the 1940s, the St. Paul District of the U.S. Army Corps of Engineers carried out pioneering research. This paved the way for future intensive research of frozen ground engineering in Alaska, as well as around the world.

Investigations by the Minnesota and Purdue Universities were funded by the Corps of Engineers for specific engineering tasks, as parts of the project. Their immense impact on permafrost studies over the last 60 years proved that there is nothing more valuable than good science.

Abstract

Non-sorted circle patterned ground features are abundant in the Arctic tundra. These features show large variability in active layer depth in summer and heave in winter. There is a lot of research devoted to measuring active layer depth, yet little is known about small-scale variability of the active layer in patterned ground systems. The active layer is sometimes used as an indicator of a warming climate which is not always correct. The active layer depth varies from year to year as it freezes and thaws. It also expands and shrinks as it accumulates ice and loses ice. We have conducted two surveys, one in the spring of 2007 and one in the summer of 2007. The surveys were taken from the Biocomplexity research site near Franklin Bluffs, North Slope Alaska. We were able to reference the surveys points to a deep well located near the site that is used for deep-permafrost temperature sampling. The well is 60 m deep and, therefore, permanently anchored in the permafrost. The surface elevation is recorded in a 25 cm dense grid over an area of 10 by 10 m. The plot contains approximately 20 non-sorted circles. The average surface elevation in winter was 85 cm below the reference point, and in the summer it was 97 cm below the reference point. This means that there was a 12 cm surface elevation difference. We suggest multiple mechanisms that could explain this amount of heave. Current active layer development shows a decreasing trend (smaller active layers over time) with long-term observations near our site, in contrast to the annual average soil temperatures that are increasing. Reasons for a decreasing trend may include a lack of a warming trend in summer, changes in thermal conditions, and greening of the Arctic, which may lead to increased transpiration rates and absorption of incoming shortwave radiation. Long-term observation of surface movement in this grid will reveal more detailed information on the behavior of ice accumulation in the active layer.

Keywords: active layer; non-sorted circles; permafrost; snow; soil; survey.

Introduction

During the annual cycle, arctic soils form an active layer in the summer that refreezes during the fall and winter. In this paper, we present a high-resolution elevation dataset of a non-sorted circle system on continuous permafrost near Franklin Bluffs, Alaska. Non-sorted circles are defined as "semi barren areas in the tundra that lack a border of stones" (Washburn 1956). The non-sorted circle system is defined here as interacting areas of vegetated and semi-barren surfaces. The system can be as small as a single non-sorted circle with its surrounding vegetation. This vegetation zone can be anywhere from 10 cm to 10 m. The vegetated surface is generally underlain by a well-developed, organic layer several centimeters thick.

Besides these data we also provided information on the soil climate (soil temperature and moisture content) at the time the survey was done, as well as historical climate variation from the area, to put the elevation data from the survey in perspective.

The survey helped our understanding of the processes of frost heave and thaw settlement. Frost heave and thaw settlement (consolidation) is scale dependent and can be viewed as one-dimensional on a landscape scale (Brown et al. 2000, Hinkel & Nelson 2003). The Circumpolar Active Layer Monitoring (CALM) sites are treated as a landscape scale measurement, where it takes many measurements to determine the average active layer depth for a region, to eliminate any local heterogeneity. On a smaller scale, however, it is a three-dimensional process. Small heterogeneities in topography, vegetation, and organic layer thickness, are observed at a typical plot scale of a 100 m^2. Micro climate at the soil surface generated by vegetation and micro relief has a strong effect on the soil surface energy balance. Soil climate, driving freezing and thawing processes, depends on: the micro climate above the soil, soil properties, wetness, and permafrost conditions below the active layer. Frost heave, driving freezing and thawing processes, causes the soil surface to move up and down within the season and between annual cycles. This aspect of movement of the soil surface is also called ice segregation and thaw settlement. These two processes are not monitored in the CALM sites and it is therefore not possible to monitor the loss and gain of ground ice within and between the annual cycles. This loss or gain of ground ice has only a limited effect on the active layer depth, due

Figure 1. Ice lens formation in silty clay loam.

to the limited amount of soil present in the ice rich transient layer (Pullman et al. 2007, Shur & Jorgenson 2007).

The annual soil surface movement is driven by frost heave or frost action, where the strongest movement is expected in frost susceptible soils. During freezing these soils accumulate ice in the form of lenses that form perpendicular to the temperature gradient (Cheng 1983, Kokelj & Burn 2005, Kokelj et al. 2007, Mackay 1983). This is also called secondary frost heave (Miller 1980). This process drives an expansion of the soil which exceeds the difference in density between water and ice. For secondary frost heave to take place water needs to flow to the freezing front, driven by cryostatic suction, to make this expansion possible (Daanen et al. 2007). The source of this water is still not resolved in the literature. Many models require an unlimited water supply to be able to generate the amount of frost heave observed. In a laboratory setup it was found that even without adding water to a frost susceptible soil during one dimensional freezing it was possible to generate heave beyond the expansion of water alone (Daanen unpublished data). This process can be explained as drying of the soil between the ice lenses (Daanen et al. 2007). The dry soil occupies a volume and in addition the ice occupies a volume.

The interannual soil movement is caused by segregated ice at the bottom of the active layer, which can cause thaw settlement (Pullman et al. 2007). Slow refreezing at the bottom of the active layer in the fall generally causes larger ice lenses compared to the upper active layer, where freezing is faster. Formation and loss of this ice depends on many of the same energy balance processes as mentioned above but in addition, it depends on variations in hydrological conditions between years (Kokelj & Burn 2005).

Soil surface movement is generally hard to detect due to a lack of a proper reference point in the tundra. Romanovsky (Walker et al. 2004) and Washburn (Washburn 1997) have used permafrost anchors as a reference point to measure the difference between frost heave in non-sorted circles and vegetated tundra. This method is good when the anchors are deep enough to prevent them from heaving out of the ground on a longer time span. Satellite observations through interferometry would be an option when data is available during a small window in the fall before freezing and spring if the signal is not distorted by the snowpack. Differences between seasons may be too small to detect. Global Positioning System (GPS) equipment could be used to identify the movement of the soil surface; however accuracy of the equipment in elevation differences is a concern (Berthling et al. 2003).

Methods

For this study we used a deep borehole casing as a reference point to survey our site with a total station, at a resolution of 25 cm. The borehole is 60 m deep (with at least 59 m anchored in permafrost) located near Franklin Bluffs along the Dalton Highway, Alaska. The site was part of a biocomplexity study "Biocomplexity associated with biogeochemical cycles in arctic frost-boil ecosystems," which ended in 2006 (Walker et al. 2004). The site can be described as "mesic" or "zonal" and therefore a good representation of the regions in terms of vegetation and soil climate conditions (Walker et al. 2004). The annual average air temperature in the region is -11.3°C. The silty clay loam soils at the site are frost susceptible and generate a lot of segregated ice lenses during freezing (Fig. 1).

These soils are capable of forming and sustaining non-sorted circles, for a more detailed description of the internal workings of these system we refer to Daanen et al. (2007). These non-sorted circles provide a heterogeneous soil and soil surface that causes a large spatial variability in the active layer depth and frost heave level (Kade et al. 2006, Walker et al. 2004). Due to the scale of the non-sorted circles we chose to survey our plot with a resolution of 25 cm to capture the smaller nuances of relief between the non-sorted circles and the surrounding tundra.

We surveyed the site with a Leica TPS400 series total station using the deep permafrost borehole as a reference point (±0.03 m). The first survey was done in the April of 2007 well before the onset of snowmelt. The second survey was done in August of 2007 near the point of maximum thaw depth. In addition to the soil surface survey we also measured the snow depth in winter and the thaw depth in the summer. Measurements of the air temperature, soil temperature, and soil moisture are collected at the site using a datalogger and presented later in the results section.

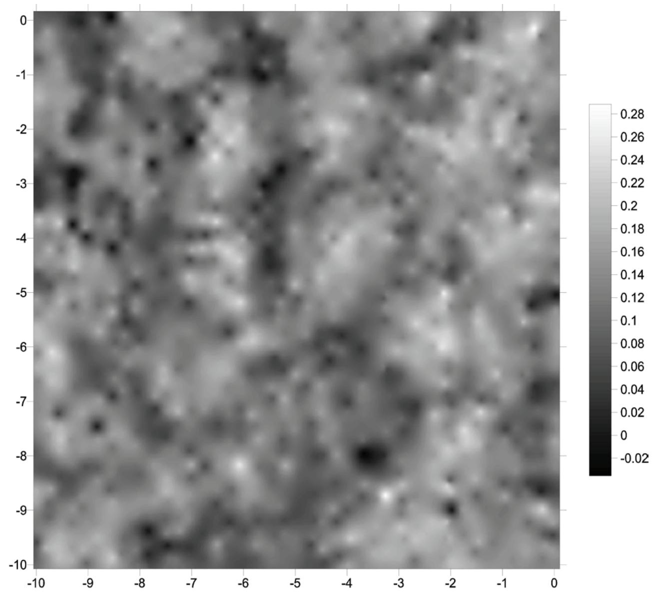

Figure 4. Elevation differences between summer and winter for the Franklin Bluffs site (units are meters). This plot represents frost heave.

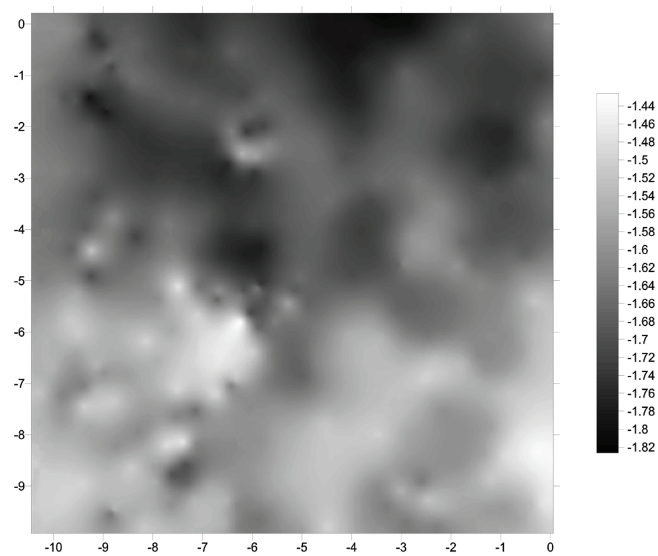

Figure 5. Permafrost table elevation for the site relative to the well casing on August 28, 2007 (units are meters)

Results

The spatial distribution of surface elevation in winter and summer is shown in Figure 2 and 3, respectively.

The winter results show a clear distribution of non-sorted circles in the lighter areas where the surface is raised above the inter circle areas (approximately 25 non-sorted circles within the domain of 10 x 10 m). Compared with Figure 3 the non-sorted circles are more visible due to increased frost heave in the circles. From Figure 3 the elevations still show the non-sorted circles, which implies that the elevation gain during freezing is not all lost during the summer thaw. Also visible from both illustrations is the gentle slope from upper left to lower right or from northwest to southeast.

We found that there was on average a 12 cm elevation difference between the summer and winter conditions. The scales on Figures 2 and 3 have an offset; for the lowest point 8 cm and the highest point 18 cm relative to the well casing.

The elevation difference for each observation point between the two data sets is given in Figure 4. Areas with the greatest difference are shown in the lighter shades. The non-sorted circles are also distinctly visible as areas with the greatest amount of annual frost heave.

The permafrost table elevation map is given in Figure 5.

The active layer depth is the difference between the surface elevation in summer and the permafrost table. A map of this depth is given in Figure 6. The average depth measured in the grid was 65.9 cm with a standard deviation of 7.8 cm. This depth is on track with active layer depths measured

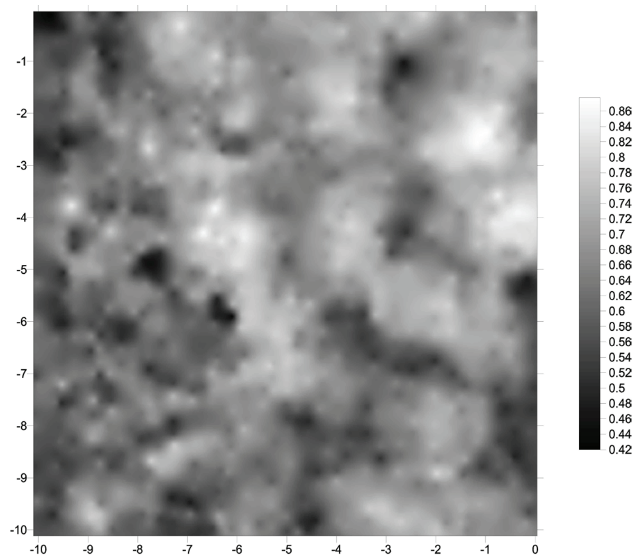

Figure 6. Active layer depth generated from the difference between the surface elevation and the permafrost table elevation (units are meters).

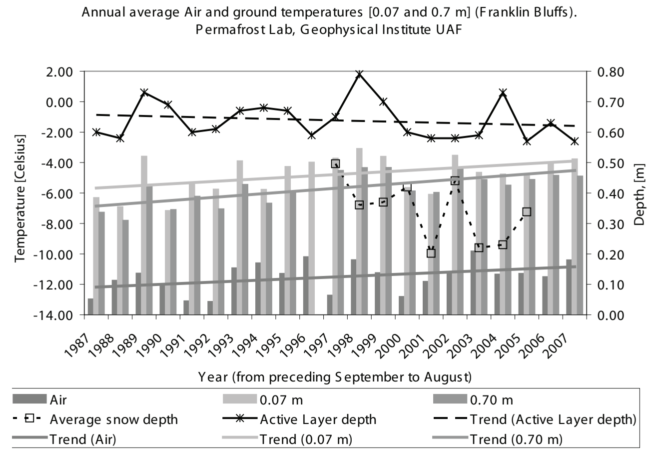

Figure 7. Long-term trends in active layer depth, air temperature, soil temperature (0.0 and 0.7 m), and snow depth near Franklin Bluffs, Alaska, from 1987–2007.

over a long period for the area as part of the long-term permafrost observation network (Fig. 7). Figure 7 also shows the trends in air and soil temperature over the past 20 years near Franklin Bluffs, Alaska. Over that period following the trend lines the annual average air temperature increased by 1.334°C, the soil at 0.07 m increased by 1.774°C, the soil at 0.7 m increased 2.34°C and the active layer depth decreased 0.036 m. Observed surface and permafrost temperatures north of our field site shows an even stronger warming trend then shown here (Romanovsky et al. 2008).

The active layer depth at the Franklin Bluffs site is measured by the permafrost laboratory at the Geophysical Institute as part of the long-term permafrost observation network. These measurements are taken in a larger 100 by 100 m grid surrounding the deep permafrost temperature well. The average thaw depth measured for long-term observations for Franklin Bluffs was 57.1 cm for August 28, 2007. The standard deviation for the larger grid was 10.4 cm.

To compare current soil conditions to recent years, we present daily air and soil temperature data in Figure 8. These data show that the winter was cooler then previous winters, and the summer was warmer than previous summers. Soil moisture data from the same period is given in Figure 9.

These soil moisture data suggest that the active layer was drying over the period presented here. This may lead to decreased frost heave during next season.

Discussion

The observed movement of the soil surface resulted in an average 12 cm of annual heave. These 12 cm cannot be explained by expansion due to phase change alone, because there is a limited amount of water in the active layer. The mineral soils have approximately 40% moisture by volume that would only result in 3 cm of heave during refreezing of the active layer. In non-frost-susceptible soils a similar amount of heave was observed in Canada (Mackay & Burn 2002). In our site, the soils are frost susceptible and water can move during freezing. However there are no obvious other large water reservoirs in the area that are close enough to make a difference to the amount of heave. The small slope to the site would drain the water just as fast as it would add water to the site. Our hypothesis is that there is additional water contained inside the soil profile, like water stored in small surface depressions and thick organic layers (inter circle area). It was observed during our spring measurements that there was no ice in the depressions where there is normally water in summer. Part of this water could have been absorbed by the freezing mineral soil, which is cooling more rapidly than the organic soils in between the non-sorted circles (Daanen et al. 2007). Additional heave can be attributed to drying of the soil as it freezes water from the soil segregates and forms ice lenses while the soil dries out. Air would replace water in the pore spaces and increase the volume of the soil column and the soil skeleton supports the overburden. Evidence was found that larger cracks within the active layer are ice free (Romanovsky pers. com.). A last reason for the low elevation of the soil surface could be attributed to the dry soil conditions during the summer survey see Figure 9. There are clay minerals in the soil profile that may have the potential to shrink as the soil dries. It has to be noted that the inter circle areas did not shrink significantly (Fig. 3).

The average active layer depths within the surveyed grid are 65.9 cm and the average active layer depth in the larger long-term grid is 57.1 cm. The difference can be explained by a difference in drainage, the surveyed grid is better drained due to small relief compared to the larger grid sampled. The draining of water would result in less ice buildup in the active layer and therefore less energy required for thawing the profile. Improved drainage also affects the vegetation at the site, which tends to have less moss than the wet vegetation plot down slope of the surveyed grid.

The active layer depth compared with other sites along

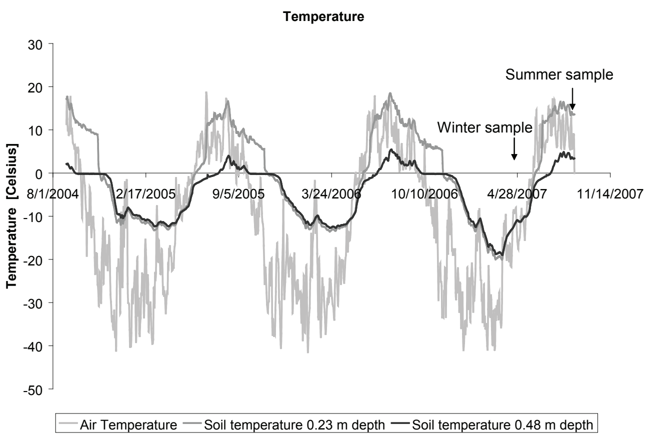

Figure 8. Air and soil temperature near the surveyed grid.

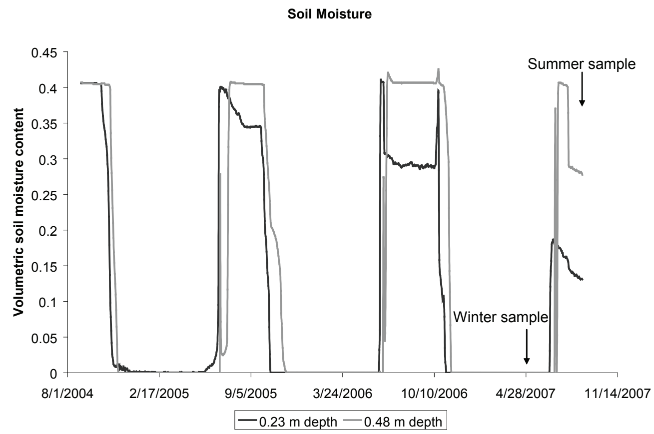

Figure 9. Soil moisture near the surveyed grid.

the Dalton Highway shows no trend that can be related to soil climate (Romanovsky et al. 2008). This is caused by differences in vegetation, with a much more developed vegetated/organic mat in the south compared to the vegetated/organic mat in the north.

The active layer depth over time shows a slight decreasing trend even though the soil temperature shows a trend toward warmer conditions (Fig. 7). There are many reasons to explain the trend. The summer air temperature did not increase. Average annual temperatures from the more recent period do not show a major trend toward warming conditions. The winter of 2006/2007 was colder (Fig. 8) than normal due to less snow compared with normal conditions, the snow data are not in the graph due to malfunction of the probe. The colder soils take longer to warm up and thaw. The dry conditions over the summer months had a reducing effect on the thermal conductivity of the organic layer. Another reason for a limited active layer depth could be loss of segregated ice near the bottom of the active layer. The potential loss of segregated ground ice is what we will measure during future surveys when we compare different years. The last reason is related to long-term observations of "greening" in the Arctic (Jia et al. 2003). Increased vegetation or Leaf Area Index (LAI) may be responsible for increased insulation (boundary layer), shading or transpiration at the site during the summer which leads to shallower thaw depths, even though the average annual temperatures have increased. Cooler conditions due to increased evapotranspiration have been observed on Banks Island where a constant wind made soils of southwest facing slopes cooler in summer (French 2007). In our situation an increase in LAI leads to increased radiation adsorption which causes increased transpiration rates. The spatial distribution of the vegetation in the non-sorted circle system shows that vegetated surfaces have shallower thaw depth.

Results from the survey also show the large variability in heave and thaw in a relatively small area of 10 x 10 m. Driven by increased insulation of the vegetation and underlying organic mat the energy flux through the surface is greatly reduced (Daanen et al. 2007). The heterogeneity on the soil surface causes temperature differences in the soil during freezing. This leads to cryostatic suction toward cooler areas where ice accumulates as the water freezes. Cryoturbation in the non-sorted circles reduces vegetation succession which keeps the non-sorted circles semi-barren and poorly insulated.

Conclusions

A high-resolution elevation survey of a non-sorted circle ecosystem near Franklin Bluffs, Alaska, shows substantial soil surface movement. The average elevation difference between summer and winter sampling is 12 cm. This heave cannot be explained with expansion of water due to phase change. Other explanations for the large difference are additional water from organic material froze as ice lenses in the mineral soil, ice lens formation in conjunction with soil freeze drying, and soil shrinkage due to dry conditions in summer.

The long-term active layer observations do not show a clear trend with average air and soil temperatures in our records. Some reasons suggested here are that the summer is not warming enough to affect the active layer, and the increased greening of the Arctic may lead to increased transpiration by the vegetation. More data is needed to identify a set of reasons that can fully explain the variability and behavior of the active layer system.

Heterogeneity of the soil surface vegetation causes heterogeneity in soil surface movement (frost heave) due to preferential ice accumulation in the semi-barren areas called non-sorted circles. The same vegetation pattern also causes preferential active layer development and thaw settlement.

Abstract

To investigate adsorbed cations effects on the unfrozen water in frozen soil, laboratory experiments were conducted on Hanover silt. Monovalent and divalent cation treatments were prepared by exchanging the soil's adsorbed cations in saturated salt solutions. Laboratory experiments included measuring unfrozen water content with pulse NMR, T2 relaxation time, ζ-potential, and specific surface area. T2 relaxation time provides insight into unfrozen water changes during freezing. As the soil temperature decreases from -0.2°C to -2°C, the T2 net magnetization signal strength decreases rapidly, and subsequently levels off for temperatures colder than -2°C. This may indicate a reduction in the mobility of unfrozen water, as it is restricted under the influence of surface potential. Monovalent cation-treated samples have shorter T2 relaxation times than divalent cation-treated samples, suggesting less mobility of unfrozen water in monovalent-saturated soil. The monovalent cation-treated samples also demonstrated greater ζ-potentials, resulting in thicker unfrozen water films.

Keywords: cation; frozen soil; mobility; NMR; T2; unfrozen water; ζ-potential.

Introduction

The presence of unfrozen water in frozen soil is an integral part of frost heave theory, permafrost studies, and frozen ground engineering. Since unfrozen water was first identified by Bouyoucos (1917, 1920), numerous different methods have been used to measure it. Tice et al. (1978, 1982) presented the nuclear magnetic resonance (NMR) method as a viable technique to measure the unfrozen water content. While the NMR method has been used by these and other researchers to quantify unfrozen water, no reference has been made to spin-spin relaxation measurements (T2) or their meaning as related to the behavior of unfrozen water in frozen soil.

As part of a larger research project, we investigated the unfrozen water content using the NMR method, ζ-potential, and other chemical and mineralogical properties of natural soil and its associated cation-treated samples. In this paper, we present NMR free-induction decay (FID) data and spin-spin relaxation (T2) data for a silty soil, and investigate the effects of cation treatments upon T2 relaxation time and ζ-potential.

Methods

Soil preparation

Hanover silt loam (HS) was sieved following the procedure implemented by Rieke et al. (1983), and all organic matter was removed from the original soil sample. This sieved soil is referred to as the "Baseline" (BSLN) sample. The results of a semi-quantitative x-ray diffraction (XRD) analysis indicated that the HS BSLN sample contained illite/mica, kaolinite, chlorite, and interlayered smectite, as well as other non-clay mineral species. The total percentage of phyllosilicates in the HS BSLN sample was 20.8%. In order to investigate the effects of surface chemistry on the unfrozen water content, cation treatments were applied to the BSLN soil. Four different salts, magnesium chloride ($MgCl_2$), calcium chloride ($CaCl_2$), sodium chloride (NaCl), and potassium chloride (KCl), were used for the various treatments. For a complete description of the cation treatment preparations, see Darrow (2007).

ζ-potential measurements

In certain clay minerals, the negative potential at the Stern layer is manifested as the ζ-potential, which can be quantified by placing a dilute soil suspension into an electric field. The negatively-charged soil particles will migrate toward the positive pole, while the remaining cation swarm in the fluid will migrate toward the negative pole. The ζ-potential is the negative potential formed at the shearing surface of the soil particle (Greenland & Hayes 1978). The ζ-potential depends on the type of cations adsorbed within the Stern layer. Thus, changing the adsorbed cations on the mineral surface affects the measured ζ-potential and the overall double layer thickness.

The ζ-potential of the HS BSLN and cation treatments was determined using a Zeta-Meter. To begin the sample preparation, 0.5 g of each sample was placed into a scintillation vial, to which distilled, deionized water was added. After the soil was completely saturated, the vial was shaken vigorously in order to suspend most of the soil particles. A small portion of the suspension was taken from the vial and mixed with additional distilled, deionized water to create a dilute suspension for ζ-potential measurements. The amount of suspension removed and diluted was not exact; instead, these samples were prepared "by eye," having the concentration necessary to provide adequate particle tracking under the Zeta-Meter microscope (Zeta-Meter Inc. 1975). The dilute suspension was poured into the Zeta-Meter's electrophoresis cell, and the time necessary for each of 50 soil particles to travel 120 μm at room temperature was recorded. The dilute suspension was replaced after 15 to 25 particles were tracked. This ensured that the heat added by the Zeta-Meter components had a minimal effect on the ζ-potential measurements. Once all 50 particles were tracked, the time measurements and charts available in the Zeta-Meter manual (1975) were used to calculate the ζ-potential of the soil particles.

As a fine-grained soil may contain several different types of clay minerals, its measured ζ-potential will form a wide particle-charge distribution curve, demonstrating the range of the ζ-potential for all clay minerals present (Riddick 1968). The median ζ-potential value for each bulk soil sample was calculated from the particle-charge distribution curve, using a procedure outlined by Riddick (1968).

Unfrozen water measurements using NMR

FID and T2 measurements were made using a pulse NMR. NMR measurements were made at the following temperatures: -0.2°C, -0.5°C, -1°C, -2°C, -3°C, -4°C, -5°C, -7.5°C, -10°C, -15°C, and -20°C. After these measurements were completed, the sample was warmed to above freezing, and FID and T2 measurements were made at 10°C. The moisture content of the soil was determined at the above-freezing temperature, and the unfrozen water content, w_U, at each sub-freezing temperature was calculated by:

$$w_U = \frac{w_{10^o C} \cdot x_T}{x_{10^o C}} \qquad (1)$$

where $w_{10^o C}$ is the measured gravimetric water content at 10°C, $x_{10^o C}$ is the NMR signal amplitude at 10°C, and x_T is the NMR signal amplitude at the corresponding sub-freezing temperature. All w_U values presented here are gravimetric water contents, and NMR signals used in these calculations represent FID peak times. Likewise, T2 net magnetization signal strength amplitudes presented are the peak values measured for each temperature.

Results

ζ-potential measurements

Figure 1 contains the ζ-potential particle-charge distribution curves for the HS BSLN sample and corresponding cation treatments, and the median ζ-potential values for the five HS samples are summarized in Table 1. The range for the Na^+ sample is larger than the other samples, resulting in a wider curve. The median ζ-potential values for the monovalent cation-treated samples are greater (i.e., more negative) than the divalent cation-treated and BSLN samples.

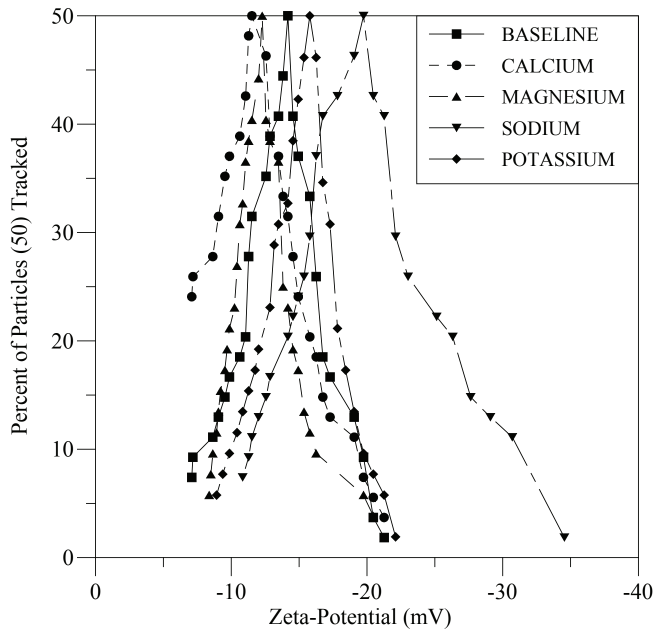

Figure 1. ζ-potential particle-charge distribution curves for the HS BSLN sample and corresponding cation treatments.

Table 1. Summary of ζ-potential median values for HS BSLN and corresponding cation treatments.

Sample	ζ-potential median values (mV)
BSLN	-14.17
Ca^{2+}	-11.76
Mg^{2+}	-12.28
Na^+	-19.74
K^+	-15.79

Unfrozen water measurements

The w_U data for HS BSLN sample and corresponding cation treatments calculated using the FID peak times are presented in Figure 2. The K^+-treated sample has the highest w_U at a given temperature, followed by the Na^+-treated sample. The w_U of the three remaining samples are very close to one another over the range of temperatures measured. The overall trend is similar for each sample, with the w_U steadily decreasing in an exponential fashion with decreasing temperature.

A plot of T2 net magnetization signal strength versus temperature for the HS samples is shown in Figure 3. The trends in these data are noticeably different from those in Figure 2. For each sample, the T2 signal strength decreases rapidly from -0.2°C to -2°C. There is little change in the T2 signal strength at temperatures colder than -2°C until -20°C, at which point the T2 signal strength drops close to 0 for all samples. This noticeable break at -2°C suggests a difference in the behavior of the unfrozen water at this temperature.

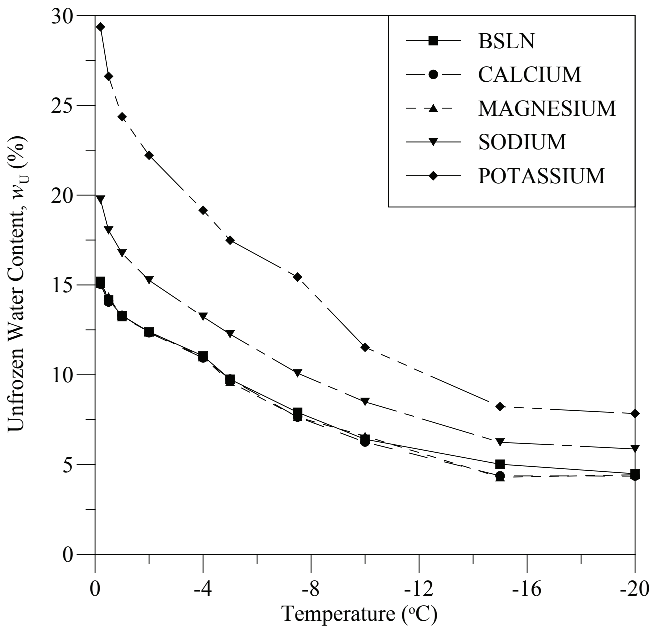

Figure 2. Unfrozen water content, w_U, versus temperature for HS BSLN and corresponding cation treatments.

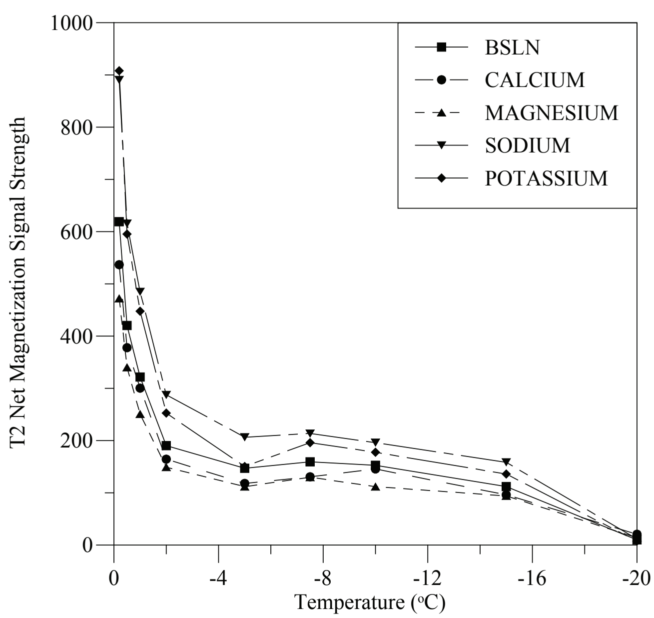

Figure 3. T2 net magnetization signal strength versus temperature for HS BSLN and corresponding cation treatments.

The raw T2 signal data was processed to yield T2 relaxation times, which are presented in Figure 4. While these data demonstrate more scatter than those in the previous figures, T2 relaxation time also decreases in an exponential fashion with decreasing temperature. Although not shown in Figure 4, T2 relaxation times were also calculated for each sample at 10°C. These times ranged from 1.69 ms to 2.59 ms, with the monovalent cation-treated samples demonstrating the shorter times.

The thickness of the unfrozen water film in each sample was calculated at each temperature using the w_U data presented in Figure 2, the measured HS specific surface area of 9.25

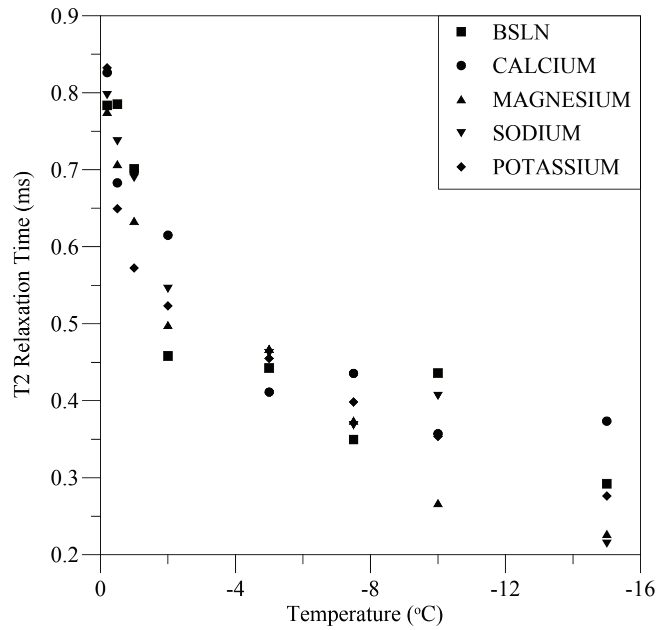

Figure 4. T2 relaxation time versus temperature for HS BSLN and corresponding cation treatments.

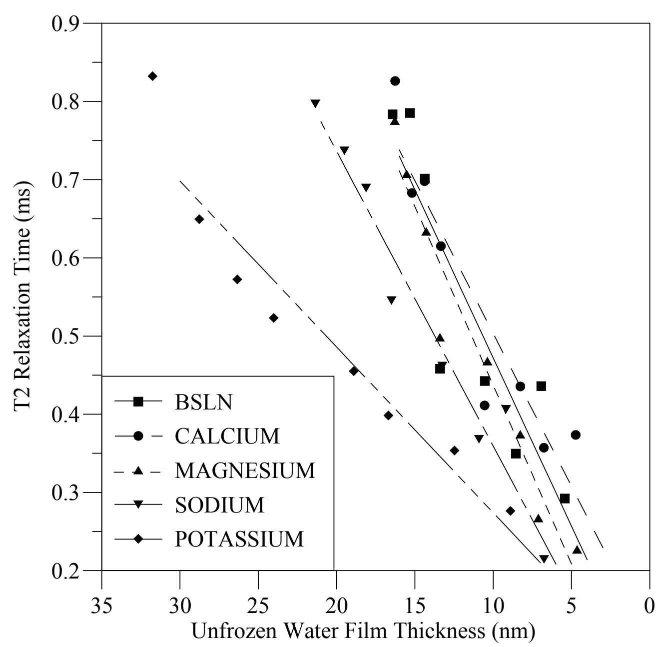

Figure 5. T2 relaxation time versus calculated unfrozen water film thickness for HS BSLN and corresponding cation treatments. Linear trend lines are shown for each data set.

m^2/g, and water densities for each sub-freezing temperature interpolated from published data (Hodgman 1956). The calculated thicknesses are plotted against T2 relaxation times for each corresponding temperature, as shown in Figure 5. For all samples, T2 relaxation time decreases with decreasing unfrozen water thickness in a linear fashion. This is indicated by the best-fit linear trend lines, with coefficients of determination (r^2) ranging from 0.81 to 0.96.

Discussion

While NMR FID signal strength data is a useful means of quantifying the unfrozen water content in a frozen soil, T2 data may yield important information about unfrozen water mobility.

Kojima and Nakagami (2002) used the magnetic resonance imaging (MRI) technique to investigate water mobility in the gel-layer of a drug. They found that the T2 relaxation time of the outer portion of the gel-layer was close to that of free water. However, in the inner portion of the gel-layer, the T2 relaxation time progressively decreased, suggesting that the water mobility around the core interface became highly restricted.

Similar interpretations can be made from the data presented here. In Figure 3, the rapid decrease in T2 net magnetization signal strength from -0.2°C to -2°C may indicate the freezing of water within the soil pores and capillaries, and some reduction in the thickness of the unfrozen water layers around individual soil particles. In Figure 5, for any given unfrozen water thickness, the monovalent cation-treated samples have shorter T2 relaxation times than the divalent cation-treated and BSLN samples. This suggests less mobility of unfrozen water in the monovalent cation-treated samples than in the divalent cation-treated samples. The monovalent cation-treated samples also demonstrated the greatest ζ-potentials of the sample group, resulting in their thicker unfrozen water films.

T2 relaxation times within water "layers" around the soil particles were calculated by taking the difference of the T2 signal strength at two sequential temperature readings. Unfrozen water "layers" with smaller numeric values are closer to the soil particle surface. These results, presented in Figure 6, demonstrate scatter because of the calculation method and variations within the data; however, generally T2 relaxation time decreases exponentially with decreasing distance to the soil particle surface.

Conclusions

The NMR method is a useful means for quantifying the unfrozen water content of a frozen soil through FID signal strength data. The results presented here indicate that T2 net magnetization signal strength and resulting T2 relaxation time provide insight into the mobility of unfrozen water. The rapid decrease in the T2 signal strength from -0.2°C to -2°C and the subsequent leveling off of the signal for temperatures colder than -2°C indicate a reduction in the mobility of the unfrozen water, as the unfrozen water becomes more restricted by the proximity of the soil particles' surfaces.

T2 relaxation time decreases linearly with the decreasing thickness of unfrozen water films. Soil saturated with monovalent cations demonstrates shorter T2 relaxation times than that saturated with divalent cations. The monovalent cation-treated soil also demonstrates greater ζ-potential, resulting in thicker unfrozen water films. Thus, the predominantly adsorbed soil cations strongly affect T2 relaxation time and the mobility of unfrozen water. T2 relaxation time decreases exponentially with decreasing unfrozen water "layers"; however, the effect of cation treatments on the water "layers" is not well-defined for this soil.

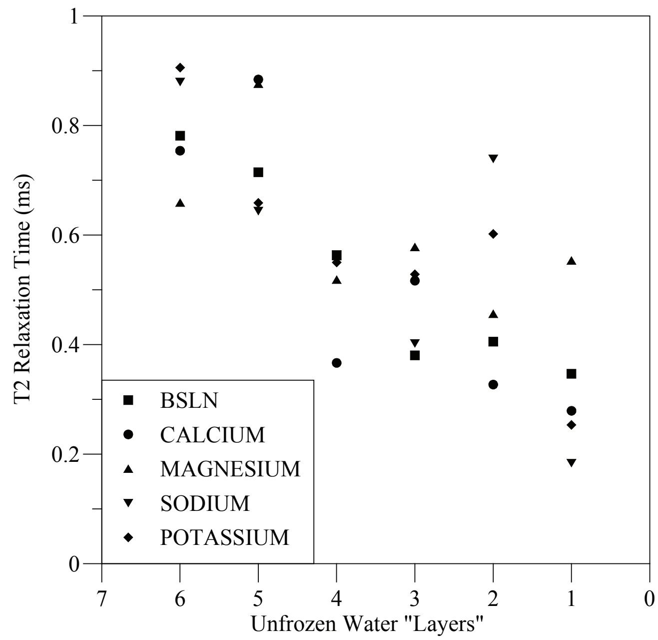

Figure 6. T2 relaxation time versus unfrozen water "layers." Each "layer" represents the difference in T2 signal strength at two sequential temperature readings. Unfrozen water "layers" with smaller numeric values are closer to the soil particle surface.

Abstract

This study investigates the relationship between changes in active layer thickness (ALT) above permafrost and the discharge of dissolved organic carbon (DOC) in streams of the Kolyma Lowland, northeastern Siberia. The results of observations indicate that the increase in ALT began in northern taiga landscapes in 2001–2005 and 2007. The contribution of melted ice from the thawed permafrost layer to the regional runoff is estimated to be 5–10% of the annual precipitation. The Kolyma Lowland is underlain by ice- and organic-rich Pleistocene deposits (Yedoma or Ice Complex). The observed increase in ALT results in involvement of ancient DOC in a contemporary biochemical cycle. This phenomenon is reflected by the structure and age of the DOC in streams in the fall. The observed effect of the increase in ALT on DOC potentially allows the use of radiocarbon dating for the integrative assessment of permafrost conditions over large territory.

Keywords: ALT monitoring; DOC; transitional layer; Yedoma.

Introduction

During the last decade, a great amount of research has underlined an increase of Siberian river discharge into the Arctic Ocean (Peterson et al. 2002, McCleland et al. 2004). This process has many sources, and permafrost thawing is among them. This study investigates the proposal to examine dissolved organic carbon (DOC) in seasonal streams for permafrost monitoring of the Arctic ecosystem.

The Kolyma Lowland occupies the northeast of the vast Siberian Coastal Plains. The region is characterized predominantly by continental climate (Table 1). The greatest positive changes of the study area occurred during recent years.

The lowland is wholly underlain by continuous permafrost that is the most ancient underground ice formation of Eurasia since the Pliocene Age. The total thickness of frozen sediments is 500–650 m with a mean temperature of permafrost from -3° to -11°C (Fyodorov-Davydov & Davydov 2006). Northern ecosystems of the Kolyma Lowland are underlain by ice-rich loess sediments with high organic content are called the Yedoma Suite or Ice Complex in Russia. Yedoma deposits are mid to Late Pleistocene continental loamy sediment with ice wedges. The total ice content in yedoma (sedimentary soil and ice wedges combined) is on average 75% (Gasanov 1971, Kholodov et al. 2003). The mean organic content in these sediments is

estimated to be from 5–12 kg/m3 (Kholodov et al. 2003) to 21 kg/m3 (Zimov et al. 2006, Zimov et al. 2006a).

The upper layer (0.1–2.0 m) of yedoma was thawed during the climatic optimum of the Holocene (6.3–9.6 thousand years ago for northeast Siberia). The consequent refreezing resulted in formation of a secondary frozen layer, called the transitional Layer (TL) (Shur 1988). This layer forms a boundary between the active and older permafrost layers of a yedoma.

Methods

Monitoring of changes in active layer thickness

The North-East Science Station (NESS) has carried out

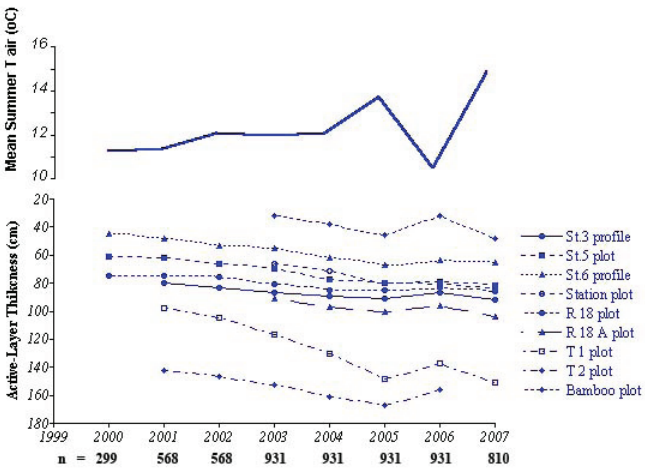

Figure 1. Annual dynamics of active layer thickness in different sites of the upland landscape of the Kolyma lowland; *n* – numbers of observation points on each year.

research of seasonal changes in ALT for more than 20 years. Since 1996, this study has been extended by participation in the network of the Circumpolar Active Layer Monitoring (CALM) Project. Sediments of the upper part of the permafrost and soils of the watershed area, both upland and lowland streams, have loamy and loamy sandy grading of soils. Therefore, measurements of seasonal changes in ALT were made by steel probes with length more than the maximum depth of the active layer. This method has an accuracy of 1–2 cm. We also used thermologgers, which were installed in thermometric boreholes.

Long-term observations for seasonal changes of ALT were made on 9 sites (Fig. 1). Each of 7 plots has 121 data points and different grids for measurements: one plot, 10 x 10 m; five plots, 1 x 1 m; and one plot, 0.5 x 0.5 m. Two profiles have 64 data points.

ALT monitoring started in all sites after the melting of snow cover. Observations were made once in 2 weeks (for profiles) or once in the beginning of every month (for plots) during the warm season. Every year the maximum of ALT was determined in the beginning of soil freezing in all points for each site.

Determination of volumetric soil moisture content

We used two methods for determination of volumetric soil moisture content in transitional horizon soils and permafrost of watersheds: (1) direct measurement of volumetric soil moisture content of undisturbed drilling soil sample; and (2) calculating the method by the N.A. Tsytovich equation (Gasanov 1971).

$$V_i = \frac{\gamma}{\Delta_i} * \frac{W_s - W_{ms}}{1 + W_s} \tag{1}$$

where

V_i = volumetric soil moisture content, %;

W_s = the gravimetric water content of frozen soil in % of soil dry weight,

W_{ms} = quantity of unfrozen water in % soil dry weight; mean content for sediments of the transitional horizon and yedoma is 2% unfrozen water for study area.

γ = density of the frozen soil of undisturbed structure, g/cm^3; mean density for sediments of the transitional horizon and yedoma 1.8 g/cm^3 for study area.

Δ_I = ice density, g/cm^3

Figure 2. Some types of cryogenetic textures of transitional layer.

Calculation of contribution of the release water partitioning by percentage of summer precipitation

For calculations of percentage of the release water partitioning of total summer precipitation we used the equation

$$P_{ALT}(\%) = \frac{\Delta_{ALT} * 0.3}{S_{\Sigma}} * 100\% \tag{2}$$

where

P_{ALT} = percentage of the release water partitioning of total summer precipitation, %;

Δ_{ALT} = annual gradient of thawing ALT, mm;

0.3 = mean part of the volumetric soil moisture content for transitional horizon of study area;

S_{Σ} = total summer precipitation, mm.

Results and Discussion

Changes in active layer thickness and hydrologic regime

Observational studies of active layer monitoring sites are characterized by different variants of the larch taiga landscapes and dispose at some watersheds of upland streams. Their active layer is characterized mainly by the soil cover of loamy cryohydromorphic soils (Cryozems and Gleyzems). Cryozems occupy more than 80% of soils (Fyodorov-Davydov & Davydov 2006). We used various methods of observation for ALT (profiles and plots) at Circumpolar Active Layer Monitoring (CALM) and North-East Science Station (NESS) sites from upland landscapes.

The observed increase in ALT is characteristic for all sites in 2001–2005. The correlation between ALT and mean summer temperatures reaches 0.96, and the maximal observed increase in ALT reaches 40% from long-term mean on some sites, which suggests that the increase in annual thawing has resulted from the abnormally high summer temperatures (Fig. 1).

The TL is characterized by very ice-rich cryogenetic textures that presented a predominance of lens-wicker, ataxitic, and lens-layered cryotextures (Fig. 2). Measurements

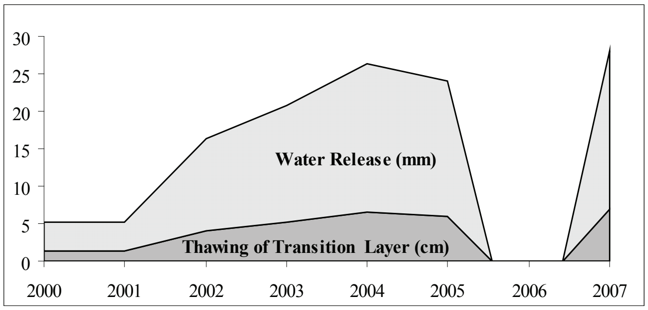

Figure 3. The relationship between thawing of the transitional layer and water release from melting permafrost.

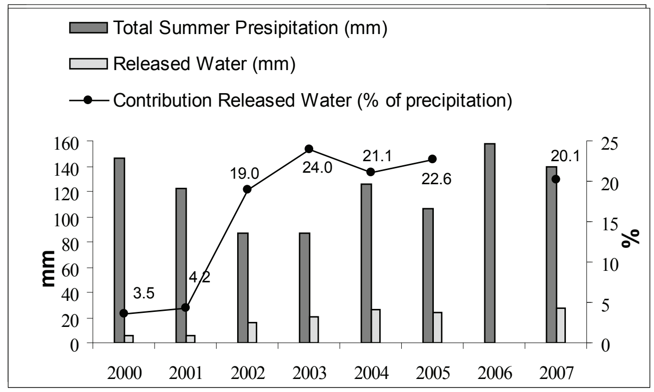

Figure 4. The contribution of the total annual water flux from the degrading transitional layer, estimated by percentage of summer precipitation.

of volumetric soil moisture content (10 cm above frozen horizon) indicate that the mean moisture content is 25% for the AL (n=128) and 55% for the TL and upper permafrost horizons (n=104) in a 10 cm layer lower depth of seasonal melting. Observations of soil moisture content were conducted at the end of the thawing season or at the beginning of winter for landscapes of watershed. We used direct or calculation methods for estimation of volumetric soil moisture. To preliminarily evaluate the release of water from the thawing of the upper permafrost, we considered the difference in volumetric water content between active and underlying transitional layers. The 30% difference translates to a 3 mm thick layer of water for each cm of thawed soil (Fig. 3). Due to moisture saturation characteristic of low-lying surfaces, wetlands were not considered for analysis.

The observed increase in ALT results in degradation of the TL. In 2003–2005 and 2007 at several sites, the transient horizon has degraded completely, causing thawing of deeper, perennially frozen layers. In 2006 the mean temperature decreased, and the summer precipitation abnormally increased, perhaps stimulated by the ice cover reduction at the East-Siberian Sea in last years. In this season the ALT decreased and there was a pause in the annual degradation of the TL. The release water and DOC fluxes stopped from the older permafrost layer. In 2007 the mean summer temperature vastly increased. That initiated thawing of the horizon, which was frozen in the previous season, and re-thawing of the TL with the formation of a new portion of release water (Fig. 3).

When the upper horizon of permafrost is thawing, a saturated layer is formed, and its water takes part in the seasonal hydrological cycle. Processes of transpiration have little influence on the release water fluxes from the permafrost, since plants vegetation of watershed landscapes in the middle of August–beginning of September basically has finished. In the same period, water migration in the upper soil horizon does not occur for the absence of soil freezing.

The contribution of the released water to the regional water runoff is estimated as 5–10% of the 280 mm of mean annual precipitation and reaches 20% of mean summer precipitation (Fig. 4).

Age and structure of dissolved organic carbon

A relatively thin layer of earth materials between the ground surface and the top of the permafrost undergoes an annual cycle of freezing and thawing (active layer) and is an important component of the Arctic ecosystem. A systematic and widespread increase in the thickness of the active layer could lead to changes in the biochemical cycle of high latitudes. Moreover, the TL and the yedoma contain a high level of dissolved organic carbon (DOC) held by frozen sediments and ice wedges. The significant increase of thawing leads to the involvement of buried, dissolved organic matter in the contemporary carbon biogeochemical cycle.

Strong seasonal trends in carbon age and chemical composition of DOC during the seasonal thawing were shown by Neff et al. (2006). Concentrations of lignin and aromatics of DOC in runoff of upland streams are decreasing from spring to fall (Fig. 5a), while relative DOC age is increasing (Fig. 5b). However, such trends are not evident in lowland streams located in the Kolyma flood plain, underlain by relatively young Holocene permafrost (Fig. 5b). The seasonal increase of DOC radiocarbon age can indicate the involvement of ancient carbon in contemporary hydrobiochemical cycles. A high water flux from the thawed horizon provides an effective vehicle for DOC to reach

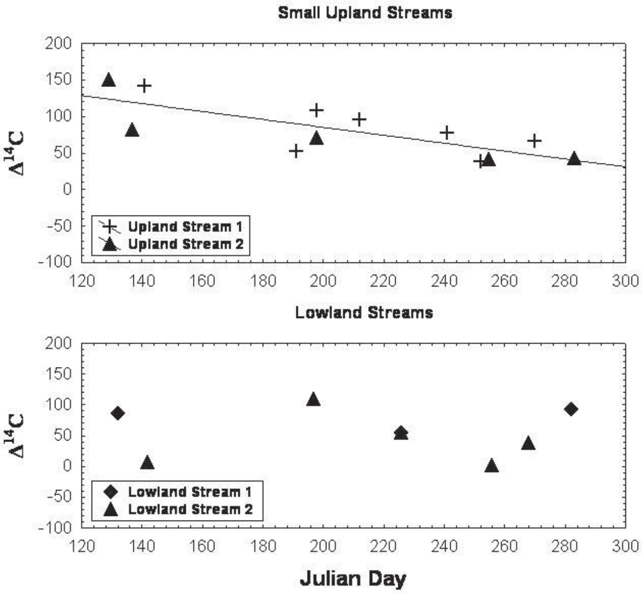

Figure 5b. Small upland streams – seasonal changes in the Δ14C content and the Δ14C of DOC. Lowland streams that drain seasonally flooded, modern permafrost – seasonal distribution of the Δ14C of DOC (Neff et al. 2006)

streams. However, the limited biochemical data (one, 2003 year) does not allow us to reach a definite conclusion about carbon release and migration due to an increase in annual thaw propagation. It is probable that the part of seasonally-released DOC, which remains in soil, migrates upward through the soil profile due to freezing and influences the age and structure of the DOC during consecutive thawing seasons.

Chemical composition and age of DOC can be measured in autumn, at the end of thawing season, when the ALT is maximal.

Conclusions

The results of observations suggest a progressive increase in active layer thickness in the Kolyma Lowland.

The observed changes in active layer thickness result in metachronous degradation of the ice- and organic-rich transitional layer.

The total annual water flux from the degrading transient layer can reach 20% of the total summer precipitation during dry and warm thawing seasons.

The seasonal dynamic of DOC composition and age suggests the involvement of ancient carbon previously stored in the upland (yedoma) sediments in contemporary hydrobiochemical cycles.

The relationship between degradation of the transient layer and DOC age and chemical composition can potentially allow the use of these characteristics for the integrative assessment of permafrost condition over a large territory at the end of the warm season.

Geophysical Mapping of Ground Ice in the Western Canadian Arctic

Gregory P. De Pascale
William Lettis & Associates, Inc., Walnut Creek, California, USA
Wayne H. Pollard
McGill University, Montreal, Quebec, Canada

Abstract

Warming in the Arctic is occurring sooner and more rapidly than was initially expected and is predicted to increase with time. The nature and distribution of ground ice is one of the most unpredictable geological variables in near-surface materials characterized by continuous permafrost. It is also the main reason permafrost is considered vulnerable to climate warming. In this study, coordinated measurements by two complementary geophysical tools—capacitive-coupled resistivity (CCR) and ground penetrating radar (GPR)—were used to map ground ice and cryostratigraphy at King Point and Richards Island in the western Canadian Arctic. Validation of geophysical interpretations was accomplished using adjacent natural exposures. The synergenistic benefits of using these two geophysical tools permitted accurate mapping of various types of ground ice including massive ice, and wedge ice, and detection of the top of the massive ice bodies.

Keywords: climate change; ground ice; ground penetrating radar; massive ice; resistivity.

Introduction and Significance of Ground Ice

The primary goals of this paper are (1) to characterize ground ice conditions at two ice-rich sites in the Western Canadian Arctic, and (2) to demonstrate the complementary nature of GPR and CCR data in the analysis of ground ice in continuous permafrost. The nature and distribution of ground ice is one of the most unpredictable geological variables in surficial sedimentary deposits characterized by continuous permafrost (Pollard & French 1980). Volumetric ground ice contents can range from <10% in relatively dry permafrost to >90% in ice-rich permafrost containing massive ice (Mackay & Dallimore 1992). Massive ground ice is defined as ice greater than 1 m thick with a gravimetric water content exceeding 250% on a dry weight basis (Permafrost Subcommittee 1988). Ice content patterns are often related to soil texture and depositional and freezing histories. In this classification, ground ice occurrence ranges from disseminated ice crystals in a soil matrix (pore ice) to discrete V-shaped linear networks of vertically foliated ice (wedge ice) to thick (10–20 m), horizontally continuous layered bodies of nearly pure segregated ice that often extends for several km^2. The significance of ground ice pertains to its geomorphic and geologic role in landscape development and geotechnical characteristics. The former includes various processes and landforms associated with either ground ice aggradation, like frost heave or the formation of ice-cored landforms, or with ground ice degradation, particularly thermokarst and associated ground ice subsidence. Ultimately, ground ice is a hazard for northern development, and disturbance of sites with ground ice present can cause thermokarst and disturbance of wildlife habitat, and create concerns with traditional land uses.

For this study, we selected two sites in the Western Canadian Arctic: King Point on the Yukon coast and a site on Northern Richards Island in the Mackenzie Delta Region of the Northwest Territories (Fig. 1).

The King Point site was selected because ground ice conditions have been well documented (Pollard & Dallimore 1988) and is known for having different types of ground ice present and visible in a large retrogressive thaw slump. Previous ground ice research in this area involves a series of cryostratigraphic studies based on detailed examination of ground ice exposures along the Yukon coast (Harry et al. 1988, Pollard & Dallimore 1988). In each case, massive ice interpreted as intra-sedimental ice was documented between 3–5 m below the surface. This research also describes a widespread thaw unconformity, which in some cases truncates massive ice (Harry et al. 1988) and the burial and preservation of surface snow patches (Pollard & Dallimore 1988). In each case, these studies provide compelling evidence of extensive massive ice and a previous deep thaw event that lead to truncation of Pleistocene ice wedges. The retrogressive thaw slump at King Point permitted direct validation of geophysical data (Fig. 2).

The Richards Island site was selected because of the presence of a large retrogressive thaw slump that is approximately 250 m long and 5 to 10 m high (Fig. 3).

This slump is unreported in the literature and appears to have formed sometime between 2005 and 2006. Again, the access to this site permitted direct comparison of the geophysical data with the stratigraphy in the natural exposure.

Methods and Data Acquisition

In this study, two geophysical tools, capacitive-coupled resistivity (CCR) and ground penetrating radar (GPR), were used to map ground ice occurrence at two sites that have not previously been investigated. Fieldwork was conducted in March 2005 and March 2006 using geophysical techniques. Winter fieldwork permitted smooth survey lines due to snow cover and noise-free datasets because during winter the active

layer is frozen. Ground resistivity and radar techniques give valuable information about subsurface conditions based on different electromagnetic properties of sediments. Electrical resistivity determines the subsurface resistivity distribution from induced current measurements made at the ground surface. From these measurements, the specific resistivity of subsurface materials can be determined. The resistivity of a material can be calculated using Ohm's law: R = V/I (resistance = voltage/current).

For geoelectrical measurements of ground resistivity, Ohm's Law is used in its differential vector form: $\rho = E/J$, where ρ is resistivity, E is electric field, and J is current density. By measuring an electric field at a known current, it is possible to calculate the resistance of the total volume of material between the transmitter and receiver to the depth of detection limit of the transmitter signal (Loke & Barker 1996). Resistivity techniques work well in regions of permafrost because there is a marked increase in electrical resistivity of water that occurs at the phase change from liquid to solid water (Hoekstra et al. 1975, Wolfe et al. 1996, Calvert et al. 2001, Calvert 2002, Hauck 2002, Hauck et al. 2003 De Pascale et al., in press). In permafrost regions resistivity will vary directly as a function of the ice content and type; for example, sediments with low ice contents are generally conductive and typically have low resistivity values. Massive ice will generally have higher resistivity values than pore ice. Sediments with high ice content will generally have resistivities higher than sediments without ground ice present, but lower resistivities than sediments containing massive ice.

Capacitive-coupled resistivity (CCR) surveys are a recent advancement in electrical resistivity mapping. Other workers have used Direct Current (DC) resistivity with success for mapping permafrost and ground ice (Kneisel et al. 2000, Hauck & Kneisel 2006), although this techniques is not as effective in cold continuous permafrost. For a detailed review of the theory behind capacitive-coupled resistivity, see Timofeev et al. (1994). As with DC resistivity, CCR uses two dipoles. In principal, current is applied to the ground by a transmitter via capacitive-coupling and the resulting potential is measured at the receiver dipole. Two previous studies using CCR techniques in permafrost were not able to distinguish between massive ice and glaciofluvial sediment with ice contents >30% (Wolfe et al. 1996), but Calvert (2002) noted that two-dimensional resistivity measurements were acquired relatively quickly in areas of ground ice. In another recent study, different resistivity techniques are compared in an area of mountain permafrost in the Swiss Alps (Hauck & Kneisel 2006). In that environment, permafrost conditions are very different from the Mackenzie Delta region; for example, mid-latitude alpine permafrost is much warmer and wetter (higher liquid water content), and contains little ground ice (extensive massive ice is largely absent), and bedrock plays an important control on landscape development. These differences limit the applicability of comparing the geophysical results between these two permafrost regions. The only study to combine CCR and GPR data in continuous permafrost regions (De Pascale et al., in press), was also the first occasion where methodology for CCR data acquisition was discussed.

Ground penetrating radar (GPR) is another geophysical tool that has been used increasingly over the last 30 years for a wide range of subsurface mapping applications. By transmitting an electromagnetic pulse into the ground and recording the travel time of reflections caused by contrasts in dielectric properties, GPR measurements are used to characterize the structure and stratigraphy of near-surface geology. Previous studies have used GPR to study permafrost (Doolittle et al. 1990, Hinkelet et al. 2001, Moorman 1994, 1995, Arcone et al. 1998, Moorman et al. 2003) and massive ground ice (Dallimore & Davis 1987, Dallimore et al. 1992, Robinson 1994). These studies have shown that GPR data reliably indicate contacts between ice and frozen sediments, ice and solid rock, and frozen and thawed regions. The only study to-date that has integrated GPR and CCR techniques to map massive ice in permafrost was De Pascale et al., in press.

In this study, geophysical surveys were conducted in March 2005 and March 2006 with air temperatures between -15ºC and -40ºC, and the ground surface was covered by wind-crusted snow. Ground resistivity was measured using a Geometrics OhmMapper TR1 system, with operating frequencies in the range of 8 to 32 kHz using a dipole-dipole transmitter and receiver. Current is run along the transmitter's

Figure 3. Photo showing the retrogressive thaw slump on Richards Island. Note person for scale and exposed white ice wedges.

dipole cables with the dipoles acting as one plate of a capacitor and the ground as the other. The resulting voltage, measured at the receiver dipole, is proportional to the ground resistivity between the two dipoles and the initial current emitted from the transmitter. The apparent resistivities are calculated from the measured resistances using the geometric factor, which corresponds to the distance between the transmitter and receiver. Multiple passes are made along each survey line to gather data over a range of n-spacings, which is the ratio of the distance between the transmitter and receiver and the dipole spacing, permitting resistivity measurements of the materials at several depths. By increasing the distance between the transmitter and receiver, a larger survey line is created, giving a greater depth of investigation. In this study, the initial n-spacing was used for two passes at each site in order to ensure data reliability and measurement consistency. The GPR system used was a MALA controller with RTA antennas operating at 50 MHz and 250 MHz. The controller triggers pulses of energy that are transmitted into the surface by the antenna which acts as a band-pass filter, emitting sine waves with the center frequency determined by the antenna. Since penetration depth of a GPR signal depends on the antenna frequency and the electromagnetic properties of the subsurface materials, the frozen ice-rich nature of our sites was favorable for penetration depths on the order of ~15 m at the frequencies used. Due to the lack of topography at the sites, static corrections were unnecessary. Sediment and ice were sampled from Richards Island for petrographic and geochemical analysis, and the results from these data are forthcoming.

Data processing

The CCR data were reduced using the DataMap 2000 software (Geometrics 2001), while inversions were completed using the two-dimensional inversion software RES2DINV (Loke & Barke 1996). These CCR data were transferred to RES2DINV, where filtering techniques such as despiking were employed to remove outliers and smooth the datasets with a 3-point running average. Data were plotted in a pseudo-section, where the depth scale is calculated as a function of the separation between the dipoles. A pseudo-section is a geometrical view of the measured apparent resistivity dataset, whereas the inversion model shows the true resistivity for each model block, which is calculated independent of the resistivities of the surrounding model blocks. Interpretations of the CCR models were constrained by other subsurface information available at each of the sites, including the natural exposures in the retrogressive thaw slumps and ice wedge troughs. GPR data were processed using the ReflexW software package. Processing involves time-zero surface correction and horizontal filtering of the direct coupling wave. This processing is standard for GPR data and removes system noise that could mask real data. Because of the frozen nature of the field sites, penetration depth estimates assumed a dielectric constant of 6 ($v = 0.12$ m/ns) for frozen sediments and a dielectric constant of 3 ($v = 0.16$ m/ns) of ground ice. Generally we used an average of $v = 0.14$ m/ns due to the varied nature of these sites.

Results

At King Point we conducted a 225 m 2-D transect parallel and approximately 5–10 m from the Yukon coast. This survey intersected several ice wedge troughs that were visible on the surface. The setting varied from ice wedge terrain, as detected by low-center polygons on the surface, to terrain with massive ice exposed in a large retrogressive thaw slump (Fig. 4).

On Richards Island we surveyed a 250 m long 2-D transect parallel and above a retrogressive thaw slump. In the exposure, ice wedges, massive ice, and stratigraphic relationships were logged using digital cameras to map site conditions during the survey for geophysical validation (Fig. 5).

King Point results

Based on our surveys we were able to map out ground ice distribution at the site. The CCR data detected wedge ice (2500 to 500 Ohm.m), massive ice (5000–10000 Ohm.m) and variations in the depth to top of massive ice. The depth of the top of massive ice is extremely variable, which is expressed as a wavy, however continuous surface and varies between 3.5 to 7 m below ground surface. The RMS value for this site was 17.4%, which is a suitable error considering the variance in resistivities of these materials. With the GPR data, we were able to show strong reflectors at two levels, with the upper reflections being mainly horizontal to wavy and extending to a depth of ~50 ns, and the lower interface appearing at ~100 ns and exhibiting more variations in topography.

Stratigraphic information from adjacent coastal exposures and retrogressive slump were used to help guide the interpretation. The region between the two areas of high reflections contains semi-horizontal structures. These areas correspond to regions of massive ice occurrence. Estimated depths were calculated using a velocity of 0.14 m/ns assuming a combination of frozen sediments and areas of massive ice. Using these depths, the upper reflections extend to ~3.5 m, and the tops of the lower reflections are at ~7 m. The semi-

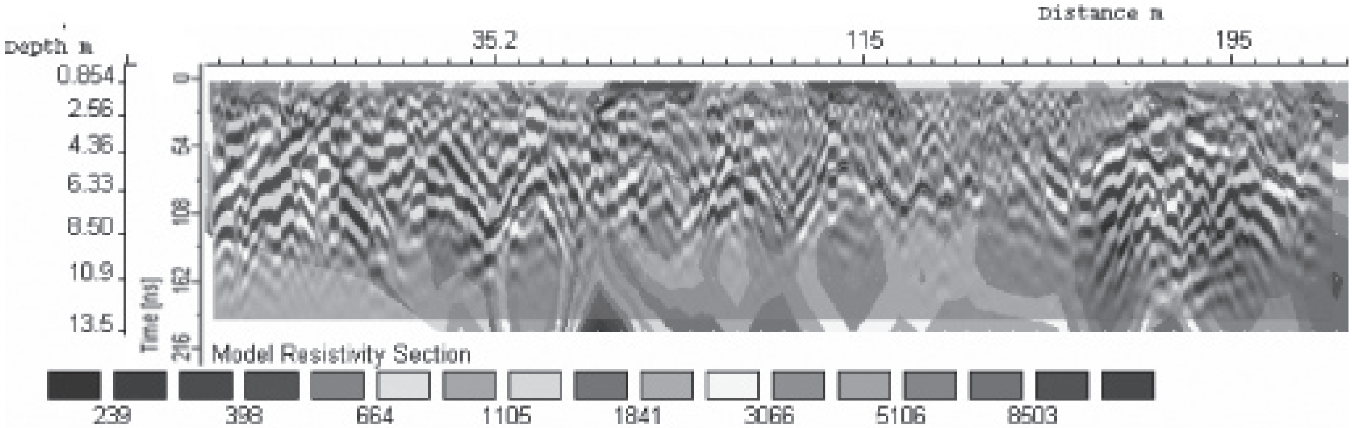

Figure 4. Combined CCR and GPR (50 MHz) data for the King's Point study site. A west-to-east transect with higher zones of resistivities (shown in red) corresponding with massive ground ice distribution and the dark brown which corresponds with wedge ice. Note the prominent reflector in pink that corresponds with the yellow increase in resistivity values and ground ice content (found between 3 and 6 m below ground surface). The increase in resistivity values east of station 160 corresponds with the transition between polygonal ground (wedge ice) and massive ice with no surface expression.

horizontal structures at approximately 3.5 m corresponds to the depth in the CCR data where resistivity levels become much larger below 3.5 m; this is the contact between frozen sediments to ice-rich frozen sediments. This could possibly be the maximum depth of the frozen Hypsithermal active layer, as noted in other sites in the Western Arctic (De Pascale et al., in press). Data with both systems were difficult to resolve below 13 m at this site. Wedge ice was detected between stations 35 and 150, and expressed as oval-shaped zones of higher resistivities with zones of lower resistivities between these zones of wedge ice. East of station 160, there is a transition from an area with ice wedges to massive ice, and there is a marked increase in resistivity values at this contact. The GPR data shows a decrease in signal attenuation east of station 160, which is consistent with massive ground ice occurrence due to a decrease in electrical conductivity.

Richards Island results

As with the King Point surveys, we were able to map the ground ice distribution at this site. The CCR data detected wedge ice (2,600 to 5,000 Ohm.m), massive ice (10,000 to 60,000 Ohm.m), and depth to the top of the massive ice. The RMS value for this site is 16.1%. The depth to the top of the massive ice varies from 7 to 8 m below ground surface. With the GPR data, we were able to detect strong reflectors at two levels, with the upper reflectors being subhorizontal to wavy and continuous for up to 60 m over a ~200 m section of the transect. The upper interface was ~100 ns and the lower interface appearing at ~225 ns. The upper interface corresponds with the top of the massive ice, while the lower interface is beyond the depth of the exposure. This reflector could be the base of the massive ice. Using these depths, the upper reflections extend from 6 to 8 m below the ground surface, while the lower reflector was at ~16 m. There was good agreement between the geophysical data and exposure adjacent to the transect, which permitted direct validation to the geophysical results. From the geophysical data, the contrast between pore-ice- rich sediments and the underlying massive ice was easily obtained. The lithologies of the materials under the major GPR reflector would be difficult to interpret without the CCR data, which demonstrated large variations in resistivity. However, this dielectric contrast between the massive ice and overlying sediments caused a strong reflector to be present in the GPR data. This contact was detected with both systems and showed 2 to 3 m of hummocky subsurface topography. The location of the ice wedges was easily detected due to geometry and increase in resistivity values, and from ice wedge troughs on the surface. Overall, the amount of massive ice found at this site permitted deeper investigations than at the Kings Point site.

Conclusions

Massive ground ice, wedge ice, ice-rich sediments, the active layer, a thaw unconformity corresponding to the hypsithermal paleo-active layer, as well as basic stratigraphic relationships found in the surrounding sediments were mapped. The two-dimensional geometry of ice bodies was obtained using these two geophysical techniques. Massive ice was consistently found at depths greater than 4 m, a depth corresponding with the Hypsithermal thaw unconformity, although modern wedge ice is often encountered at depths less than 2 m. It was found that that the hummocky surface of the massive ice body and the top of ice wedges were variable at both locations. This was possibly due to differential melting during the hypsithermal, prior to re-aggredation of permafrost within this section. A number of authors (e.g., Burn 1997, French 1998) describe the hypsithermal as a well-developed, shallow thaw unconformity in permafrost exposures in numerous locations throughout the western Canadian Arctic that appears between 2–3 m below the ground surface as an abrupt change in ice content, ice chemistry, soil colour,

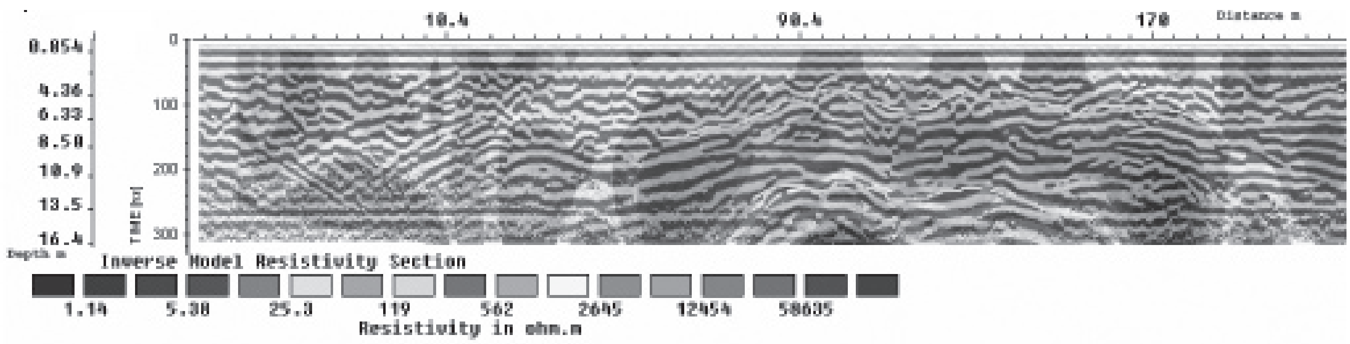

Figure 5. Combined CCR and GPR (50 MHz) data for the Richards Island site in a west-to-east transect. Higher zones of resistivities (shown in red) correspond with massive ground ice distribution. Note the anticline at station 90 m at a depth of approximately 14, and how there is a reduction in resistivities that corresponds with anticline structures found at depth. Green picks outline top and base of massive ice body. Note the wedge ice at stations 10 and 20 at depths near the surface and below 6 m.

organic content, and cryostructure. Examination of the King Point exposure revealed a number of these features, as well as several truncated ice-wedge tops (Harry et al. 1985) at a depth of ~2.5–3.0 m. The strong reflector at between 3 to 5 m depths seen in both the GPR and CCR data is interpreted as this transition. Dating of organic material (French 1998) from the overlying thawed zone from other sites confirms that this unconformity is related to an early Holocene warm interval referred to as the Hypsithermal (8.0–9.0 ka BP), when active layers were 2–2.5 times deeper than present. Another important finding is the large variation in resistivity values, almost a magnitude in the case of this study, for similar types of ground ice found in different settings. Coastal ground ice exposures have lower resistivity values than those found inland, and this is most likely due to the higher levels of cations present in the system from proximity to saline coastal conditions. The overall reduction in depth of investigation between our coastal site (King Point) and our inland site (Richards Island), suggests that the influence of coastal cations reduces the electrical resistivity values for all materials at a site. Because of this, more work needs to be undertaken to better understand the resistivity "signatures" of continuous permafrost.

Fieldwork on ground ice characterization at Richards Island in the Mackenzie Delta and King Point on the Yukon Coast, utilizing non-invasive geophysical methods like CCR and GPR, provided an opportunity to assess the synergistic benefits of using two complementary geophysical systems. Our results support previous research showing that, individually, CCR and GPR are useful tools for obtaining general subsurface information in permafrost (e.g., Calvert 2002, Dallimore & Davis 1987, Arcone et al. 1998, Moorman et al. 2003, De Pascale et al., in press), and clearly show the added value that results by combining their outputs. This study, based on the examination of sites at King Point and Richards Island, together with De Pascale et al. (in press), which focuses on massive ice in coarse-grained sediments, illustrates the enhanced benefit of integrating two complimentary geophysical techniques. These techniques detect and map the distribution of permafrost materials and structures containing ground ice, and if GPR is properly constrained using CCR data, a more accurate estimate of depth is possible. There was excellent agreement between these two systems that permit accurate mapping of ground ice locations. To our knowledge this is the first report of the young retrogressive thaw slump on Richards Island. Future work with these techniques can help us to better understand complex ground ice settings where various different ground ice are present, without damaging the natural environment using these non-destructive methods. To date our research has used observed cryostratigraphic relationships (nature sections or boreholes) and surface geomorphic expression (ice wedges polygons) to constrain our interpretation of subsurface permafrost conditions. Like any form of remote sensing, confidence levels increase when ground truthing confirms interpretations based on proxy data. For example, given the range of resistive values we have observed for massive ice, we are reasonably confident that in areas of deep continuous permafrost, where surface geomorphology does not indicate any unusual hydrologic phenomenon (e.g., saline ground water), we can detect the location, extent, and thickness of a massive ice unit. We are also confident that the distinct pattern of reflection together with resistivity can detect ice wedges, even relict ice wedges beneath a thaw unconformity. Ultimately, with the appropriate configuration (antenna frequency, spacing, …) of equipment, the combination of GPR and CCR is an effective and non-invasive technique to detect and map ground ice.

Acknowledgments

Funding for this research was provided by a NSERC Discovery Grant, ArcticNet, the Canadian Space Agency, and a PERD/DIAND financial agreement managed by R. Gowan with McGill University (W. Pollard). Field support for this research was provided by the Aurora Research Institute (ARI) in Inuvik and was conducted under NWT research License numbers 13560 and 13753 and Inuvialuit Land Administration (ILA) License number 03TIN055. Abstract

Recent interannual variations of rock glacier surface motion are compared for 16 landforms monitored for a few years in various parts of the European Alps. Large fluctuations have been observed particularly since 2002. Most investigated rock glaciers have shown a similar behavior whatever their location in the Alpine arc, their size, or their velocity. The observed interannual variations appear to be primarily related to external climatic factors rather than to internal characteristics. They are mostly well correlated with mean annual ground surface temperature shifts with a delay of a few months, reflecting the thermal wave propagation deeper into permafrost. Seasonal factors may also play a significant role: a lower intensity of winter ground freezing and/or a larger winter snow accumulation appear to facilitate a higher rate of rock glacier surface motion.

Keywords: creep; European Alps; interannual variations, rock glaciers; surface motion.

Introduction

Rock glaciers act as sediment conveyors in cold periglacial mountain environments. Where a rock glacier is perched on a steep valley side, it may be the source of slope instability processes (mainly rock falls and debris flows). Any change in the rate of permafrost creep may modify the delivery of loose materials at the rock glacier snout and affect the frequency, the magnitude, and even the type of related slope instabilities (e.g., Roer et al. 2008). In this context, and paying regard to the ongoing climate warming trend, there is an increasing request in the densely inhabited European Alps for precise and up-to-date data documenting the evolution of the high-altitude permafrost environment. In addition to the assessment of longer term (decadal to pluri-decadal) changes affecting rock glacier dynamics, which can be precisely determined by airborne photogrammetric analysis (Kääb et al. 2003), documentation of the short-term (interannual and even seasonal) variations is needed. Two decades after the pioneer work on the Gruben rock glacier (Haeberli 1985), the systematic survey of annual velocities was reinitiated a few years ago by several research teams by means of terrestrial measurements. This paper provides a first comparison of time series that have been measured since 1999/2000 or later on a sample of 16 rock glaciers located in six regions of the Alpine arc.

Background

Mostly located in the lower half of the mountain discontinuous permafrost belt, Alpine rock glaciers are rather warm. They may move relatively fast and are highly sensitive to small temperature changes (Kääb et al. 2007).

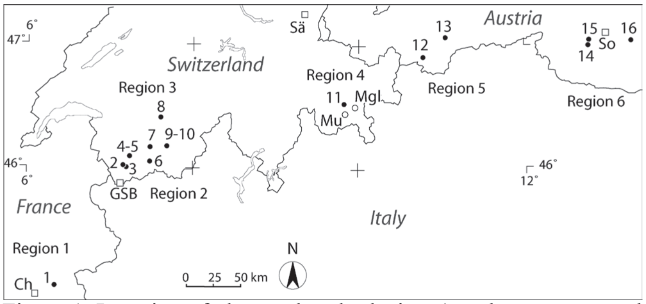

Figure 1. Location of observed rock glaciers (numbers correspond to Table 1). Other cited rock glaciers : Mu: Murtèl; Mgl : Muragl. Regions: 1. southwestern Alps (France), 2. western Swiss Alps (Valais), 3. northwestern Swiss Alps (Bernese Alps), 4. eastern Swiss Alps (Upper Engadine), 5. western Austrian Alps, 6. central Austrian Alps. Weather stations : Ch: St.-Christophe-en-Oisans; GSB : Grand-St-Bernard; Sä : Säntis; So : Sonnblick.

Three types of temporal variability in surface motion are superimposed on a secular time scale in response to ground surface temperature variations (e.g., Kääb et al. 2007, Perruchoud & Delaloye 2007): a decadal to pluri-decadal trend, interannual variations, and a seasonal rhythm. Non-thermally induced changes in rock glacier dynamics (e.g., topography effect) may also influence the creep rate particularly at longer time scales, whereas the infiltration of snowmelt water (Ikeda et al. 2008) and the influence of subpermafrost groundwater (Haeberli 1985, Krainer & Mostler 2006) are also advanced as controlling factors at shorter time intervals. The early measurements on the Gruben rock glacier already indicated that strong short-term velocity variations occur where the permafrost base is above bedrock, and that these variations can be different in lower and upper rock glacier parts (Haeberli 1985).

Studies carried out in various parts of the Alps (e.g., Roer et al. 2005, Kääb et al. 2007, Kaufmann et al. 2007) have shown that the motion of alpine rock glaciers has drastically accelerated since the 1980s, probably in response to an increase in permafrost temperature consecutive to warmer air temperatures. For the past 15 years or so, however, no clear further warming trend has been visible in the borehole temperatures time series on the Murtèl rock glacier in the eastern Swiss Alps (Vonder Mühll et al. 2007).

Seasonal variations have been reported for several rock glaciers (Haeberli 1985, Kääb et al. 2003, Hausmann et al. 2007a, Perruchoud & Delaloye 2007), whereas almost constant annual velocities have also been observed (Krainer & Mostler 2006), particularly where permafrost is reaching into bedrock as on the Murtèl rock glacier (Haeberli et al. 1998). Where existing, seasonal fluctuations can be large, reaching up to 50 % from the annual mean. They occur every year more or less at the same time but are not fully synchronous for all rock glaciers. Highest velocities are reached in most cases between summer and early winter, whereas the lowest values are usually observed in spring or early summer. The seasonal increase in velocity can be rapid and connected to the snowmelt process (Perruchoud & Delaloye 2007) or slower and delayed (Kääb et al. 2007). On the Muragl rock glacier (eastern Swiss Alps), the annual amplitude of the seasonal rhythm varies significantly, the winter/spring decrease being reduced by warmer winter ground surface temperature (Kääb et al. 2007).

Interannual Velocity Survey and Dataset

Interannual velocities are surveyed by terrestrial measurements (geodetics or real-time kinematic GPS) with accuracy in the mm to cm range. The annual campaign at each rock glacier is carried out as closely as possible on the same date - ideally by late summer - in order to avoid an effect of potentially strong seasonal variations on the reliability of the data. Ten to more than 100 marked points, covering part or the whole of the rock glacier or disposed along longitudinal and/or transversal profiles, are surveyed. The compared value is then the mean horizontal velocity for all moving points with uninterrupted series. This value is considered to be a proxy for the activity of a whole rock glacier, keeping in mind that local differences in flow rates and amplitudes of annual changes are probable.

The 16 observed rock glaciers (Fig. 1) are located in six distinct regions and are briefly described hereafter and in Table 1. There is a distance of 600 km between Laurichard (southwest) and Dösen (east) rock glaciers.

Region 1: Southwestern Alps (France)

Laurichard is a tongue-shaped rock glacier which displays longitudinal furrows in its steepest part and transversal ridges near the edge. Surface velocities have been measured since 1983 (Francou & Reynaud 1992) along a 420 m long longitudinal profile of 17 painted blocks. Mean horizontal velocity over the 1983–2007 period is 0.75 ma^{-1}.

Region 2: Western Swiss Alps (Valais)

Mille is a rock glacier looking inactive on morphological criteria (Delaloye 2004), however moving slowly in its steeper lower half (0.02 to 0.05 ma^{-1}).

Aget-Rogneux is a low active back creeping push-moraine located in the Little Ice Age forefield of a small vanished glacier (Lambiel & Delaloye 2004).

Mont-Gelé B and C are two coalescent small rock glaciers. Whereas Mont-Gelé B is moving faster, the deformation of Mont-Gelé C is much reduced despite an apparently higher ice content (Lambiel & Delaloye 2004).

Tsarmine is a tongue-shaped, currently very active rock glacier ending at the top of a steep gully and providing large amounts of loose materials. Local disturbances of the block surface point to a recent drastic acceleration of the rock glacier movement (Lambiel et al. 2008).

The Becs-de-Bosson rock glacier is an active feature consisting of two adjacent lobes. There is no permafrost—and no creep—in the rooting zone of the rock glacier due to the former development of a local glacier during the Little Ice Age. Significant seasonal variations are observed on the whole rock glacier (Perruchoud & Delaloye 2007).

HuHH1 and HuHH3 are two adjacent multilobate rock glaciers situated below cirques. Both landforms are of similar size and showed maximum horizontal velocities up to 4 ma^{-1} in 2003/04 (Roer 2007).

Region 3: Northwestern Swiss Alps (Bernese Alps)

Furggentälti is a small, tongue-shaped rock glacier with annual surface displacement currently 5 to 10 times larger than during the period 1960–1974 (Mihajlovic et al. 2008). Seasonal fluctuations were observed in 1998/99.

Region 4: Eastern Swiss Alps (Upper Engadine)

The Büz North (Trais Fluors) pebbly rock glacier comprises two superimposed lobes, 70 and 90 m long. At the beginning of the survey in 1998, no pronounced morphological expression of flow was noticed. However, the movement turned out to be in the order of 1 ma^{-1} and more (Ikeda et al. 2008, Kääb et al. 2007).

Region 5: Western Austrian Alps

Ölgrube rock glacier consists of two lobes of varying activity. Maximum annual velocities (1.5 ma^{-1}) occur in the central lower part. Seasonal variations were observed with a velocity decrease of about 50% during winter 2003 (Krainer & Mostler 2006, Hausmann et al. 2007a).

Reichenkar is a 1400 m long, very active tongue-shaped rock glacier. Highest velocity (up to 3 ma^{-1}) occurred in 2003/04. No seasonal variation was noticed in 2002 and 2003 (Krainer & Mostler 2006, Hausmann et al. 2007a, b).

Region 6: Central Austrian Alps

Weissenkar is a slowly moving, tongue-shaped rock glacier consisting of an upper lobe overriding a lower one, and characterized by well developed furrows and ridges at the entire lower half. Weissenkar rock glacier moves on average 0.02 to 0.11 ma^{-1} (Kaufmann et al. 2006).

Hinteres Langtalkar houses a highly active, tongue-shaped rock glacier advanced over a prominent terrain ridge into steeper terrain most likely in 1994 (Avian et al. 2005). Several transverse crevasses have developed since (e.g., Roer et al. 2008). The current movement pattern differentiates a faster lower part and a substantially slower upper part.

Dösen is a tongue-shaped rock glacier. Displacement measurements started in 1995—including photogrammetric work of the preceding period until 1954—revealing mean velocity rates of 0.13–0.37 ma^{-1} (Kaufmann et al. 2007).

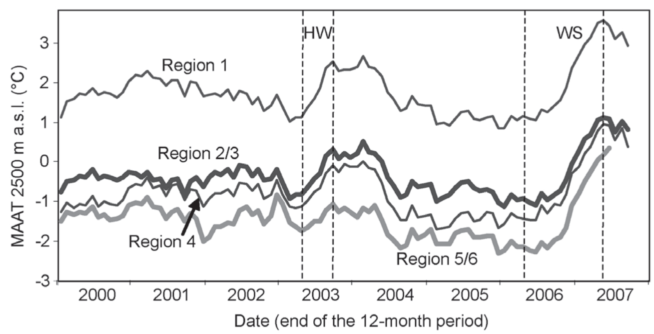

Figure 2. Mean annual air temperature (12-month running mean) standardized at 2500 m a.s.l. (gradient: -0.56°C/100 m). HW: heat wave 2003; WS: warm swell 2006/07. (ZAMG –Central Institute for Meteorology and Geodynamics).

MAAT and MAGST in 2000–2007

Air temperature

The 1987–2007 mean annual air temperature (MAAT) in the Alps was on average 1°C to 2°C warmer than during the preceding decades. Since 2000, two extreme, warm climatic events affected the Alpine region: the heat wave of summer 2003 and the 2006/07 warm swell, namely 15 months of quasi continuous, large, positive temperature anomaly between April 2006 and June 2007 (except August 2006). The 2003 heat wave induced a rapid warming of MAAT towards values exceeding those of earlier and later years (except in the Austrian Alps), and the 2006/07 event resulted in an exceptionally high MAAT, which exceeded everywhere the 2003 value by 0.5°C to 1.5°C (Fig. 2).

Ground surface temperature

There are no boreholes on the 16 observed rock glaciers, except a shallow one (6 m) at Trais Fluors. Ground surface temperature is nevertheless monitored on several of them. Variations of the mean annual ground surface temperature (MAGST)

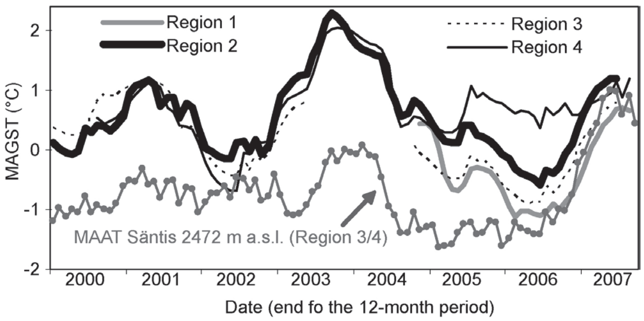

Figure 3. Interregional comparison of MAGST behavior in the western and central Alps (12-month running mean). Region 1: Laurichard rock glacier (average of 2 sites of measurement). Region 2: Becs-de-Bosson/ Réchy (2). Region 3: Furggentälti/ Gemmi (1). Region 4: Trais Fluors (1).

are used as a proxy for the permafrost thermal regime at shallow depth, even if the intensity of the winter cooling and summer warming (freezing and thawing index) should not be neglected. The snow cover buffers the ground-atmosphere heat exchanges for a long part of year, varying annual snow cover conditions alter the behavior of MAGST in comparison with MAAT: both are not evolving in a parallel way (Fig. 3). Despite the effect of snow, a homogeneous MAGST behavior is observed at the regional scale (e.g., Delaloye & Monbaron 2003). The larger variations of MAGST are also similar at the interregional scale in the Alps with, however, some differences in 2005–2006—colder values in the western regions 1–3 (Fig. 3). Three periods of warmer MAGST occurred in 2001, 2003/04 and 2007, with the 2003/04 event as the warmest.

Both 2003 and 2006/07 warm climatic events did not affect MAGST in the same way. In 2003 a strong MAGST increase already had occurred during the winter due to earlier snow insulation (e.g., Vonder Mühll et al. 2007); a second phase of warming succeeded in summer and was caused by the heat wave. An extremely high MAGST value was reached by the end of 2003. In 2006/07, the situation was the reverse. Later and lesser snowfalls in early winter favoured the cooling of the ground surface in spite of the persistence of mild air temperature. The extremely high MAAT was strongly attenuated in MAGST.

Results

Despite variable size, morphology, complexity of flow field, mean annual velocity, seasonal rhythm, etc., the compared rock glaciers have shown a rather homogeneous and synchronous behavior (Fig. 4). Three phases of higher creep rate can be quoted in 2000/01, 2003/04, and 2006/07. They all followed immediately a period of warmer MAGST.

Every rock glacier reached an absolute or relative maximal creep rate in 2003/04 before a drastic drop occurred for most of them between 2004 and 2006 (up to -81%, Table. 1). The drop was generally stronger to the west (Regions 1–3) than to the east (Regions 5–6). Stationary or slightly increased velocities were observed everywhere in 2006/07.

The situation in 2000/01 was more contrasted. A peak rate of deformation occurred in Region 4 and was also almost reached in Region 1. Relative maxima are reported from Regions 3 and 6 (no data in Region 2) whereas no maximum is documented in Region 5. Neighboring regions did not display similar behavior in rock glacier movement.

Discussion

Neglecting small differences in interannual variations that may be due to either internal and topographical characteristics of the rock glaciers or to the variability of the seasonal rhythm or to a shift in the measurement date, the rather homogeneous behavior of Alpine rock glaciers allows us to state that: (1) the driving processes are likely to be the same for all observed rock glaciers; (2) there should be a common climatic control of the permafrost creep rate; (3) a dominant effect of active layer solifluction or surface boulder creep can be excluded, as corroborated, for instance, by borehole deformation measurements on the Trais Fluors rock glacier (Ikeda et al. 2008).

As the interannual changes of surface motion appear to be mostly correlated to the evolution of the MAGST with a delay of a few months (Fig. 4) - the warmer the MAGST, the larger the velocity, - one can infer that they should be caused by a thermally induced process. The delay being not long enough for the surface thermal signal to penetrate deeply into permafrost, interannual changes would thus be primarily caused by shifts in the deformation rate of shallow permafrost layers mostly located—if existing—above the shear horizon.

Higher creep rates should also be caused by the development of a thick winter snow cover, which during early summer provides more meltwater to penetrate into a warm rock glacier system. This process is evoked by Ikeda et al. (2008) to explain the high activity of the Trais Fluors rock glacier in 2001. In that region, the snow cover in winter 2000/01 was much deeper than for both the previous and the following winters. The unusually high amount of meltwater in early summer 2001 is advanced as a factor which facilitated permafrost creep. A similar situation occurred in the Laurichard area in the French Alps. The snow accumulation (2.42 m we) recorded that winter on the Sarennes glacier at a distance of 24 km was 0.65 m we above the 1984–2007 mean and the only value exceeding 2 m we since 1995 (Fig. 5). Among the six regions defined in this study, both Laurichard and Trais Fluors regions are the most exposed to southerly precipitations, a situation which prevailed in winter 2000/01.

Changing interannual creep rates may finally be related to the intensity of winter ground freezing. Where data is available, the maximal activity of rock glaciers appears to be linked to lower freezing index values. In the western and eastern Swiss Alps, the highest annual velocities occurred after the warmest winters on the ground surface, in 2001 and 2003 (Fig. 6). On the Muragl rock glacier, close to Trais Fluors, seasonal velocity surveys carried out between 1998 and 2003 (Kääb et al. 2007) showed that, contrary to other winters, the velocity of the rock glacier did not decrease during winter 2000/01. The higher annual velocity was caused by the absence of a winter deceleration.

Conclusions and Perspectives

Rapid and slow rock glaciers have shown mostly a similar kind of annual velocity variations in the whole arc of the

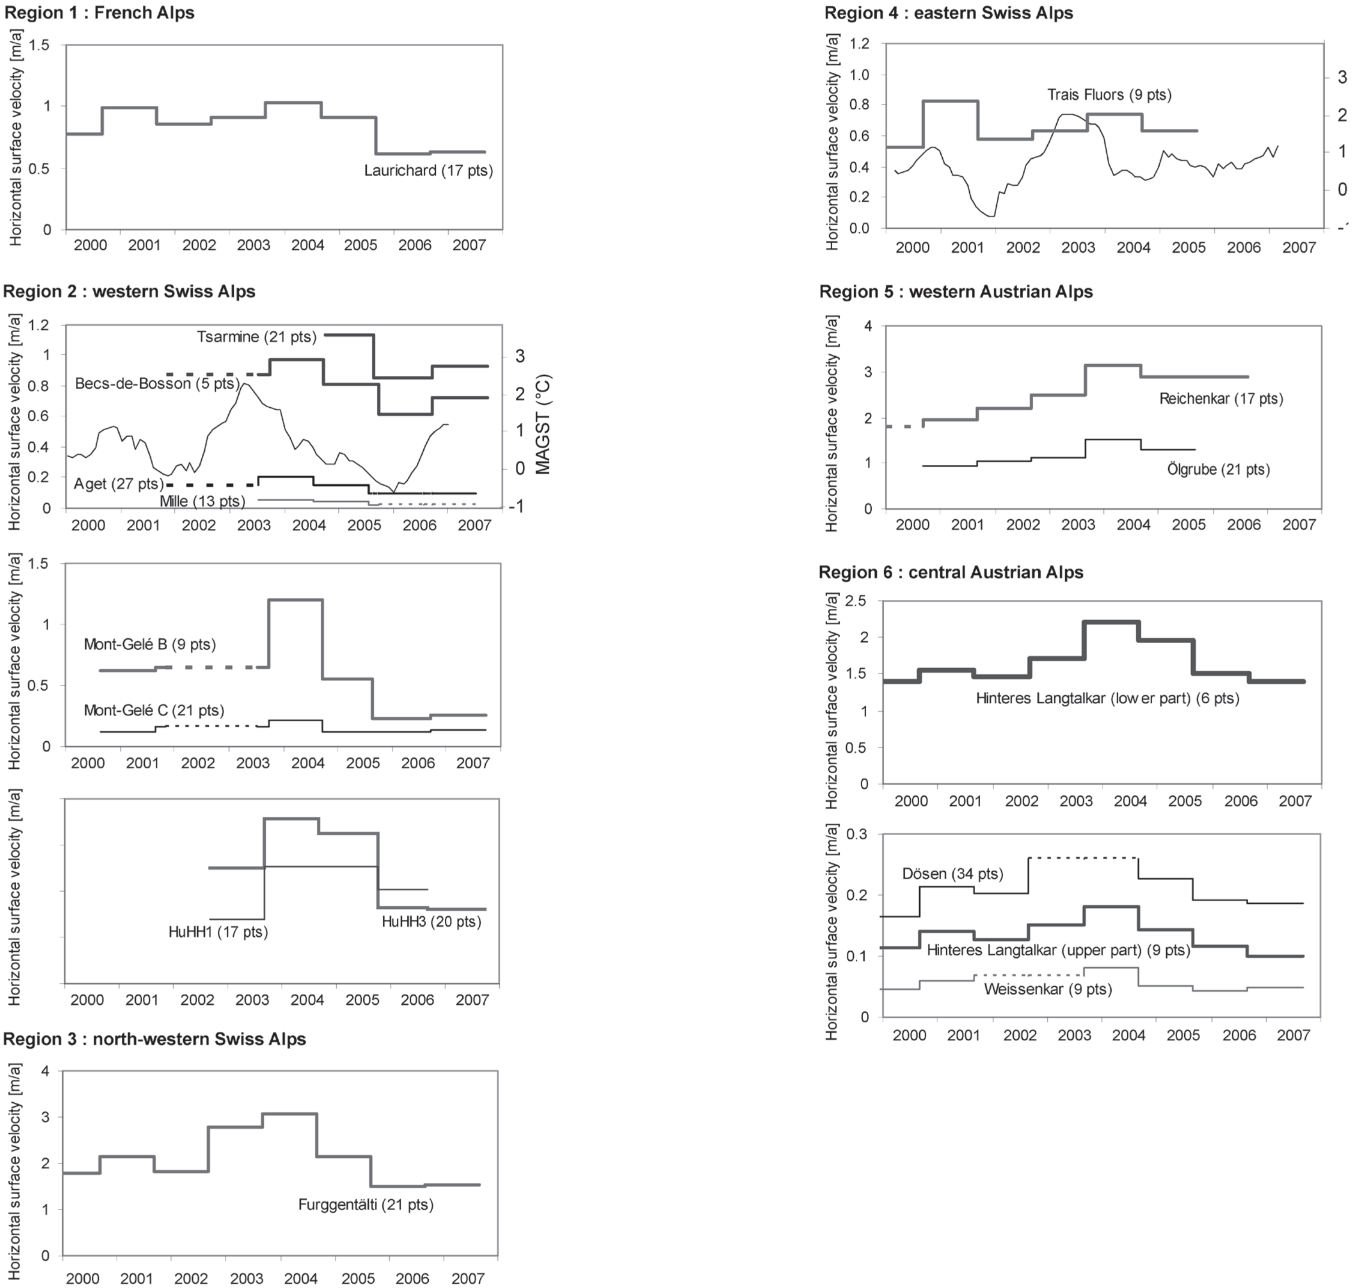

Figure 4. Annual horizontal velocities of alpine rock glaciers. The velocity scale is not identical on every graph. Dotted lines indicate a 2-year interval of measurement. Mean annual ground surface temperature (MAGST) at Becs-de-Bosson and Trais Fluors rock glaciers are inserted in the respective chart with date corresponding to the median of the 12-month period.

European Alps since 2000. Interannual variations of rock glacier dynamics appear so far—with probably a few exceptions—to be primarily related to external climatic factors rather than to the internal characteristics of the rock glaciers. They are mostly well related to shifts in mean annual ground surface temperature with a few months of time lag reflecting the delay in propagation of corresponding anomalies deeper into permafrost. Seasonal factors may also play an important role. A lower intensity of winter ground freezing and/or a larger amount of winter (October–May) snowfall facilitate a higher rate of annual rock glaciers surface motion.

The set of 16 rock glaciers is representative of six alpine regions. It establishes a pioneer network for the observation of short-term variations of rock glacier activity. The first synthetic results strongly encourage the continuation of the monitoring effort and the extension of the network to further regions, particularly in the southern Alps for which such data is still mostly lacking. The availability of uninterrupted series, complemented by ground surface temperature and snow data acquired on the rock glaciers or in their close vicinity, will serve a more precise identification and quantification of the factors driving the short-term behavior of permafrost creep rate in temperate mountain areas.

Acknowledgments

Special thanks are due to both reviewers and to the reviewer editor for their comments, and to all involved in the field survey campaigns for their inestimable contribution.

Ground-Based LIDAR Data on Permafrost-Related Rockfall Activity in the Mont Blanc Massif

Philip Deline, Stéphane Jaillet, Antoine Rabatel, Ludovic Ravanel
EDYTEM Lab, Université de Savoie, CNRS, Le Bourget-du-Lac, France

Abstract

It is hypothesized that climatic warming since 1980 increases rock wall instability in high mountains due to permafrost degradation. This is supported by the observation of ice in several rockfall scars. Due to a lack of systematic observations, magnitude and frequency of high mountain rock failures remain poorly known. As part of the French-Italian *PERMAdataROC* project, we apply ground-based LIDAR to monitor instability on representative permafrost-affected rock walls (3000 to 4650 m a.s.l.) in the Mont Blanc massif. Initial results indicate that rockfall activity probably relates to different conditions at the 3 reported sites. The Piliers de Frêney and Grand Pilier d'Angle, both above 4000 m, are virtually stable (0 m^3 of rockfalls) and indicate conservation of permafrost at high altitudes even on south-facing rock walls. With a probably critical state of permafrost, Tour Ronde E-Face and Arête Freshfield NE-Face (3460–3792 m) released ca. 1000 m^3 of rockfall from 2005–2007. On Les Drus (2700–3700 m a.s.l.), 560 m^3 of rockfalls were observed; we argue that these occur due to slope readjustment to the 2005 rock avalanche and are not directly linked to permafrost degradation.

Keywords: LIDAR; Mont Blanc massif; *PERMAdataROC* project; permafrost; rockfall; terrestrial laser scanning.

Introduction

Recently, large rock and rock/ice avalanches have occurred in high mountain areas worldwide (*e.g.,* Kolka-Karmadon, Caucasus 2002, Huggel et al. 2005). In the Alps, Brenva Glacier (1997), Punta Thurwieser (2004), the west face of Les Drus (2005), and the east face of Monte Rosa (2006, 2007) are the most recent examples (Deline 2001, Noetzli et al. 2003, Fischer et al. 2006, Ravanel 2006). In addition, innumerable smaller rockfalls detached from steep rock walls during the hot summer of 2003 (Gruber et al. 2004). The hypothesis that the increase of high mountain rock wall instability relates to permafrost changes gains force (Haeberli et al. 1997, Gruber & Haeberli 2007) from the fact that (1) ice was observed in many starting zones; (2) the mean annual air temperature in the Alps has increased more than 1°C during the 20^{th} Century; and (3) the warming trend has accelerated since 1980.

However, frequency and volume of instability events in high mountains are still poorly known because of the lack of systematic observations, and ongoing permafrost changes in rock walls remain poorly understood due to the difficulties in carrying on in situ measurements. So far, permafrost studies are mainly based on modeling, with a few existing instrumented sites.

The PERMAdataROC project

The *PERMAdataROC* project aims at studying the relation between permafrost degradation and high mountain rock wall instability in two west Alpine areas, the Mont Blanc massif and the Matterhorn, based on the interface of three research assignments (Ravanel & Deline 2006).

The first assignment deals with the collection, maintenance and analysis of recent rockfall/rock avalanches in the Mont Blanc massif in a data base, based on (1) systematic survey of slope instability events (localisation, exposition, time, meteorological conditions, snow conditions, estimated volume, path) carried out by local, trained people (mountain guides, rescue people, hut keepers) in collaboration with the researchers; (2) digitalisation of the events in a GIS; and (3) analysis of the topographical, geological and climatic parameters of the affected rock walls. This data base is complemented by past events that are documented by newspapers, hut, and guide books, as well as previous studies and guide interviews.

The second research assignment deals with measuring and the thermal regime in rock walls. The instrumentation (thermistors at 5, 10, 30, and 55 cm depth) and measurement of relevant properties (albedo, irradiation, thermical conductivity) of rock wall superficial layer and surface at the selected study sites, combined with high altitude climatic data recorded by a movable automatic weather station, will contribute to validate the models of temperature distribution and variations.

The third research assignment is provided by the monitoring of the instability of representative rock walls, by (1) frequently repeated surveys with long-range ground-based LIDAR (LIght Detection And Ranging) and terrestrial photogrammetry, and (2) the installation of a geophone network in one of the study sites to determine the frequency and volume of rockfalls, considering variable parameters (altitude, aspect, slope angle, lithology, fracturing, shadow effect, height drop).

Italian (CNR-IRPI Torino, ARPA Valle d'Aosta and FMS Courmayeur) and French (EDYTEM Lab) partners are involved in the *PERMAdataROC* project, with collaboration with the GGG of University of Zürich.

Here we present initial results of the monitoring of the

Figure 1. Largest glaciers are highlighted. This paper presents initial results from sites 1, 3, and 6.

instability of rock walls at three sites in the Mont Blanc massif since 2005.

Study Area

The Mont Blanc massif covers an area of approximately 350 km², 40% of which is glacierized. It reaches its highest point at 4808 m a.s.l., but many of its granitic, fractured faces, peaks, and aiguilles stand well above 3000 m. The water divide between Rhône and Pô basins is a 35 km long crest line which always exceeds 3300 m and is often higher than 4000 m. Being one of the most active uplift spots in the Alps (>1.5 mm.an^{-1}), the massif is not only characterized by very high, but also steep faces and rock walls.

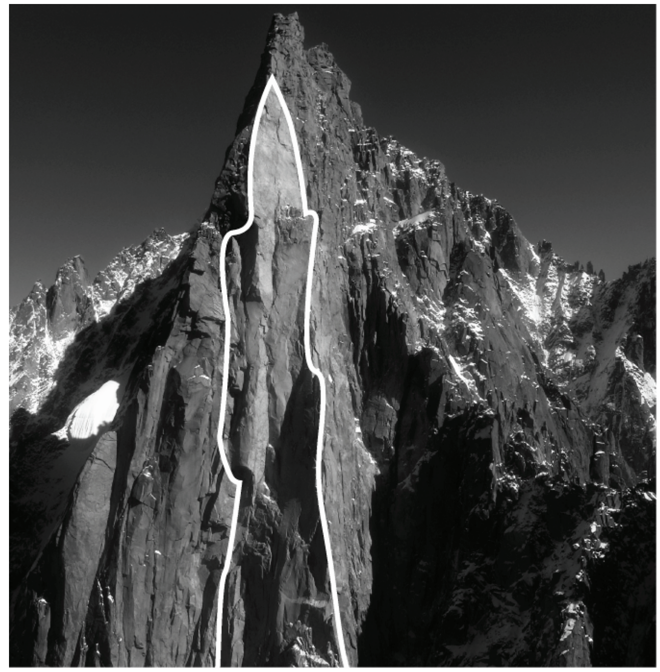

Figure 2. Upper part of the west face of Les Drus. The upper part of the 2005 rock avalanche scar is delimited by the white line. To survey the face, the ground-based LIDAR is set up on Les Flammes de Pierre (crest on bottom right).

Seven study sites from 3000 to 4650 m with different aspects were selected in the Mont Blanc massif within the *PERMAdataROC* project (Fig. 1): the west face of Les Drus, a >70° rock wall between 2700 and 3700 m affected by a series of rockfalls since 1950 with increasing magnitude until June 2005, when collapse of the Pilier Bonatti generated a rock avalanche of >250,000 m^3 (Fig. 2) (Ravanel 2006); the surveyed area at Les Drus is between 3000 and 3700 m; the Piton Central of the Aiguille du Midi (3770–3842 m) which towers above the cable car station, with all aspects; the east face of the Tour Ronde, and the NE-facing Arête Freshfield which develops at the south (3460–3792 m), where rockfalls have been active for several years; the west face of the Aiguilles d'Entrèves (3490–3591 m); the Grand Flambeau (3410–3561 m), close to the Helbronner cable car station, with all aspects; the east-facing Piliers de Frêney (4000–4650 m) and the south face of the Grand Pilier d'Angle (4050–4308 m), on the south side of Mont Blanc summit, and the NW face of the Aiguille Blanche Nord de Peuterey (4000–4103 m). These high elevation sites are complemented by a low-elevation control site (2200–2700 m) without permafrost, on the SW-facing side of the Vallon du Miage.

Methods

Since June 2005, ground-based LIDAR measurements are realised seasonally (summer/autumn) or annually at the eight sites in the Mont Blanc massif, using helicopter or cable cars for access. Data are processed for calculating high-resolution (centimeter-scale) triangulated irregular networks (TIN). Volumetric changes, extracted on the rock faces by comparing the successive TINs, represent the fallen rocks between the measurement periods (Ravanel & Deline 2006).

LIDAR survey

LIDAR measurements are performed using an Optech® ILRIS 3D ground-based LIDAR. This laserscanner works at distances of up to 800 m if surface reflectivity and visibility are good. The angle of view is 40°×40°, and the sampling rate reaches a maximum frequency of 2000 points per second. At a distance of 100 m, the laser beam diameter is about 30 mm (perpendicular shot), and the accuracy on a flat surface is about 3–5 mm. The LIDAR point to point distances on the rock walls we are surveying range between 61 mm and 246 mm (in 2006 and 2007), on the closest and farthest areas, respectively.

Data processing

Data processing (Rabatel et al., submitted) is realised using InnovMetric PolyWorks® software, with (1) alignment of individual point clouds using the IMAlign module: they are merged with a rototranslation matrix into a unique local reference system, after cleaning individual scans from outliers (Fig.3); and (2) creation of the TIN using the IMMerge module.

The computation of the fallen rock volume in a rock wall between two successive field work campaigns is achieved with the PolyWorks® IMInspect module, which compares two point clouds and quantifies the thickness changes. A reference plan is built, and the volume between the surface topography and this plan is computed for each date.

Error estimation

The total uncertainty can be estimated by the quadratic sum of the different independent errors in the processing. (1) LIDAR error is 3–5 mm at 100 m (manufacturer data). (2) TIN is interpolated from existing points of the global point cloud (set of 3D images). To merge it into a unified polygonal mesh, most parameter values are calculated using input point cloud values. Due to the average mesh used, the TIN construction error is ca. 7 cm. (3) To be compared, diachronous TINs have to be very overlapped. But because of very large TINs, there is a TIN overlapping error, which is 5 cm as measured by Polyworks. This yields an overall uncertainty of 9 cm, which is reduced by directly comparing the point clouds.

Mask effect

Masks result from (1) the topography of the rock wall (roofs, ledges, corners, spurs); (2) the common scarcity of sites to set up the LIDAR (e.g., for the west face of Les Drus, there is only one possible on Les Flammes de Pierre: Fig. 2); and (3) the snow cover, whose extension differs each year. Masks could represent an important part of the surface surveyed, and appear as holes in the TINs. This is particularly

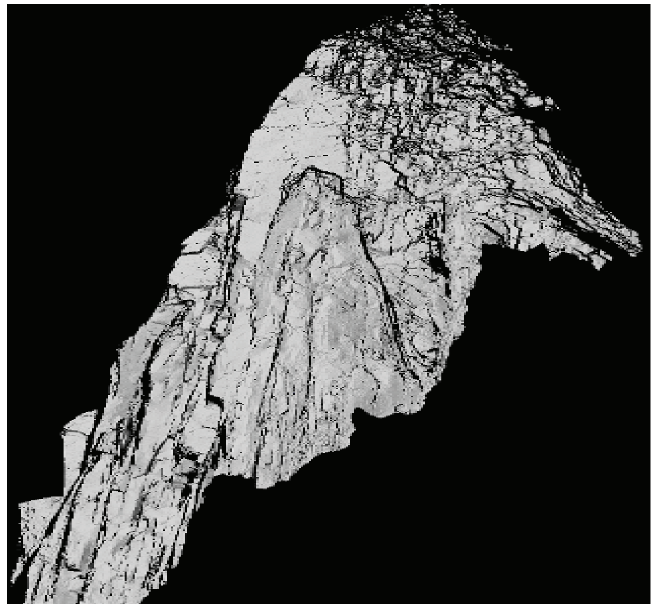

Figure 3. Point clouds of the west face of Les Drus derived from LIDAR surveys (left: October 2005; right: October 2006). The height of the 2005 rock avalanche scar here represented is 500 m.

the case if there are no multiple viewing angles (Les Drus), or if the snow-ice cover is important (Peuterey).

The Polyworks® IMEdit module allows to reduce their extension. The hole area is first selected. A tool allows the holes to fill automatically using irregular triangles. Only the maximum distance between the vertices of a triangle has to be specified. The longer this distance, the greater resulting size of the plugged hole.

Results

We present initial results from three of the seven high-elevation selected sites in the Mont Blanc massif: (1) the west face of Les Drus; (2) the east face of the Tour Ronde and the NW side of the Arête Freshfield; and (3) the Piliers de Frêney and the south face of the Grand Pilier d'Angle (Table 1).

West face of Les Drus

Comparison of October 2005 and October 2006 TINs reveals a detachment from the 2005 rock avalanche scar of height rock elements of a volume ≥1 m³: five boulders are ≤6 m³, and three are larger. At about 3600 m a.s.l., a notch of 29×10×1.8 m (426 m³) is present on the 2006 TIN; the rocks reached the small debris-covered glacier of Les Drus, at the foot of the west face. Lower on the rock wall, two elements of 19 and 84 m³ also collapsed in this one-year period. In total, 546 m³ of rock were released in the surveyed area between October 2005 and October 2006.

The third survey, carried out at the end of September 2007, shows reduced rockfall activity over the period extending from October 2006 to September 2007: only one small rockfall occurred (22 m³), out of the 2005 scar.

Table 1. Rockfall data from LIDAR surveys (2005–2007).

Site	Period of measurement (d/m/y)	Surface of surveyed area by LIDAR (m²)	Volume of rockfalls (m^3) Total	Volume of rockfalls (m^3) 2 main	Mean rock wall retreat rate in surveyed area ($mm\ a^{-1}$)	Extreme distance of point to point on rock wall (mm)
Drus (W face)	11/10/2005–11/10/2006	70,500	546	426 + 84	7.7	Not calculated
	12/10/2006–24/09/2007		22	-	0.3	71–208
Piliers de Frêney - Grand Pilier d'Angle (S face)	14/07/2005–10/10/2005	115,600	0	0	0.0	Not calculated
	11/10/2005–30/06/2006		0	0	0.0	Not calculated
	01/07/2006–13/10/2006		0	0	0.0	61–246
	14/10/2006–12/10/2007		0	0	0.0	61–246
Tour Ronde (E face) – Arête Freshfield (NE face)	13/07/2005–18/07/2006	67,400	536	382 + 154	8.4	Not calculated
	19/07/2006–12/10/2006		0	0	0.0	75–207
	13/10/2006–12/10/2007		448	448	6.6	75–207

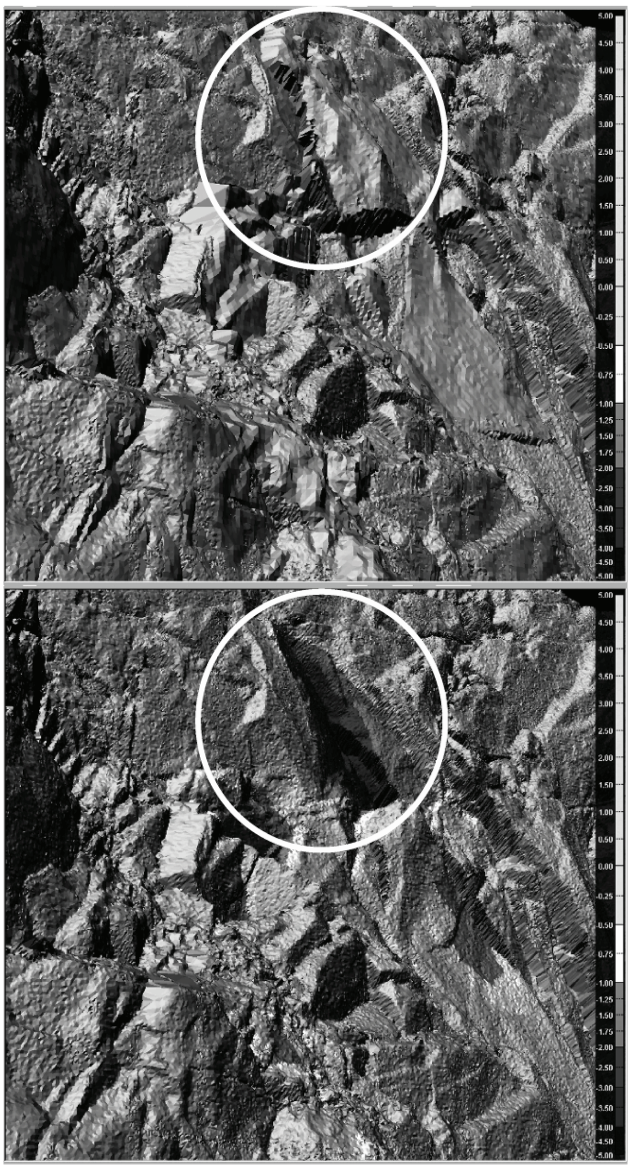

Figure 4. East face of the Tour Ronde TIN (detail). The view focuses on the area affected by the main rockfall between July 2005 (top box) and July 2006 (bottom box). Dimensions of the main scar (visible in bottom box circle) are 17.5×7.8×4.3 m, with a volume of 382 m^3 (image size: ca. 45 m × 45 m).

East face of La Tour Ronde-NE face of Arête Freshfield

At the Tour Ronde, the evolution of the surface topography of the east face between July 2005 and July 2006 shows two main rockfall events, with a volume of 382 m^3 (Fig. 4) and 154 m^3 (main scar sizes are 17.5×7.8×4.3 m and 15.1×9.3×1.4 m, respectively). The total volume of these two rockfall reaches 536 m^3.

The comparison of LIDAR measurements for the second period, between July 2006 and October 2006, shows no significant change during the 2006 summer.

During the third, and last, period of survey, no change was observed on the east face of Tour Ronde. On the other hand, at least two rockfalls occurred on the NE side of the Arête Freshfield, involving a set of large boulders (total volume: 448 m^3) which detached from a small area where bedrock is highly dislocated.

Piliers de Frêney-south face of Grand Pilier d'Angle

Five successive LIDAR surveys performed since July 2005 display no change on the rock walls during a period of 27 months, including 3 summers. Mask effects are important, due to the rough topography of the area (large pillars separated by deep couloirs) and the unique site available to set up the ground-based LIDAR. Thus, only a part of this area is surveyed, but no significant rockfall was observed over the 115,000 m^2 it represents.

Discussion and Conclusions

Results indicate that rockfall activity probably relates to different conditions at the three sites.

On the west face of Les Drus, the rockfalls which occurred probably represent slope readjustment after the large rock avalanche of 2005 and are not directly related to permafrost degradation. For example, the detachment of 84 m^3 between October 2005 and October 2006 is due to the fall of an individualized, hanging, and poorly-rooted slice. Moreover, the small pieces of rock (<1 m^3) identified between 2005 and 2006 were probably destabilized during the fall of the largest element (426 m^3). Lastly, no rockfall occurred into the 2005 scar between 2006 and 2007: this suggests that the mesoscale slope readjustment in the scar is now achieved.

But it is noteable that a new permafrost active layer forms in the 2005 rock avalanche scar.

On the other hand, on the east face of La Tour Ronde and on the NE side of the Arête Freshfield, the rockfalls (2005–2006: 536 m^3; 2006–2007: 448 m^3) probably result from permafrost degradation. This is suggested both by (1) the high rock fall activity during recent years: the normal route to the summit of Tour Ronde is not used when snow cover has melted; and (2) the modeling of the surface temperature of rock walls in alpine areas with similar weather conditions. For instance, mean annual surface temperatures range between -2°C and -4°C at Junfraujoch at 3500–3750 m a.s.l. for E/NE aspect (Gruber et al. 2004: Fig. 2), without taking into account the local topography of the rock faces.

Contrary to the two others sites, the area of the Piliers de Frêney and the south face of the Grand Pilier d'Angle show stable conditions. The results suggest that no or very occasional degradation of the permafrost occurs at very high altitude (>4000 m), including south-facing rock walls like the Grand Pilier d'Angle. Several large grey scars at the foot of the Piliers de Frêney and the nearby Piliers du Brouillard and Mont Maudit, which clearly contrast to the reddish surrounding granite, indicate that rockfalls and rock avalanches have occurred at elevations greater than 4000 m; but preliminary studies (Böhlert et al. 2008) suggest that these grey scars could have formed before 1,500 yr BP, during previous Holocene cold periods.

Given that high-alpine rock walls are a poorly known system, the introduced methodology shows a great potential to reveal quantitative data on geomorphological processes in permafrost-affected rock walls

Abstract

The Pine Barrens of southern New Jersey has a well-documented periglacial legacy, evidenced by traces of relict frost fissures and related deformational structures. This study measures the potential of three-dimensional ground-penetrating radar (3D GPR) techniques to detect and identify subsurface cryogenic macrostructures investigated previously in the region, including deformed wedges, sediment-filled pots, and frost-fissure casts. Radar images are especially useful where infill is sandy, and the host sediments are indurated. Although geometric relations between cryostructures are more subtle than in the few contemporary permafrost environments where 3D GPR has been employed and interpretation is more difficult, the ability of 3D GPR to detect networks of fossil features warrants further investigation. The methodology complements traditional field observation and appears to have considerable potential as a tool for detecting and analyzing networks of relict subsurface permafrost features.

Keywords: cryostructures; ground-penetrating radar; New Jersey Pine Barrens; permafrost; remote sensing; thermokarst.

Introduction

The Pine Barrens of southern New Jersey is a highly weathered landscape lying 50 to 150 km beyond the maximum extent of late Pleistocene ice sheets. Its regolith repeatedly experienced cold, dry, and windy conditions during the late Pleistocene, leaving behind a long-debated fossil signature of climate change (Wolfe 1953, Newell & Wyckoff 1992, Demitroff 2007). Permafrost was present in at least three intervals during the last 200,000 years (French et al. 2007). Various periglacial geomorphic processes operated intermittently in the region, including thermal-contraction cracking, desiccation, and thermokarst displacement.

Alternating cold and warmer intervals created a complex suite of distinctive soil phenomena in southern New Jersey (French & Demitroff 2003, French et al. 2003, 2005), including sand-wedge casts, "soil wedges," and thermokarst features. We refer to these features collectively as cryogenic macrostructures (Huijzer 1993). Recent investigations (French & Demitroff 2001, French et al. 2003, 2005) indicate that the coarse-textured soils, sparse vegetation, and thin snow cover of the region during cold intervals favored deep frost penetration. Gravel-rich hilltops and proximal slopes composed of near-surface gravelly colluvium are the best locations to observe macrostructures, because the features are best preserved in such topographic situations. This study evaluates the ability of ground-penetrating radar (GPR) to image cryogenic macrostructures on both two-dimensional (2D) radar records and three-dimensional (3D) pseudo-images.

Frost-Fissure Casts

Sand-wedge casts

Ice wedges are commonplace in contemporary Arctic landscapes. This was not the case in Pleistocene New Jersey. Moisture was minimal when thermal-contraction cracking occurred in the Pine Barrens, so open fissures were mostly filled with wind-blown sands instead of ice. Primary mineral-filled frost cracks are called *sand wedges* (Murton et al. 2000). Pine Barrens sand wedges were epigenetic. They are found just below the uppermost 0.5 to 1.0 m of the soil surface, range in depth from 1.5 to 3.0 m, and average from 20 to 40 cm in width. Two distinct types of sand-wedge-cast forms are recognized in southern New Jersey, "older" (Fig. 1A) and "younger" (Fig. 1B), based on luminescence ages (French et al. 2003). Both exhibit variable spacing (10 to 40 m apart), although smaller sand-wedge casts can grade toward closer spacing.

Older sand-wedge casts typically extend 2–3 m below the surface and are found in higher landscape positions. They contain slightly indurated, fine loess-like to medium sand laminae that stand in sharp contrast to the indurated enclosing matrix, which is interpreted as a fragipan. Small amounts of near-vertically oriented gravels are present towards wedge tops. Luminescence dates indicate that these structures are Early Wisconsinan (Oxygen Isotope Stage 4 [OIS-4]), Illinoisan (OIS-6), or even older structures. Younger sand wedges are 1 to 2 m in depth and can be located across various landscape elevations. They are filled with coarse, loosely packed sand grains that that have been less abraded by wind than those found in older macrostructures. Infill is massive, and lacks the vertical foliation common to older

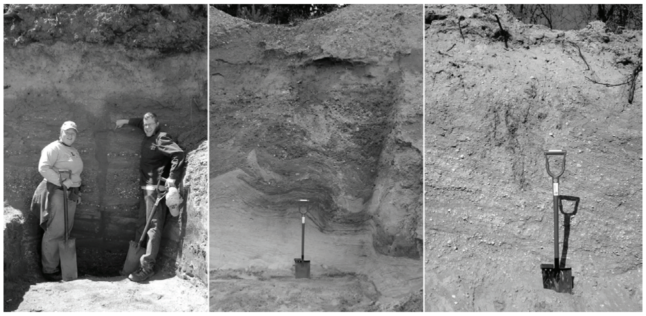

Figure 1. Examples of frost-fissure cast forms at study sites. (A) Older sand-wedge cast, Dorchester. (B) Younger sand-wedge cast, Unexpected 1. (C) "Soil wedge," Unexpected 1.

sand-wedge casts. Luminescence dating indicates that they formed during the Late Wisconsinan (OIS-2).

Soil wedges

In addition to sand-wedge casts, smaller, more closely spaced (2 to 6 m) wedge casts (Fig. 1C) have been described in the Pine Barrens (French et al. 2003). These structures are shallower in depth (<1.5 m) and often narrower in width than sand wedges. Due to their superposition on older features, these structures may be of similar age or possibly younger than the late Wisconsinan sand-wedge casts (OIS-2). Little is known of the dynamics of these features, which have been termed *soil wedges* by Romanovskij (1985). They appear to be artifacts of a dry, cold period at the end of the late Wisconsinan. Active soil wedges have been described from Siberia, but are uncommon under current climatic conditions. Their origin is attributed to cryodesiccation in a seasonally frozen soil layer. Permafrost need not be present for such wedges to form (Jahn 1975, French & Demitroff 2001).

Thermokarst-Modified Wedges

Deformed wedges

Downslope from salients and relict plateaus, the fragipan, which preserves the wedge features, dissipates and the moisture gradient increases. Accompanying this change is modification of upland sand wedges into deformed, furrow-like structures (Fig. 2A) up to 3 m by 3 m. These features are created through deformation of the original macrostructures by thaw erosion, gullying, cryoturbation, and slumping (French et al. 2005). The modifications occurred during periods of climatic amelioration and permafrost degradation, approximately 30 ka (French et al. 2007).

Sediment-filled pots

Associated features known as sediment-filled pots (Fig. 2B) occur at the intersection of deformed wedges. These kettle-like features appear as large elongated to bulbous shaped structures up to 3 to 5 m wide, extend 3 to 4 m below the surface, and extend horizontally up to a few meters in distance. Sediment-filled pots are complex vessels of sands, and silty-to-clayey-to-gravelly diamict.

Locations and Methods

Study sites

Sites investigated in this study are located in two commercial sand and gravel operations in southern New Jersey where various cryogenic macrostructures have been identified. The sites are referred to as the Dorchester (39.29013˚N, 74.95023˚W) and the Unexpected (originally named Brimfield Crossing) (39.56707˚N, 74.91448˚W) sites. The Dorchester site is in an area of Aura sandy loam, with 0 to 2 percent slopes. The Unexpected site is located in an area of Downer loamy sand, with 0 to 5 percent slopes. The very deep, well-drained Aura and Downer soils were formed in unconsolidated alluvial sediments on the Outer Coastal Plain's Bridgeton Formation. Aura soils are moderately deep (50 to 100 cm) to fragipan. Aura is a member of the coarse-loamy, siliceous, semiactive, mesic Typic Fragiudults family. Downer is a member of the coarse-loamy, siliceous, semiactive, mesic Typic Hapludults family. At the Unexpected site, the upper 25 to 50 cm surface materials had been removed in preparation for mining. A very dense and compact B horizon is also present at the latter site.

Field methods

Survey grids were established at each site. At the Dorchester site, a 2.5 × 2.5 m grid was established immediately behind an excavation wall that contained an older sand-wedge cast. Traverse-line spacing was 25 cm. Two grids were established at the Unexpected site. A 20 × 15 m grid was established near an excavation wall containing deformed wedges, soil wedges, and sediment-filled pots. A 20 × 13 m grid was established near an excavation wall that contained younger sand-wedge casts and soil wedges. For each of these grids, the traverse line spacing was 50 cm.

All grids were established across recently cleared, accessible, and level areas adjacent to excavation walls. For each grid, two parallel axis lines were laid out and spaced either 2.5 m (Dorchester) or 20 m (Unexpected) apart. Along these two parallel axes, survey flags were inserted into the ground at a spacing of 25 cm (Dorchester) or 50 cm (Unexpected), and a reference line was extended between matching survey flags on opposing sides of the grid using a graduated rope. GPR traverses were conducted along this reference line (the X-axis). A 400 MHz antenna was pulled along the graduated rope, which was stretched across the soil surface, and, as it passed each 50 cm (Dorchester) or 100 cm (Unexpected) graduation, a mark was impressed on the radar record. Following completion of a transect, the reference line was moved to the next pair of survey flags to repeat the process.

The radar unit is the TerraSIRch Subsurface Interface Radar (SIR) System-3000, manufactured by Geophysical Survey Systems, Inc. (GSSI; Salem, New Hampshire, USA). The system consists of a digital control unit (DC-3000) with keypad, SVGA video screen, and connector panel, weighs about 4.1 kg (9 lbs), and is backpack portable. The system requires two people to operate.

The *RADAN for Windows* (version 5.0) software program developed by GSSI was used to process the radar records. Processing included: setting the initial pulse to time zero, color table and transformation selection, marker editing, distance normalization, range gain adjustments, high-pass filtering, and migration. The Super 3D QuickDraw program developed by GSSI was used to construct 3D pseudo-image of the radar records.

Calibration

Ground-penetrating radar is a time-scaled system measuring the time required for electromagnetic energy to travel from the antenna to an interface (e.g., soil horizon, stratigraphic layer) and back. To convert the travel time into a depth scale, either the velocity of pulse propagation or the depth to a reflector must be known. The relationships among depth (D), two-way pulse travel time (T), and velocity of propagation (v) are described in the following equation (Daniels 2004):

$$v = 2D/T \tag{1}$$

The velocity of propagation is principally affected by the relative dielectric permittivity (ε_r) of the profiled material (s) according to the equation (Daniels 2004):

$$\varepsilon_r = (C/ v)^2 \tag{2}$$

where C is the velocity of propagation in a vacuum (0.298 m ns^{-1}). Velocity is expressed in meters per nanosecond (m ns^{-1}). In soils, the amount and physical state (temperature dependence) of water have the greatest effect on ε_r and v. The velocity of propagation through the upper part of the soil profile at each grid site was based on the measured depth and the two-way pulse travel time to a known buried reflector, and using equation (1). At the Unexpected Site, the estimated velocity of propagation was 0.119 m ns$^{-1,}$ and the relative dielectric permittivity was 6.3 m ns^{-1}. At the Dorchester Site, the estimated velocity of propagation was 0.136 m ns$^{-1,}$ and the relative dielectric permittivity was 4.8. Daniels (2004) has detailed GPR processing techniques for those who wish to go beyond the scope of this paper.

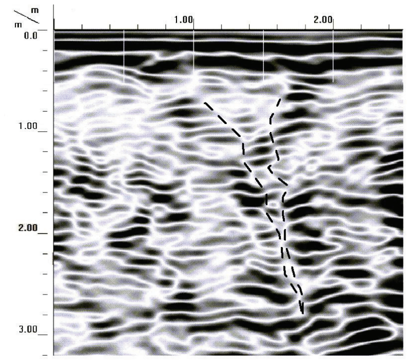

Figure 3. An older sand-wedge cast is faintly expressed in this radar record from the Dorchester site.

Results

Dorchester site

The radar record in Figure 3 was obtained immediately behind an excavation wall in which a well-documented sand-wedge cast (French & Demitroff 2001, French et al. 2003) was exposed. The depth and distance scales are expressed in meters, with depth based on an estimated velocity of propagation of 0.136 m ns^{-1}. A majority of the radar reflections are of moderate to high signal amplitude (darker images) and appear nearly level to slightly inclined. These characteristics are considered typical of fluvial to marine-marginal Coastal Plain sediments. However, these reflectors are not laterally continuous, but appear segmented, with noticeable breaks appearing on the radar record. On radar records, segmentation can be caused by truncation of layers, lateral gradation in the degree of contrast between reflectors, and/or superposition and cancellation of reflected signals.

A sand-wedge cast can be identified on this radar record between the 1.0 and 1.6 m marks at the surface (Fig. 3). Segmented lines highlight the inferred boundary of this sand wedge. The fissure is most clearly expressed in the upper meter of the radar record, where the loosely cemented, smaller grain-sized infill contrasts with the encircling very hard, indurated, and coarser sandy-gravelly matrix. Sand wedges display a wide variety of geometric forms and structures. They may consist of massive or highly stratified materials, have sharp and planar to diffuse and irregular boundaries, and can be wedge-shaped and tapered to irregular, or bulbous (Murton et al. 2000). The morphological characteristics of older sand-wedge casts, in particular, do not favor radar interpretations, owing to their, narrow width and indurated infill. Below depths of about 1 meter, the thin width, tortuous vertical descent, and variable physical properties of the wedge casts contribute to poor, ambiguous boundary expression with the host materials.

In Figure 4 an exposed sand-wedge cast is located on the wall of the excavated pit. All radar traverses were conducted parallel to the X-axis (right foreground). Radar traces were sampled more continuously along this axis, and reflectors are more strongly represented, with little distortion, along it. Along the Y-axis, however, data were not recorded continuously but were instead interpolated over a 25 cm

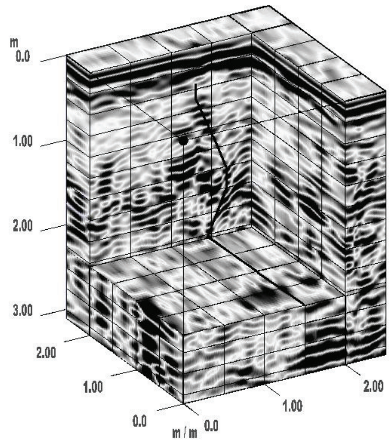

Figure 4. A 3D pseudo-image cube of the Dorchester grid area, with a 2.0 by 2.0 by 2.3 m inset removed.

interval (the distance between radar traverses). As a result, some subsurface information was lost during interpolation, and features appear smudged, less resolved, and more generalized along the Y-axis.

In Figure 4, a bold dashed line emphasizes the inferred centerline of the ancient sand-wedge cast on the back wall and base of the cutout section. The wedge is more evident on the back wall of the cutout. Along its base, only a very weakly expressed and ambiguous trace of very low signal amplitudes (white color) marks the inferred location of the wedge. This frost crack, while evident, was not clearly expressed on either the 2D radar records or the 3D pseudo images prepared from data collected with the 400 MHz antenna. Interpretations are ambiguous and, without knowledge of its location, the fissure may have been missed using GPR. Older sand-wedge casts often defy visual detection as well, requiring careful site preparation and prior familiarity with feature identification. Wedge borders are often faint, with little contrast between infill and enclosing sediments. Wedge outlines may not be fully apparent until hours after excavation. Upon exposure to air, the loose sandy infill dries more rapidly than denser enclosing sediments, creating visible differences in tonal contrast.

Unexpected site

At the Unexpected site, two small grids were established near areas of known cryogenic macrostructures. One grid was established near an area underlain by younger sand-wedge casts and soil wedges that were traced backward and downslope along an excavation wall. Figure 5 is a 3D pseudo-image of the 20 m × 13 m grid area. In this image, the excavation wall parallels the X-axis (right foreground). A 12.0 m × 10.0 m × 1.0 m inset has been removed. All radar traverses were conducted parallel to the X-axis.

The grid was established across an area recently cleared of forest vegetation. In Figure 5, the occasional, high-amplitude, hyperbolic reflections apparent in the upper 70 cm of the image may represent larger tree roots. In general, subsurface reflectors apparent in this pseudo-image suggest the dominance of linear, level to slightly inclined interfaces. These reflectors are presumed to represent the boundaries of contrasting stratigraphic layers within the fluvial sediments.

Along the back wall of the cutout, two perceptible, high-amplitude concavities with downturned reflection patterns are apparent at depths ranging from 70 to 100 cm (“A” in Fig. 5). These features probably represent a continuation of the younger sand-wedge casts clearly visible in the front-wall exposure. Though discontinuous, faint, and somewhat ambiguous, these structures appear to form lineations that extend across the base of the cutout. These lines appear to represent the traces of wedges running parallel to the slope. Beneath the traces are areas with more complex reflector patterns on the front wall of the diagram (right foreground). This plot represents a front-to-back view of a transitional zone, in which sediments that formerly contained little ice (foreground) grade into those that were once ice-rich (30 m beyond the study plot)(Demitroff 2007).

Thermokarst involutions observed by French & Demitroff (2001) and French et al. (2005) were just 30 m downslope from the back of this study plot. Fissures, marked in bold dashed lines on Figure 5, are oriented directly toward these deformed sediments. Recent excavations in this vicinity revealed a younger sand-wedge cast (Fig. 1B) superimposed upon a load-deformed portion of an involution (Demitroff 2007). The underlying thermokarst-affected layer appears to have been deformed by thawing of an ice-rich wedge aligned with the slope-oriented fissures demarcated on the radar image. Older frost cracks appear to have been modified along a moisture gradient. Forms are modified gradually along such gradients, from sand wedges to deformed wedges to thermokarst involutions. Younger sand-wedge casts and soil wedges are little deformed, because thermokarst appears not to have developed during late Wisconsinan (OIS-2) warming (French et al. 2007). Although linkages may be extrapolated from the radar image, their true relationships will soon be revealed as the intervening 30 m of forest is removed and quarrying continues. In the Pine Barrens, younger wedge structures commonly form within earlier cryogenic macrostructures, as these are the most likely locations for

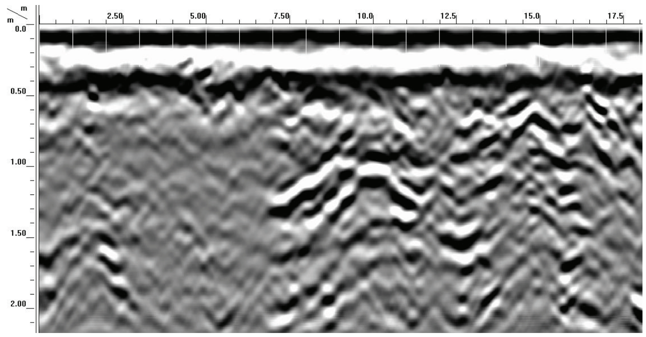

Figure 6. The radar record from the Line Y =10 m at the second Unexpected site.

stress to be relieved during episodes of cracking.

At the Unexpected site, a second grid was established near an exposure containing soil wedges, modified sand wedges, and sediment-filled pots. An 18 m section of a radar record from this site is shown in Figure 6. The number, intensity, and geometry of subsurface reflectors vary across this radar record. The left part of this diagram is comparatively devoid of high-amplitude reflectors, and may be underlain by more homogenous and less anisotropic materials. The right part of this diagram contains multiple, irregularly shaped and sized reflectors, which form a distinct zone about 10 m wide. However, most individual reflectors within this zone are less than 2 to 3 m wide.

The number and complexity of reflectors confound individual interpretations. It is assumed that this portion of the radar record consists of multiple strongly deformed layers and inclusions of soil materials that vary in grain-size distribution, moisture content, and/or density. This portion of the radar record is believed to represent a complex of cryogenic macrostructures. The difficulty in using a planar view is the diverse orientations of many wedge-like features. If viewed from an oblique angle, the radar image may be difficult to interpret. In some cases, the upper portion of a wedge may be perpendicular to the ground, and the lower portion sharply angled.

Figure 7 is a 3D pseudo image of a 20 m × 15 m survey area at Unexpected. In Figure 7, all radar traverses were conducted parallel to the X-axis (right foreground). The base of the cutout contains a diversity of both linear and curved features that vary in width and are not evenly distributed beneath the grid area. Linear features were interpreted as representing deformed wedge furrows (Fig. 2A). Large circular-to-elongate patterns evident on the base of the cutout are interpreted as sediment-filled pots (Fig. 2B).

Figure 8 documents the excavation wall when it had progressed midway across the former GPR grid site. Several well-defined deformed wedges (1st, 2nd and 5th arrows, left to right) and sediment-filled pots (3rd and 4th arrows) are exposed in the pit wall (Fig. 8). Dark patches mark their presence along the diagonal line. The fifth feature is just outside the study bounds. These features support earlier GPR interpretations. The loose, light-colored, aeolian structure-fill markedly contrasts with the indurated, orange/

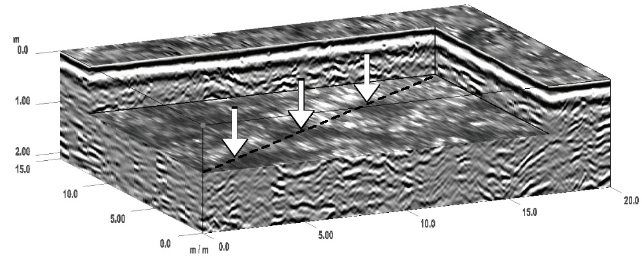

Figure 7. A 3D GPR pseudo-image from the grid site. In this image of the 20 m x 15 m survey area, a 17 m x 12 m x 0.95 m volume has been removed. The dashed diagonal line indicates the location of the wall section of Figure 8 when the photo was taken. Three white arrows mark the location of sand-filled cryogenic macrostructures marked by the inner arrows on Figure 8.

Figure 8. The second Unexpected site with half the soil diagonally removed by excavation. Arrows indicate the locations of larger (eolian) sand-filled cryogenic macrostructures. Smaller periglacial structures occupy the intervening space.

red-colored host materials. Here, the macrostructures are infilled with fine to medium sand with some sandy gravel diamict. Their loosely packed materials contrast with the indurated enclosing matrix of sands and gravel (French et al. 2003). The indurated layers helped to preserve these features as permafrost thawed (French et al. 2005).

Conclusions

GPR has been used extensively in glacial and periglacial environments (Munroe et al. 2007, Woodward & Burke 2007), where ground ice provides sharp radar reflection contrast with other frozen sediments. Near Barrow, polygonal ice -wedge networks provided impressive geometric patterns in 3D radar images (Munroe et al. 2007). This study indicates that not all paleoperiglacial landscapes are so amenable to ground-penetrating radar application. Relict macrostructures are problematic: (1) primary and secondary fill often provides little contrast with host sediments; (2) subsequent, often polycyclic, modification creates complex, indistinct boundaries; (3) many relict structures are smaller than their Arctic counterparts; and, at least in the Pine Barrens, (4) complete geometric expression of frost-crack polygons is absent. Although rarely observed in plain view, deformed wedge/furrows may form incomplete polygons or lineations parallel to the slope gradient. The absence of well-defined polygons in the uplands indicates that conditions were marginal for their development (French et al. 2003).

Ground-penetrating radar can be used to help locate and characterize various buried cryogenic macrostructures. Uplands of the Pine Barrens are a protean landscape, an epigenetic tableau that was repeatedly subjected to the waxing and waning of ice-marginal periglacial conditions. The broad suite of composite cold-climate structures present can be baffling, even with careful field scrutiny by experts. In the absence of heavy excavation equipment, the well-developed dense fragipan of the Pine Barrens drastically limits a three-dimensional perspective of cryogenic macrostructures. In lieu of arduous quarrying, radar records are a useful tool for use in identifying the presence, size, and directional trend of generic structures. However, only careful excavation can reveal a structure's origins with certainty.

The study areas have favorable soil properties (i.e., low in clay, soluble salt, and moisture content) for the use of GPR. The features under investigation often lack sufficient contrast and/or have geometrical forms that limit the amount of energy that is reflected back to the radar antenna. Owing to the limited size and complexity of many cryogenic macrostructures in southern New Jersey, some of these features are more difficult to recognize than in other regions such as in Wisconsin (Doolittle, unpubl.).

In southern New Jersey, older sand-wedge casts are narrow and indurated, making detection by GPR alone difficult. Delineation is often problematic even under visual scrutiny in pit sections. The steep inclination and tortuous nature of the wedges produces weak, nearly indistinguishable reflections that are difficult to trace laterally in plan view and preclude recognition of the full extent of their traces. Narrow wedges can be indistinguishable on radar records. Wider deformed sand wedges and related thermokarst features are much more amenable to interpretation. These structures are more nearly linear and are often slope-aligned, producing recognizable GPR images. Boundaries between cryogenic macrostructures and host sediments can be complicated where sloughing of sediments and reworking from the sides has occurred through thaw erosion, gullying, and slumping, especially with deformed wedges and sediment-filled pots. Intricate arrangements of segmented, inclined, or contorted subsurface reflectors, separated by abrupt vertical fissures, may serve to identify these features on radar records.

Acknowledgments

Students from the University of Delaware Geography and Geology Field Geomorphology course in Spring 2006 provided field assistance. Aggregate extraction operations access was kindly provided through Dave Hergert (Mays Landing Sand and Gravel) and another operator who wishes to remain unacknowledged. MD thanks both for long-term support of his field investigations. Manufacturers' names are provided for specific information, and use does not constitute endorsement.

Tomodensitometric Analysis of Basal Ice

Matthew Dillon, Daniel Fortier, Mikhail Kanevskiy, Yuri Shur
University of Alaska Fairbanks, Institute of Northern Engineering, Fairbanks, Alaska, U.S.A.

Abstract

Basal ice of contemporary glaciers was studied in an attempt to find convincing evidence of a genesis of buried glacial ice in permafrost. As a part of this study, tomodensitometric scans of basal ice from the Matanuska Glacier in Alaska were made using a micro-computed tomographic scanner. Scans are an excellent complement to field studies of cryostructures because of the level of detail obtained regarding the ice distribution. Two- and three-dimensional models were generated from the scans and were used to study patterns of ice distribution, the volume of ice, sediment, and gas inclusions.

Keywords: basal ice; buried glacial ice; computed tomography; cryostructure; Matanuska Glacier; x-ray.

Introduction

X-ray computed tomography, also known as tomodensitometry, has been widely used in two- and three-dimensional (3-D) visualization of the internal structures of various materials since its inception (Ambrose & Hounsfield 1973). Tomodensitometry is a computer-controlled x-ray photography procedure. By taking a single x-ray photo from multiple angles, a 3-D interpolation of the interior of the sample can be revealed. Tomodensitometry usage is expected to undergo sustained growth due to the relatively low cost of scanner apparatus, the non-destructive aspect of its application, the clear penetration of x-rays into samples, and the high resolution imaging potential related to advances in computing power. One of the immediately recognizable benefits of tomodensitometry is that it is a non-destructive technique. Non-biological objects, such as soils, remain structurally unaffected by x-ray radiation.

In soil sciences, tomodensitometry has been used in multiple ways. Porosity has been calculated by separating phase components post-scanning by Alshibli et al. (2006) and Rachman et al. (2005). By various methods, many typical soil index properties have been determined, such as bulk density distribution, water content distribution, and mineral type distribution (Phogat et al. 1991, Macedo et al. 1998, Rogasik et al. 1999, Pralle et al. 2001, Pedrotti et al. 2004). Computer simulations using real-world geometries of soils for determination of hydraulic conductivity have been performed by Fourie et al. (2007) and Bastardie et al. (2003).

In fresh-water ice studies, tomodensitometry has been used to characterize air inclusions in river ice to aid in synthetic aperture radar interpretation of river ice (Gherboudj et al. 2007).

In permafrost studies, Torrance et al. (in press) used tomodensitometry to study the pattern of ice lenses in soil. Calmels et al. (2004, 2008) used tomodensitometry to image faulted ice and sediment layers in palsas, to infer direction of soil freezing and to provide volumetric content of ice, gas, and sediment components. The thresholding technique used to determine the volumetric contents and the error associated with it has not, however, been specified.

This paper presents some results of tomodensitometric studies of basal ice of glaciers. To the best of our knowledge, this is the first time that this technique has been used to study the structure of basal ice of glaciers. Basal glacier ice is formed at the bed of glaciers due to several processes, such as entrainment and incorporation of sediments by overriding ice, regelation, glacio-hydrologic supercooling, glaciotectonics, basal freeze-on, ice segregation, and downward propagation of cold temperatures in the sediment at the glacier bed (Sharp et al. 1994, Knight 1998, Lawson et al. 1998). We want to develop a classification of basal ice cryostructures for permafrost studies to identify and to distinguish basal glacier ice buried in the permafrost from other types of massive ice (e.g., massive segregated ice and injection ice); however, this paper only addresses the application of tomodensitometry to basal ice analysis. It is focused mainly on the technical aspects of 2-D and 3-D imaging of the samples in order to extract key parameters such as basal ice structure and the volumetric contents of its phase components.

Methods

Sampling

Field work was conducted at the Matanuska Glacier, Alaska (61°46′11″N, 147°44′3″W). We logged, sketched, and photographed the cryofacies and cryostuctures of several basal ice exposures. The description of the basal ice cryostratigraphy is beyond the scope of this paper, and those results will be presented elsewhere. Cores were retrieved from the exposures using a CRREL-SIPRE corer barrel. The cores were covered in plastic wrap and aluminum foil and brought back frozen to the laboratory.

In the lab, cores approximately 50 mm in diameter and 50 mm tall were extracted from the large-barrel cores to accommodate the maximum sample size that the scanning equipment can accept. These smaller cores were wrapped in plastic wrap to prevent sublimation, as well as in cellulose insulation, encased in a hollow plastic container, and kept in a freezer at -10°C

Tomodensitometry

The scans were acquired with a Skyscan 1172™ scanner, equipped with a rotating scan platform, a stationary camera, and an x-ray source. The scans were commenced in a cold room environment at -6°C. In order to ensure adequate "penetration" of the x-rays through dense materials, the scans were performed at 80 kV and 100 µA, the highest voltage and current permitted by the system. An exposure time of 1264 ms, a rotation step of 0.3°, and a scanning domain of 360° were experimentally determined to maximize scan quality. The camera's pixel size was 34.46 µm.

Image processing methods

The scanner results are a "stack" of grayscale images that represent the total volume for the sample. Reference volumes 27.57 mm high by 27.57 mm wide by 13.71 mm deep were selected from each scanned core for streamlined analysis. The resized samples had a pixel size of 68.93 µm. Each image is 400 pixels by 400 pixels and 1 pixel thick. One unit pixel in the image is also called a voxel for 3-dimensional image data. Each voxel is assigned a grayscale value based on its density relative to that of gas—low density values are black pixels with a grayscale value of 0; high density values are white pixels with a grayscale value of 255. All the shades of gray vary linearly between grayscale values of 0 and 255. The Mathworks MATLAB R2007a™ Image Processing Toolbox software was used to process the volume's grayscale values that are obtained from the scanner.

The samples contain three components: gas, ice, and sediment. These components were separated in the scans using a thresholding technique which reassigns a range of

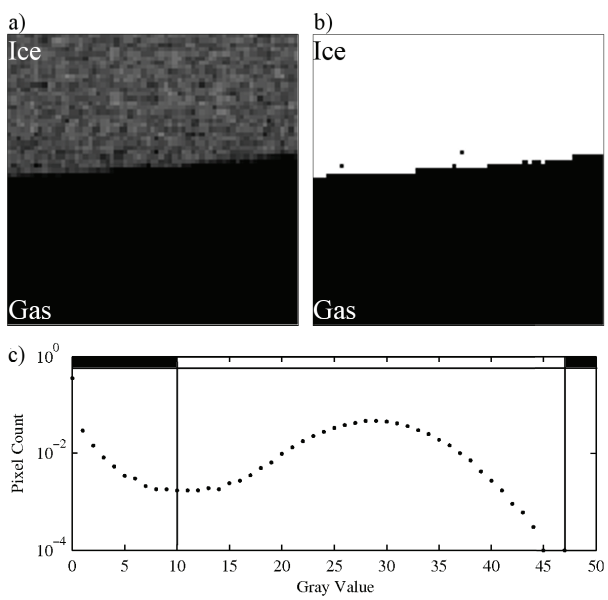

Figure 1. Scan images of an ice cube edge made of de-aired and de-ionized water. a) Cross sectional scan image of ice and gas before thresholding (varying gray values represents ice, black is gas). b) Cross sectional scan image of ice and gas after applying threshold limits at 10 and 48. c) Histogram of grayscale values for the cross section, threshold limits of 10 and 48 define grayscale values for ice.

grayscale values to white, while everything outside of this range is black. Threshold values were determined from the grayscale histogram on scans of ice made of de-aired and de-ionized water (Fig. 1a). By determining the minima of the gray values on the histogram (Fig. 1c), the limits of thresholding can be applied at these points for a binary image (Fig. 1b). For this study, ice was found to generally range between 10 and 48 in grayscale values, based on several scans of pure ice. Therefore gas was defined as 0–9, ice as 10–48, and sediment as 49–255 grayscale values. The threshold values were applied to the raw scan images (Fig. 2a) to create component reduced images (Fig. 2b).

Volumetric content profiles of gas, ice, and sediment were generated in an iterative process by thresholding each individual slice. Microvariations with height were derived by obtaining a content profile for a cryostructure. The volumetric contents for each component were then calculated using

$$\%Volume_{component} = \frac{\Sigma Voxels_{x-y}}{\Sigma Voxels_{0-255}} \qquad (1)$$

where x and y are the range of grayscale values for the component (0–9 for gas, 10–48 for ice, 49–255 for sediment).

We created 3-dimensional models in MATLAB from the 2-dimensional cross section images (Fig. 3). To smooth the data for enhanced processing, and to attempt to account for the partial volume effect (the probability that more than one phase can exist in a single voxel), cross sectional images were eroded and dilated with a kernel of 1 pixel in 2-D (Fourie 2007). The models were created using the "isosurface" function, which creates a three-dimensional contour line representing an area of constant density.

Volumetric component content profiles for two samples are presented in Figure 4. A set of profiles for each component was generated for each sample by determining the percent area occupied by each component in each cross sectional image. By calculating the average for each component profile in each sample, an approximation of the sample's typical component contents was determined. The standard error, σ_{mean}, was calculated by using the standard error of the mean method

$$\sigma_{mean} = \frac{\sigma}{\sqrt{n}} \qquad (2)$$

where σ is the standard deviation of the profile, and n is the number slices in the profile.

Results

Many samples with different cryostructures were sampled and scanned, but for the sake of illustration, only one cryostructure will be presented. This type of cryostructure is called *suspended-intergranular* (Fortier et al., in submission) which defines a cryostructure with the sediments located between ice crystals. Two samples (I and II) of this basal

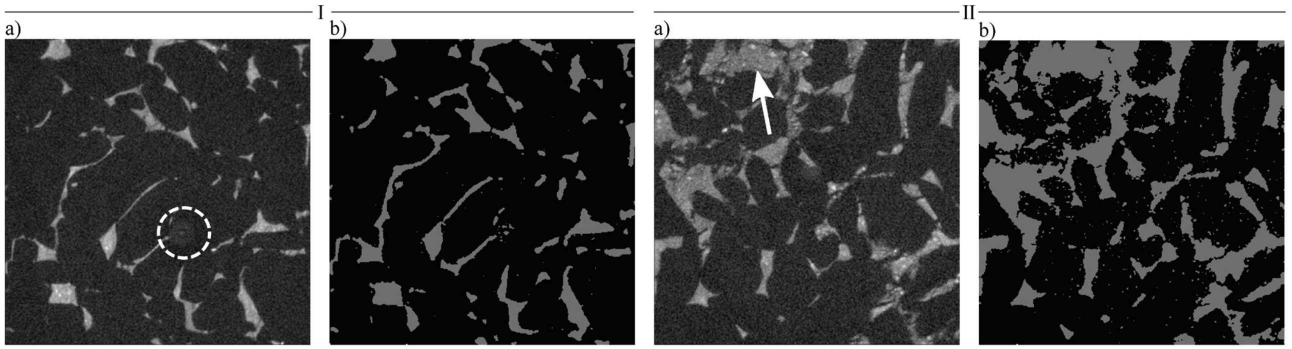

Figure 2. Cross sections from 2 scans of basal glacier ice. a) Raw scans of suspended-interganular cryostructure. Coarser and denser mineral grains are observable (arrow). A ring artifact (circle) is observable on both scans; b) processed images after thresholding showing the three phase components (air is not visible in images at this scale).

ice are presented in Figure 2. Both samples are very ice-rich with volumetric amount of ice 86% for sample I and 66% for sample II.

Figure 2a for both samples shows a raw scan image of the suspended-intergranular cryostructure. In the upper left corner of Figure 2a for sample II, the various mineral grains (see arrow) in the sediment may be observed due to the varying densities as reflected in the grayscale. A ring artifact (circle) is observable on the raw scans, as well (Fig. 2a, sample I).

After applying the threshold values, the complexity of the scan image may be decreased by reducing it into its 3 phases for structural analysis. Figure 2b for both samples shows the results of thresholding. The grey, black, and white represent the sediment, ice, and gas, respectively. Gas bubbles (white) are hardly visible due to their small size and low concentration. The ring artifact has been suppressed by the thresholding technique in Figure 2b.

Figure 3 is a series of 3-D models of the samples with the suspended intergranular cryostructure presented in Figure 2. Figure 3a models the ice, sediment, and gas components together. Figure 3b models the ice component only and shows the ice-rich nature of the samples. Figure 3c models the sediment component only and shows that the sediments are located in between the sub-rounded grains of ice (or ice crystal aggregates).

By applying Equation (1) to each cross section, volumetric profiles for the samples were produced (Fig. 4). The total volume of each phase is given for each cross section (because each cross section has a thickness of 1 voxel) taken along the x-y plane and plotted against the vertical location. The profile for the ice (Fig. 4a) shows a 10% decrease and a 20% increase in ice content from the bottom to the top of samples I and II, respectively, while the sediment (Fig. 4b) shows a 10% increase and a decrease of 20% in samples I and II, respectively. The gas (Fig 4c) remains close to constant (0.10–0.20% and 0.25–0.55%, I and II, respectively) in content which indicates a fairly uniform distribution in the samples. By applying Equation 1 to the entire reference volume, the total volumetric content for each phase was determined (Table 1).

Table 1. Average volume per component and associated error.

	Component Volume (%)		
	Ice	Gas	Sediment
Suspended Intergranular I	85.50±0.16	0.16±0.01	14.34±0.16
Suspended Intergranular II	66.05±0.38	0.38±0.01	33.58±0.39

Discussion

Settings should be consistent, because scan results are highly dependent on the scanner settings. Appropriate settings for voltage, current, pixel size, and exposure time must be determined via calibration with a known substance, such as pure ice.

Ice scans, however, require a sub-freezing temperature-controlled environment to avoid thawing of the sample during testing. Under these conditions, detailed testing and evaluation of an individual sample can be repeated. This is a challenging operation because temperatures colder than -6°C often resulted in mechanical problems in the scanner apparatus, such as the sample stage freezing in place instead of rotating, and the sample door freezing open.

By using a computational software package, such as MATLAB™, quantification of the phase components is a powerful alternative to traditional destructive lab techniques, such as oven drying of samples.

Thresholding effects

Determination of appropriate levels for thresholding is the most critical aspect to this study, as well as the most difficult. Under- and over-estimation of a component can occur if the selected threshold range is too small. While calibration with ice serves as a good reference point, it is not perfect. Scan output data is based on the attenuation of x-rays through a sample; however, the attenuation is not only dependent on the material it is passing through, but on the surrounding materials at any given point, as well. The results of overestimating the selection are exemplified by the slight difference in the boundaries between the ice and sediments in Figure 2b.

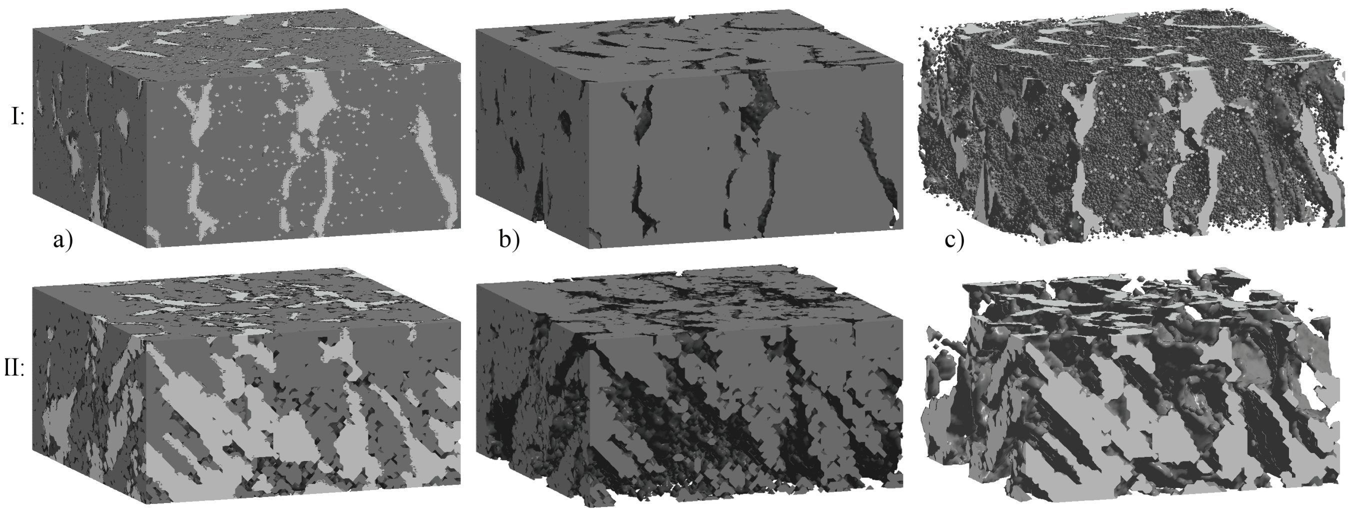

Figure 3. Three-dimensional images created for samples I and II. a) Combined ice and sediment, b) ice component, c) sediment component. Volume dimensions: 25.57 mm by 27.57 mm by 13.71 mm. It is important to note that the 3-D renderings have lighting effects on them. This creates the shading observable on the models which make it possible to distinguish depth in the image.

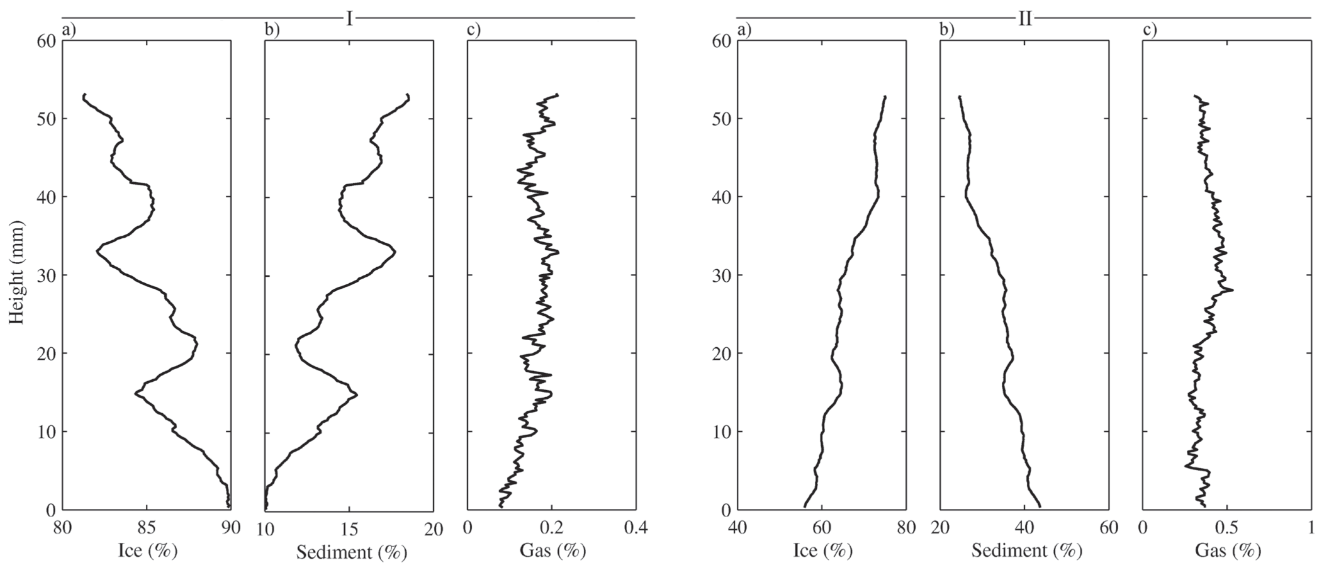

Figure 4. Volumetric content of ice, soil, and gas phases in samples I and II with suspended-intergranular cryostructure.

Cryostructure visualization and phase component quantification

Traditionally, cryostructures are evaluated and classified via visual inspection, typically from cores of frozen soil. When viewing an exposure, the investigator is usually limited to a 2-D view of the cryostructure. The scanner results can be viewed in 2-D "slices," which allow for an in-depth comparison with detailed exposure descriptions from the field.

After applying the limits of thresholding to the cross sections, it became easier to focus on the general structures and patterns in each sample. However, identification of mineral grains is not possible anymore because the thresholding lumps the full range of mineral densities together. A solution to this would be to apply more threshold limits in a series of steps, to show varying degrees of mineral density, however, this study focused on the cryostructure of the sample, so this was not performed. Thus, a side-by-side analysis of the raw scans images and the images with thresholding in 2-D is very beneficial. For instance, Figure 5 shows well the presence of sand grains in the sediments which can not be observed on a processed image. On the other hand, visualization of gas bubble distribution in a section is better realized with a processed scan signal.

Visualization of cryostructures was greatly aided by utilizing both cross sectional images, and 3-dimensional isosurfaces. Three-dimensional spatial relationship between the phase components is a great advantage of tomodensitometry, because of the ease of generating 3-dimensional models. Gas bubble distribution in ice has traditionally been a very difficult subject to study, because of the inherent problems and time requirements related to generating thin sections

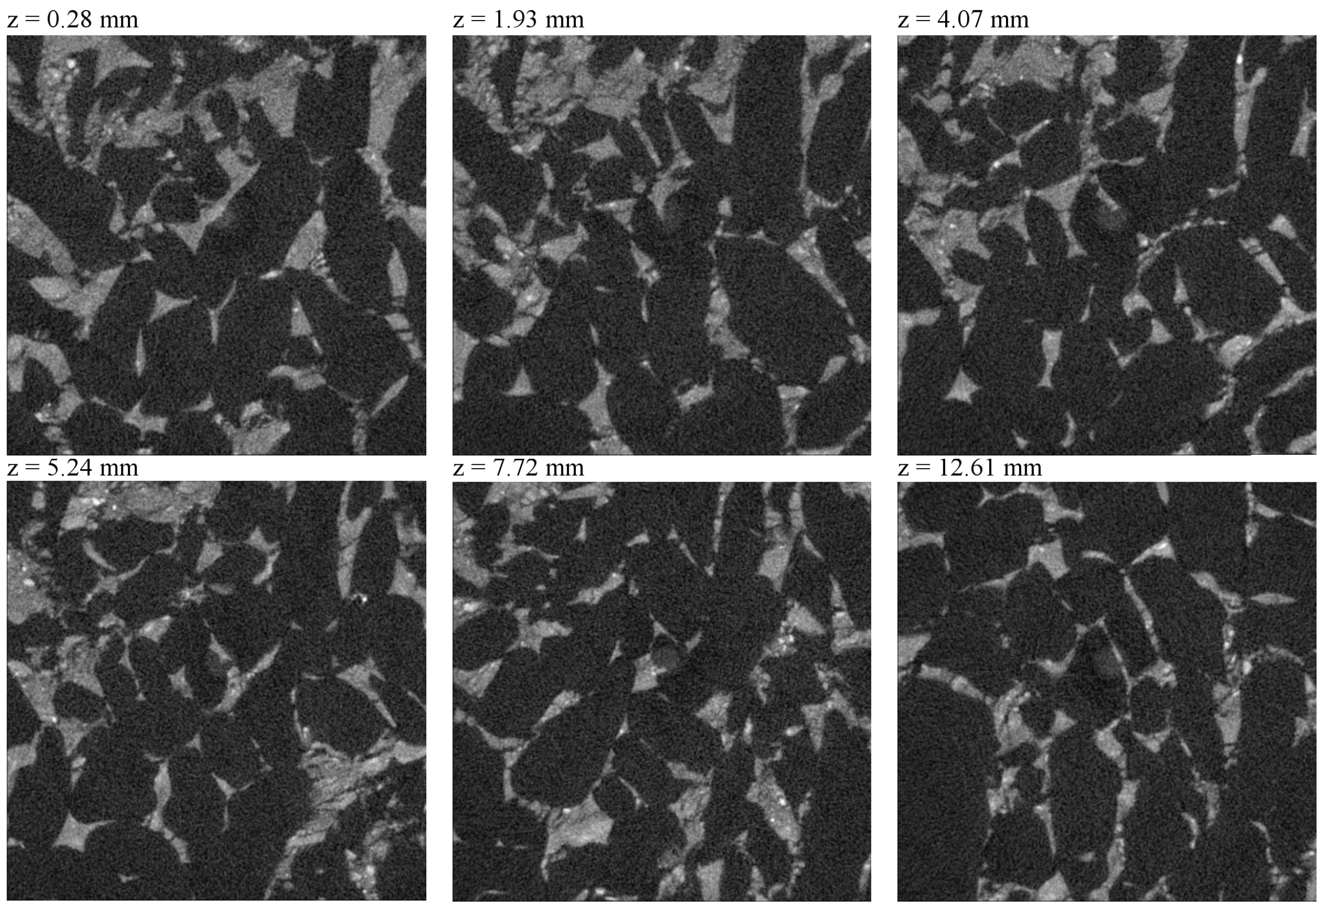

Figure 5. Sequence of cross sectional height for sample II with suspended-intergranular cryostructure. Dark areas are less dense materials such as gas and ice, while light areas are denser, such as different minerals in the sediments. All image dimensions are 27.57 mm by 27.57 mm. The position of a cross section in the sample is denoted by the "z" measured from the bottom of the sample.

(Gherboudj et al. 2007). The cross sectional images show the spatial distribution of components against each other. By comparing cross sections throughout an entire sample (Fig. 5), evaluation of structure and phase component variation along the sample's height is possible.

Understanding how components relate and are distributed in a volume is easily aided by the isosurfaces. These are models of the boundary between one component, and the rest of the sample. These models can "strip away" all of the other components in a sample, and isolate one to have a better representation of its 3-D structure. In Figure 3b, for instance, it can be observed that the samples are mainly composed of ice, which is typical of a suspended cryostructure. The ice content and its geometry typically vary between two samples. In Figure 3c, it can be observed that the sediment particles are located at the junction and in-between the ice grains. This is easier to see than in the 2-D scans. By analyzing a large number of samples, statistics can be derived to obtain a range of values for a given cryostructure type.

The determination of the individual components relies on the output from the thresholding of the original scan data. Once the components have been divided, the calculation of their volumetric content are found using Equation 1.

Traditionally, in the lab, methods for the calculation of volumetric ice content for frozen soil cores requires measurements of the bulk volume of a core, then oven drying the sample, determining the gravimetric water content, and determining, finally, the volumetric ice content. By utilizing the methods presented, all of the intermediate steps may be bypassed, and, the original specimen is completely preserved.

Conclusions

X-ray computed tomography can become a powerful complementary method to traditional field observations and laboratory work. Cross sectional images generated from scans may be viewed as raw images and as images with thresholding. Raw cross sections have the advantage of showing a complete picture of any plane in the sample. Cross sections that have thresholding allow for more direct interpretation of structure in the sample, which aids in cryostructure classification. Three-dimensional models reveal variations of cryostructures in three-dimensions, a key element for generating a new classification. In terms of cryostructure classification, this would be one more method in the field of cryostratigraphy.

Tomodensitometry has applications in many other cold region studies, such as evaluation of cryostructures in permafrost, and evaluation of river ice, icings, glaciers, and sea ice. Besides being an important tool for research, the practical applications for determining component contents is important in many frozen ground engineering design considerations.

Acknowledgments

We would like to thank the UAF Research Center's Undergraduate Research Symposium and Flint Hills Resources for providing funds to M.D. for this study and Alaska EPSCoR for providing support for technical training. The authors are appreciative of the support received by Skyscan, Inc. This work was supported by the USA National Science Foundation by grants EPS-0346770 to D.F. and M.K., and ARC-0454939 to M.D. and Y.S. New Patterns of Permafrost Occurrence in a Mountain Environment, Based on an Example from the Tatra Mountains, Poland, and Abisko Area, Sweden

Wojciech Dobinski

University of Silesia, Faculty of Earth Sciences, Department of Geomorphology, ul. Będzińska 60, 41-200 Sosnowiec, Poland

Abstract

At present, research into the occurrence of mountain permafrost concentrates on its relationship to the currently changing climate. Modern research shows that in northern Scandinavia the permafrost extent is much wider than it has been believed so far. Comparative studies on the occurrence of permafrost in the Tatra Mountains and in the Abisko area concern both active and fossil permafrost. A set of geophysical research into permafrost of the Tatra Mountains and the Abisko area conducted in similar geological and climatic conditions reveals that two similar high-resistivity anomalies can be distinguished in both places. Shallower anomalies were interpreted as permafrost which is connected with current climate (contemporary permafrost). Deeper ones were interpreted in two ways: in the Tatra Mountains, as a layer of dry, much older, probably fossil permafrost, whereas in the Abisko area, as thermal differentiation within the permafrost layer occurring there, which probably indicates climate variability in the Holocene.

Keywords: Abisko; electroresistivity; fossil permafrost; geophysics; permafrost occurrence; tomography; Tatra Mountains.

Introduction

Recent decades show an increased interest in issues related to permafrost occurrence in mountain environment (Harris 2001, Gorbunov 2003, Haeberli 2003). The main research concentrates on the most current problem in earth sciences, which is climate warming and its impact on the components of earth surface. The frozen lithosphere (cryolithosphere), including seasonal snow cover, permafrost, glaciers and continental glaciers, as well as floating ice (Dobinski 2006), is the most sensitive to climate change. The predicted consequences of climate warming and their social aspect result in research being predominantly focused on the active layer and subsurface layer of permafrost.

Research into mountain permafrost in the Tatras and in Abisko is conducted in areas where permafrost occurrence is relatively poorly recognized (Svensson 1986). As a result, the main aim of this project is to determine permafrost extent and its forms of occurrence, its geophysical properties, probable origin and evolution and its relationships to the warming climate.

The first results of the research conducted in the Abisko area were presented last year (Dobinski 2007). Here a new hypothesis of permafrost occurrence in mountainous areas will be presented, based on geophysical data collected by the author and published last year.

Location

The survey areas—the Abisko Mountains (A) and the Tatra Mountains (B)—are located far away from each other, at a distance of 2100 km (Fig.1). Despite a relatively big latitude gradient, both areas of detailed surveys have properties that suggest the necessity of comparing one to the other. Two meteorological stations operating in the Tatras indicate a mean annual air temperature (MAAT) similar to the one in the survey area. The MAAT of Kasprowy Wierch stands at -0.8°C at the altitude of 1986 m a.s.l. and of Łomnicki Szczyt at -3.8°C at the altitude of 2632 m a.s.l. (Dobinski 1997, Niedzwiedz 1992) In the Abisko area, close to the research station ANS at the altitude of 388 m a.s.l., MAAT stands at -0.8°C and in the mountainous areas nearby, it drops to -4.0°C (Ridefelt & Boelhouwers 2006, Jonasson 1991). Nearby Tarfala Research Station (1151 m a.s.l.) has MAAT of -3.9°C, which is similar to the one measured on Łomnicki Szczyt.

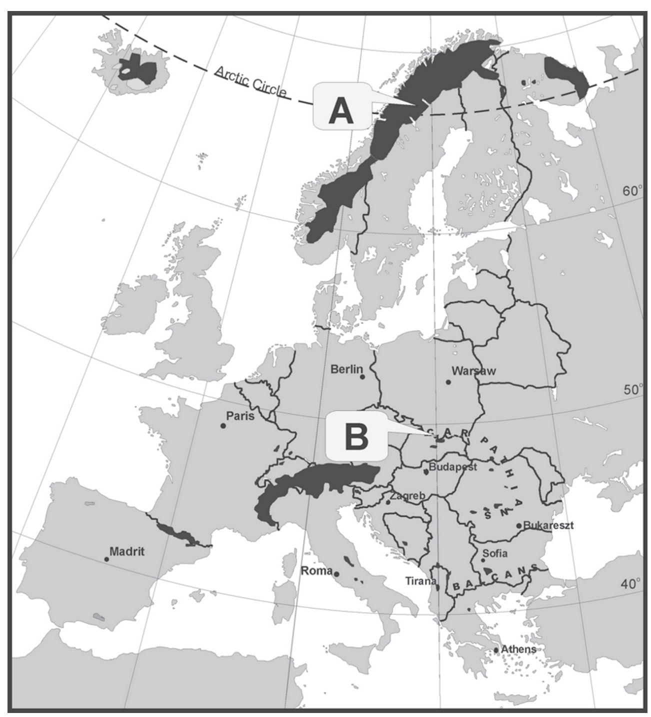

Figure 1. Location of the research areas within the map of mountain permafrost in Europe (modified from Dobinski 2005).

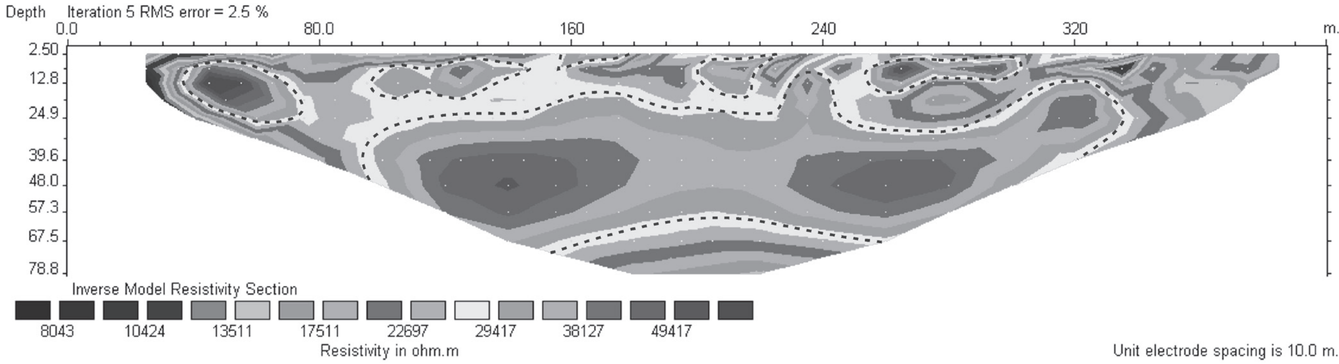

Figure 2. ERT profile performed on the mouton in the Abisko area. High-resistivity anomalies surrounded by the dashed line. Note high-resistive area at a depth of 25–65 m.

Nearby Tarfala Research Station (1151 m a.s.l.) has a MAAT of -3.9°C, which is similar to the one measured on Łomnicki Szczyt.

Both of these mountain regions underwent glaciation several times in the Pleistocene. It finished about 10,000 years BP in the Tatra Mountains (Baumgart-Kotarba & Kotarba 1995) and about 9,000 years BP in the Abisko area (Karlen 1979). Glaciation significantly altered the relief of the areas; in the final stage of evolution they were affected by periglacial processes, which ultimately shaped their relief. A considerable difference between the two areas observed in their topography lies mainly in the difference in relative altitude. In the Tatras, relative altitudes are much higher and due to this fact the mountains are steeper than the ones in the Abisko area. Such a topography results in lower dynamics, compared to the Tatras, of geomorphological processes occurring in the Abisko Mountains at present. Steep slopes in the Tatra Mountains, dominating above the permanent snow line, prevent formation of glaciers.

Geophysical surveys in northern Sweden were conducted on a granite mouton—a tor-like bare rock polished by the glacier—(ca. 450 m a.s.l.) located about 20 km west of Abisko, ca. 200 m north of the Kiruna–Narvik Road, near the Bjorkstugans station, beyond the exact mountain area. This mouton, not very high and with a bit fractured surface, was chosen as a particularly suitable area to be compared with the granite dome of Kasprowy Wierch, the Tatras, Poland, where electroresistivity and electromagnetic profiling was also performed. The mouton is slightly covered with glacial blocky deposits which accompany a slightly weathered *in situ* granite. It is partly overgrown with moss and grass, and wherever there are more deposits, a process of frost sorting can be observed. In Poland, the surveys were carried out on the dome summit of Kasprowy Wierch, which is also built of granite and has a 4 m thick cover weathered *in situ* in periglacial conditions and which is mostly overgrown with grass.

Methods

The following geophysical methods were applied in the surveys on the occurrence of mountain permafrost in the Abisko area and the Tatras: one-dimensional (1D) DC resistivity soundings (e.g., Vonder Mühll 1993), two-dimensional (2D) resistivity tomography (e.g., Kneisel 2006), shallow and deep electromagnetic soundings (EM) (Hauck et al. 2001), and measurement of bottom temperature of the winter snow cover (BTS) (Haeberli 1973). Such methods are quite commonly used in geophysical surveys on detection and mapping of permafrost in a mountain environment and can be said to be standard at present (Vonder Mühll et al. 2001, Hauck 2001).

Abisko area, Sweden

Two intersecting electrical resistivity profiles were carried out in the NS and WE directions. The WE profile was 200 m in length and had electrodes spaced at 2.5 m intervals. Suitable terrain conditions and the assumptions underlying the survey, which aimed at detection of permafrost at a considerable depth, resulted in the second profile being carried on the distance of 400 m, with electrode spacing of 10 m (Fig. 2). The electromagnetic method was chosen under similar assumptions. In the surveys, a EM-34 conductivity meter with a variable transmitter-receiver spacing was used, which allowed reaching the depth of about 80 m below the ground surface.

Kasprowy Wierch, Tatra Mountains, Poland

On Kasprowy Wierch, two 200 m 2D electroresistivity tomography with electrodes spaced at 2.5 m intervals and shallow electromagnetic sounding surveys were carried out. One of the ERT profiles was located above the tourist path and ran along it, while the other descended from the summit. Additionally, BTS temperature measurements were made on the summit dome and in the surrounding area.

Results

Mouton in the Biorkstugans area, Abisko.

The interpretation of the second profile, running N-S, reaches the depth of almost 80 m, and it presents a significant variation in resistivity values, but they all occur in a high value range. Note that the interpretation of the research in the second ERT profile probably did not include the active layer, the thickness of which in such an environment varies

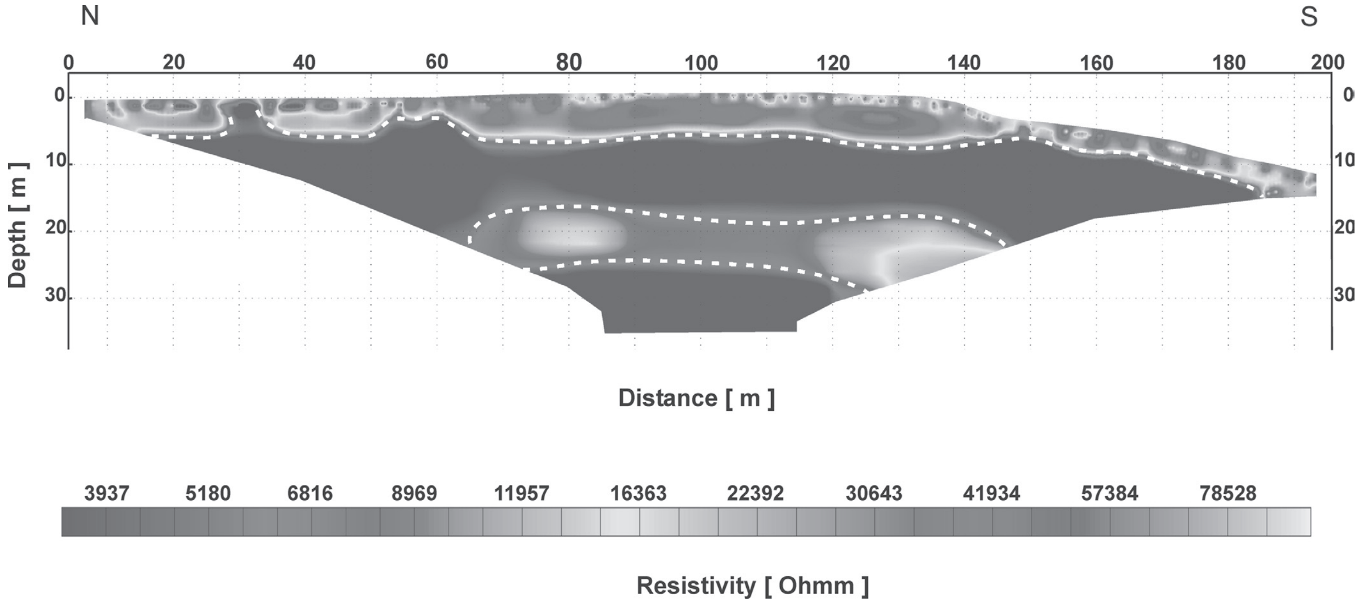

Figure 3. ERT profile performed on Kasprowy Wierch. High-resistivity anomalies surrounded by the dashed line. Note high-resistive area at the depth 15–25 m, and different vertical scale. (Due to appear in Hauck, C. & Kneisel, C. (in press), *Applied Geophysics in Periglacial Environments*. Cambridge University Press, reproduced with permission.)

between 1.5–2.5 m (Knutsson 1980) or more. At a depth of 3–15 m, a series of high-resistivity anomalies can be observed; their resistivity values range between 30 and 50 kOhmm, and they form an unclear layer. Below the depth of 25 m resistivity drops to around 20–30 kOhmm and it increases again to 30–50 kOhmm at the depth between 30 m and 60 m. In deeper places, resistivity falls again to stand at about 17 kOhmm or more. Lower resistivity values, below 10–13 kOhmm, are registered exclusively on the edges of the survey site; that is, in the places where the area could have been locally watered, as there is a river flowing nearby and the terrain there is wet. The profile does not show any anomalies characteristic of deep fractures. The image of the two high-resistivity anomalies, especially the deeper one, has a characteristic, more or less horizontal course.

The results are supported by deep electromagnetic soundings made by means of EM-34 conductivity meter. The findings of these surveys reveal variation in electromagnetic conductivity in various depths. The map of electromagnetic conductivity created for the depth of 15 m shows very little variation in values within the 3.2–4.0 mSm range. At the depth of 30 m, conductivity falls to 1.7–2.1 to rise again to 8.4–11.0 mSm at the depth of 60 m.

Kasprowy Wierch, Tatra Mountains, Poland

In the 2D resistivity tomography (Fig. 3) made on Kasprowy Wierch, two distinct high-resistivity anomalies can be distinguished. The first one, of a horizontal course, is discontinuous, and its fragments come over the surface. Electrical resistivity interpreted in it indicates the values from 30–90 kΩm. Such high electrical resistivity is characteristic of both: coarse blocky cover with numerous air voids and of places of permafrost occurrence (Dobinski et al. 2006, Vonder Mühll 2001).The layer is 3–4 m thick and its upper end is at a depth of 1–2 m. The horizontal arrangement of anomalies can be regarded as permafrost, whereas single, small, high-resistivity anomalies which come over the surface are probably air voids in blocky-cover. The layers below the delineated limit can be treated as a homogenous granodiorite massif with characteristic resistivity of approximately 4 kΩm. In its upper sections there can be fractures. In the massif, at the depth of 15–25 m, another high-resistivity anomaly, of 15–60 kΩm resistivity can be identified.

BTS temperatures measured on the summit dome of Kasprowy Wierch range from -2.7°C in the place of southern exposure, to -3°C on the summit, to -3.2°C in the place of slight northwest aspect (Dobiński 2004). In both places**,** high-resistivity anomalies running near the surface and much more deeply are observed. The shallow ones can be interpreted as active permafrost**;** the one connected with contemporary climate, where ice may occur. If we accept a highly probable assumption that geological structure in the survey sites, which are built of granite, is uniform, the change in resistivity and electromagnetic conductivity values should be mainly attributed to physical factors other than petrographic variety of rocks. A deep fracture would be accompanied by the infiltration of water of meteoric origin (Kasprowy Wierch) and of water coming from the stream and small water reservoirs near the mouton (Abisko). Such a change would rather lead to a decrease in resistivity values due to permafrost degradation and higher conductivity of water.

Discussion

Resistivity values and those of electromagnetic conductivity which occur on the mouton in the Abisko area, as well as resistivity values and BTS temperatures in the

Tatra Mountains, indicate that in both places high-resistivity anomalies should most likely be interpreted as permafrost occurrence, which would comply with the recent findings on permafrost occurrence in the Abisko area (Johansson et al. 2006) and in the Tatras (Dobinski et al. 2006). The results of surveys conducted both on Kasprowy Wierch and on the mouton in the Björkstugans area reveal that permafrost occurrence in both areas is probably not always accompanied by the occurrence of ground ice. Thus, the most likely interpretation of the obtained results is that these deep high-resistivity anomalies should also be regarded as occurrence of dry permafrost, older than permafrost present above it, which has relic character. This is the most probable hypothesis as it is commonly known that permafrost occurrence in the world is mostly the effect of Pleistocene cooling and such is its age (French 1996).

The thesis is supported in publications of other authors who have conducted surveys in this area. Ekman (1957) confirms the presence of at least 70 m thick permafrost near the Låkktajåkka tourist station at the altitude of 1220 m a.s.l.; that is a few kilometers away from the survey site. A borehole directly documenting this fact was drilled there in 1941. Another place where 20 m thick permafrost occurs is the Moskogaisa mine near Lyngen in Norway, at the altitude of 750 m a.s.l. (Ekman 1957). Relic and active permafrost is also distinguished in Scandinavian mountains by King (1984, Table 6, p. 36), who states that an active layer of relic permafrost is 4 m deep. He estimates the thickness of relic permafrost at 50–100 m and of active one at 40–140 m. A similar regularity is also registered in the Tatras (Dobinski et al. 2006), where under a layer of active permafrost there is probably fossil permafrost at the depth of about 15–25 m.

Fossil permafrost presence is documented in other places as well. The 100 m deep borehole drilled in March 2000 near the Tarfala Research Station (MAAT between -6 and -7°C) showed a temperature of -2.8°C in 100 m depth. Linear extrapolation of the borehole temperatures suggests permafrost thickness of 350 m (Isaksen et al. 2001). It is not possible for permafrost of such thickness to be solely an effect of contemporary climate influence (Lunardini 1995).

In the Alps (Zermatt) and in southern Scandinavia (Jotunheimen), a regularity similar to the one occurring in the Tatras (Kasprowy Wierch) and in the Abisko area can be observed. In 2D resistivity tomography performed near Stockhorn, one can distinguish two distinct high-resistivity anomalies, the first one in the 1–7 m depth and the second at the depth of about 20 m and more (Hauck 2001). Permafrost thickness in this place is estimated at about 160 m (King 2001), so both anomalies that occur there probably indicate its presence. A similar situation is on Jotunheimen (Fig. 6a) (Hauck et al. 2004), where a high-resistivity anomaly is visible in the lower part of the profile. Permafrost thickness for the borehole drilled in this area is estimated to be 380 m (Isaksen et al. 2001), which indicates that this high-resistivity anomaly might be interpreted as probable fossil permafrost. The possibility of its presence in this area is acknowledged by other researchers as well. (Ødegård et al. 1996). Nevertheless, as the resolution of the 2D resistivity tomography model decreases near the model boundary, the possibility of an inversion artifact must also be taken into account in the deeper part of both sections

The above assumptions are supported by an analysis of climate evolution in northern Scandinavia after glaciation. Long-term climatic history, deglaciation, and tree limit changes in the Holocene have been described mainly by Karlén (1976, 1979). The deglaciation of the Tornetrsk area took place around 9000^{14}C years BP (Karlen 1979). This information leads to the conclusion that in the mountain region of Abisko, in the entire Holocene period, temperature did not rise enough to reach MAAT >0°C, whereas in lower places the warming period was too short. During the Holocene there was not a period of time long enough to allow for a complete degradation of permafrost in the survey area. Rough estimates show that such an evolution took place in the Tatras too (Dobinski 2004).

Conclusions

Geophysical surveys carried out in the Abisko area indicate that active permafrost occurrence in this region is not solely limited to mountain and hill areas above 800 m a.s.l. (Jeckel 1988), and to muirs and palsa, but is also possible in other, lower places which are not covered with vegetation but constitute exposed convex forms (moutons) (Johansson et al. 2006). Thus, the occurrence of altitudinal and latitudinal permafrost probably overlaps.

Surveys on permafrost in Scandinavia and published results show that mountain permafrost, just like permafrost in western Siberia, reflects climatic fluctuations dating from at least postglacial period and that it occurs in both active and fossil forms. This allows for a more synthetic view on permafrost occurrence in the world. The published data indicate that such a hypothesis could also be applied in other mountain areas. Although it can be put forward at the present stage of research, it requires verification. It is impossible to prove the existence of permafrost by using the geophysical methods alone.

Abstract

The Fairbanks Permafrost Experimental Station was established in 1945 near Fairbanks, Alaska. In 1946 vegetation was removed from two plots (the Linell plots) to investigate the impacts of vegetation disturbance on permafrost degradation. We revisited the sites in 2007 to evaluate the permafrost table using probes and direct current electrical resistivity. The permafrost table has expanded downward to 9.8 m at a site where all surface vegetation and organic material was removed. The permafrost surface has remained at 4.7 m depth since 1972 at a second site where vegetation was removed but organic material was left intact. In 2005 a Circumpolar Active Layer Monitoring Network (CALM) site was established at an undisturbed plot nearby to provide a baseline assessment of the permafrost. The response of permafrost at the site to the hypothesized future climatic warming of the Alaskan Interior can be assessed, once a long-term record is available.

Keywords: boreal forest; electrical resistivity; monitoring; permafrost degradation; vegetation disturbance.

Introduction

Permafrost in thermal equilibrium can be drastically affected by disturbances such as clearing vegetation (Linell 1973, Nicholas & Hinkel 1996), forest fires (Viereck 1982, Burn 1998, Hinzman et al. 2003), or climatic change (Shur & Jorgenson 2007). The Fairbanks Permafrost Experiment Station near Fairbanks, Alaska (64.877°N, 147.670°W) was established by the U.S. Army in 1945 as a location where geotechnical, geophysical, and engineering studies could be performed on permafrost. The site has a rich history and was designated as a National Geotechnical Experimentation Site in 2003. In 1946 vegetation was removed from two plots at the site (the Linell plots) to investigate the impacts of vegetation disturbance on permafrost degradation. This paper summarizes the results of recent investigations focused on measuring the current state of permafrost at the site. Our results provide information on permafrost degradation where vegetation disturbance has lead to a change in the thermal regime either through engineering activities, fire, or climatic change. Permafrost at the study site is considered "warm" (the mean annual air temperature is -3.3°C) and mean annual temperatures in the area are increasing. As a consequence, future degradation of permafrost during climate warming can be assessed once a long-term record is available from the site.

Results

Linell plots and Circumpolar Active Layer Monitoring site

In 1946 three square plots 61 m on a side (3721 m^2) were identified at the Fairbanks Permafrost Experiment Station to investigate the influence of vegetation removal on permafrost (Linell 1973). Herein these plots are referred to as the *Linell plots*. One of the Linell plots was left undisturbed to preserve the subarctic taiga forest with dense white and black spruce. Vegetation was removed from the other two plots. One plot was stripped of trees by hand but the roots and organic mat were left intact (Fig. 1) while at the other plot all of the vegetation and surface organic material were removed (Fig. 2). Linell (1973) described permafrost degradation at the two disturbed sites 26 years later. In the completely disturbed site the thaw depth reached 6.7 m after 26 years while at the partially disturbed site the melting expanded to a depth of

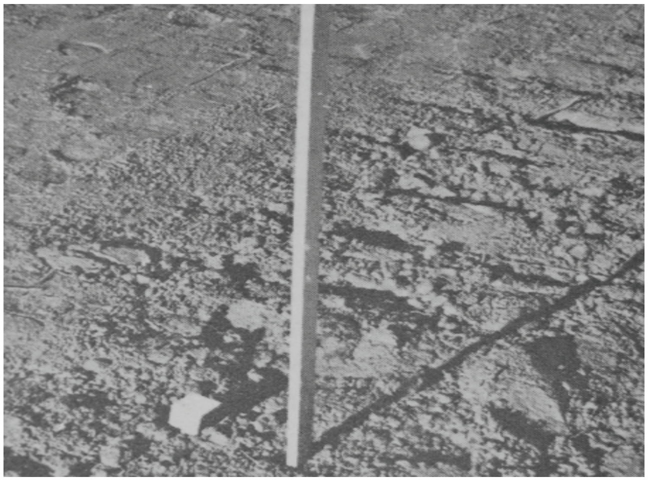

Figure 2. The completely disturbed Linell plot where trees, shrubs, the organic mat and roots were removed. From the U.S. Army Corps of Engineers, Permafrost Division, 1950.

Figure 3. The CALM site at the undisturbed plot in August 2006.

4.7 m. The results showed that permafrost degradation is linked to surface vegetation disturbance and that in warm permafrost random, mixed, low vegetation will not provide a stable thermal regime for permafrost.

In 2005 a Circumpolar Active Layer Monitoring Network (CALM) site was established in the undisturbed Linell plot. Thaw depths have been measured yearly in early October at 121 locations on an 11 by 11 cell grid with 3 m spacing. This provides thaw depth measurements over a 33 by 33 m (1089 m^2 area). Moss thickness and total thaw depth were measured and recorded at each probe location. In the fall of 2007 direct current electrical resistivity measurements were made along an 85 m long line at both of the disturbed Linell plots to quantify the state of permafrost 61 years after modification. A borehole was installed at the completely disturbed plot in 2007 to measure the current thaw depth and to ground truth the geophysical measurements.

Climate, soils, vegetation and permafrost in Interior Alaska

Fairbanks, located in Interior Alaska, has a continental climate with a mean annual temperature of -3.3°C and

Figure 4. A photograph in August 2007 of the Linell plot where in 1946 the surface vegetation was removed but the organic material was left intact.

typical monthly average temperatures of 20.2°C in the summer (July) and -31.7°C in the winter (January). Absolute extremes range from -51°C to 38°C (Jorgenson et al. 2001). The average annual wet precipitation is 407 mm and the typical average annual snowfall is 1.7 m. The Fairbanks Permafrost Experimental Station site sits on a gently sloping southward facing hill 6 km north of Fairbanks, Alaska.

Soils in the study area consist of tan silt and wind blown loess near the surface and grey silt at depths below 1.4 m. Permafrost gravimetric percent moisture contents range from 26% to 41% for the frozen silts which makes this relatively low moisture content permafrost (Linell 1973). The thin (2 to 32 cm thick) surface peaty organic mat has a gravimetric moisture content as high as 258% (Linell 1973). Organic rich silt and peat layers are common as are layers and inclusions of charcoal.

Vegetation at the Fairbanks Permafrost Experimental Station (Fig. 3) is typical of the Alaskan Interior- subarctic taiga forest with white and black spruce towering above a thick moss layer interspersed with low-bush cranberry and Labrador tea. Feather and sphagnum moss and woody debris cover the terrain surface (Hamilton et al. 1983).

Forest succession following disturbance is evident at both Linell plots. At the two disturbed plots dead or dying shrubs covered in moss are being replaced by white and black spruce and birch trees. The trees are taller at the less disturbed site where the surface vegetation was removed but the organic material was left intact (Fig. 4).

Permafrost in Interior Alaska is discontinuous, generally underlying north facing slopes and valley bottoms (Jorgenson et al. 2001). A detailed description of the types of permafrost in the Alaskan Interior is provided in Osterkamp et al. 2000). The thickest permafrost at the Fairbanks Permafrost Experimental Station, 60 m, is near Farmers Loop Road and the thickness decreases with increasing elevation. The mean annual temperature at 10 m depth from 1946 to 1972 was -0.5°C (Linell 1983).

Circumpolar Active Layer Monitoring site measurements

Thaw depths at the CALM site from 2005 to 2007 are generally between 20 and 80 cm (excluding moss) in early October (Table 1). Moss thickness ranges from 0 to 32 cm (Fig. 5). Linell (1973) presents consistent thaw depth readings of ~85 cm at the undisturbed plot from 1946 to 1972. This suggests recent climatic warming in the Alaskan Interior (1.5°C warmer at Fairbanks from the 1960s to the 1990s (Osterkamp & Romanovsky 1999)) may not be greatly affecting thaw depths at the Fairbanks Permafrost Experiment Station. In all three years of measurements the shallower moss cover is associated with deeper thaw depths.

Geophysical measurements at the Linell plots

Direct current (DC) electrical resistivity measurements have been used to quantify the presence of permafrost at many locations worldwide (e.g., Gilmore & Clayton 1995, Hauck et al. 2003, Hauck & Kneisel 2006). The electrical resistivity of a soil is controlled by its mineralogy, porosity, moisture content, cation/anion concentration of moisture, temperature, and whether the pore water is frozen or thawed. The resistivity (ρ) values of frozen soil are generally 10- to 1000 times greater than those of unfrozen or brine-rich soils (Harada & Yoshikawa 1996).

Direct current electrical resistivity measurements were run across the two disturbed Linell plots in September 2007 to quantify current thaw depths. We used two-dimensional resistivity profiling (IRIS instruments; Syscal pro R1 48-72 channel) for this investigation using a Wenner electrode configuration. The DC resistivity sounding employed four electrodes for measurement whereby a current (I) was delivered and received between the outer two electrodes and the resulting potential difference (V) was measured between the inner two electrodes. For this array on the ground surface, an apparent resistivity (ρ_a) between electrodes separated by distance (a) is:

$$\rho_a = 2\pi a(V/I) \tag{1}$$

The inversion analysis was performed with changing values of resistivity and layer thickness by using the linear filter method for a one-dimensional investigation (Das & Verma 1980). We do not have measurements of pore water salinity or moisture content across the resistivity lines and this limits the confidence of our interpretation of the resistivity measurements. However, based on the data presented in Linell (1973), the soil moisture contents, the soil temperature, and our probing and borehole measurements we are confident the resistivity markers we interpret as the upper boundary of the permafrost table are accurate.

For the acquisition of the two-dimensional apparent resistivity data we used multi-channel, equally spaced electrodes at 1.5 m for the minimally disturbed Linell plot and 2 m for the completely disturbed Linell plot. Each measurement was repeated up to 16 times, depending on the variance of the results. Two-dimensional model interpretation was performed using RES2DINV (Geotomo software) which performs smoothing and constrained inversion using finite difference forward modeling and quasi-Newton techniques (Loke & Barker 1996).

Resistivity profiles across the disturbed Linell plots show that in one case the permafrost continues to degrade while in another a small zone of potentially refrozen material has been recreated since 1973 (Linell 1973). Figure 6 includes a DC resistivity cross section of the plot where surface vegetation was cleared by hand but the surface organic material was left intact. Undisturbed permafrost is present at 0 m on the line (x-axis). The dark mass to the right center of the plot corresponds with a low lying grassy area along the DC resistivity line with standing water and minimal shrubs or trees. This wet soil affects DC resistivity measurements and yields an apparent highly resistive mass at a depth of 3 m that is not present based on frost probing. This is signified by the bulbous mass with resistivities >200 Ω-m from 34 to 47 m along the section. To the left (east) the resistivities that are >200 Ω-m likely signify permafrost at 9 m depth. This depth to permafrost was confirmed at two locations with an expandable frost probe. Figure 7 includes a DC resistivity cross section of the plot where surface vegetation and organic material were removed in 1946. Undisturbed permafrost is present from 0 to 25 m on the line (x-axis). A borehole encountered permafrost at 9.8 m (Fig. 8) which corresponds with the tabular region (black) consistently yielding a resistivity of >450 Ω-m.

Table 1. A summary of the summer average temperatures, active layer depth, and moss thickness from 121 points at the undisturbed Linell plot (CALM site) for 2005–2007.

Year	May-October mean air temperature (˚C)[1]	Mean thaw depth without moss (cm)	Mean moss thickness (cm)
2005	13.7	44.5	13.0
2006	12.6	40.1	13.5
2007	12.9	43.7	13.6

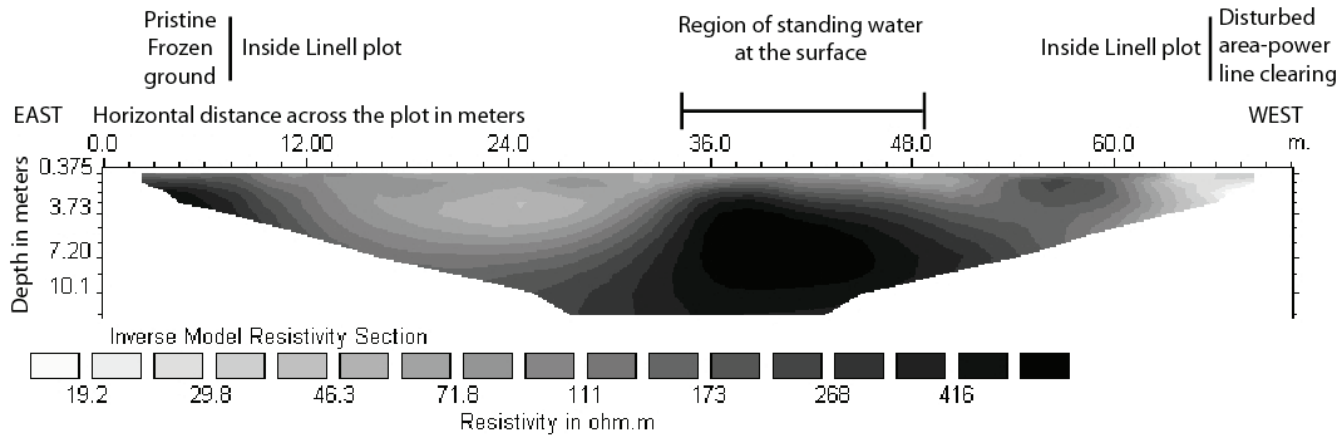

Figure 6. A direct current resistivity profile across the Linell plot where, in 1946, the surface vegetation was removed but roots and organic material were left intact. The unit electrode spacing is 1.5 m.

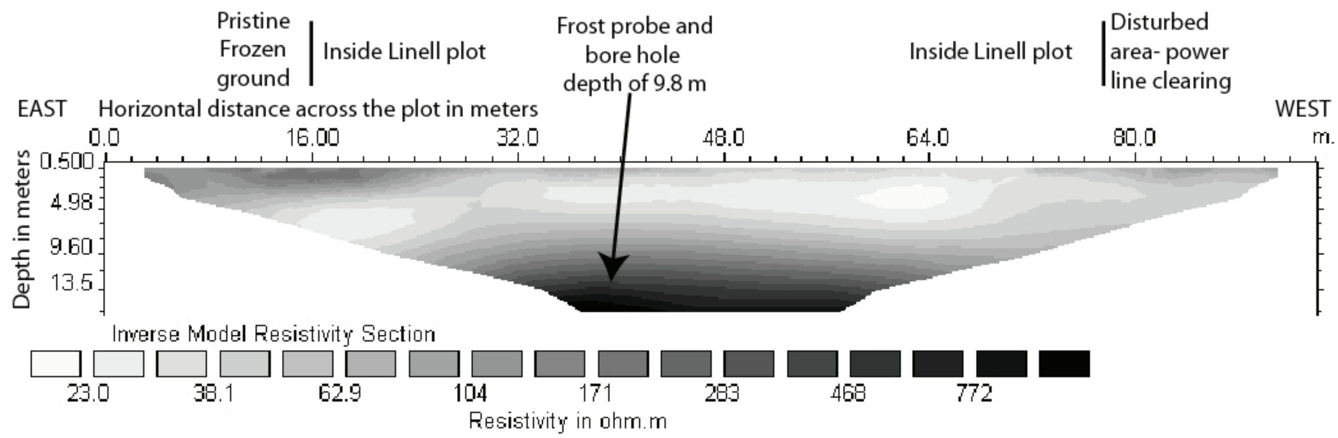

Figure 7. A direct current resistivity profile across the Linell plot where, in 1946, the surface vegetation, roots, and organic material were removed. The unit electrode spacing is 2 m. The arrow denotes where a borehole encounters permafrost at 9.8 m depth (Fig. 8).

The DC resistivity values here are ~450 to 800 Ω-m when permafrost is encountered. This is on the low end for studies reporting resistivity values for permafrost. Hoekstra and McNeill (1973) report values of 300 to 7000 Ω-m for "Fairbanks silt" with the values approaching 800 Ω-m for "Fairbanks silt" at -5°C. This is within the range of values we measured for soils that are similar to Fairbanks silt. Harada et al (2000) report values of 2100 and 12,000 Ω-m for permafrost at the Caribou-Poker Creek Research Watershed (CPCRW) located 20 km north of our study site. Yoshikawa et al. (2006) report values of 1000 to 14,000 Ω-m for permafrost at the top of a pingo at the CPCRW and 600 to 10,000 Ω-m for frozen ground at a pingo located 4 km west of the Fairbanks Permafrost Experimental Station. Permafrost in northern Quebec (Seguin and Frydecki 1994) yields values between 1000 and 5000 Ω-m. DC resistivity values are strongly controlled by the moisture content and the salinity (or conductivity) of the permafrost. In the Fairbanks area the mean annual temperature is -3.3°C. The permafrost is roughly 0.5°C to 1°C (Fig. 8) which is considered warm for permafrost. As a consequence, there is likely unfrozen water in the pore spaces of silt rich sediment at the top of the permafrost table. This could result in lower resistivity values than are measured at locations where colder temperatures and less unfrozen water are present.

A summary of our measurements combined with the data reported by Linell (1973) is provided as Figure 9. Permafrost destruction at the site where surface vegetation was removed but organic material was left intact appears to have ceased since 1973. While probing along the DC resistivity line at the site we identified a thin (50 cm) frozen layer between 1 and 1.5 m depth. This likely signifies a zone of aggrading permafrost. At the site where all vegetation and surface organic material were removed the depth to permafrost has increased to 9.8 m depth (based on frost probing and a bore hole installed at this location in the fall of 2007 that yielded temperatures below freezing at 9.8 m depth in October 2007 and January 2008 (Fig. 8).

If one assumes a maximum volumetric ice content of ~30%, the loss of 9.8 m of ice at the disturbed site and 4.7 m of ice at the partially disturbed site would lead to subsidence of ~2.9 m and ~1.4 m, respectively. This assumes all the ice was lost (as melt water) through evapotranspiration or subsurface flow which is not likely. The ground surface appears visibly

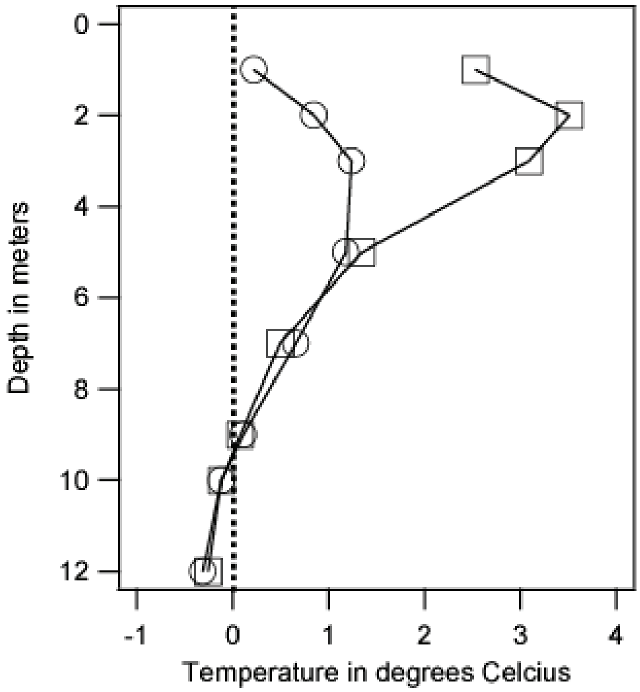

Figure 8. Borehole temperatures on October 19, 2007 (open boxes) and January 20, 2008 (open circles) at the Linell plot where surface vegetation, roots, and organic material were removed.

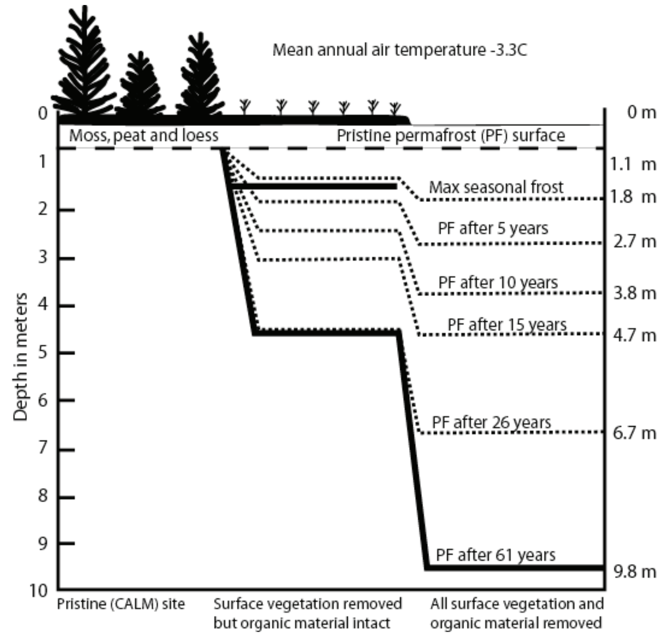

Figure 9. A cross section based on Linell, 1973. Vegetation removal from the two disturbed sites occurred in 1946. The bold line denotes the measurements collected in the fall of 2007, representing 61 years since disturbance.

depressed at the two disturbed Linell plots compared to the edges of the plots and to the control plot. However, the degree of subsidence cannot be ascertained beyond a visual estimation due to a lack of high resolution elevation measurements at the site prior to disturbance in 1946.

Discussion

Comparing the results from this investigation with that of Linell (1973) it is apparent that at both of the plots where vegetation was removed the permafrost expanded downward for the first 26 years while the permafrost table eventually stabilized at the partially disturbed site. This is likely due to the reestablishment of a boreal forest at the site within 25 years. This forest succession did not lead to the upward migration of the permafrost table, most likely due to the fact that ambient temperatures in the area are relatively warm. However, the small frozen layer at roughly 1.5 m depth at this site may signify that an epigenetic (downward freezing) regime is currently in place.

At the site where all the surface vegetation and organic material were removed the permafrost surface has migrated downward for the past 35 years. Vegetation is continuing to evolve and is currently transitioning from a shrub, birch, and willow forest to one with a higher density of spruce trees and moss. The downward migration of the permafrost surface has not been linear in nature (Fig. 10). In fact, the rate of permafrost degradation at both of the disturbed sites is best represented by a second order polynomial.

Since the climate of Interior Alaska has warmed slightly over the past three decades it is possible some of the permafrost degradation at the Linell plots is attributable to climatic change. The downward migration of the permafrost surface may be augmented by warming temperatures in addition to the changing thermal regime caused by vegetation disturbance. Thaw depths at the pristine Linell plot (the CALM site) are ~80 cm and are within the range of values presented by Linell (1973) for the period from 1946 to 1972. The recent establishment of a Circumpolar Active Layer Monitoring Network (CALM) site at the undisturbed Linell plot will provide a baseline of the current and future state of permafrost which can be assessed once a long-term record (>10 years) has been measured.

Conclusions

Based on the results from this and previous studies, it is evident that the downward degradation of permafrost is highly dependent on the type of surface degradation and time. This has ramifications for forest succession following fire or human-caused disturbances to vegetation in permafrost terrains.

This study supports previous work showing that vegetation disturbance greatly affects permafrost stability. The regrowth of boreal forest vegetation at the partially disturbed Linell plot has lead to the cessation of permafrost degradation. In fact, a thin layer of frozen ground slightly below the typical thaw depth may be evidence of the reestablishment of permafrost. The site with greater vegetation disturbance has exhibited permafrost degradation since 1946, but the rate of degradation is not linear and is decreasing as the re-establishment of boreal forest continues. Resistivity values we measured for permafrost (~450 to 800 Ω-m) are relatively low compared to measurements in ice-rich permafrost. However, our site is characterized by low-moisture-content silts. Further studies of the thermal state and moisture content of the frozen silt at the site are warranted. Finally, ambient air temperatures have increased over the past few decades in the study area, and they are expected to continue to increase in the future. Though thaw depths in the permafrost at the CALM site appear to be somewhat stable since 1946, we will only be able to determine how future warming will continue to affect permafrost at the site with continued monitoring.

Acknowledgments

Many people donated time, equipment, and information to support this collaborative study. Site history was provided from Charles Collins and Karen Henry of CRREL. Field assistance from Stephanie Saari, Art Gelvin, Allan Delaney, Charles Collins, and Tohru Saito has been invaluable. Beth Astley shared her geophysical information for Birch Hill and Farmers Loop. Comments from two anonymous reviewers and Editor D. Kane strengthened the manuscript.

Recent Advances in Russian Geocryological Research: A Contribution to the International Polar Year

D.S. Drozdov, G.V. Malkova, V.P. Melnikov
Earth Cryosphere Institute, Russian Academy of Sciences, Siberian Branch, Tyumen, Russia

Abstract

Fifty years have passed since the previous Polar Year (1957–1959). After the relatively cold climatic period of 1950–1960, the abrupt warming of air and ground temperatures was evident for the north of Russia. The geocryological observations suggest that the rise in ground temperature slowed down in the early 1990s; the recent trend of changes in geocryological conditions is uncertain. Ongoing and future permafrost research and modeling of permafrost evolution under the impact of climate change and man-induced development should be based on wide-ranging scenarios. Generally, the permafrost and climatic trends show that there will be no significant changes in geocryological conditions in the upcoming 20 to 25 years. The decreasing continentality of the climate can increase the extent of destructive cryogenic processes on the continent and in the coastal zone, especially in the case of significant impact caused by development. Cryogenic structure of permafrost will control significantly the activity of external processes.

Keywords: air and ground temperatures; cryogenic processes; GIS; geocryological monitoring; geosystem; permafrost change.

Introduction

The International Polar Year (IPY) provides one of the most significant events for geocryologists. Fifty years have passed since the previous Polar Year (also International Geophysical Year, 1957–1959). Some of its participating Russian geocryologists are still active (G.F. Gravis, A.V. Pavlov, M.M. Koreisha, and others). The end of the 1950's was a time of rather cold climate and the main investigations in the permafrost zone concerned cryogenic structure of the upper permafrost layers. At present, due to the concerns for global warming, the main attention is focused on the problem of permafrost degradation and destructive external processes, especially in case of man-made impacts. The basic problem is the study of seasonal and annual changes in climate and permafrost conditions and their interaction. Our contemporary investigations are coordinated with numerous international IPY programs: Arctic Circumpolar Coastal Observatory Network (ACCO-Net) and our Coastal Cryolithozone of the Russian Arctic (COCRA); Thermal State of Permafrost and our International Network of Permafrost Observatories (INPO); Greening of the Arctic: Circumpolar Biomass (GOA) and, also, various Russian Integrative and Regional Programs to assess permafrost changes. Collecting and processing of climatic and geocryological data are performed using GIS-techniques applied to models at global, regional, and localscales.

The IPY research in the Eurasian polar region concerns the following general items (Melnikov et al. 2007):

- Contemporary changes in climate and sea hydrodynamics in Arctic regions;
- Geocryological structure and cryogenic features;
- Continental and subsea permafrost formation and evolution;
- Natural and man-made cryogenic physical and geological processes;
- Permafrost monitoring (including coastal permafrost);
- Development of GIS databases and maps as conceptual and graphical models;
- Development of the new techniques for permafrost research.

This report highlights some of the recent results from these investigations with a focus on Western Siberia.

Geosystem Approach and Processing of Geocryological Data

Geocryological studies, mapping, and monitoring of the northern territories affected by climate change and intensive development are aided by global, regional, and local GIS applications. Digital maps of onshore and offshore areas with attribute databases of geomorphology, landscapes, lithology, soil properties, geocryological conditions, bathymetry, etc. are efficient tools for the analysis of available data and for assessing the environment (Melnikov & Minkin, 1998). A wide-ranging generalization of information from databases, and the compilation and redrafting of thematic digital maps, makes it possible to reflect the present-day state, trends and dynamics of coastal processes (Drozdov et al. 2005).

The landscape (geosystem) approach is used to pass from the low hierarchical level to the higher level (and vice versa) while processing the data. This is necessary for the collection and generalization of primary data with the development of general small-scale maps, on the one hand, and for displaying general regional regularities on the large-scale maps, on the other hand. The landscape maps display geomorphology, lithology, geocryology, vegetation and their longitudinal and altitudinal zonality. Thus, it reflects the main features and properties of the modern environment. The overlay of the landscape and climatic maps allows one to generate spatial geocryological forecast as an element of general environmental forecast.

Climate-Permafrost Relationships: General Regularities

Global and regional modes are used to predict the evolution of permafrost as related to the climatic and economic conditions. Extrapolation of contemporary permafrost and climate trends indicates that there will be no significant changes in geocryological conditions in the upcoming 20 to 25 years. But the decreasing climatic continentality (Fig. 1) can accelerate the development of the destructive cryogenic processes, causing permafrost degradation. In the areas with significant summer warming (e.g., in Western Siberia), the active layer thickness should increase, and thermokarst, thermal erosion, and cryogenic landslides should be more intense. In the areas with prevailing winter warming, intensification of frost heave, cryogenic cracking, and ground-ice formation are predicted. Global and regional GIS and databases are used to reveal and describe these phenomena.

The most negative tendency for the permafrost stability is expected for the regions where climate warming is accompanied by continued economic development. The potential decrease in the permafrost stability in this case is not related to climatic feedback effects caused by development, as there are no direct evidences for this process (Pavlov & Malkova 2005).

The long-term prognosis (20 to 50 years) is developed from the assessment of Russian permafrost sensitivity to the short-term climatic change (one year). This assessment is based on temperature and precipitation calculations. The basic argument for the short-term prognosis is the changing of the active layer thickness and moisture. Thus, according to a short-term prognosis of the geocryological processes, no catastrophic events were expected in 2006 and this forecast proved to be correct (Gravis & Konchenko 2007). In 2007, cryogenic processes were expected to be more active in the eastern regions of Russia, and to result in disturbance of the natural landscapes. This forecast is yet to be verified.

It is established for the offshore Arctic areas that changes of coastal destruction are rhythmical and have no meaningful trend. All temporal anomalies in the coastal destruction rate are synchronous with the climatic fluctuations, including characteristics of sea hydrodynamics and the state of ice in the Arctic seas. The smoothed hydrodynamic forecast makes it possible to assume a subsequent stable rate of coastal destruction that would not exceed contemporary rates by more than 10%–20%. If all other conditions are equal, the dominant role in coastal processes is related to the spatial

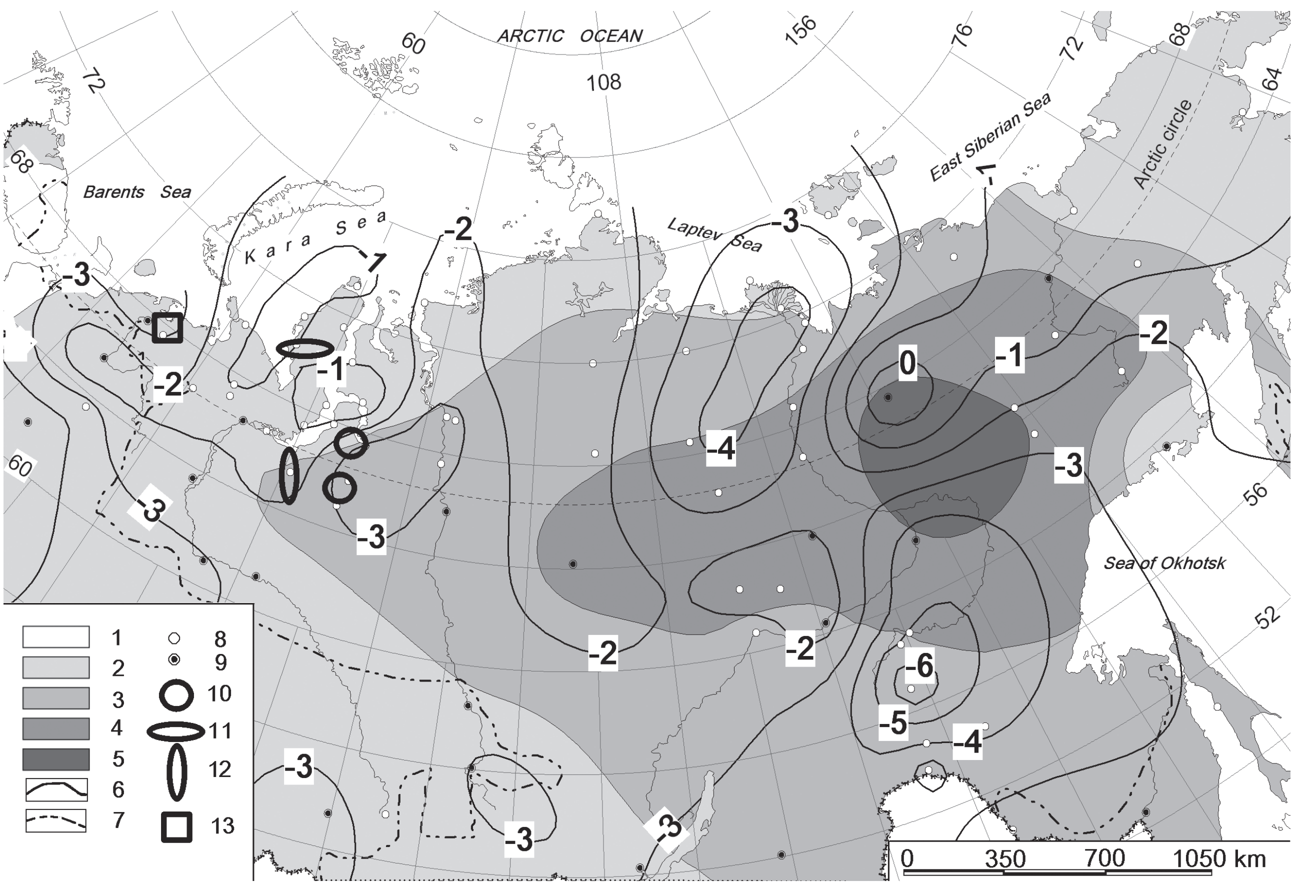

Figure 1. Map of climate continentality change owing to climate warming (amplitude contraction map). *1 – 5 – Annual amplitude of air temperature, °C: 1 – 20-30; 2 – 30-40; 3– 40-50; 4 –50-60; 5 – 60-70. 6 – change of annual amplitude since 1970, °C; 7 – southern limits of cryolithozone; 7 – 8 – weather stations with weather record: 7 – less then 100 years, 8 – more then 100 years; 10 – 13 – ECI SB RAS geocryological key-sites at: 10 – Urengoy gas-field, 11 – Yamal (Marre-Sale), 12 – Nadym, 13 – Pechora River mouth (cape Bolvanskii).*

variability of the cryogenic structure of permafrost (Vasiliev et al. 2005). The thermal erosion of the seacoast is considered to be the most destructive process, particularly in the case of ice-rich permafrost. Some anomalies are evident during the last decade, such as the correlation with fluctuations in the coverage of sea ice.

Monitoring of Unique Regions and Territories

Mapping and monitoring of unique territories are based on the regional and local landscape maps as the graphical tools. GIS techniques are used for the multivariate generalization of the experimental field data and for developing maps of the different conditions. Repeated geocryological surveys (for example, for the territory of Urengoy gas field, Western Siberia) show there have been no statistically significant changes in the permafrost temperature during the last several years. Compilation of these repeated maps is based on the reprocessing of existing data and on geocryological parameters aided by the new annual observations. Unfortunately, these regime data do not characterize all types of the geosystems. This limits the comprehensiveness of the repeated mapping.

Our experience in using insufficient data sets for compiling prognostic geocryological and environmental maps in the regions of new economic development is of particular interest. These maps are extremely important for feasibility studies and for the potential environmental impact assessment.

The medium-scale maps (1:100,000 to 1:200,000) of the natural and disturbed ecosystems, engineering-geocryological conditions, external geological processes, and permafrost stability were developed using GIS modeling (Drozdov et al. 2007). Expected gas and oil pipeline corridors cover about 3000 km^2. These are wide swaths of land ranging from 20 to 70 km as in: a) the Vankor oilfield to the north and to the south in Western Siberia; b) the Bovanenkovo deposit to the south in Western Siberia; and c) the northern branch of VSTO pipeline in East Siberia to the Pacific Ocean (Ust-Kut–Lensk–Aldan–Tynda). New geocryological information of limited extent made it possible to display up-to-date ground temperature and cryogenic processes in these regions.

Geo-Indicators of Cryogenic Processes

New data necessary for the reconstruction of Pleistocene-Holocene evolution and assessment of cryogenic stability of Russian Arctic are developed from offshore, on-shore and coastal expeditions. Geocryological structure, geocryological conditions, ice-content, ice-complex distribution, and external processes were examined in the European and Siberian North and in the coastal zone of Barents, Kara and Laptev seas. Some new conclusions can be made.

The investigations in Yenisey Bay (Kara Sea coastal zone) showed that polygenetic Pleistocene plains have very different geological and cryological characteristics. The sites with displaced sandy and loamy sediments and low ice content can be found in close proximity to the territories with horizontal sediment bedding and the presence of the ice complex. Sometimes, the ice-complexes occur in several layers. The alternation of ice-rich and ice-poor sites is observed along the coast; they are characterized by different rates of thermal abrasion and thermal erosion. Numerous slopes subjected to strong thermal erosion is indicative of the presence of ice-complexes even in the case when the latter cannot be diagnosed by either standard landscape surveys and remote sensing in this northernmost region of the Yenisey River (Streletskaya et al. 2007).

The traditional on-shore and coastal regime investigations that have been carried over a long time at the Bolvanskii key-site in the mouth of Pechora River (Barents Sea) were accompanied by seismic surveys. Geophysical seismic research and monitoring were conducted to analyze slope stability. This special seismic technique is based on theoretical relationships and experimental correlation between seismic characteristics of the soil and stress-strain condition of the soil massif. A very important feature of this technique is the opportunity to monitor and predict initial changes of the slope stability before significant change occurs. The length of forecasts range from months to several years. The error in expected spatial discontinuity does not exceed several meters (Skvortsov & Drozdov 2003). Repeated investigations during 2002–2006 showed that the relaxation of the stress-strain conditions took place, and slope stability increased. This micro-landscape mapping indicated that an existing crack on the surface, indicative of a weakened zone, became less noticeable from year to year. The seismic research, extended to the offshore zone, showed that the permafrost table is found at a depth of 8 m under the beach and descends to about 20 m at a distance of 200 m offshore (Skvortsov et al. 2007).

The theory of "landslide plains" explains how the changing of soil-biota conditions causes the new cryogenic landslides and how the new brine laden horizons are entrained into the active layer within the period of about 300 years (Leibman & Kizyakov 2007).

Frost heave and permafrost degradation are the main cryogenic processes in central part of Western Siberia. Complex monitoring near the town of Nadym revealed natural and anthropomorphic changes of landscape. The old peat mounds resulting from heaving are growing and new mounds continue to appear. The growth of the peat mounds is most active in the coldest winters; in milder winters, it is less intense. In contrast there are other processes like the increase in the active layer thickness and the rise of ground temperature. Temperature rise was very pronounced at the end of the 20th century. Locally it caused significant degradation of the permafrost. This tendency is moderated now, and geocryological conditions have become more stable. Man-made development increase permafrost degradation (Moskalenko & Ponomapeva 2006).

The micromorphological indicators of cryogenic conditions and processes during the early Cenozoic have been studied. The so-called cryogenic type of microstructure of sub-aerial sediments has been described. It is widespread and very stable. It can be traced in polygenetic syn-cryogenic and epicryogenic soils presently frozen or thawed. The established differences in the microstructure of Quaternary and Late-Cenozoic sediments make it possible to reconstruct features of paleo-cryogenic origin and the sequence of permafrost aggradation and degradation cycles for the past 3,000,000 years (Slagoda 2003).

Geocryological Monitoring in the Important Economic Regions

The important economic regions in the permafrost zone are influenced by substantial development that, together with the natural climate fluctuations, change landscapes and geocryological conditions. The studies of ecological and geocryological regimes concern both spatial and temporal description and forecast changes to the properties of the geological environments. Several key sites are located in Western Siberia and the European North in different natural settings and under different cryological conditions: for example, at Urengoy gas field, near the town of Nadym, on the Yamal peninsula, and on the mouth of Pechora River (Fig. 1). The landscapes, external processes, cryolithology, active layer, and ground temperature are studied there. These studies are important both for the ecological and geological estimation of current state of the territories and for detection of general regularities governing the observed changes.

Changes of average annual ground temperature are smoothed in comparison to external changes (e.g., in air temperature). They make it possible to observe general cryological trends not hidden by the highly variable fluctuations and extremes. At Urengoy gas field, the ground temperature measurements were made in 1974, 1975, 1977, 1978, 1992, 1993, 1994, 1997, 1999, 2005, 2006, and 2007.. According to these data, the temperature of the permafrost increased approximately 1°C during the period 1975–1993 owing to the natural climatic warming. Land use changes added an extra 1°C to 2.5°C, but this ground temperature rise is located close to human constructions. Changes in the ground temperature are not identical at the different landscapes (geosystem rank). They vary over wide limits. In the southern forest-tundra the ground temperature increase ranges from 0.6°C to 2.1°C. In northern forest-tundra and southern tundra, its increase is somewhat lower (0.1°C to 1.6°C, Drozdov 2002). The continuous temperature observations of 1994–1999 testify to the retardation in the increase of the frozen ground temperature. In the next five years, a decrease in ground temperature was registered at some sites. The pattern of ground temperature change in the southern forest-tundra landscape zone is shown in Figure 2.

For areas with high shrubs, where much snow is accumulated during winter and where the frozen ground temperature at the beginning of the warming cycle was close to 0°C, the degradation of permafrost was observed. The top of the degrading permafrost can be found at a depth of approximately 10 m. Analogous processes occur at the forested sites. The thawing of ground has not ceased. At some tundra and boggy sites, the warming of permafrost was followed by significant

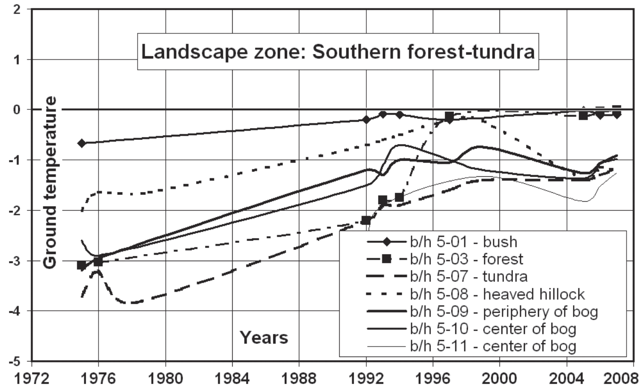

Figure 2. Ground temperature changes in southern forest-tundra at ~10 m depth (Urengoy gas field, Western Siberia) *b/h – borehole number and type of landscape site.*

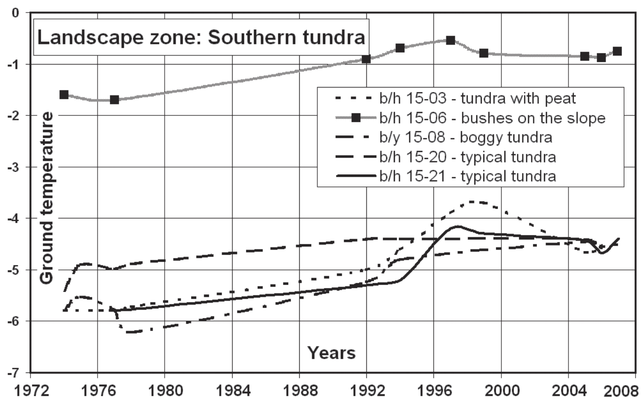

Figure 3. Ground temperature changes in southern tundra at ~10 m depth (Urengoy gas field, Western Siberia); *b/h – borehole number and type of landscape site.*

cooling in the mid 1990's. The more significant freezing can be found on hillocks. It is interesting that the temperature conditions in different geosystems become closer to one another under the impact of recent temperature changes; in the areas with degrading permafrost, the ground temperature is close to 0°C; in the areas with stable permafrost, it varies from -1°C to -1.4°C.

The same processes can be observed in the southern tundra landscape zone, but they occur generally under conditions of lower mean temperatures (Fig. 3).

All the geosystems are characterized by some temperature maximum in the mid-1990s. In most of the boreholes, temperatures at the depth of 10 m were very similar and rather cold: from -4°C to -5°C for the typical conditions.

A common feature for the northern part of Western Siberia is the rise in the ground temperature in the last three years (2005–2007). In the previous years, a decrease in the ground temperature took place. Thus, it is difficult to judge the real temperature trend in this region

The spatial and temporal distribution of permafrost temperatures are displayed on a series of temperature maps of Urengoy gasfield area, Western Siberia (Fig. 4). The first temperature map (B) is compiled on the basis of the results of the geocryological surveys in the period 1972 to 1977;

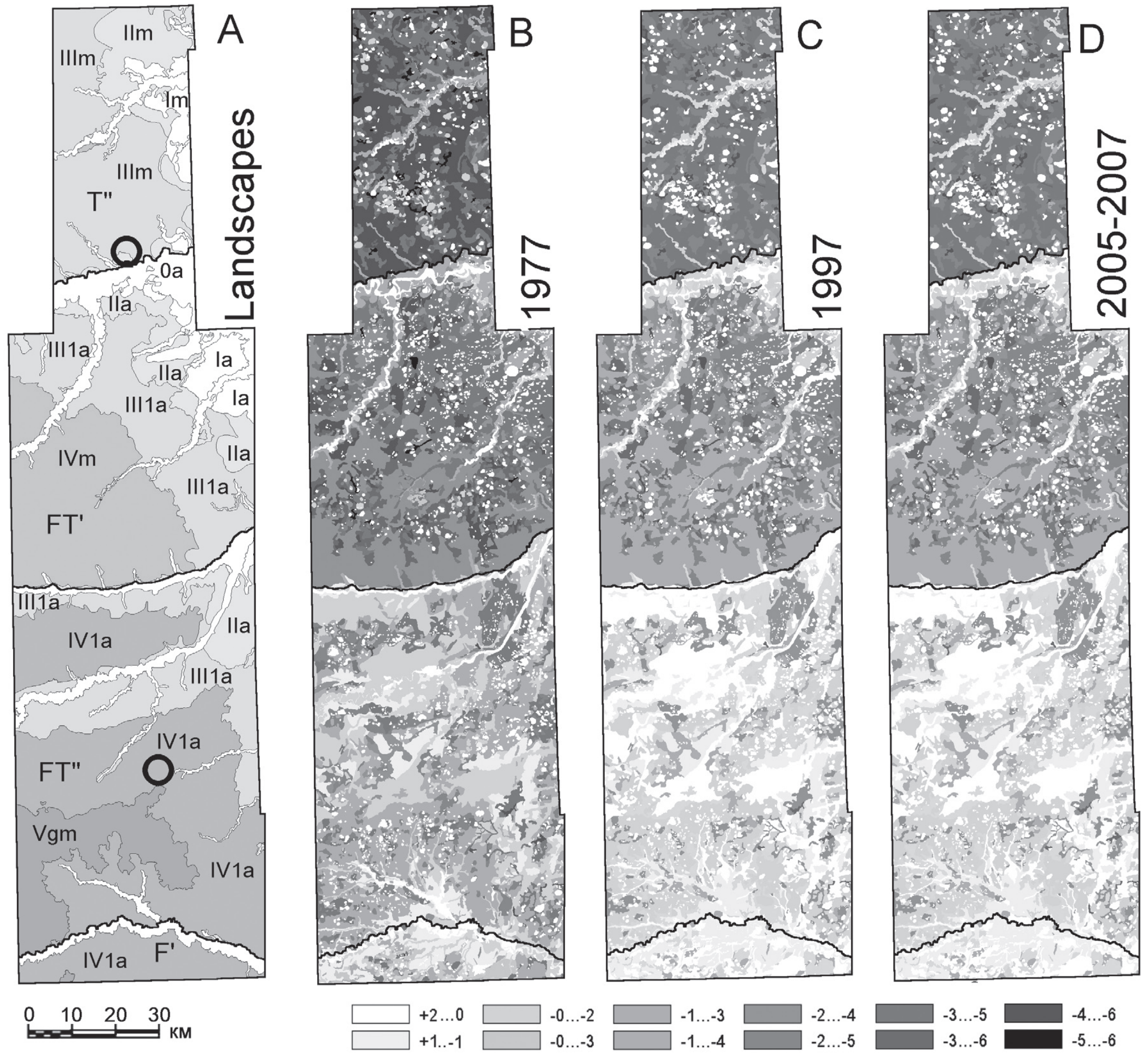

Figure 4. Natural dynamics of permafrost temperatures at the territory of Urengoy gas field (Western Siberia). *A – geosystem types (the larger letters – indexes of landscape zones; the smaller letters – landscape type index – number of geomorphologic level and genesis; black circle – geocryological regime key-site); B, C, D – ground temperature at 1977 (B), at 1997 (C) and at 2005-2007 (D).*

the second map (C) is drawn according to the data of the repeated simplified survey and thermal observations (1992 to 1997); the third map (D) is created on the basis of new thermal observations (1999, 2005 to 2007). Examining the gray-scale saturation of these maps, one can see that maps B and C reflect an average increase in the ground temperature of approximately ~1°C over a span of 20 years. Maps C and D indicate the absence of considerable temperature change during the last decade.

Conclusions

After the relatively cold period of the late 1950s, the decades of the 1970s and 1980s were characterized by the sharp warming of air and ground in the north of Russia. According to geocryological observations, the rise in ground temperatures slowed down and practically stopped since the middle 1990s. This invites us to assume that the warming tendency can be replaced by a cooling tendency. However, the recent short period of 2005–2007 showed an increase in ground temperatures. Thus, the real trend of modern geocryological condition is not factually clear. The modeling of permafrost evolution concerning the climatic and industrial influences should be performed for an ensemble of the scenarios. Extrapolation of contemporary permafrost climatic trends shows that there will be no significant changing of geocryological conditions in the coming 20 to 25 years, but the reduction of climatic continentality can increase the development of the negative cryogenic processes related to the increase in the active layer thickness, permafrost degradation, thermokarst, thermal erosion, and landslide activation in regions of summer warming. The most hazardous changes are expected in the regions, where climatic warming is accompanied by active land use change caused by development. The long-term prognosis (20 to 50 years) can provide an assessment of permafrost sensitivity to the short-term climatic changes that differ from year to year in the Russian North.

The seacoast thermal erosion is considered to be stable and rhythmic and shows no significant trend. Some anomalies are observed during the last decade and are associated with fluctuations in sea ice coverage. The activity of coastal processes relies on the spatial variability of the coastal cryogenic structure. The theory of "landslide plains" explains how the changing soil-biota conditions cause the new cryogenic landslides and the inclusion of new brine laden horizons into the active layer.

The knowledge of recent geocryological regularities allows the development of the medium-scale map-models of natural and man-influencedt geosystems, engineering-geocryological conditions, geo-environmental situation and permafrost stability, even in case of insufficient data.

GIS-techniques, geosystem methods, new meteorological and geocryological data, different landscape-geocryological field experiments, geophysics, and lab analyses allow us to extend our knowledge about permafrost and its interactions with other environments within programs of IPY.

Abstract

Transient numerical ground temperature modeling conducted within an ARC-GIS-resident spatial analysis system was employed to predict the current and future distribution and character of permafrost in three study areas of the Mackenzie River Valley. Future impacts of progressive climate warming to 2055 were also predicted. Modeling results illustrate the variability in the evolution of permafrost characteristics, such as active layer and talik development, for representative terrain types. A clear north-to-south trend towards higher ground temperature was confirmed, paralleled by a north-to-south decrease in the areal extent and thickness of permafrost. Predicted ground thermal conditions for 2055 show minor changes at the base of permafrost, with the most substantive permafrost degradation being realized through the deepening of the active layer and the development of taliks in the top few to several meters below the ground surface.

Keywords: active layer; climate warming; Mackenzie River; numerical model; talik.

Introduction

The Mackenzie River Valley is characterized by widespread permafrost terrain of thickness ranging from more than 600 m in areas of the Mackenzie and Beaufort coastal plain, to only a few tens of metres or less in the southern extent of the valley (Judge 1973, Taylor et al. 1998). Heginbottom et al. (1995) mapped the continuous, discontinuous, and sporadic zones of permafrost in Canada, but at finer scales the distribution and character of permafrost are not well known. Numerical ground temperature models integrated within a geographic information system (GIS) provide a means for estimating the current distribution and character of permafrost across extensive geographic regions, and for generating time-series predictions of future impacts to permafrost under a progressively warming climate. This paper presents modeling results for three study areas in the Mackenzie River Valley (Fig. 1): Fort Simpson located in the discontinuous zone (15,405 km^2), Norman Wells overlapping the discontinuous and continuous zone (12,117 km^2) and Inuvik in the continuous zone (9089 km^2).

Numerical Models

Smith and Riseborough (1996) have proposed a simple analytical relation (TTOP) demonstrating direct linkages between key climate and terrain factors influencing ground temperatures. Under assumed thermal equilibrium, the model estimates the mean annual temperature at the top of permafrost (TTOP) or, when permafrost is not present, the mean annual temperature at the base of the annual freeze-thaw layer (TBAL). The model was applied to regional mapping of permafrost distribution in Norway's mountainous regions (Juliussen & Humlum 2007), and in the Mackenzie River Valley (Wright et al. 2003). For investigations of the transient impacts of climate change, the T-ONE one-dimensional, finite-element, heat conduction model provides reliable solutions to ground thermal problems in both natural and engineered environments (Goodrich 1982).

Both the TTOP and T-ONE models utilize similar model parameters representing the dominant climate and terrain factors

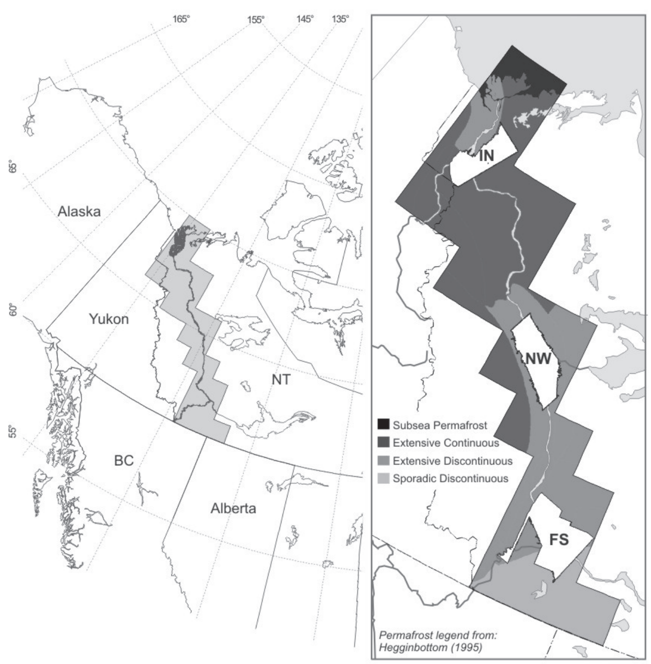

Figure 1. General and detailed location of the study areas modeled, northwestern Canada. IN: Inuvik, NW: Norman Wells, FS: Fort Simpson.

influencing the ground thermal state. The two models have been integrated within an ARC-GIS platform, enabling a quasi 3-dimensional grid space for generating predictions of permafrost occurrence, distribution, and temperature at local and regional scales, over selected time frames of interest.

Methods

Modeling parameters

To successfully apply the models to regional-scale mapping of permafrost, it is necessary to specify model parameter values which adequately reflect prevailing terrain and climate conditions within the study regions. The influence of atmospheric climate on the ground thermal regime is assumed to be primarily a function of air temperature as represented by thawing and freezing degree-day indices, and assumes that heat transfer in permafrost terrain is dominated by conductive processes (Outcalt et al. 1990). Thus, heat transfer through convective transport of water vapour and air within soil pore spaces, and the transient influences of rainfall infiltration and surface runoff (mass fluxes) are not considered. The use of seasonal n-factors links atmospheric temperatures to the ground thermal regime (Lunardini 1981) and provides a simplified representation of the influence of the buffer layer in modulating heat flow between the atmosphere and the ground surface. The summer vegetation cover is represented as a thawing n-factor, while the influence of snow cover is assumed to be implicit in the freezing n-factor (Wright et al. 2003, Jorgensen & Kreig 1988). Local topographic influences (as represented by a potential insolation index Ip), were not considered in this work in order to limit the number of unique terrain conditions modeled.

The general distribution of earth materials was obtained from available regional surficial geology maps (Hughes et al. 1972, Hanley et al. 1973, Rutter et al. 1980) supporting the assignment of model parameter values representing soil bulk density, soil mineralogy, and soil texture (Wright et al. 2003). These values are subsequently used for estimating the frozen/ unfrozen thermal conductivity (Johansen 1975) and specific heat capacity of surficial materials.

Information about the nature and extent of surface vegetation cover was obtained from conventional polygon maps based on regional surveys, and from multi-spectral classifications of Landsat TM satellite imagery at 30 m spatial resolution (GNWT Forest Management Division 2002). Integration of these data sources provided a basis for the assignment of seasonal n-factor values and soil moisture levels (Wright et al. 2003).

Calibration and validation

The GIS coupled T-ONE model was initially calibrated and validated using the TTOP analytical solution (Wright et al. 2003; Wright et al. 2001, unpubl.). Under conditions of thermal equilibrium, TTOP and T-ONE predictions of the temperature at the top of permafrost are virtually identical, meaning that although the model calibration was conducted using the computationally simple TTOP model, identical results regarding the presence/ absence of permafrost within the borehole dataset would have been obtained using the computationally more complex T-ONE finite element model. The model is capable of adequately reproducing observed trends in the regional distribution of permafrost occurrence and thickness within these regions, as documented in records from 154 geotechnical boreholes located in undisturbed, natural terrain (IPL 1982). Overall, the calibrated model correctly predicted the presence/ absence of permafrost in 134 of 154 cases (87%), and reasonably predicts the thickness of permafrost as compared to regional observations and limited borehole data (Wright et al. 2003). Also, the north-south distribution of ground temperatures data as estimated by TTOP agrees favourably with limited ground temperature data for the Mackenzie Valley presented by Judge (1973).

Climate and model equilibrium

The TTOP equilibrium ground temperature model was used to conduct an initial assessment of the likely range of ground temperatures expected within the individual study areas and supported the specification of initial equilibrium ground temperature profiles. Although true thermal equilibrium is never achieved between atmospheric climate and the ground thermal regime, initial conditions for forward modeling (including assumed equilibrium ground temperature profiles) were established circa 1730 AD (Ednie et al. 2008). This provided a basis for estimating current (year 2000) ground temperature profiles in support of transient ground thermal modeling through to 2025 and 2055, (although, due to space constraints, only results for 2000 and 2055 are presented in this paper). This approach was motivated by the observation that ground temperatures at numerous sites within the more southerly extents of permafrost terrain in the Mackenzie Valley appear to be near-isothermal close to 0°C (Smith et al. 2005), which we interpret as an indication that ground temperatures have been warming for an extended period of time. Measured and proxy records also suggest that there has been no extended period of stable climate in the northern hemisphere during the past few hundred years (Ednie et al. 2008). Figure 2 illustrates the initial equilibrium temperature and reconstructed paleo-climate trends used by the forward model to generate estimates of the current (year 2000) ground thermal state.

Burn et al. (2004) ranked scenarios from seven Global Climate Models (GCMs) and presents a series of plausible projections of climate warming in the Mackenzie Valley over the next 55 years. The median warming scenario with a temperature increase (over 1961–90 normals) of 1.3°C and 2.9°C for 2025 and 2055, respectively, was used to specify rates of regional climate warming in the Fort Simpson and Norman Wells study area. Since 1980, the recorded data for the Inuvik area indicate a steady increase in mean annual air temperature (Environment Canada 2002). Imposing a best-fit line through the data record suggests an increase in MAATs by 2000 which is well beyond the median warming scenario presented by Burn et al. (2004). Hence, for the Inuvik study area only, we have opted to extend the trend in recorded MAAT though to 2055, as this describes a more realistic scenario of future climate warming for this area (Fig. 3). With this trend, the MAAT for 2055 falls just below the projection for maximum warming as proposed by Burn (2004). For comparison purposes, modeling was also

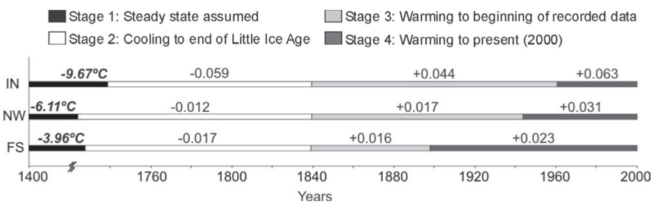

Figure 2. Paleo-climate trend used in the modeling. Stage 1: equilibrium temperature; Stage 2 to 4: subsequent ramps applied in °C/year.

conducted following an extension of the trend in recorded MAATs through to 2025, followed by a slight warming to 2055 based on the median warming ramp of +0.006ºC per year as specified by Burn et al (2004).

Configuration of the problem space

The T-ONE model was initiated using a single-layer geological substrate for all terrain types except in organic terrain, for which a two-layer substrate was modeled. In both cases, simulations were run at 6 hour time steps with grid spacing of 0.01 m at the ground surface exponentially increasing to a maximum of 8 m at greater depths. The depth of the grid was optimize according to TTOP estimation of the base of permafrost and was set at a minimum of 45 m in the Fort Simpson study area to 167 m in the Fort Good Hope region. A lower boundary heat flux of -40 mWm^{-2} was assumed. Within each 30 m grid element, ground temperatures were calculated at the specified depths below ground surface and iterated at successive time steps extending over the specified time intervals of interest (2000, 2025, and 2055). Model outputs are provided as a mean annual ground temperature.

T-ONE Modeling Results

Transient ground temperature modeling enables prediction of the incremental impacts to permafrost in response to a changing climate, and provides estimates of the timing of those changes. Typical model outputs include mean annual ground temperature profiles, permafrost distribution and thickness, active layer development and talik formation. A talik in this context is defined as the thawed layer between the seasonal active layer and the top of permafrost.

Inuvik

In general, moraine deposits cover ~45% of the Inuvik study area, with glaciofluvial/alluvial deposits occupying ~33%. Vegetation is dominated by shrubs (31%) followed by open black spruce (24%) and mixed forest (14%). Modeling using the extended trend in recoded MAATs predicts that 100% of the Inuvik area is underlain by permafrost at both 2000 and 2055. Mean ground temperatures at year 2000 range between -1.7°C in barren lichen cover underlain by glaciofluvial/alluvial deposits to -0.08°C in deciduous forest underlain by moraine deposits, increasing to -0.38°C and -0.01°C, respectively, by 2055 (Table 1).

Overall permafrost thickness ranges from ~40 m to over 150 m for white spruce on coarse-grained sediments. Modeling of

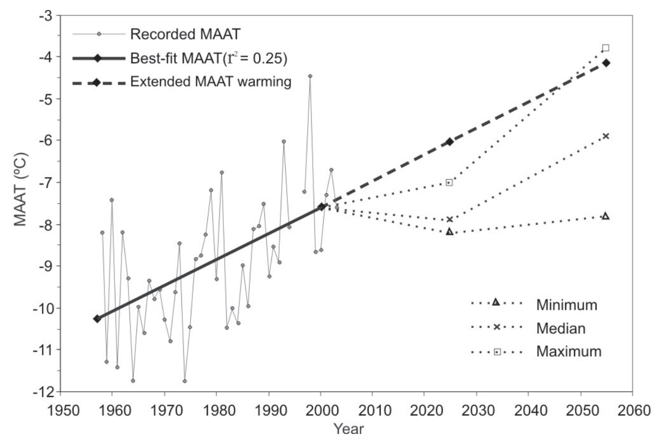

Figure 3. Minimum, mean, and maximum climate scenarios (Burn 2004) and extended trend of the 1970–2000 MAAT data for Inuvik.

Table 1. Predicted areal extent of permafrost and range of mean annual ground temperature (TTOP) in terrain modeled (excluding water bodies and bedrock) for each study area.

		Current conditions (2000)			Warming to 2055		
	% of study area modeled	% Frozen	Ground Temp. Min. (ºC)	Ground Temp. Max. (ºC)	% Frozen	Ground Temp. Min. (ºC)	Ground Temp. Max. (ºC)
IN	85.5	100	-1.65	-0.08	100	-0.38	-0.01
NW	79.6	96.0	-0.60	+2.13	85.9	-0.25	+2.90

present-day (2000) conditions predicts the absence of taliks overlying permafrost in the Inuvik area. Representative cases in Table 2 highlight the presence of thick permafrost in open and closed black spruce forests through to 2055 with increases in thaw depth of less than 1 m. Permafrost in shrub- and deciduous-dominated terrain is marginally thinner, with thaw depths of between 0.5 m and 3 m in 2000, with the development by 2055 of substantial taliks of up to 4.5 m for shrubs and 9 m for deciduous forest. Figure 4 shows the changes in permafrost thickness, thaw depth, and talik development for representative terrain units. The results for the median warming scenario presented by Burn et al. (2004) predicts slightly thinner seasonal active layers and more subdued talik development.

Norman Wells

About 50% of the Norman Wells study area is underlain by moraine deposits, followed by eolian/lacustrine deposits (18%) and glaciofluvial/alluvial deposits (12%). The dominant vegetation class is open black spruce forest (37%), followed by open white spruce (10%) and mixed forest (10%). The model predicts permafrost underlying 96% and 86% of the Norman Wells study area in 2000 and 2055, respectively (Table 1). Present-day (2000) ground temperatures range from -0.6°C to 2.1°C, with taliks over permafrost present in 13% of the study area). Continuous permafrost underlies

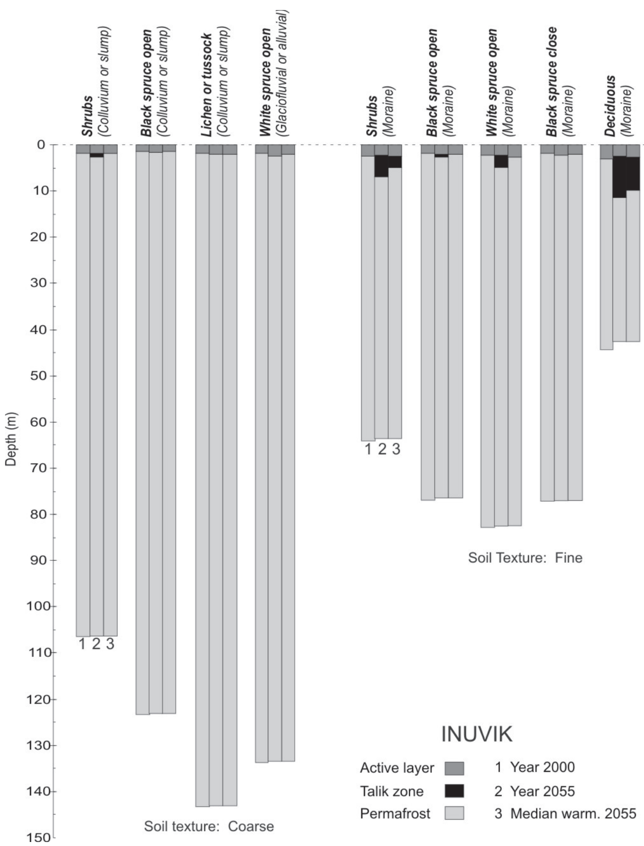

Figure 3. Summary of predicted active layer, talik and permafrost for representative terrain units in the Inuvik study area, 2000 and 2055; and 2055 median warming model of Burn (2004).

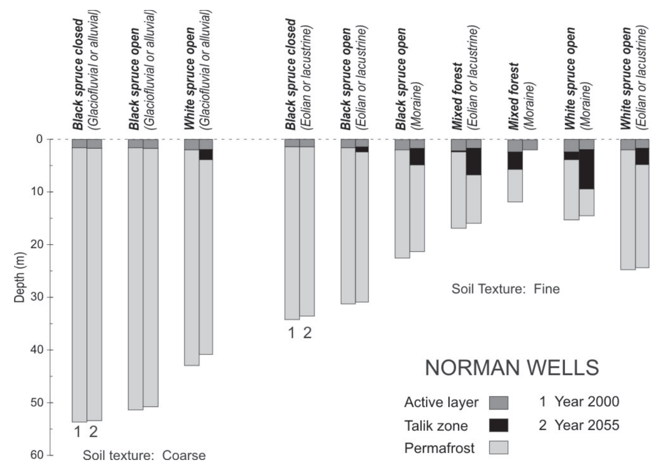

Figure 4. Summary of modeling results for representative terrain units in the Norman Wells study area.

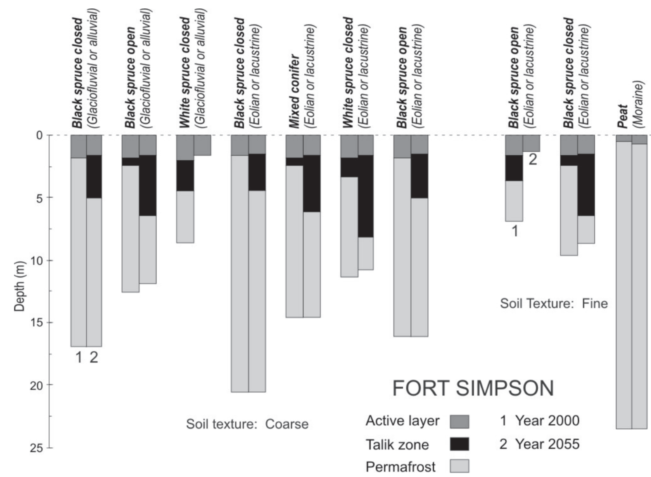

Figure 5. Summary of modeling results for representative terrain units in the Fort Simpson study area.

the majority of vegetation classes with the exception of deciduous forest (90% unfrozen), and fens and graminoids (100% unfrozen). Permafrost thickness ranges from 2.4 m under some deciduous forests to greater than 60 m beneath undifferentiated spruce, with a predicted thaw depth range from 0.6 m to 6.3 m. By 2055, relatively thin permafrost underlying deciduous forests, shrubs, and mixed forest is predicted to thaw completely, and for most representative terrain units, substantial taliks up to 8 m in thickness are predicted to develop under open white spruce on moraine. Table 2 and Figure 5 indicate changes in thaw depth ranging from a few centimetres to several meters, with complete permafrost thaw in the case of shrubs on moraine deposits. Only minimal permafrost thaw is predicted for open black spruce forest underlain by coarse-grained glaciofluvial/alluvial deposits.

Fort Simpson

Moraine deposits underlie ~65% of the Fort Simpson area, followed by eolian/lacustrine and glaciofluvial/alluvial deposits, which underly about 24% and 8% of terrain, respectively. Closed black spruce and open black spruce forests each cover ~24% of the study area, with closed white spruce occupying ~12%. Modeling predicts that approximately 22% of the Fort Simpson study area is underlain by permafrost, decreasing to about 17% by 2055 (Table 1). Estimated current (2000) ground temperatures range from about -0.24°C in peat bogs to almost 3°C in graminoids underlain by till. In 2000, taliks are predicted to overlie 54% of permafrost (11% of the study area). Overall, permafrost thickness ranges from just a few meters to 20 m or more in peat bogs. Relatively thick permafrost will persist in peat bogs and closed black spruce forests through 2055 (Table 2). Permafrost thaw during this period varies significantly between vegetation classes, ranging from less than 1 m in peat plateaus to 5–6 m beneath white spruce forests. Under current conditions, the model estimates that permafrost temperatures in the Fort Simpson region are only slightly below freezing, and that most permafrost-bearing terrain will remain marginally frozen (near-isothermal close to 0°C) through to 2055. However, permafrost beneath some black and white spruce forests is predicted to disappear by 2055. The thickness of the thaw layer above permafrost is predicted to increase by 3–5 m by 2055, with the exception of peat bogs that will see only small changes in thaw depth and permafrost thickness (Fig. 5).

Discussion

Our modeling results illustrate the variability in permafrost evolution for different terrain conditions (i.e., combinations of surficial materials and vegetation cover), under a continued climate warming. Where not already the case circa year 2000, ground temperatures are predicted to progressively warm towards isothermal, followed by the development and deepening of talik zones above permafrost. The formation of taliks has also been predicted by Kane et al. (1991). At the same time, the base of permafrost will slowly degrade upward towards the deepening talik zone. Latent heat effects are implied by the general increase in warming rates once ground temperatures increase above 0°C. For peat bogs characterized by relatively high heat capacities, active layer thickening and permafrost degradation is minimal within the time frames modeled. The model suggests that for much of Norman Wells and Inuvik terrain, only modest changes in permafrost thickness will be realized during this period, although increases in thaw penetration will be substantial for certain terrain types. The results may be summarized using the permafrost classification system of Shur & Jorgenson (2007). MAAT in the Inuvik area ('"climate driven,"' even with a warming trend) would still be cold enough to sustain permafrost. In contrast, in the Fort Simpson area much of the terrain would be underlain by '"climate-driven, ecosystem-protected"' permafrost where disturbance (e.g., change in the insulation layer) can cause the complete degradation of the permafrost with no re-establishment of initial permafrost conditions.

Numerical modeling affords a systematic and rigorous means for assessing ground thermal characteristics across extensive geographic areas. In the case of the TTOP and T-ONE models employed in this study, limited ground truthing and statistical validation of modeling outputs have established a reasonable level of confidence in model performance within the broader

Mackenzie Valley. While the T-ONE model generates apparently precise predictions (to multiple decimal points) of permafrost attributes such as temperature and thickness, it would be prudent to apply appropriate caution when evaluating model predictions, given that a -0.1°C change in ground temperature is equivalent to ~5 m of permafrost in typical surficial sediments. Also, we have noted that in the Inuvik area particularly, the model appears to overestimate active layer thickness and therefore possibly future rates of thaw penetration (Nixon, pers. com.). This may be related to our use of a one-layer system in which latent effects of excess ice and/or organic veneer are not adequately simulated.

Conclusion

Modeling of present-day (2000) ground thermal conditions confirms a clear north-to-south trend towards warmer ground temperatures, paralleled by a north-south decrease in areal extent and thickness of permafrost. The results also illustrate a north-to-south increase in thaw depth and development of taliks above the permafrost table. Predicted ground thermal conditions for 2055 (with a warming climate) confirms minor degradation at the base of permafrost with the greatest permafrost degradation occurring in the top few to several meters below the ground surface.

Abstract

In periglacial regions, frozen river banks are affected by thermal and mechanical erosion. In Siberia, bank retreat of up to 40 m per year is observed. This thermal erosion occurs during a few weeks, at springtime, with high enough water temperatures and river discharges. Until now, models of thermal erosion have been based on the assumption of a constant melting rate. We have developed a more general model at variable rate, whose solution is calculated with the integral method. Results of this model are compared with experiments, carried out in a cold room. The model has contributed to better understanding of the roles of each parameter during the thermal erosion process. The duration of such an acceleration phase is systematically studied.

Keywords: ablation; heat balance integral method; periglacial river; permafrost; phase change; thermal erosion.

Introduction

Most periglacial rivers exhibit a breakup period and a flood season associated with high discharge rates and high water temperatures. The Lena River in Siberia and its tributaries can be divided into two classes (1) the Lena basin outlet and (2) the southern sub-basins (Aldan, upper Lena, Vilui valley). A relatively low stream temperature variation and a high discharge variation characterize the Lena basin outlet. The stream temperature varies from 0°C to 14°C, and the discharges can reach 100,000 m^3/s in early June (Gautier et al. 2003, Liu et al. 2005, Yang et al. 2002). In the second case, the southern sub-basins are characterized by relatively high stream temperature and low discharge. For these rivers, stream temperatures are up to 4°C higher than those of the Lena outlet (Liu et al. 2005) and can reach 18°C; the discharges are about ten times smaller than those in the Lena basin outlet (Liu et al. 2005, Yang et al. 2002). During the break-up and flood seasons the water flow in permanent contact with frozen river banks induces both a fluvial thermal and mechanical erosion. This problem is non-linear because it involves a moving boundary (an interface between solid and liquid) whose location is unknown. Until now, models of thermal erosion based on the assumption of a constant melting rate for a constant convective flux at the interface have been used to study thermal erosion of ice and permafrost (Costard et al. 1999). The objective of this study is to propose a model of thermal erosion of permafrost without the simplified assumption of a constant melt rate. Once validated by the comparison with laboratory experiments, the model will be applied to the Siberian rivers case.

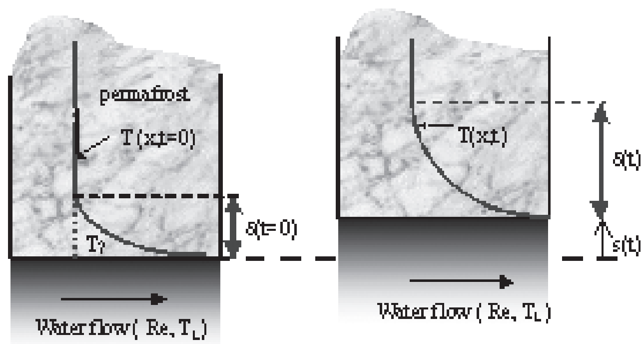

Figure 1. (a) The initially isothermal permafrost (T_∞) is suddenly heated by a permanent water flow (Re, T_L). After a rapid transient phase, the interface reaches the melting temperature (T_m=0°C). Then the thermal erosion initiates, and the interface starts to move. (b) The interface progressively moves. Its instantaneous position and erosion rate are given by s(t) and ds/dt. The instantaneous thickness of the thermal boundary layer is δ(t).

The Ablation Model at Variable Rate

Mathematical model

A semi-infinite permafrost sample initially at a uniform negative temperature (T_∞) is suddenly heated by a turbulent water flow of permanent temperature (T_L) and discharge (Q_L) (Fig. 1).

We suppose that all the sediment is immediately swept away by mechanical action of the water flow. The heat transfer occurs by conduction inside the permafrost (Eq. 1). At the permafrost-water interface, the convective heat flux from the water flow must balance the latent heat absorbed by melting, added to the conductive heat flux in the solid (Eq. 2).

$$\frac{\partial T}{\partial t} = \left(\frac{k}{\rho.c_p}\right)\frac{\partial}{\partial x}\left(\frac{\partial T}{\partial x}\right) \qquad x \geq s(t) \tag{1}$$

$$h(T_L - T_m) = \rho L \frac{\partial s}{\partial t} - k\left(\frac{\partial T}{\partial x}\right)_{x=s} \quad x = s(t) \tag{2}$$

where k [W m^{-1} K^{-1}], ρ [kg m^{-3}], cp [J kg^{-1} K^{-1}] and L [J/kg] are the thermal conductivity, the density, the specific heat, and the latent heat of melting of the permafrost, and h [W m^{-2} s^{-1}] is the heat transfer coefficient between turbulent water and permafrost.

Resolution by the heat balance integral method

The heat-balance integral method consists of integrating the heat conduction equation (Eq. 3) over the thermal layer $\delta(t)$. It is based on the assumption of a quadratic boundary layer temperature (Eq. 4).

$$\frac{\partial}{\partial t}\int_s^{\delta} T dx = \left(\frac{k}{\rho.c_p}\right)\left[\left.\frac{\partial T(x,t)}{\partial x}\right|_{x=\delta} - \left.\frac{\partial T(x,t)}{\partial x}\right|_{x=s}\right] \tag{3}$$

$$T(x,t) = T_\infty\left[-2\left(\frac{x-s}{\delta-s}\right) + \left(\frac{x-s}{\delta-s}\right)^2\right] \quad s(t) < x < \delta(t), \tag{4}$$

The temperature distribution (Eq. 4) is substituted in Equation 1 and the heat equation is integrated (Eq. 3), applying boundary and initial conditions. Then, solutions in a-dimensional form are obtained (Goodman 1958). The system of Goodman (1958) is solved for every time t during the thermal erosion process in order to get the instantaneous thermal boundary layer $\delta(t)$ and eroded thickness $s(t)$ (Randriamazaoro et al. 2007).

Results

Both the thermal boundary layer and the ablation rate increase (acceleration phase) and stabilize (stationary phase) towards asymptotic values (Eqs. 5, 6), which correspond to the solutions of the constant rate-melting model (Aguirre et al. 1994, Costard et al. 2003).

$$\delta_{lim} = \frac{2.k.L}{c_{p.}.q_{conv}} \tag{5}$$

$$\left(\frac{ds(t)}{dt}\right)_{lim} = \frac{q_{conv}}{\rho L + \rho.c_{p.}(T_\infty - T_m)} \tag{6}$$

where q_{conv} is the heat flux exchanged by convection at the interface between the water flow and the permafrost and includes both the effects of water temperature and discharge (Eq. 7).

$$q_{conv} = h.(T_L - T_f) \tag{7}$$

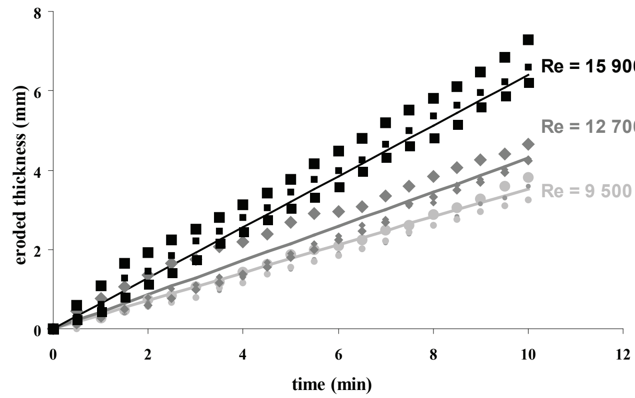

Figure 2. Measurements of eroded thickness of pure ice initially at –7.5°C, heated by a turbulent water flow at 5.5°C. In 10 minutes, the measured eroded thickness of the ice sample is 3.5 mm, 4.5 mm, 6.5 mm for Re=9500, 12,700, and 15,900 respectively.

Our model is validated by measurements of instantaneous eroded thickness of ice and permafrost samples in contact with a turbulent water flow in a cold room (Costard et al. 2003). One set of experiments is done on ice samples at an initial temperature equal to -7.5°C and the water temperature remains at 5.5°C during the experiments. Different Reynolds numbers are investigated. The ablation rate increases with the Reynolds number (Fig. 2).

Experiments suggest that the eroded thickness increases linearly with time (Fig. 2). Considering a stationary erosion rate, the measured erosion rate of ice is equal to 0.35 mm/min, 0.45 mm/min, and 0.65 mm/min for Re = 9500, 12,700, and 15,900 respectively. We tested our model to these particular experimental conditions (Fig. 3). The model predicts a first phase of acceleration during which both the thermal boundary layer and the erosion rate increase (Fig. 3). This first phase lasts a few minutes. The asymptotic values of the calculated ablation rate (Fig. 3) are consistent with the measured values (Fig. 2).

Other experiments are done on frozen ice sand samples (initially at –7.5°C) with different massic ice contents (ω=20%, 80%) and are compared with pure ice (Fig. 4). The turbulent water flow remains at 5.5°C and the Reynolds number is equal to 15,900.

The model is applied to these particular conditions, and again the experiments and the model are consistent (Figs. 4, 5).

The effects of the water temperature and the ice temperature are also investigated. The effects of the water temperature are predominant, whereas the effects of the ice temperature are very weak. The erosion rate increases with water temperature, ice temperature, and Reynolds number and decreases with the ice content. The model at variable rate predicts a first acceleration phase whose duration is typically greater for smaller erosion rates.

Then the model is applied to the Lena River. The convective heat flux is calculated (Eq. 7) for water temperature between 0°C and 20°C and for water discharges between 0 m^3/s and 120,000 m^3/s. The heat transfer coefficient h is estimated,

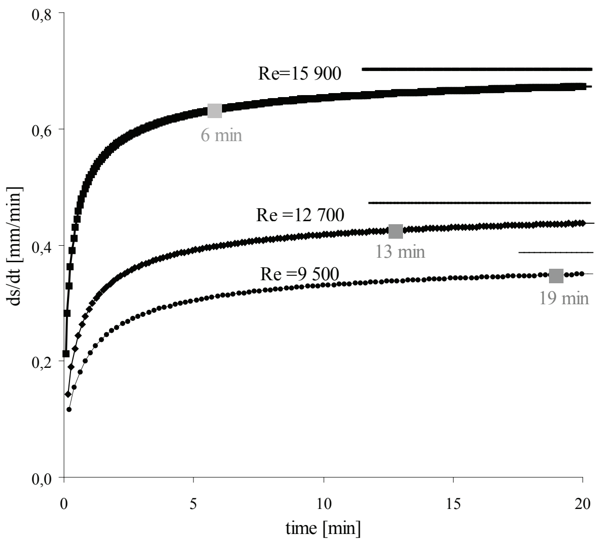

Figure 3. Theoretical erosion rate as a function of time for a water temperature equal to 5.5°C, an ice temperature equal to 7.5°C and different Reynolds numbers (Re=9500, 12,700, and 15,900) applied to the geometry of our hydraulic channel. The erosion rate increases rapidly (acceleration phase) and stabilises (stationary phase). The duration of the acceleration phase is calculated from the time necessary to reach 90% of the asymptotic value. The greater the Reynolds number, the greater the erosion rate and the smaller the duration of the acceleration phase. Measured values (Fig. 2) are consistent with the asymptotic calculated values.

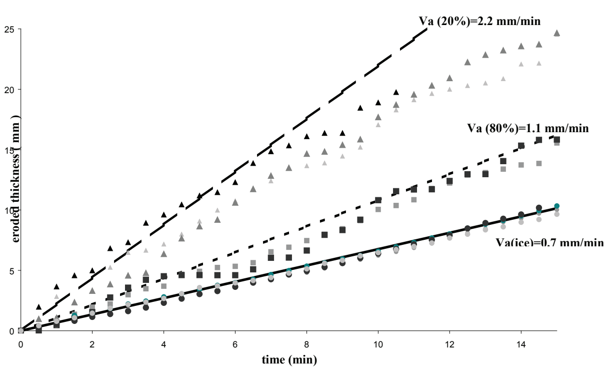

Figure 4. Measurements of eroded thickness of pure ice and sandy permafrost with different ice contents, initially at −7.5°C, heated by a turbulent water flow (5.5°C and Re=15,900). In 10 minutes, the measured eroded thickness is about 6 mm, 11 mm, 18 mm for pure ice, permafrost with ω=80%, and ω=20% respectively. Linear fit gives measured erosion rates equal to 0.7 mm/min, 1.1 mm/min and 2.2 mm/min for pure ice, permafrost with ω=80% and ω=20% respectively.

using the empirical law of Lunardini (1986) (A=0.0078, α=0.3333, β=0.9270) and the Manning equation applied to the geometry of the channel (Eqn. 8) (Costard et al. 2003).

$$h = A\left[\left(\frac{\sqrt{s}}{n}\right)^{3/5} l^{\,3/5-\beta}\right]\left[\mathrm{Pr}^{\,\alpha}\,\frac{k_w}{\upsilon_w{}^{\beta}}\right]Q^{\,\beta-3/5} \tag{8}$$

where S = 0.0001 m/m, n = 0.1, l = 10 km, k_w, v_w, Pr are the

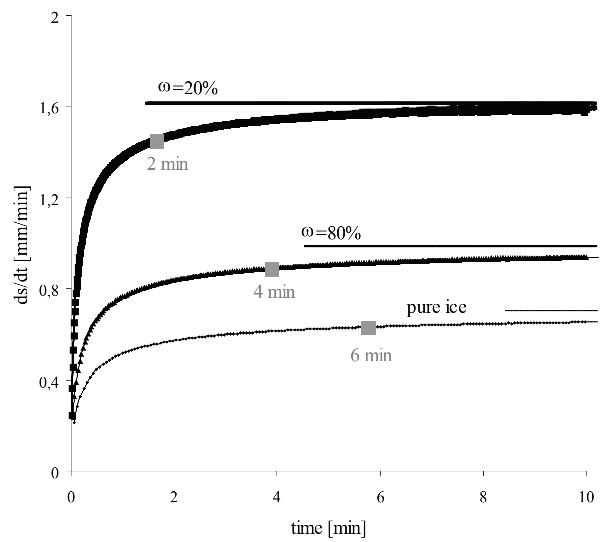

Figure 5. Theoretical erosion rate as a function of time for a water temperature equal to 5.5°C, an ice temperature equal to 7.5°C a Reynolds number equal to 15,900, applied to the geometry of our hydraulic channel. The erosion rate increases rapidly (acceleration phase) and stabilizes (stationary phase). The smaller the ice content, the greater the erosion rate and the smaller the duration of the acceleration phase. Measured values are consistent with the asymptotic values.

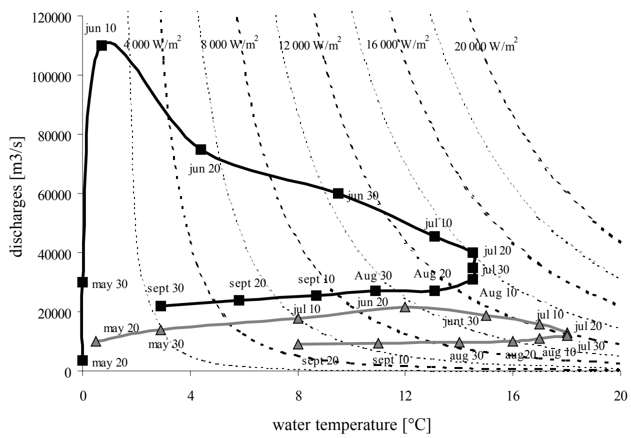

Figure 6. Diagram of heat flux versus discharge and water temperature.
---------- Isoflux lines (2 000 – 20 000 W/m²)
■ Water mean temperatures and discharges in the Lena basin outlet (Yang et al. 2002, Liu et al. 2005)
Δ Water mean temperatures and discharges in the Lena sub-basins (Aldan, Upper Lena, Vilui basin (Liu et al. 2005)).

longitudinal slope, the Manning roughness coefficient, the width of the river, the thermal conductivity of water [W m^{-1} K^{-1}], the cinematic viscosity of water [m^2 s^{-1}], and the Prandtl number, respectively.

Isoflux lines are plotted from the calculated values of the convective heat flux (Fig. 6). On this diagram, simultaneous measurements of water temperatures and discharges in the Lena basin outlet and the southern Lena sub-basins (Yang et al. 2002, Liu et al. 2005) every 10 days during the flood season are reported.

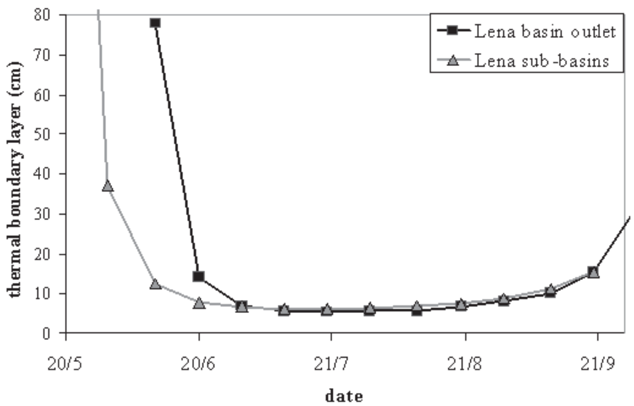

Figure 7. Evolution of the calculated thermal boundary layer thickness for the Lena basin outlet and the Lena sub-basins.

As expected, the heat flux increases when the water temperature and the discharge increase simultaneously from May to mid-June. By contrast, from June to July the water temperature is still increasing, while the discharge decreases by about 50%, and a positive trend of the heat flux is still observed. The maximum (12,000 W/m² and 14,000 W/m² for the southern Lena sub basin and for the Lena basin outlet, respectively) of the heat flux occurs during July when water reaches its maximum temperature. It appears that the convective heat flux evolution mainly depends on the water temperature evolution for Siberian rivers during the flood season. The heat flux variation for the Aldan, Upper Lena, and Vilui Rivers is similar to the one of the Lena basin outlet. The relative higher values of water temperatures for the southern Lena sub-basin are compensated by the relative higher values of the discharges for the Lena basin outlet.

With regards to specific heat flow, the application of the model of variable rate on pure ice or permafrost should allow determination of the thermal boundary layer thickness (Fig. 7), the ablation rate, and the duration of the acceleration phase (Fig. 8).

The greater the convective heat flux, the greater the erosion rate and the smaller the duration of the acceleration phase. The most favorable conditions to get the longer acceleration phase are obtained for the smaller values of the erosion rate at the beginning (early May) or at the end (October) of the flood season. For example, considering a small thermal erosion rate 0.06 mm/min (early May), the acceleration phase should last about 14 days.

Conclusions

A model of the fluvial thermal erosion has been formulated at variable rate. This mathematical model has been applied to a typical frozen river bank in permanent contact with a turbulent water flow. The expressions of the instantaneous melting thickness, ablation rate, and thermal boundary layer have been obtained by integral method and validated by experiments on ice samples. An acceleration phase occurs at the beginning of the process. The duration of this acceleration phase is quantified. Typically, the acceleration phase lasts longer for a low ablation rate. The ablation rate increases with water temperature and discharge and decreases with ice content. The effects of stream temperature and discharge can be represented by the convective heat flux. The heat flux along the river banks are identical for the Lena basin outlet and for the southern Lena basin because relative higher values of stream temperatures for the southern Lena sub-basin are compensated by the relative higher values of the discharges for the Lena basin outlet. From our studies, the stream temperature is an important parameter which controls the evolution of the erosion rate during the flood season. Further studies will take into account the possible effect of global warming on the thermal erosion rate.

Modeling Mountain Permafrost Distribution: A New Permafrost Map of Austria

Barbara Ebohon
Department of Geography and Geology, University of Salzburg, Austria
Lothar Schrott
Department of Geography and Geology, University of Salzburg, Austria

Abstract

Alpine permafrost response is very sensitive to climate change. Thus, it is of great interest to estimate and assess permafrost distribution in high mountain areas. In this study, the permafrost distribution of the Austrian Alps was modeled by using commands of the programs PERMAKART (for steep slopes) and PERM (for footslope-positions) which were applied in a DTM with a resolution of 50 m. Possible and probable permafrost areas of the Austrian Alps comprise approximately 1600 km². The potential permafrost area has been compared with BTS, spring temperature measurements, alpine meadows, and isotherms of the MAAT (mean annual air temperature). The results of the validation show that the map still needs some improvement on a local scale, but simulates the possible and probable permafrost distribution of the Austrian Alps as a good general overview.

Keywords: alpine permafrost; Austrian Alps; simulation; validation.

Introduction

Several studies carried out in the Austrian Alps have shown permafrost distribution above approximately 2500 m a.s.l. (Lieb 1998). Current global warming already causes a degradation of permafrost in some mountain regions.

Of particular interest are areas with discontinuous permafrost on steep talus slopes and rock walls. Due to the absence of a blocky layer, rock faces react quickly to climate change compared with debris-covered slopes (Gruber et al. 2004, Mittaz et al. 2000). In densely populated and developed mountain areas (e.g., ski resorts, etc.), where a degradation of permafrost, in particular at its lower limit could cause enhanced debris flow and rockfall activity, mapping and modeling of permafrost distribution is an important prerequisite to prevent natural hazards and risks.

In Switzerland, Haeberli has already started to publish profound knowledge about permafrost distribution in the year 1975. Afterwards a lot of empirical models were developed (e.g., PERMAKART: Keller 1992, PERMAMAP: Hoelzle 1994, PERM: Imhof 1996, PERMAMOD: Frauenfelder 1998). Now, also complex process-oriented models (e.g., PERMEBAL: Stocker-Mittaz et al. 2002), which are based on the particular understanding of the energy fluxes between permafrost and the atmosphere (Hoelzle et al. 2001, Etzelmueller et al. 2001), are already available. However, until recently, the possible and probable permafrost distribution in Austria has been mapped and modeled for only a few local regions (e.g., parts of the High and Low Tauern range) (Lieb 1996, Lieb 1998, Kellerer-Pirklbauer 2005).

Compared to Switzerland, Austria has much less direct (e.g., BTS, geophysics) and indirect data of permafrost occurrence; therefore, modeling of permafrost distribution is just slightly developing.

The aim of this study is to model the permafrost distribution for the entire Austrian Alps by adjusted lower limits for possible and probable permafrost with a simple model considering the relation between slope, altitude, aspect, and permafrost occurrence. In this approach, the often-used trisection of sporadic (<30%), discontinuous (30–80%) and continuous (>80%) permafrost (Nyenhuis 2006) is applied, where sporadic equals possible and discontinuous equals probable permafrost.

Table 1. Values used for the simulation.

	Permafrost possible (sporadic)		Permafrost probable (discontinuous)	
	Steep Slopes	Foot-slope positions	Steep Slopes	Foot-slope positions
N	2300 m a.s.l.	1690 m a.s.l.	2500 m a.s.l.	2410m a.s.l.
NE	2450 m a.s.l.	2100 m a.s.l.	2600 m a.s.l.	2500m a.s.l.
E	2575 m a.s.l.	2220 m a.s.l.	2720 m a.s.l.	2520m a.s.l.
SE	2700 m a.s.l.	2230 m a.s.l.	2850 m a.s.l.	2630m a.s.l.
S	2900 m a.s.l.	2340 m a.s.l.	2900 m a.s.l.	2690m a.s.l.
SW	2650 m a.s.l.	2230 m a.s.l.	2850 m a.s.l.	2630m a.s.l.
W	2600 m a.s.l.	2160 m a.s.l.	2700 m a.s.l.	2510m a.s.l.
NW	2530 m a.s.l.	2120 m a.s.l.	2580 m a.s.l.	2470m a.s.l.
Flat areas	Permafrost possible (sporadic)		Permafrost probable (discontinuous)	
Wind-exposed	2590m a.s.l.		2710m a.s.l.	
Sheltered from wind	2640m a.s.l.		2900m a.s.l.	

Although such a map has, inherently, a limited accuracy, it allows approximations of the permafrost distribution on a national scale and enables comparisons with other Alpine provinces and countries (Frauenfelder et al. 1998).

Austria is positioned at the edge of the eastern margin of the Alps. The absolute heights of mountain ranges decline from west to east in Austria, so that the permafrost areas have their maximum extension in the western federal states.

Methods

The first well-known permafrost model in Central Europe, known as PERMAKART, has been introduced by Keller (1992). PERMAKART is implemented into the GIS-software ARC INFO. On the basis of the topo-climatic key from Heaberli (1975), which analyses the relation between slope, altitude, aspect, and permafrost occurrence, the model is able to distinguish between probable, possible, and no permafrost.

The model PERM (Imhof 1996) is also mostly based on the topo-climatic key from Heaberli (1975), but has been implemented into the raster-GIS-system IDRISI. For the calculation of the foot-slope positions, the differentiating GIS-System didn't offer the same possibilities as ARC VIEW. Therefore, foot-slope positions are generated manually through a smoothing of the DTM.

To work in detectible paces, every step was reproduced in ArcGIS9. Since the empirical values for the simulation (limits of possible and probable permafrost distribution related to altitude, aspect, slope- and footslope-positions) were originally deduced and calibrated for the Upper Engadine in the eastern Swiss Alps (Haeberli 1975), it was necessary to adjust them to the eastern Alps. Values of the lower limits of discontinuous permafrost in the central Alps of Austria were used after Lieb (1998) to model the probable permafrost distribution. Since values for the lower limit of possible permafrost were not available, they have been deduced from the relation between lower limits of possible to probable permafrost in Switzerland.

For the calculation of the lower limit of permafrost for wind-exposed areas, mean elevation values of steep slopes are generated for probable and possible permafrost. Concerning regions of possible permafrost, the lower limit for wind-sheltered areas lays 50 m above the one for wind exposed regions. For wind-sheltered areas, the highest value (2900 m a.s.l.) is used to determine the lower boundary of probable permafrost.

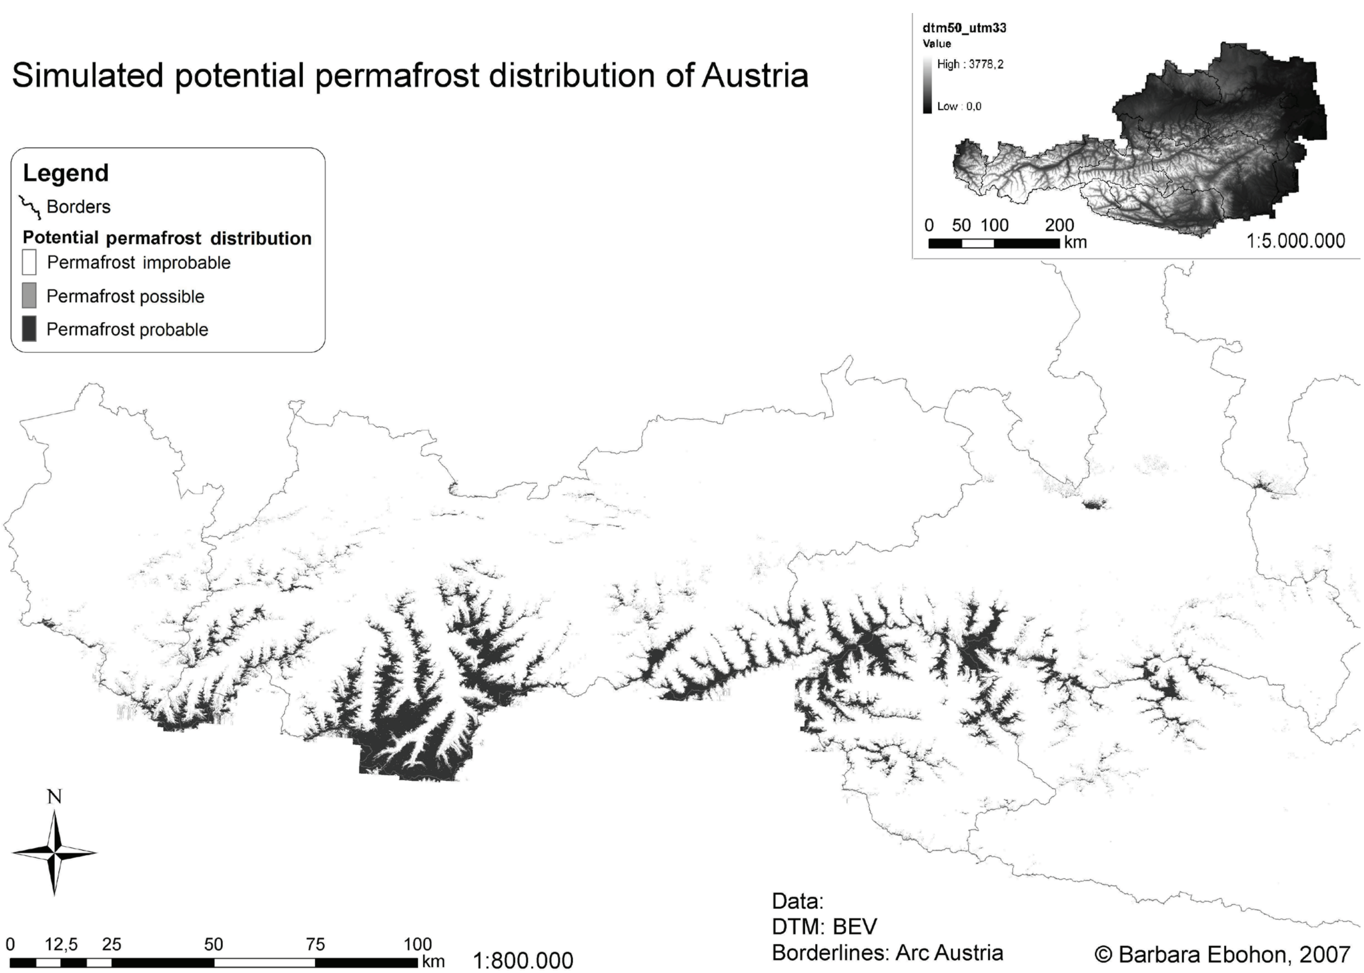

Figure 1. Map of the permafrost distribution of Austria showing the total permafrost territory of about 1600 km² (The difference between possible and probable permafrost can not be seen in this resolution: for higher resolution please see Figs. 5 and 6.).

Previous studies using PERMAKART and PERM show that this application of permafrost modeling, utilized on a nationwide scale, allows good approximations of permafrost distribution.

In a first approach, queries similar to the model PERMAKART (Keller 1994) were used to simulate permafrost of steep slopes. A map of inclination was produced and utilized to highlight all areas above the limits of possible and probable permafrost steeper than 10°, subdivided into different aspects.

The footslope-positions were worked out through a calculation of the curvature similar to the model PERM (Imhof 1992): First the DTM was smoothed, and then the original DTM was subtracted from the smoothed DTM. Areas which show values above zero are supposed to be convex regions, while all values below zero show concavities. In a next step, a map which pointed out all regions flatter than 10° was produced. This step allowed determining all flat and concave areas.

Afterwards all areas steeper than 10° were extracted and hemmed with a 150 m buffer. Following those queries, areas could be extracted which are concave, flat, and not more than 150 m away from steep slopes. On these footslope-positions the values for possible and probable permafrost were applied.

In this context, Haeberli (1975) and Etzelmueller (2001) stated that, in flat areas, the influence of air temperature is much more important than differences in radiation. Following that, flat, concave (troughs), and convex (domes) areas with less than 10° inclination above the lower limit of possible and probable permafrost were pictured.

All queries were summed and applied on a DTM with a resolution of 50 m using the UTM-coordinate system.

Table 2. Comparison of the results from the model starting to calculate steep slopes at 5° and at 10° inclination.

	5°model	10° model
Permafrost possible	711 km²	721 km²
Permafrost probable	899 km²	873 km²
Permafrost distribution (total)	1610 km²	1594 km²

Table 3: Relative permafrost areas of Austria (%) by federal states.

	Permafrost total	Permafrost possible	Permafrost probable
Burgenland	0.00	0.00	0.00
Carinthia	1.65	0.87	0.78
Lower Austria	0.00	0.00	0.00
Upper Austria	0.04	0.03	0.01
Salzburg	2.76	1.48	1.28
Styria	0.05	0.05	0.00
Tirol	9.28	3.84	5.44
Vorarlberg	1.90	1.28	0.61
Vienna	0.00	0.00	0.00
Austria	1.90	0.86	1.04

Results and Validation

Results

The permafrost map displays areas with improbable (equals no permafrost), possible, and probable permafrost and gives an overview of regional differences. At first sight, there is a strong dominance of permafrost occurrence in the western higher part of Austria, whereas the eastern part shows a somewhat patchy distribution.

To pay attention to different inclination thresholds discussed in the literature (5°/10°), two models with different conditions were applied. It is surprising that there are hardly differences in the calculated permafrost areas between the model which started calculating steep slopes at 5° inclination and the second one taking 10° into consideration. In the calculations that follow, the results of the 10° model were used.

Modeling results show that 1.9% of the territory of Austria can be assigned to mountain permafrost. This corresponds to an area of approximately 1600 km².

In Tyrol, 9.3% of the area is underlain by permafrost. This is a significant proportion compared to values for Switzerland (between 4 and 6%). Estimates for Salzburg, Vorarlberg, and Carinthia vary between 2 and 3%.

Validation

Validation was primarily a comparing of the modeling results with data from basal snow temperature measurements (BTS) and spring water temperatures.

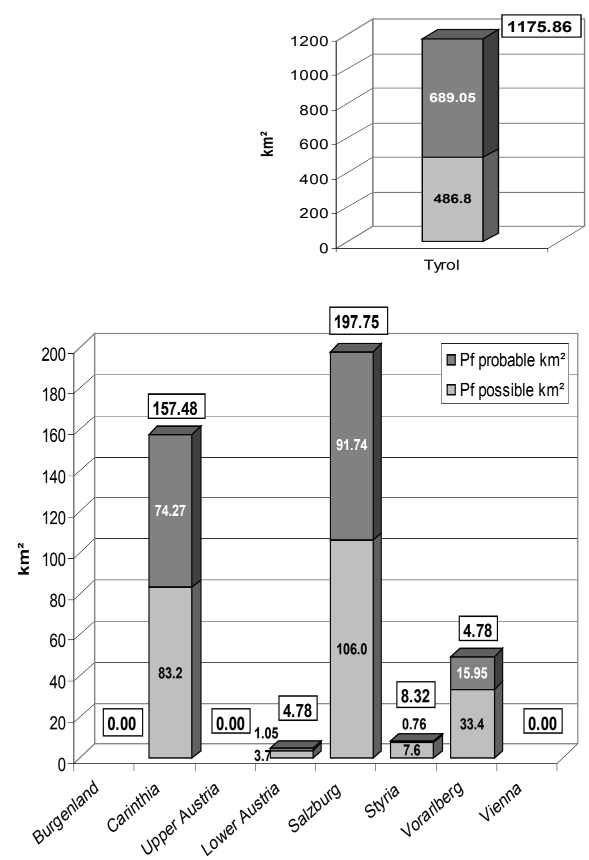

Figure 2a, 2b. Potential permafrost distribution of Austria in km².

Summarizing all measurements from local study sites such as Kaisergratspitz, Oelgrube, Sulzkar, Goessnitzvalley/ Langvalley, Hoher Sonnblick, Doesener Valley, Reisseck, and Hafergruppe, data from 300 point measurements allow a quick and reasonably good approximation of regional permafrost distribution.

Following the comparison between the simulated area with the measuring points, 48.7% of the measurements (BTS, spring water temperatures) match the three simulated categories (no PF, possible PF, probable PF). However, it should be noted that many points are just slightly outside the simulated permafrost area and probably a problem of DTM resolution or imprecise information of the point measurements which were mostly analogue and subsequently digitized for the validation. Combining the two categories, "PF possible" and "PF probable," into one entire zone, already 71.1% of the point measurements (BTS and spring water temperature data) used for validation accord with this calculation. Zoning the area of simulated permafrost after different exposures, it should be stated that N, NE, and SE are mapped well, and E, S, and SW are relatively well-presented. W and NW need further investigation on a local scale.

It can also be mentioned, that areas of rockslopes without vegetation, extracted from CORINE-Data 2000 (Aubrecht 1998), often match the modeled areas of permafrost.

Comparing the simulated permafrost area with the distribution of alpine meadows (CORINE 2000), only about 3% (44.5 km²) of simulated potential permafrost distribution intersects with them (Fig. 5). It has to be considered that permafrost and vegetation exclude each other often, but not always. It is notable that most intersections are northerly exposures. Therefore, northern aspects should be investigated more precisely on a local scale (e.g., grain size analyses, lithology, etc.).

It is well known that permafrost probably exists above certain threshold values concerning the MAAT (mean annual air temperature). Following this approach, another adjustment is made through the comparison of simulated permafrost areas with calculated isotherms based on MAAT from 1961–1990 and a total of 117 measurement stations and contour lines. The calculated isotherms mostly lay some few meters above the contour lines applied by Lieb (1996), who used the threshold of 2250 m a.s.l. for discontinuous permafrost

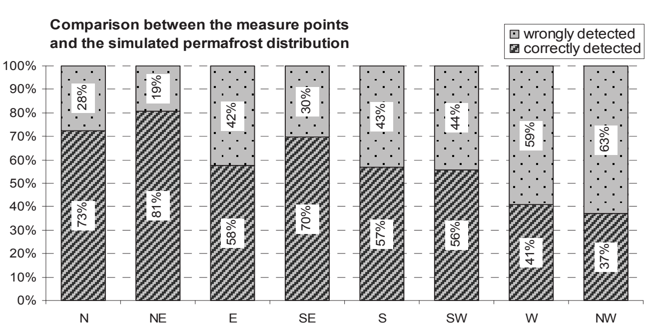

Figure 3. Comparison between measurement points (BTS, spring water temperatures) and permafrost occurrence (simulated permafrost distribution), differentiated in aspects.

and 3250 m a.s.l. for continuous permafrost. Comparatively, areas above the -2°C isotherm refer to discontinuous permafrost, while areas above the -6°C isotherm point to continuous permafrost. It must be stated, that only a small zone of continuous permafrost can be expected in Austria because most of the areas above -6°C MAAT are occupied by glaciers. In the N, NW, and NE aspects, the borderlines of discontinuous permafrost match the modeled area quite well, while in the SW, S, and SE aspects, borderlines are much lower than the limit of simulated permafrost.

Discussion

In summary, the simulation gives a useful overview of possible and probable permafrost distribution in the Austrian Alps. There are, however, still some unsolved problems and inaccuracies. As Keller & Hoelzle (1996) stated, one big issue is the appointment of the critical inclination, which differentiates between steep and moderate slopes. The approach presented has shown that there are minor differences between the permafrost areas calculated with the two models (5 and 10° inclination), but it remains unclear whether a threshold above 10° would show better results.

Also, the distinction between western and eastern Austria should be analyzed in more detail according to well-known temperature differences.

Improvements to this study would also be achieved by including more data on rock glaciers and higher resolution DTM data to better represent the strongly differentiated relief of the Austrian Alps.

Moreover, the distinction between the two categories—"permafrost possible" and "permafrost probable"—is still problematic because the data used on existing permafrost occurrences are based on point measurements (BTS and spring temperatures) only. The interpolation of these data produces simulated lower boundaries of permafrost distribution with limited accuracy. A further problem is related to the semantic differentiation of possible and probable permafrost, and to the unknown quantitative proportion of permafrost in these categories (Heginbottom 2002).

There are also problems with the values used themselves: they represent only mean values derived from one region in the Upper Tauern. Because of a lack of values for other areas, they were used to model the permafrost distribution for the entire area of Austria.

To improve the accuracy of the regional permafrost distribution map, more validation data from BTS measurements and field geophysics are needed. Furthermore, data should be more uniformly distributed over the Austrian territory.

It would then be possible to rework the empirical approach and to derive values for permafrost distribution. The more empirical data available, the better the adjustment to regional and local conditions would be.

Lieb (1996) stated that the difference between N and S orientation concerning intact rock glaciers is about 273 m (mean value for entire Austria). Whether the accuracy can be raised by adjusting the permafrost boundaries to this value is still an open question.

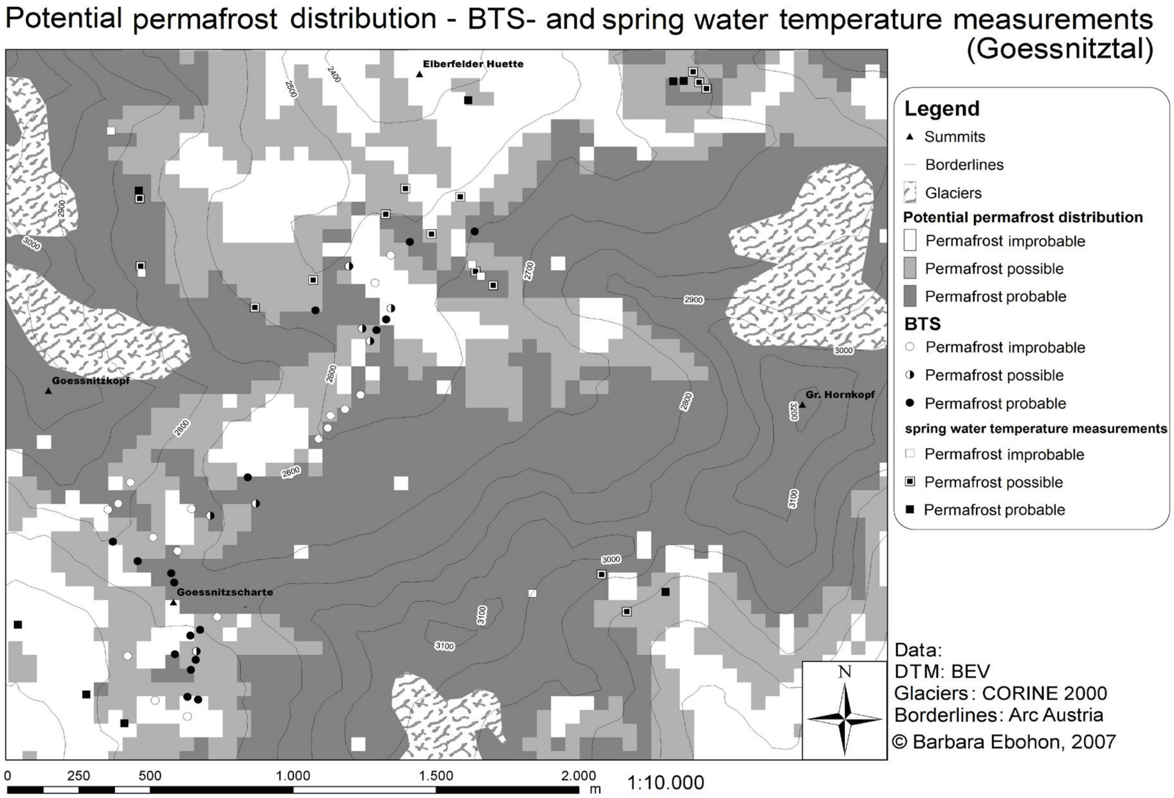

Figure 4. Permafrost distribution compared with BTS data and spring temperature measurements (data: G.K. Lieb, pers.com.).

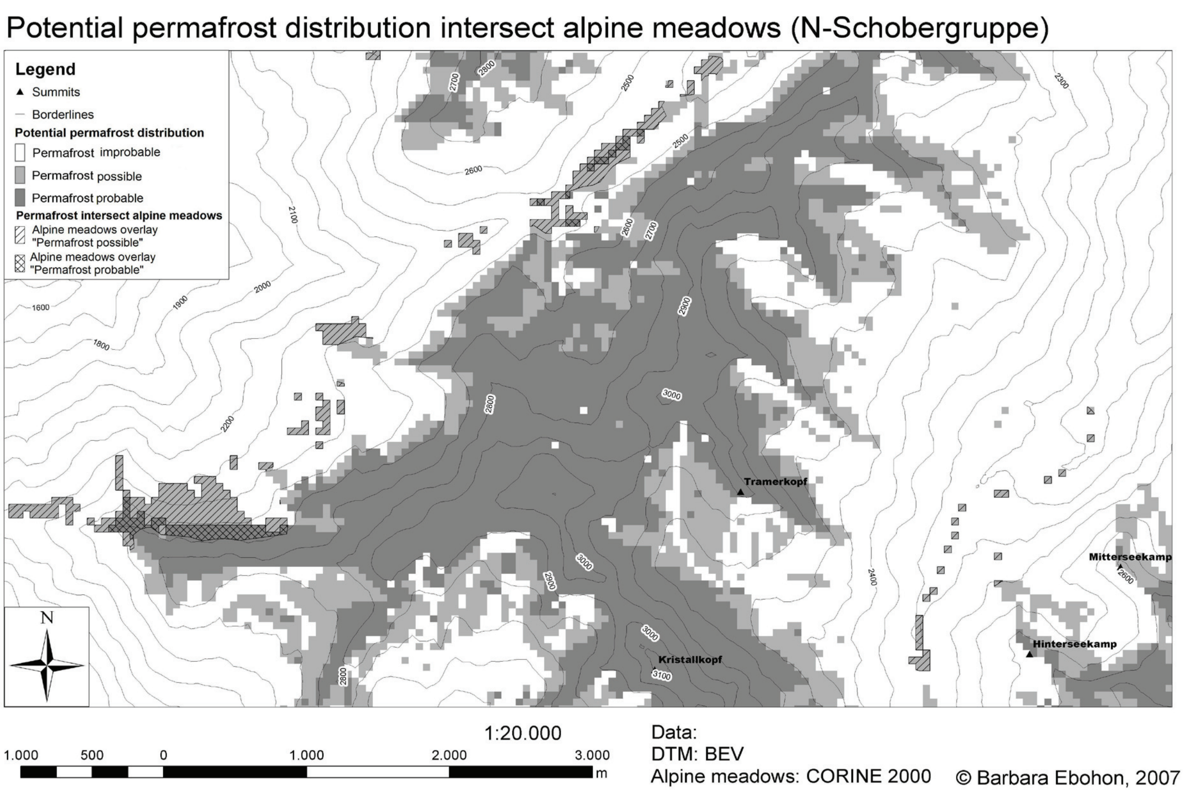

Figure 5. Comparison of simulated permafrost distribution with vegetation (alpine meadows).

Another important issue is the indication of permafrost areas at lower altitudes than expected, which is probably only possible to be pictured through a physically based model. This kind of model is able to reproduce the energy balance, and therefore, can record those areas and should be further developed in future.

Abstract

The Geological Survey of Canada has implemented a GIS-coupled, finite-element ground thermal model for simulating the response of permafrost in the Mackenzie Valley to progressive climate change. Near-isothermal ground temperature profiles observed in southern portions of the Valley indicate that ground temperatures are presently in disequilibrium with the current climate, and have likely been warming for many decades or centuries. Finite-element methods require specification of initial conditions from which forward modeling can proceed. However, due to the lack of detailed information about current ground temperatures in the region, initial ground temperature profiles for forward modeling must be estimated based on available proxy data. In this work, climate trends observed in the paleo-climatic record are used to reconstruct regional air temperature trends over the past several hundred years. Numerical simulations using this paleo-climate reconstruction successfully reproduce the essential characteristics of the ground temperature regime as observed in borehole records.

Keywords: climate change; numerical model; permafrost; Mackenzie Valley.

Introduction

The Geological Survey of Canada has implemented the T-ONE one-dimensional finite-element ground thermal model (Goodrich 1982) into an ArcGIS platform to simulate the response of permafrost in the Mackenzie valley to progressive climate change. The purpose of the model is to facilitate rigorous and systematic study of the climate-driven evolution of regional ground temperatures as expressed in the present and future distribution and thickness of permafrost (Duchesne et al. 2008). Finite-element models require specification of initial conditions from which forward modeling can proceed, including an initial ground temperature profile for each geographic grid location modeled. Given the limited availability of actual data from instrumented boreholes, present-day ground temperature profiles can be estimated based on transient modeling from an assumed earlier period of quasi-equilibrium to the present. Apart from an initial ground temperature profile, our configuration of the T-ONE model requires specification of rates of change in atmospheric temperature (upper boundary condition) to drive the model according to past and/or future scenarios of climate change, and specification of the regional geothermal heat flux (lower boundary condition). For modeling near-surface ground temperatures, initial profiles can be equilibrated to the atmosphere and ramped using short meteorological data sets (Möldes & Romanovski 2006). However, the deeper ground thermal regime will continue to reflect aspects of the initial climate (such as the presence of deep permafrost) during the equilibrium period even when the ground surface is exposed to sustained atmospheric warming. The specification of initial ground temperature profiles and the time frame selected for modeling from past to present can potentially exert a strong influence on model predictions of the current ground thermal state. Available borehole observations in the discontinuous permafrost zone of the Mackenzie Valley frequently identify near-isothermal conditions close to 0ºC, implying that present day permafrost is in disequilibrium with the current atmospheric temperature regime. This notion is consistent with the observed progressive increase in mean annual air temperatures throughout the Mackenzie Valley during the past century. Taking into account this historic warming trend, we are unlikely to establish a reasonable representation of current ground thermal conditions by employing present-day, or even 20th century climate conditions as a starting point for forward modeling.

This paper describes the reconstruction of mean annual air temperature (MAAT) trends for the Fort Simpson region, NWT, using available climate records and proxy reconstructions of paleo-climatic data to (1) identify a suitable period of quasi-stable regional climate for estimating initial equilibrium ground temperature profiles, and (2) establish an appropriate scenario of climate change from past to present to facilitate prediction of present and future permafrost conditions. We have also compared the results of both equilibrium modeling (driven by contemporary climate data) and transient modeling (from past to present) to ground temperature profiles from selected boreholes in the Mackenzie Valley to illustrate the importance of initial conditions and specification of an appropriate start date for forward modeling.

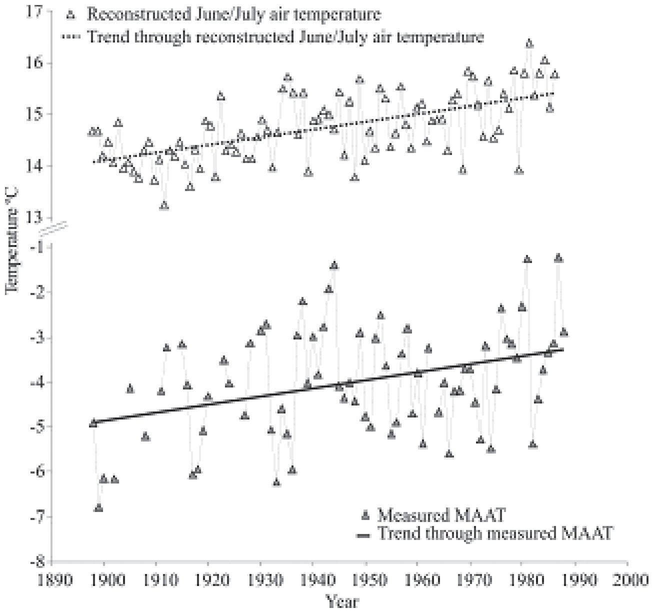

Figure 1. Best-fit lines through MAAT of measured June/July for Fort Simpson and of summer temperature reconstructions (Szeicz & MacDonald 1995) for the period 1898–1988.

Climate Data

Mean annual air temperatures from climate records

We have consolidated available climate data for the study area, consisting of two daily mean air temperature series. (Environment Canada 2002). The most recent data (for the period 1963–2002) were combined with older data (1898–1963) to produce a single continuous temperature series of daily averages. MAAT was calculated from the daily mean values from January 1 through December 31.

Proxy data for reconstructing paleo-climatic trends

A variety of different proxy records can be used to reconstruct past climatic conditions (Gajewski & Atkinson 2003), such as tree rings, lake sediments, ice cores, etc. Proxy data requirements for this study include: acceptable temporal resolution, ready availability, and suitable spatial extent of the reconstruction (site specific, regional, hemispherical, or global). Of these proxy types, tree rings satisfy the majority of the requirements. A limitation of the temperature reconstructions from tree rings is that they are specific to summer temperatures only and lack the contribution of winter months on the MAAT (Jones et al. 2003). A summer air temperature (June/July) reconstruction by Szeicz and MacDonald (1995) was selected out of a group of available data sets. The authors used age-dependent tree ring modeling to derive estimates of average summer air temperatures from AD 1638–1988. Their study provides important information on climate change trends over a relatively long time period for a region that is geographically consistent with the Fort Simpson study area. The data used for the climate reconstruction are available from the NOAA paleoclimatology web site (http://www.nc dc.noaa.gov/paleo/recons.html.)

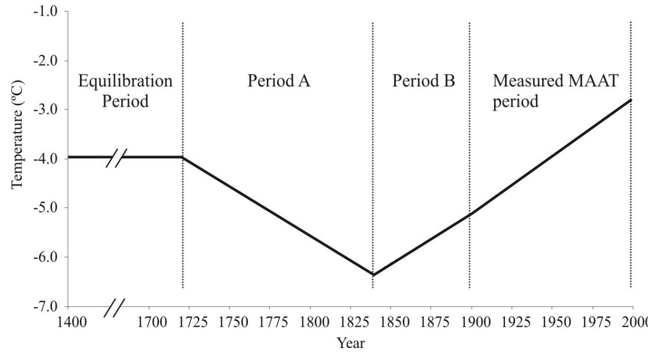

Figure 2. Reconstructed MAATs from 1720–1897 following trends in Group A and Group B, and measured MAAT from 1898–2000 with best fit line for Fort Simpson.

Mann et al. (1999) documented mean annual air temperature anomalies specific to the northern hemisphere for the period 1000–1998, based on tree ring and ice-core data. The reconstructed climate data are presented as MAAT anomalies relative to the 1961–1990 northern hemispherical mean. We used data for the period 1400–1746 to estimate a long-term MAAT representative of an extended period of quasi-stable climate assumed to exist prior to 1750. In this work, the hemispheric temperature anomalies provided by Mann et al. (1999) were examined for general climate trends in order to establish a long term deviation from the 1961–1990 air temperature normal (-3.72ºC) for Fort Simpson. Although not ideal for our purposes, the lack of available data alternatives has dictated that we rely on hemispheric rather than regional proxies to establish regional paleo-climatic trends prior to 1900.

Methods

Available temperature records and proxy climate data (Begin et al. 2000) indicate that Canada's western Arctic has experienced significant variations in mean annual air temperature over the past 250 years, with a modest cooling during the Little Ice Age followed by a progressive warming of climate from the early 1800s to present. As such it would be inappropriate to attempt to reproduce current permafrost conditions in the Mackenzie Valley by relying only on an equilibrium model of the ground thermal state. Neither would it be appropriate to initiate transient numeric modeling at any time during the past century or so without having initial ground temperature profiles specific to the time of initiation of the transient model.

Model initialization at quasi-equilibrium

In order to implement the transient numeric model, we specify a time at which a state of quasi-equilibrium was assumed to exist between atmospheric temperatures and the ground thermal state, from which forward modeling is initiated. For modeling purposes we assume the existence of an extended period of quasi-equilibrium prior to about 1750 AD, characterized by a long-term mean annual air temperature for Fort Simpson of about -4°C, based on the work of Mann et al. (1999). These equilibrium ground temperature profiles serve as the starting point for forward modeling from past to present (i.e. AD 2000), through incorporation of the paleo-climatic trends described below.

Identification of paleo-climatic trends

We examined the relations between measured and reconstructed summer air temperatures and measured MAAT using simple linear regression. A low correlation (R2 = 0.14) for measured summer temperature regressed against measured MAAT indicates that summer temperatures are ideal predictors of MAAT for the Fort Simpson study area, although other studies have used summer temperatures in such a context (Juliussen & Humlum 2007).

A higher R2 value was obtained for winter air temperatures (December/January/February) regressed against measured MAAT. However, given the lack of reliable proxy data representative of regional winter temperatures, summer temperature reconstructions from tree-ring data were employed in this work. Linear regression of available data described trends in measured MAAT for Fort Simpson and the reconstructed June/July tree-ring temperatures for the period 1898–1988 (Fig. 1).

As mentioned above, the weak correlation between measured June/July air temperature and MAATs from climate records inhibits the direct use of predictive models for estimating past MAATs from proxy indicators of mean summer temperature. Alternatively, the slopes of the best fit lines through recorded MAATs and reconstructed June/July temperatures are very similar, being 0.018ºC/year and 0.015ºC/year, respectively. According to the general trends, MAAT has increased by about 1.8ºC over the past 100 years, and reconstructed June/July temperatures have increased by a similar amount (1.5ºC). Based on this similarity, it is feasible to use the reconstructed summer temperature trends as an indicator of general trends in regional MAAT. Therefore, the recorded MAAT for the year 1898 for Fort Simpson is used as an anchor point from which to transform the temperature trends observed within the summer proxy data to estimate MAAT for the entire proxy period. This transformation must be used with caution as previous studies, together with the relation mentioned above, suggest that summer temperatures explain less yearly variance than winter temperatures and can lead to potentially flawed indications of past climate if summer values alone are used to reconstruct yearly temperatures (Jones et al. 2003). Linear regression was also used to characterize the general trends in summer temperature data for discrete time intervals prior to 1898 (i.e. the beginning of recorded temperature data).

A three-year running average was applied to the tree-ring temperature reconstruction of Szeicz and MacDonald (1995) to clarify general trends in the data (Fig. 2). According to the smoothed data, a general cooling trend from quasi-equilibrium at 1746 reached a minimum temperature around 1838. This cooling period was followed by a general warming trend through to the present.

Based on the general trends observed, the reconstructed summer temperature data were partitioned at AD 1838, corresponding to the apparent minimum temperature of the contemporary Little Ice Age. The paleo-climate record was separated into two periods: period A from 1746–1838 and period B from 1839–1897 (Fig. 2). Period A is characterized by a pronounced cooling trend. A best fit line through the data (r^2 = 0.41) indicates a cooling rate of 0.0171ºC/year over 92 years with a total change in temperature of 1.57Cº. Period B is characterized by a warming trend from 1838 to the start of the modern temperature record in 1898. Based on a best-fit line through the data, mean annual air temperatures warmed by 0.98Cº during this 58 year period at a rate of 0.0169ºC/year.

A best-fit line through the modern MAAT record for Fort Simpson (r^2 = 0.27) was used to specify an anchor point from which the trends identified in Figure 1 were used to estimate MAAT previous to the modern record. At the beginning of period A, the observed trend was forced backward by 25 years to 1721, intersecting with the assumed long-term equilibrium MAAT of -3.96ºC. This allowed for a smooth transition from the assumed long-term MAAT to the cooling trend characteristic of period A. Figure 3 shows the equilibration period using an average value from 1400–1720, reconstructed MAATs between 1721 and 1898 and the MAAT trend at Fort Simpson determined from the modern temperature record, which together comprise the paleo-climate scenario employed in transient ground thermal modeling from 1721 to present.

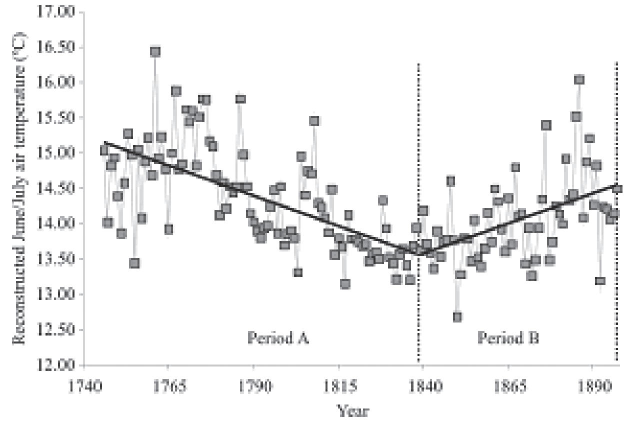

Figure 3. Reconstructed summer air temperatures from Szeicz & MacDonald (1995) smoothed wit h a 3-year running mean.

Comparison of modeled vs. recorded ground temperature

To facilitate evaluation of the influence of initial conditions and start date on model predictions, six measured ground temperature profiles from the Fort Simpson area are compared to results of transient numerical modeling, using the temperature reconstruction and an equilibrium solution based on the 1971–2000 normal. The boreholes are a part of a Geological Survey of Canada network for observing permafrost conditions throughout the Mackenzie Valley. The physical parameters assumed for each borehole site and corresponding modeling run are presented in Table 1. At this point it would prove useful to give a simple description

Table 1. Parameters recorded at each borehole and associated modeling properties.

Borehole properties				Modeled properties				
Borehole	Vegetation	Surficial geology	Material	Saturation (Sr)	NT	NF	Bulk density (Kg/m^3)	Texture
94TC1	Closed bs.	Glacio-lacustrine	Sand	0.80	0.55	0.24	1500	Coarse
97TC1	Aspen	Glacio-lacustrine	Silt	0.55	0.30	0.90	1500	Fine
97TC2	Closed bs.	Glacio-lacustrine	Sand	0.80	0.24	0.55	1500	Coarse
97TC4	Open bs.	Glacio-lacustrine	Fine sand	0.85	0.24	0.60	1500	Fine
99TC1	Open bs	Glacio-lacustrine	1.5 of organic over silt	1.0	0.14	0.50	300/ 1500	1.5 organic over fine
99TC2	Fen	Glacio-lacustrine	7 m organic over clay	1.0	0.12	0.70	300/ 1500	7 m Organics over fine

Note: Sr refers to soil water content in terms of the degree of pore saturation; bs. refers to Black spruce (*Picea mariana*).

of the mechanics of the T-ONE model. A more complete description of model parameters can be found in Duchesne et al. (2008) and Wright et al. (2003, 2001). Annual air temperature trends are incorporated in the model through seasonal thawing and freezing degree days. N-factors reflect the thermal off-set between ground surface and atmospheric temperatures. The thawing (summer) n-factor incorporates effects of vegetation on the ground thermal regime, while the effect of winter snow pack is assumed to be implicit in the freezing (winter) n-factor.

Moisture content is described in terms of the degree of pore saturation, based on porosity values derived from specifications of dry bulk density of earth materials. The model assumes a purely conductive heat flow, following the assumption that conduction is the dominant heat transfer process in permafrost landscapes (Hinkle & Outcalt 1994, Outcalt et al. 1990). The effect of latent heat due to the freezing of water or the thawing of ice is incorporated in the model. In the cases present in this paper, the one-dimensional modeling space was set at depth of 45 m with grid spacing ranging from 0.01 m at the surface to 2.0 m at depth. The lower boundary condition is defined in terms of geothermal heat flow, set at a regional value of -0.40 Wm^{-2} (Judge 1975).

The transient model was equilibrated using a -3.96ºC MAAT, with forward modeling initiated at 1721, following the generalized climate change scenario described in Figure 3 to the year 2000. For comparison purposes, a separate equilibrium solution was obtained for each borehole case using a MAAT of -3.01ºC, which is representative of the 1971–2000 climate normal at Fort Simpson.

Results and Discussion

The results of two modeling solutions (transient and equilibrium) were compared with measured ground temperature profiles from six boreholes located in the vicinity of Fort Simpson, NWT (Fig. 4). The largest discrepancy between modeled and measured ground temperatures occurs at borehole 97TC1, a deciduous forest site on glacio-lacustrine silt. Both transient and equilibrium modeling confirm the absence of permafrost at this site, but modeled ground temperatures are about 1ºC warmer than recorded values. This result may indicate an error in the specification of n-factor values for this vegetation category, as comparatively few deciduous cases were included in the initial parameter calibration process (Wright et al. 2003). For cases where borehole data show the presence of permafrost, both transient and equilibrium modeling predict ground temperatures slightly warmer than those observed in the borehole record. In general, the transient model captures the near-isothermal character of ground temperatures in boreholes 94TC1, 97TC2, 97TC4, and 99TC2, although transient model predictions for the latter are somewhat warmer than measured values, and equilibrium predictions even more so. In all cases except 99TC1 equilibrium modeling predicts ground temperatures at depth that are significantly warmer than those indicated by borehole data.

A close agreement of ground temperatures between measured values and those predicted by T-One transient modeling is observed at borehole 97TC4, with the prediction of 8 m of permafrost being close to that indicated in the borehole (~9 m), although a somewhat deeper thaw zone is indicated by the transient model in the upper few metres of the profile. In contrast, equilibrium modeling predicts substantively warmer ground temperatures with unfrozen conditions throughout the profile.

At borehole 97TC2, measured permafrost temperatures tend towards colder values at depths below about 5 m. This again confirms the notion that permafrost is progressively warming from the surface downward in response to climate warming during the past century or so. Transient modeling predicts the isothermal tendencies apparent in this borehole data, but predicts significantly warmer ground temperatures at depth. Actual permafrost thickness at this site is not known, but based on the temperature at the bottom of the profile, the transient model prediction of 22 m of permafrost is likely a reasonable estimate. In contrast, the equilibrium modeling based on the 1971–2000 normal significantly over-predicts ground temperatures at depth and grossly under-predicts permafrost thickness at this site.

Boreholes 99TC1 and 99TC2 are located in strikingly different settings, although they are separated by a distance of only about 10 m. Site 99TC1 is located on a raised peat plateau, while 99TC2 is situated in a wet collapse feature

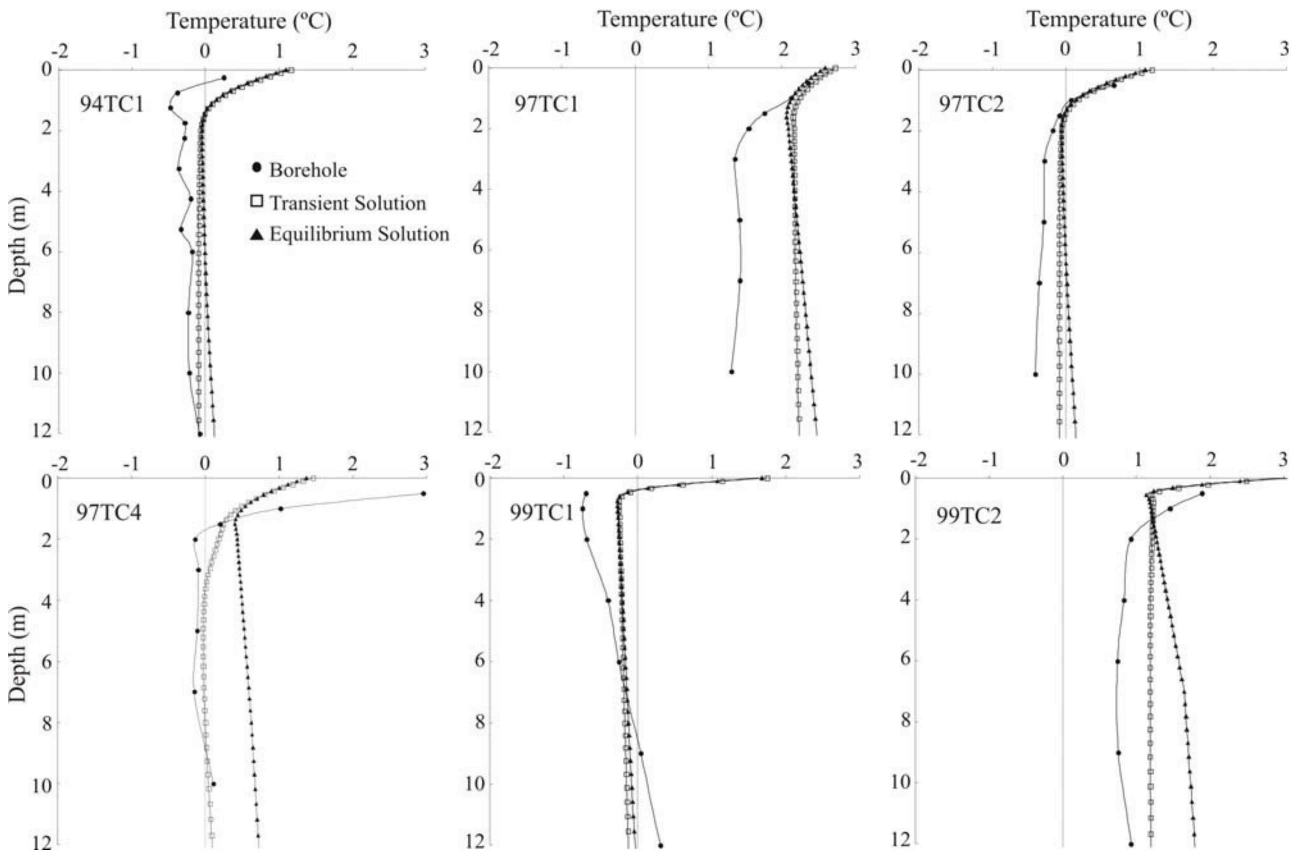

Figure 4. Measured ground thermal profiles from boreholes and results from a transient model using the climate reconstruction and an equilibrium solution based on 1971–2000 climate normal for the Fort Simpson area.

immediately adjacent to the peat plateau. Both sites are separated from an extensive fenland by a low ridge only a few metres wide. Recorded temperatures indicate that 99TC2 is unfrozen as correctly predicted by both transient and equilibrium modeling. The transient solution over-predicts ground temperatures at depth by about 0.5°C, while the equilibrium model over-predicts by about twice that amount. Borehole 99TC1 is characterized by a steep temperature gradient with uncharacteristically cold temperatures (~-0.8°C) at the near-surface, with unfrozen conditions below about 9 m depth. When examining this profile it is useful to consider that the raised peat plateau is about 2 m higher than the surrounding terrain. It is potentially exposed on its western face to winds from an extensive fen immediately adjacent to the site. Consequently, this site may experience reduced snow accumulation and therefore more direct exposure to cold winter temperatures at the ground surface. The presence of a 1.5 m layer of peat also insulates the ground during the summer months, promoting potentially colder near-surface ground temperatures. On the other hand, given the perhaps anomalously cold permafrost temperatures at 99TC1, the relatively shallow depth of permafrost at this site may reflect the influence of the adjacent fenland and/or its close proximity to the collapsed bog feature. Indeed, neither model adequately reproduces the ground thermal characteristics at this site, possibly due to the role of non-conductive and/or significant lateral heat fluxes in this environment.

In general, both the transient and equilibrium models tend to over-predict ground temperatures to some degree, relative to the borehole measurements. While near-surface ground temperature predictions are similar, the equilibrium model tends towards warmer temperatures at the base of the profiles. This difference can be explained by two factors: (1) the transient model was equilibrated at a slightly colder MAAT leading to a greater initial depth of permafrost circa 1721, and (2) transient modeling simulated approximately 100 years of cooling through to the end of the Little Ice Age (circa 1840) before warming to present-day conditions. It is also possible that the assumed thermal equilibrium between the atmosphere and ground circa 1700 is invalid, with either colder temperatures prevailing at that time or during some period earlier in the proxy record.

The differences between recorded borehole temperatures and the predictions of equilibrium modeling (as shown in Figure 4) illustrate that current ground temperature profiles are not in equilibrium with the modern climate regime, and that current ground temperatures at depth are colder than would be expected based on late 20th century climate. Furthermore, the near-isothermal character of ground temperatures observed in the majority of boreholes is not reflected in the equilibrium modeling, but is characteristic of the transient modeling from circa 1721, in spite of the 100 years or more of cooling prior to 1840. The results of equilibrium modeling based on a late 20th century climate are likely to underestimate permafrost occurrence and thickness and to overestimate ground temperatures at depth. Although the transient modeling predicts somewhat warmer ground temperatures in comparison to available measured ground temperature profiles, the general characteristics of the ground thermal regime in permafrost environments are reasonably well replicated.

Conclusion

Using available proxy records to identify general trends in the paleo-climatic record, a reasonable estimation of regional trends in MAAT was reconstructed from an assumed quasi-stable climate prior to the mid-1700s through to present day. Trends in summer air temperature deviation determined from proxy data (1740–1890) were transformed into estimates of annual temperature trends in MAAT for the Fort Simpson region and intersected with the centurial trend identified in the modern temperature record (1900–2000). Transient numeric ground thermal modeling driven by this reconstructed climate scenario captures the general characteristics of the current ground thermal regime in the southern extent of permafrost terrain, as indicated by the congruency between model predictions and borehole measurements. Differences between recorded borehole temperatures and the results of equilibrium modeling (based on the 1971–2000 climate normal) indicate that ground temperatures in the Fort Simpson region are not in thermal equilibrium with the current climatic regime. Our results suggest that permafrost models incorporating present day or even 20th century climate will not adequately reproduce the essential characteristics of the current permafrost regime, and so are unlikely to produce reliable predictions of the future evolution of permafrost when standard scenarios of climate warming are applied. The results also indicate that there is considerable opportunity for improvement of our transient ground thermal modeling capability, including refinement of the paleo-climate trends established for forward modeling from past to present. A detailed analysis of modeling outputs from this work, together with additional comparisons of modeling results with more widely distributed borehole temperature records, will support refinement of model parameter assignments and increase confidence in model performance for regional and local-scale applications.

Seasonal Variations of Surface Radiowave Impedance of Frozen Ground

V.N. Efremov
Melnikov Permafrost Institute, SB RAS, Yakutsk, Russia

Abstract

The depth of superficial seasonal thawing observed in permafrost bodies with a thickness of hundreds of meters results in substantial seasonal variations in radiowave impedance for radio frequencies. This report outlines the results of an investigation of seasonal variations of radiowave impedance in Central Yakutia at a frequency range of 10–1000 kHz. The peculiarities of seasonal variations in the region include a significant influence of thawed layer conductivity on wave impedance magnitude and phase angle at the freezing of the seasonally thawed layer. This report reveals and analyzes the diverse nature and degree of seasonal variations of wave impedance magnitude, phase angle, and apparent resistivity in different frequencies during seasonal ground freezing and thawing at two sites of differing landscape but identical geological structure. Subsurface conductivity structure models were suggested, reflecting results of radiowave impedance sounding on the sites. Stabilization of apparent resistivity level change was registered in the period from August to October.

Keywords: frozen ground; seasonal variations; seasonally thawed layer; surface radiowave impedance.

Introduction

Our work during past years (Efremov 2007) was aimed at assessing physical properties of frozen ground, based on surface wave impedance (Wait 1962) or input impedance (Berdichevsky 1966) measurements.

$$Z = \frac{E_x}{H_y} = |Z| e^{-i\varphi} \tag{1}$$

The results of mathematical simulation demonstrated that radiowave sounding, used to study the structure and properties of permafrost, must involve measurement of surface wave impedance at a frequency range of 10–1000 kHz (Efremov 1995). The range of frequencies includes very-low-frequency (VLF from 10 kHz to 30 kHz), low-frequency (LF from 30 kHz to 300 kHz), and, partially, medium-frequency (MF from 300 kHz to 1000 kHz) belonging to the radio-frequency spectrum, propagating above the ground surface. For frozen ground, VLF sounding conduction currents prevail, which make it possible to assess frozen rocks resisitivity. At frequencies of 30–1000 kHz (LF-MF) the influence of displacement currents increases, but does not dominate. At these frequencies, there is a possibility of assessing resistivity and other physical properties of frozen ground, as a result of processing and interpretation of surface wave impedance measurement data.

To interpret the measured data, we use two components of wave impedance: |Z| magnitude and φ phase angle, as well as apparent resistivity that is determined using these components, taking into account the displacement currents (Veshev, Egorov 1966).

$$\rho = \frac{|Z|^2}{2\pi f \mu \cdot \sin 2\varphi} \tag{2}$$

Nevertheless, measurements of surface wave impedance within LF and MF bands, could be considerably affected by the conductive layer, formed in an active layer on the frozen ground surface as a result of seasonal thawing. The freeze-thaw cycle of the seasonally thawed layer is the reason for seasonal variations in components of surface radiowave impedance.

Results and Discussion

Some regional results

The results of surface radiowave impedance measurements in Central Yakutia and in numerical simulations demonstrate that the seasonal variations are significant and have some regional peculiarities. The region is characterized by a relatively deep seasonal thawing of permafrost, making 1.5–2 m, while its thickness is 300–400 m. With freezing of the seasonally thawed layer, its resistivity increases, and the phase angle grows at all frequencies. At frequencies of f >300 kHz at freezing we observe a significant increase of phase angle, and wave impedance magnitude grows, due to upper layer longitudinal conductivity reduction. At frequencies of f <300 kHz the wave impedance magnitude increase is less significant due to the effect of the formation of a cumulative non-conductive layer of frozen unconsolidated deposit above a more conductive layer composed of frozen rocks, in accordance with a two-layer model. At thawing of the seasonally-thawed layer, phase angle decreases as well as the wave impedance magnitude, which is more significant at f >300 kHz. The phase angle reduction, since some size of magnitude of longitudinal conductivity, is dependent on resistance permafrost (for example 0.05 $\Omega^{-1}\cdot$m for ρ=1000 Ω·m), accepts an asymptotic value. The decrease of wave impedance magnitude is proportional to the increase of longitudinal conductivity of such layers. We observed a sufficient convergence of apparent resistivities within MF range and seasonally thawed layer resistivity at

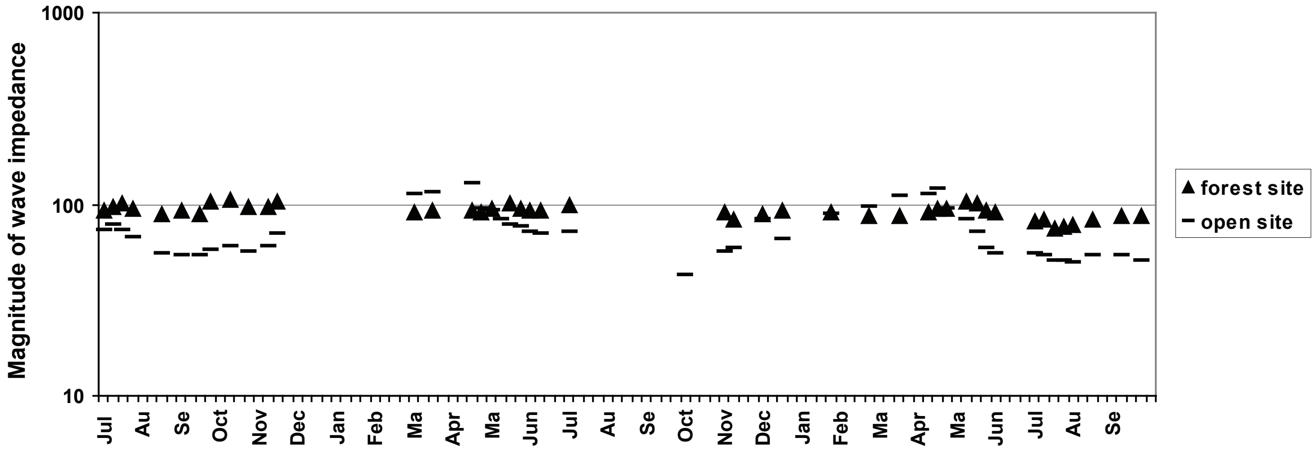

Figure 1. Seasonal variations of magnitude of wave impedance in MF (549 kHz) in test sites from July 2005 to September 2007.

constant current, which speaks to a significant influence of the seasonally thawed layer on wave impedance magnitude within the given range, as shown in the following.

According to experimental data obtained along the 200 km-long highway at the same sites (first in August, then in April of the following year), the fluctuation at LF, caused by the seasonally thawed layer (STL) freezing, gave on average: for wave impedance +18%, for phase angle +19°. At higher frequencies, in MF range, the fluctuation of wave impedance reached +40%, and phase angle fluctuation made +16° on average.

The increase of wave impedance magnitude at STL freezing, as well as the increase of this fluctuation at higher frequencies of the field were expected and totally fit into the results of numerical simulation (Efremov 1995). The increase of phase angle with freezing of the seasonally-thawing layer indicates that there is a thin conductive layer within the permafrost, and that the effect produced by this layer during the warm period is partially mitigated by the presence of a conductive seasonally thawed layer. This suggestion is proven by the results of numerical simulation for the frequency dependence of surface wave impedance for permafrost including a thin conductive layer.

Other factors than thawing, resulting in seasonal variations of surface impedance, may be abundant rainfall, or long absence of precipitation. In the first case, resistivity decreases and permittivity of the seasonally thawed layer increases as a result of the moistening; in the second case we see an inverse effect as a result of dehydration of the upper layer, evaporation, and gravitational moisture transfer to the bottom of the permafrost.

Results in test sites

Over the last years, observations of surface impedance seasonal variation were carried out in Central Yakutia at two test sites located 200 m away from each other in the same geological conditions, but in different landscapes – in forest with thawing of the ground down to 1.3 m, and in open space with thawing down to a depth of 1.9 m. The area where the sites are located is composed of sandy-loamy deposits with a total thickness of 30 m, overlying frozen rocks up to 300 m deep. Geological and geocryological profiles of both sites are typical for Central Yakutia.

The surface impedance measurements were carried out using reception of horizontal electric-field component E_x on a symmetric ungrounded receiver circuit, and of horizontal magnetic component of the field H_y - on a frame magnetic antenna. The measurements were carried out at the same sites with periodicity of 1–2 weeks during the warm period and on occasional days of thaw during winter. A surface impedance indicator IPI-1000 (Parfentyev & Pertel 1991) was used as a measuring instrument. The instrument represents a selective microvoltmeter, phase-angle meter, operating within a frequency range of 10–1000 kHz and measuring the magnitude of wave impedance accurate within 5%, and a phase angle inaccuracy rate of 1°.

The results of observations showed that the profiles of seasonal variations of complex wave impedance components for forest- and open sites do not have distinctions of kind (Figs. 1, 2).

At the forest site, the variations of surface radiowave impedance magnitude were not as significant, as variations of phase angle, with a range of deviation reaching 35°. At the open site, on the contrary, there was not as substantial a variation in phase angle as there was in surface radiowave impedance magnitude, reaching 58%. This difference can be explained by the presence of a thin conductive layer at different depths and by distinctions in cryogenic structure of the ground at the sites, resulting in different subsurface conductivity structures. According to the sounding data interpretation, at the forest site a conductive layer is indicated at the bottom of unconsolidated deposits, and in the open site at the bottom of a seasonally thawed layer. This presumes different subsurface conductivity structures, different depth of sounding on the sites, and consequently a different level of influence of conductive layers constituting the ground. The range of seasonal variations of apparent resistivity is wider at the open site than at the forest one. This can be explained by higher ice content in the ground and a thicker seasonally thawed layer at the open site.

At each of the sites, the components of wave impedance and the apparent resistivity seasonal variations profiles

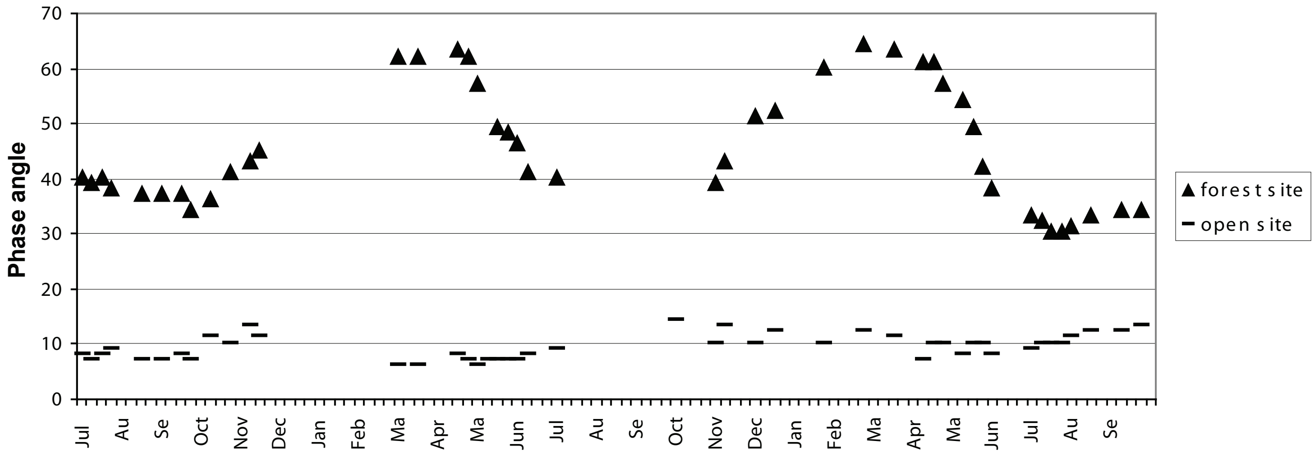

Figure 2. Seasonal variations of phase angle in MF (549 kHz) in test sites at period from July 2005 to September 2007.

substantially differ for different frequencies (Figs. 3, 4).

At the forest site, a sudden increase of phase angle within LF and MF (VLF remaining almost unchanged) was observed since the freezing of the seasonally thawed layer started in October and finished in April of the next year (Fig. 2). Here, the wave impedance magnitude decreased to VLF by the end of April and did not significantly change in higher frequencies (below than 800 kHz). Decrease of wave impedance magnitude reaching 56% occurs here in higher frequencies (higher then 800 kHz) during the period of intensive STL thawing from April until July. During the same period, at the forest site, we observed a rapid decrease of phase angle in LF-MF range, reaching 34°, apparent resistivity increasing within VLF and decreasing within MF (Fig. 4).

At the open site, the growth of wave impedance magnitude and of apparent resistivity occurs in LF-MF range, at freezing of the STL during the period from November until April of the following year and is accompanied by a slight decrease of impedance magnitude in VLF. At STL thawing during the period from April until June, wave impedance magnitude and apparent resistivity decrease within LF-MF and increase within VLF (Fig. 3). During the same period, the phase angle decreases within the range of frequencies lower than 400 kHz. During the period from May until July, the phase angle increases at high frequencies (higher than 800 kHz). It is essential to note that in 2007, STL thawing led to a more abrupt decrease of wave impedance magnitude within LF-MF than in the previous years.

Based on the analyses of our experimental data, we suggest four-layer and five-layer models of subsurface conductivity structure of the sites for warm and cold periods of the year, shown in Tables 1 and 2.

Besides STL freezing and thawing, seasonal variations of the surface radiowave impedance in Central Yakutia, a region of high temperature permafrost, are substantially influenced by temperature variations in the layer of annual temperature fluctuations (to a depth of 3 m). These temperature variations can result in changes of the resistivity. This part of the ground is freezing, and consequently, resistivity increases during the period from November until April. From May until July, while ground temperature rises, a decrease of resistivity is recorded in this part of the ground; and from August until October the resistivity change stabilizes. In the open site, the stabilization of wave impedance magnitude changes, phase angle, and correspondingly of apparent resistivity is indicated within the LF-MF band during the period from June until September. This is the result of compensation of the effect of a non-conductive layer made of frozen unconsolidated deposits, by the effect of the conductive STL (Fig. 4). Based on the results of numerical simulation, full compensation can be achieved under the condition given by (Efremov 1995):

$$\frac{h_1}{\rho_1} = \frac{h_2}{\rho_3} \tag{3}$$

where h_1/ρ_1 is the longitudinal conductivity of seasonally thawed layer; h_2 is the thickness of frozen unconsolidated deposits; ρ_3 is the resistivity of frozen rocks. It is significant to note that the levels of stabilization of wave impedance magnitude changes and apparent resistivity are lower in 2007 than in 2005 and 2006.

Over the last years, both open and forest sites have depicted a trend towards decrease of ground resistivity variations amplitude, correlated with decrease of freezing degree and increase of thawing degree (Fig. 4). These changes can be explained by increased snow cover thickness and warming of the climate. The increase of thawing depth is evidenced by measurements of thawing at sites with the help of a test prod. All this indicates a connection between seasonal variations of surface radiowave impedance and climatic changes.

Conclusions

Regional peculiarities of surface radiowave impedance seasonal variations for frequencies ranging between 10 – 1000 kHz have a significant influence on the thawed layer conductivity magnitude and the increase of phase angle at

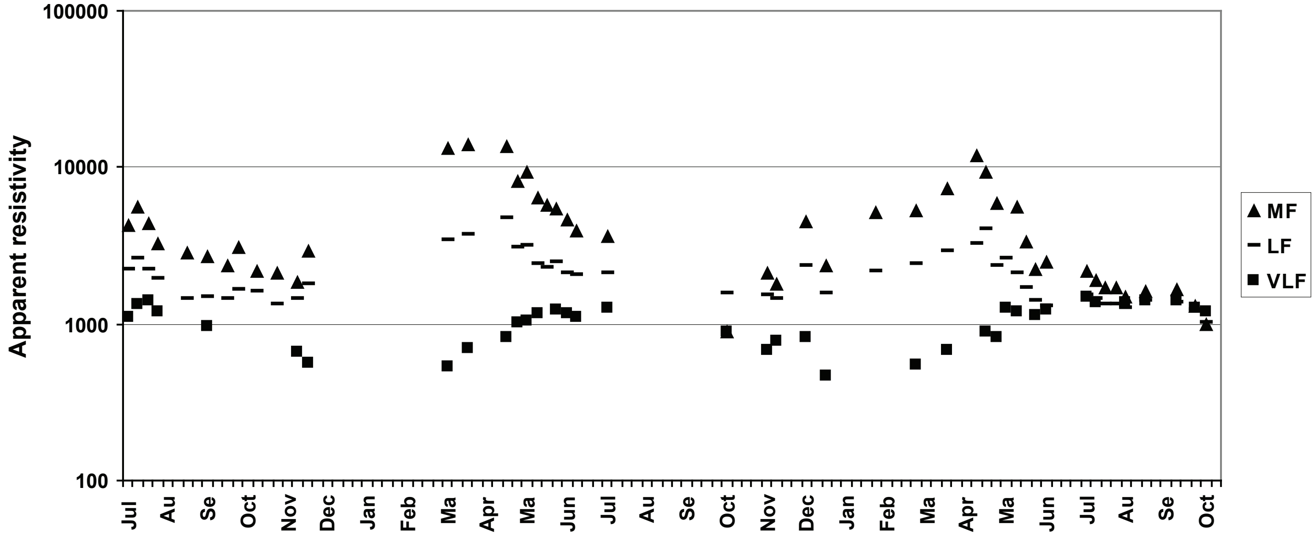

Figure 3. Seasonal variations of apparent resistivity (Ω·m) in MF-LF-VLF in the open site from July 2005 to October 2007.

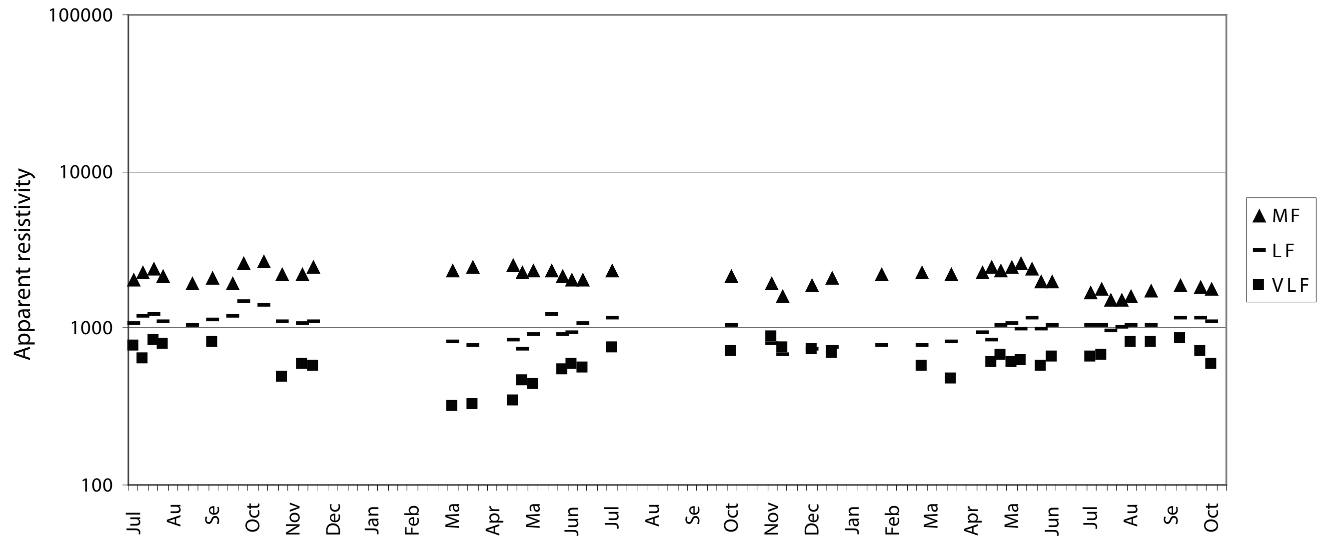

Figure 4. Seasonal variations of apparent resistivity (Ω·m) in MF-LF-VLF in the forest site from July 2005 to October 2007.

freezing of the seasonally thawed layer. This fact proves that within permafrost there is a thin conductive layer of cryolithological nature.

Seasonal variations in surface radiowave impedance components differ dramatically by character and degree of change in sites with differing landscapes, resulting from different geocryologic profiles. Besides, there is a difference in character and degree of change for different frequencies of 10–1000 kHz range at one and the same site. It results in the necessity to consider seasonal changes in frozen ground research by radiowave methods. On the other hand, the analysis given about seasonal variations of the surface radiowave impedance at various frequencies will allow gaining more specific information on the geocryological structure of the ground and the dynamics of seasonal changes occurring in it.

Freezing and thawing of the upper layer, to a considerable extent, change the subsurface conductivity structure of permafrost and the ratio of conductive and non-conductive layers within it. This consequently changes the ratio of conduction and displacement currents for the given frequency, which in its turn determines the phase angle. Therefore seasonal changes in the upper layer at thawing can hide (and at freezing intensify) the anomalies caused by conductive bodies within permafrost.

Stabilization of components of wave impedance and apparent resistivity during the period from August until October, caused by the compensation of influence from frozen unconsolidated deposits by conductivity of the seasonally thawed layer, gives us a chance to assess the resistivity of frozen rocks according to measured apparent resistivity. The period from August until October is the

most practical for research of frozen rocks using radiowave methods in Central Yakutia and other regions, similar by climatic and geocryologic profiles.

Correlation of the seasonal variations of the surface radiowave impedance magnitude and phase angle with the degree of ground freezing and depth of thawing, allows us to assume the possibility of monitoring of changes in frozen ground caused by climatic changes.

Abstract

The overland travel routes from Barrow, Alaska, to inland regions are assessed using indigenous knowledge of Iñupiaq elders and hunters, as well as historic documents, aerial photos, and satellite imagery. Route information is superimposed on a satellite image within a geographic information system to identify areas of observed impact. The overall pattern for summer travel routes has not changed significantly over the past 50 years, despite the change from travel by foot and river boats to motorized vehicles, predominantly all-terrain vehicles. Route elements have altered, however: whereas traditional routes depended on conveyance by boat and included waterways, modern traffic detours around lakes and streams, are increasing the impact on tundra vegetation, soil, and permafrost.

Keywords: Alaska; GIS; indigenous knowledge; off-road vehicles; permafrost; thermokarst; trails.

Introduction

The traditional travel routes of the Iñupiaq people are an important and useful area of study for cultural geographers and anthropologists. Ethnographic studies have recognized so-called traveling landscapes as a rich repository of information about hunting and fishing resources, trading relations and kinship ties, and survival mechanisms. Our current research in northern Alaska utilizes indigenous knowledge (IK) of elders and hunters, who have primary and secondary information on natural and anthropogenic landscape changes. During the course of interviews with Iñupiaq elders from Barrow, Atqasuk, and Wainwright, informants repeatedly called attention to their present and past travel routes for both summer and winter travel. We consequently began to examine this information to determine how and why inland travel routes have changed, and to assess the impact of routes on the landscape.

We have collected and georeferenced relevant Iñupiaq summer inland travel information in a Geographic Information System (GIS) database. This includes overland trails on the tundra and river routes that utilize watercraft. Our informants have indicated on maps and satellite images the routes currently in use, as well as traditional routes that have been abandoned due to changes in ground-cover, hydrology, transportation technology, and viability (that is, the route no longer leads to useful sites). We are able to compare modern routes to those of the traditional Iñupiaq route system that existed in the 1950s (Spencer 1959), or before the proliferation of affordable snowmachines and All-Terrain Vehicles (ATVs). We also utilized some inland travel route information from the 1970s (Tremont 1987) and, more recently, trails that are visible on 1:50,000 color infrared (CIR) photography captured for the Barrow Peninsula in 2005.

The objective of this report is to identify the changes in travel routes on the Barrow Peninsula over the past half-century, assess the cause for route changes, and identify visible effects on the landscape. We will focus only on terrestrial travel in the summer period, when the potential for damage to the tundra is maximal. The use of snowmachines has, until recently, been restricted to winter and will not be considered here.

Background

The pre-motorized Iñupiat had a variety of reasons for traveling long distances inland, and food acquisition was just one of these. Spencer (1959) writes that the main interaction between the *nuunamiut* (inland Iñupiat) and the *tareumiut* (coastal Iñupiat) was based on organized trade. Trade was important for commodity exchange, but also vital for maintaining social ties and enabling groups to achieve economic stability. Trading generally commenced at specific times of the year, and often centered around traditional trading sites or areas. Other reasons to travel include accessing seasonal hunting and fishing areas, attendance at festivals, and travel to engage in warfare (Burch 2005).

The mode of transportation depended on the season of travel and the terrain along the specific route. The method of conveyance depended to a large degree on the season. Some portion of summer and early fall travel was simply done on foot. The traveling *umiaq*, a skin boat which is a smaller version of the whaling *umiaq*, was used to travel the rivers and lakes between May and October. The loaded *umiaq* was difficult if not impossible to navigate in head- or cross-winds, and was often towed from the banks by dogs and family members (Spencer 1959, Burch 2005, Flossie Itta in Atqasuk August 2003 interview, Roy Nageak Sr. of Barrow in August 2006 interview). Rivers and streams were usually only deep enough for continuous travel in the spring; by summer gravel bars and boulders posed considerable obstacles. A sledge was often part of the boatload, and could be used when ice was encountered. In areas where the waterways were blocked or not connected, the travelers would portage. Overland travel was most intense during the summer and covered the maximum territory because people were accessing distant trading centers.

Several of our informants spoke of traditional travel by boat along inland waterways, and informants still use larger, motorized boats along the sea coast and bays. When feasible, they will enter larger, deeper rivers to navigate to their summer camps. Thus, boats still provide a viable alternative for moving large amounts of supplies to inland sites. The *umiaq* is no longer used for inland travel, having been effectively replaced by ATVs in the snow-free period. Similarly, snowmachines have entirely replaced dog teams for spring and winter travel. However, whereas a snowmachine can pull a large sledge with supplies, the ATV remains largely a single-person transport unit. One strategy is for inhabitants to haul their goods to summer camps while the snow cover is still in place. More recently, we have noticed a disturbing trend of snowmachine use on the tundra after snowmelt.

Dramatic change to summer tundra travel was triggered by the introduction of motorized vehicles for personal use. Commercially-manufactured, one-passenger ATVs for personal use became common in northern Alaska during the 1960s. Before that time, overland vehicles such as Caterpillar tractors were used exclusively by industry and government due to the excessive cost.

The introduction of the ATV has caused long-term effects not only on the environment, but on the traditional culture of the North Slope communities as well. Hunters are now able to make longer journeys inland after game. These are not expeditions, but short-term hunting forays based on expediency or opportunity, and can be made by an individual traveling with light gear. The Iñupiaq people are no longer dependent on waterways, but instead have to navigate along high, dry ground and are forced to avoid the wettest, marshiest areas. Streams, the former transportation arteries of inland travel routes, are now obstacles.

Study Area and Methodology

The Arctic Coastal Plain of northern Alaska is a flat, low-lying region of tundra vegetation with numerous thaw lakes developed in ice-rich permafrost**.** Approximately 22% of the land area on the Barrow Peninsula north of ~71° latitude (which constitutes the area of study for this article) is covered with thaw lakes, and at least 50% is scarred by basins formerly occupied by lakes (Hinkel et al. 2003). In this cold maritime climate, the seasonal thaw zone (active layer) is typically less than 50 cm deep.

Over the past four years, our team has conducted extensive interviews with over 40 Iñupiaq elders and hunters from Barrow, Atqasuk, and Wainwright. These interviews have focused primarily, but not exclusively, on thaw-lake dynamics. We integrated interview methods to include unstructured talks (Bernard 2002) as well as semi-directive interviews (Huntington 2000, Fox 2002), a format which encourages informants to speak freely about their observations and knowledge of environmental changes. During videotaped interviews, informants located sites on detailed 2002 Landsat 7+ satellite images and USGS topographic maps. Afterwards, the interviews were logged and all sites located on maps were geocoded and entered into an ArcGIS database.

We also utilized 1:63,360 and 1:50,000 scale CIR aerial photography captured for the Barrow Peninsula in 1979 and 2005, respectively.

Analysis

Comparison of modern and traditional summer routes

The modern summer travel routes on the Barrow Peninsula identified by the majority of IK holders are shown in Figure 1. These closely coincide with the traditional trade routes mapped by Spencer (1959), shown in Figure 2. Both show two main trails extending southward from the traditional village of Barrow, and generally heading toward the Inaru River and Admiralty Bay. However, there are substantial changes that occurred over the half-century period.

The first modern summer travel route (Fig. 1: Route A) begins at Isatquaq Lagoon near the eastern end of the Wiley-Post Airport runway. It runs in a southerly direction along the banks of an existent lake (Iksrugagvik: I; Note that all letters and numbers within parentheses refer to figure labels). The trail, which mainly follows the course of the Avak River, crosses Iksrugagvik Creek beyond the lake at Maloney Bridge (M) which was constructed by Roy Nageak Sr. about ten years ago to enable ATVs to cross. The route continues eastward along the Avak River, going past several recently drained lake basins (Sikiluk—K—is one named) and then toward Iko Bay and associated inlets.

The second modern summer travel route (Fig. 1: Route B) is an important link between Barrow and inland settlements. It originates near Imaiqsaun Lake (also called Fresh Water Lake) slightly south of Barrow, and runs along the margin of Pinguatchaiq Lake (P) towards the Sungugruak Lake (S) complex. It passes to the east of the now drained Ikkalgugruaq Lake (G) and then splits toward either eastward to Iviksuq (V) or continuing north toward Puluyaaq (U), both important historic settlements. This demarcates the limit of the routes as specified by our informants, although some indicated that the eventual goal was access to Admiralty Bay.

Both traditional routes (Fig. 2; digitized from Spencer's 1959 map) joined a larger network of trade routes across

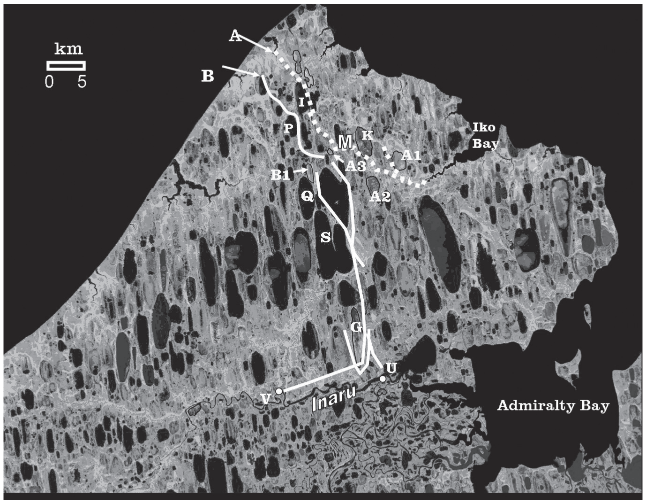

Figure 1. Modern summer travel routes A (dotted line) and B (solid line). Route information is superimposed on a 2002 Landsat 7+ satellite image within a GIS. Labels refer to place names and sites discussed in text.

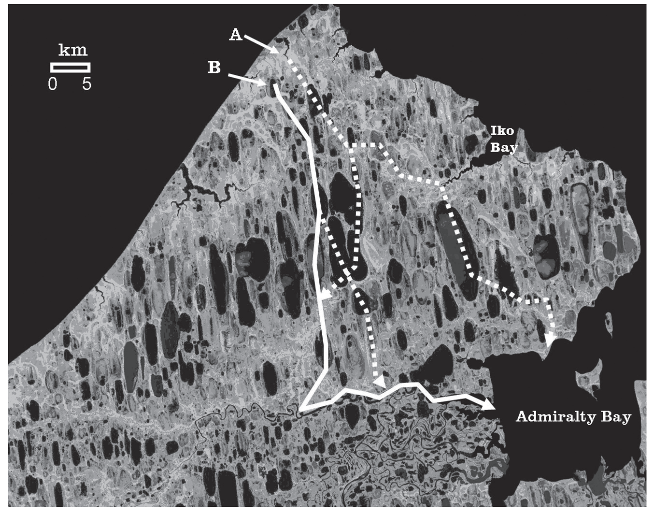

Figure 2. Traditional summer travel routes digitized from Spencer (1959).

northern Alaska and northwestern Canada. Beginning near Barrow, they utilize different streams and water bodies to eventually reach Admiralty Bay. From there, they traveled eastward to Lake Teshekpuk, and finally to the mouth of the Colville River, where there was an important trading center. Spencer (1959) noted that the people from Barrow took the inland fresh-water routes because often during the trading periods—early spring or fall—the sea ice posed too great an obstacle for safe travel along the coast of the Beaufort Sea. By contrast, the inland route through the rivers and lakes eventually arrived at Admiralty Bay, which was usually relatively ice-free at these times.

It is striking that the traditional route and the modern route are so similar, given the drastically different methods of conveyance. Modern routes are mainly used by hunters on ATVs and skirt around the lakes, often following raised shorelines. By contrast, the map by Spencer (1959) demonstrates traditional routes A and B taking full advantage of the lakes and streams for water passage. Several of our informants indicated that, in some places near Barrow, streams were artificially extended across shallow drainage divides to connect with nearby streams and thus reduce the number of portages.

We also compared these routes to those identified in a Minerals Management Service (MMS) survey report from 1987 (Tremont 1987). On the Barrow Peninsula, these routes coincide neither with our map nor with Spencer's traditional trading routes. The MMS map appears to follow waterways, but there is no indication as to whether these are river routes for boat traffic, ATVs trails, or even snowmachine trails.

Both the traditional and modern Route A (Figs. 1, 2) pass along the shores of three drained lake basins (Sikiluk (K), A1 and A2) that are shown as extant lakes prior to 1955. Interviewed Iñupiat noted that these lakes drained recently, although they were unable to specify the timing of these events. Another small basin (A3) was identified from satellite imagery as having drained between 1955 and 2002 (Hinkel et al. 2007). Route B passes along the margin of another drained lake basin (B1), identified by our informants on satellite imagery as having drained in the past 50 years. The southerly basin was formerly Ikkalgugruaq Lake (G) which drained in 1985 based on IK and satellite imagery. Lake drainage or changes in lake level would almost certainly necessitate changes in the route. One of the most experienced modern hunters in the Barrow area, Roy Nageak Sr. explained that he often chose the dry, flat shore on one side of the lakes as optimal for ATV travel.

Satellite imagery and aerial photography

The extent of permanent damage to the tundra from vehicular traffic is evident from the scars caused by vegetation disruption that are visible in aerial photography and high-resolution satellite imagery. We have examined the impacts on the area around Imaiqsaun Lake by using aerial photographs from 1979 and 2005 (Fig. 3). Because this lake was for many years an important source of fresh water for the Barrow community, there is a gravel road approaching it from the north that is visible on both photos. A seismic trail, dating to earlier times, can be seen to the far east in both photos. However, a very distinct ATV trail is apparent in the 2005 image. It departs from the gravel road going southeast, traveling along the dryer and elevated shoreline of an old drained lake basin. Eventually it converges with the traditional route as it follows the modern route B. We can detect the seismic trails in both the 1979 and 2005 photos, indicating visible damage persisting over 25 years. The impact of ATV use in the 2005 photo suggests recent and ongoing damage.

Modern routes are not absolutely fixed in space, and even traditional routes show deviations. This is especially true in the vicinity of Sungugruak Lake (S), where the narrow land bridge between Sungugruak and Qimuksiq Lake (Q) was breached around 1992. This narrow stretch of land was traditionally used as a corridor to access the hunting

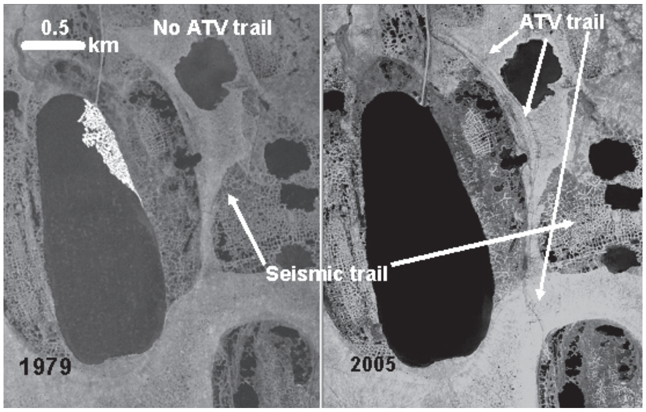

Figure 3. CIR aerial photography captured for the Barrow Peninsula showing ATV and seismic trails in 1979 (1:63,360) and 2005 (1:50,000).

and fishing cabins on the south side Sungugruak Lake. The Miller family of Barrow has a cabin on the south side of Lake Sungugruak; since the neck was breached in 1992, the family must travel a greater distance to reach their cabin (Donna Miller of Barrow in August, 2004 pers. comm.). The modern trails also diverge and converge as they approach cabins and popular hunting and fishing areas.

Discussion

The consequences of ATV usage on the culture and landscape of the Arctic Coastal Plain is profound. The inland regions have become increasingly accessible, but as more people travel the routes, they are subject to heavy vehicular traffic. This damages the vegetation, disrupts the protective organic mat, and destabilizes the underlying permafrost. Past researchers recognized and monitored the deleterious effects of motorized vehicles of all sorts on permafrost landscapes (Brown 1997, Lawson 1986, Nelson et al. 2003, Slaughter et al. 1990). They found that the long-term impacts depended to a large extent on the specific environmental setting: vegetation type and density, ice-content of permafrost, and soil type. The severity of impact also depended on the intensity of human use such as traffic frequency, vehicle weight and width, and even vehicle operation (Slaughter et al. 1990). A comprehensive study by Lawson (1986) emphasized that the ice content of the sediments, coupled with elevation and slope, were the most important factors in determining impact severity. Lawson (1986) also differentiated between the relative impacts of types of activities and their subsequent level of disturbance. Footpaths, even when they get heavy use, do not have the equivalent impact as off-road vehicles. Vehicle weight and the tearing effect of spinning, rough-studded tires are critical factors.

Repeated use by ATVs will eventually disrupt the surface vegetation to the extent that thermokarsting can occur. Depending on the topography of the landscape and the ice-content of the sediments, subsidence, melting wedge ice, slope instability, and lake drainage are a few of the possible outcomes.

Hunters that travel modern routes are cognizant of the environmental effects of ATVs and modern hunting practices, but feel they are caught in a double bind. In a recent interview, Roy Nageak Sr. (Barrow, August 2006 interview) said that the area around Maloney Bridge (Fig. 1, M) is getting swampier due to heavy traffic, and that he would soon be forced to move the bridge. Another hunter, Evelyn Donovan (Barrow, April 2006 interview) reported that the stream near the bridge is getting deeper, and expressed concern about the impact of increased traffic on the tundra. Roy explained that he sometimes “kicked himself” for building the bridge, since it facilitates ease of travel and focuses traffic along the route near the bridge, thus exacerbating damage to the tundra. He explained that the increased use was justified because of the rising cost of purchased food, giving the people of Barrow little choice but to depend to a greater extent on subsistence hunting. At the same time, the increase in gasoline prices has put pressure on hunters to economize by taking shorter routes. Whereas it used to take Roy more than half a day to get to the caribou hunting grounds on his ATV, by taking the bridge shortcut, he can reduce his travel time to an hour.

A recent study (Sonnenfeld 2002) showed an increase in disorientation and loss of geographic knowledge among the Iñupiat who travel on the North Slope. Although the study did not differentiate between summer and winter travel, nor did the author discuss the recent changes in transport mode as a factor in this disorientation, he did note how the loss of traditional knowledge has diluted the wayfinding ability of Iñupiat. During our own interviews, some informants were very outspoken in their concern that younger members of the community did not have the necessary skills to safely navigate in the tundra environment, especially in winter when the surface appears uniform (Thomas Itta Sr. Atqasuk, August 2004 interview). Further afield, Yup’ik Elders have voiced serious concerns about the inexperience of young people when it coincides with their increased travel through the tundra on ATVs and snowmachines (Bradley 2002). Again, during interviews in which we specifically asked about changes to the tundra, some informants expressed frustration at what they perceived as their own reduced knowledge of the landscape. They noted that, either they only went inland during the winter when the tundra was snow-covered and hence observed no changes, or else that they traveled through the landscape on their ATVs too quickly to notice any significant changes.

Concluding Remarks

There are a number of preventative and mitigation measures that have been recommended for addressing tundra disturbance due to ATV traffic. Residents and especially experienced hunters recognize that some terrain types are more resistant to disturbance, and therefore they may be interested in working with scientists to select routes which avoid sensitive areas (Slaughter et al. 1990). Regulation of ATV use may not be a realistic alternative, but the use of synthetic surface protection materials has been successful in some areas. In a 2006 interview, Roy Nageak Sr. said that he recommended to the North Slope Borough that small portions of Route A be covered with a high-strength polymer ground stabilizing mesh. Use of this protective cover would have the dual advantage of directing traffic to a specific track, thus spatially restricting the damage, and stabilizing the vegetation and soil beneath the mesh. Ground stabilizing mesh is already being used in high-traffic areas within Barrow city limits, but is quite expensive.

The IK GIS enables us to compare earlier movements of peoples with current tundra usage and in assessing natural versus anthropogenic landscape change. By combining IK, information gathered from historic reports, and modern aerial photography, we are able to hypothesize causes for route modification or disappearance, and add a new perspective as to how human activities translate to the local landscape.

We can also observe how indigenous communities are adjusting to the impacts of landscape change and how they may be initiating or enhancing some of these changes themselves. Recently, we have noticed a somewhat alarming trend. Visible from the air are heavily traveled tracks across the tundra which extend from Barrow southward to near the Inaru River. The tracks are wide because the damage to the tundra causes local ponding, requiring users to shift to one side or the other. Further, conversations with local residents indicate that it is no longer uncommon for people to use snowmachines on the bare tundra in summer, especially in spring when heavy loads of goods are hauled to inland sites on attached sledges. The snowmachine track and sledge runners tear up the vegetation mat, and the large number of travelers exacerbates the damage. Concerned individuals have installed protective synthetic mats near traffic funneling points such as bridges, but this is a local and temporary solution. It is our hope that the information collected on routes and trail damage will enable community leaders to forecast how the landscape, travel routes, and access to resources will evolve in the future.

Abstract

This paper provides an overview of distribution and thermal characteristics of mountain permafrost in Iceland. Borehole temperature monitoring since summer 2004 and simple distribution modeling suggest widespread mountain permafrost in Iceland above 800 to 900 m a.s.l. The permafrost temperatures are close to 0ºC and some tens of meters thick in the elevation range of 800 to 1000 m a.s.l. At that elevation, the permafrost distribution is mainly governed by the distribution of snow, while above 1200 m a.s.l. smaller areas of continuous permafrost do exist. This presentation presents new borehole temperature data that have been collected until the summer 2007 and associated numerical modeling of snow influence on ground temperatures.

Keywords: ground temperatures; Iceland; modeling; permafrost.

Introduction

Within the context of climate-permafrost relationships in the North Atlantic region, Iceland represents a link between Scandinavia and Greenland. The regional distribution of permafrost in Iceland has been addressed by means of gridded mean annual air temperatures (MAAT) for the 1961–1990 period interpolated from point meteorological data (Etzelmüller et al. 2007) (Fig. 1). Etzelmüller et al. (2007) showed that MAAT~-3ºC gives an indication of the lower limit of widespread permafrost in Iceland, not regarding snow conditions or topographic aspect variability. Figure 1 suggests the presence of widespread mountain permafrost outside the already known sporadic permafrost zone in central Iceland. The lower limit increases in elevation towards the southeast, with elevations between 800 m a.s.l. in the north and more than 1000 a.s.l. in the southern part of Iceland. Permafrost is also predicted on the highest mountain peak areas along the southeastern coast above c. 900 m a.s.l. This paper presents new data series and modeling exercises to elaborate the influence of surface temperature and snow variation on permafrost temperatures in Iceland.

Setting

Iceland is located where the asthenospheric flow under the Mid-Atlantic Ridge interacts and mixes with a deep-seated mantle plume (Shen et al. 1998, Wolfe et al. 1997). This implies generally high geothermal heat fluxes due to heat conduction from the partly molten layer at approximately 10°-km depth (Flóvenz & Sæmundsson 1993). Iceland is characterized by maritime conditions with cool summers and mild winters. In the lowland areas, the MAAT for the 1961–1990 period was 4°–5°C in southern parts, 3°–4°C in the eastern and western parts, and 2°–3°C in northern, coastal parts of the country (Tveito et al. 2000). A large part of the precipitation falls with winds prevailing from eastern and southern directions (Einarsson 1984). Thus, mean annual precipitation increases from above 500 mm in the central and northern parts of the country to more than 3000 mm in the southeast.

In four boreholes, ground temperatures were monitored since 2004 (Farbrot et al. 2007) (Fig. 1). They are located in central and northeastern Iceland at ~890–930 m a.s.l. All boreholes are relatively shallow (12–22 m deep), penetrating through a shallow sediment cover into basaltic bedrock. All sites are on elevated plateaus, and significant slopes are more than 100 m away from the boreholes. The sites are not vegetated and are exposed to wind drift of snow.

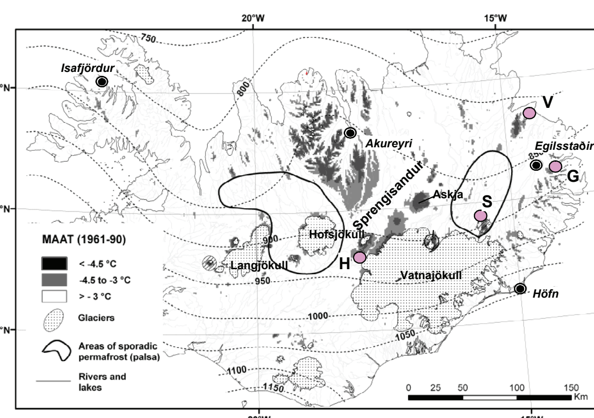

Figure 1: Key map and permafrost map of Iceland (based on Etzelmüller et al. 2007). G=Gagnheiði; S=Snæfell; V=Vopnafjörður; H=Hágöngur. The dotted contour lines indicate the lower limit of permafrost based on the distribution of MAAT~-3ºC.

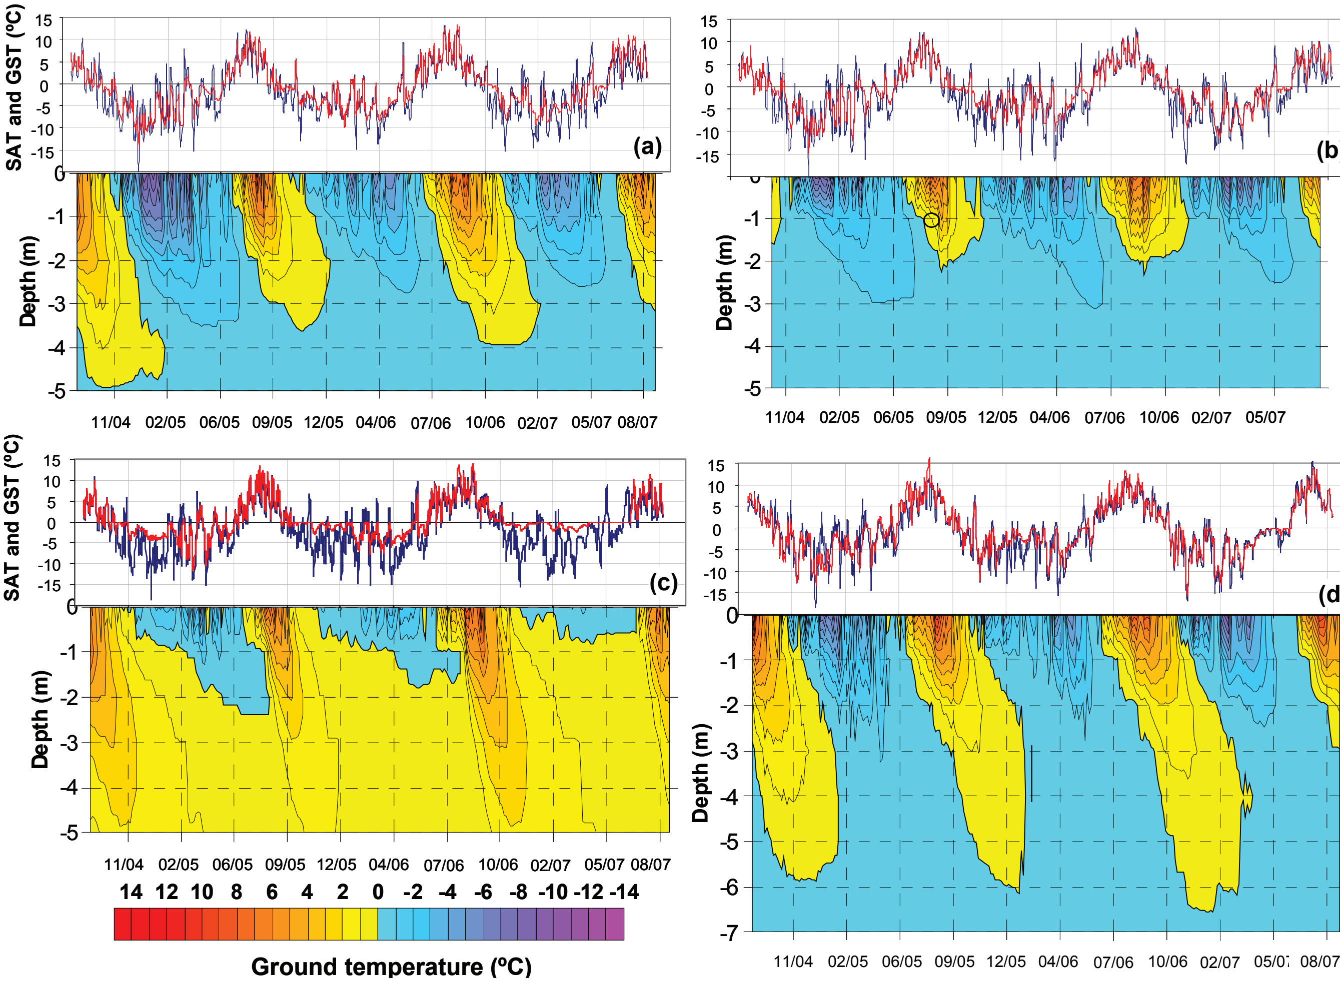

Figure 2: Depth-time series for air, surface, and ground temperatures at the four monitoring stations. The upper graph show SAT (surface air temperature) (blue) and GST (ground surface temperature) (Red) during the measurement period (August 2004 to August 2007). The lower diagram shows an interpolated depth-time series of ground temperatures. The contour interval is 1ºC, (**a**) Gagnheiði, (**b**) Snæfell, (**c**) Vopnafjörður, and (**d**) Hágöngur.

Methods and Results

Temperature monitoring and analysis

Instrumentation: All boreholes were initially equipped with UTL-1 miniature temperature dataloggers (MTDs) having an accuracy of ±0.27°C or better (cf., Hoelzle et al. 1999). In August 2005, the boreholes at Snæfell and Gagnheiði were equipped with thermistor chains consisting of 26 and 15 YSI S40006 thermistors, respectively. These thermistors have an absolute accuracy of ±0.05°C (Vonder Mühll 1992). Close to each borehole, single MTDs, measuring at intervals of 2 hours, were installed near the ground surface (i.e., at 1–5-cm depth) to record ground surface temperature (GST) and in radiation shields 1.5 m above ground to measure surface air temperatures (SAT). At Gagnheiði, the SAT from the meteorological station was used. Minor data gaps existed for air temperature measurements, which were filled in using linear regression to one of the other stations, usually with a $R^2>0.95$. More details of borehole location and characteristics are given in Farbrot et al. (2007).

Calculations: A set of parameters is calculated, representing an average over the three seasons reaching from September 1 to August 31 (Table 1). The frost number for air (F) and ground surface ($F+$) are calculated following Nelson and Outcalt (1987):

$$F = \sqrt{DDF_a} / \left(\sqrt{DDF_a} + \sqrt{DDT_a} \right) \quad (1)$$

and

$$F_+ = \sqrt{DDF_s} / \left(\sqrt{DDF_s} + \sqrt{DDT_s} \right) \quad (2)$$

where DDF are freezing degree days, DDT are thawing degree days and the indexes a and s refer to air and surface, respectively. The n-factors simply follow the equation

$$n_T = DDT_s / DDT_a \text{ and } n_F = DDF_s / DDF_a$$

for the freezing factor n_F and the thawing factor n_T, respectively, $TTOP$ (top of permafrost) temperatures are estimated following, for example, Smith & Riseborough (2002):

$$TTOP = (r_K * n_T * DDT_a - n_F * DDF_a) / P \qquad (3)$$

where P is the period (365 days) and r_K is the quotient between thermal conductivity of soil in thawed and frozen state, respectively. Values of thermal conductivity are taken from literature, with values varying between 1.7 and 1.9 $Wm^{-2}K^{-1}$ (Flóvenz & Sæmundsson 1993).

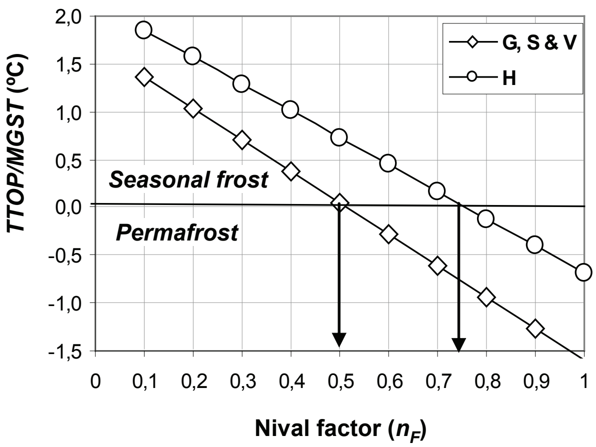

Figure 3: Modeled *TTOP* as a function of n_F, *G, S,* and *V* stands for Gagnheiði, Snæfell, and Vopnafjörður, respectively. For the three stations, it is assumed *DDF=1200* and *DDT=620* according to the last three seasons average (*MAT=-1.6ºC*), *H* stands for Hágöngur, assuming *DDF=1030* and *DD=780* (*MAT=-0.7ºC*), $r_K=1$ and $n_T=1$, as calculated from temperature measurements at the permafrost stations.

Results: The three records from Gagnheiði, Snæfell, and Vopnafjörður are highly correlated with respect to air temperatures with similar annual pattern, and have corresponding DDF_a and DDT_a values. Snæfell is slightly warmer than the two other stations (Table 1). However, ground temperatures are dissimilar (Fig. 2). The Vopnafjörður borehole has no permafrost and only shallow seasonal frost. The two others have permafrost, with *TTOP* temperatures above -0.5ºC. The active layer thickness was higher at Gagnheiði (3.5–4.5 m) than on Snæfell (~2 m), despite higher GST and SAT at the Snæfell station. This is due to higher water content at Snæfell, as discussed in Farbrot et al. (2007). The SAT at the Hágöngur station was slightly higher than the three others (0.7° to 0.8ºC); however, marginal permafrost is present, with an active layer thickness of ~5 m.

It is obvious that permafrost existence and temperatures are highly related to the snow cover at the stations. At the Vopnafjörður station the n_F-factor was at 0.5 or below, while all other stations showed n_F-values *>0.7*, up to *>0.9* (Hágöngur station). We have no recordings of snow cover thickness. All sites are wind-exposed, and thick snow accumulations are unlikely. According to Smith & Riseborough (2002) the obtained nival factors correspond to average snow depths of below 0.2 m, which is in accordance to winter observations at the field stations. No stations show persistent <0ºC winter temperatures, but numerous events of melting episodes throughout the season (Fig. 2). This has two effects: First, snow cover becomes isothermal even with low thicknesses because of latent heat release during refreezing, leading to lower n_F-factors. Second, snow cover decreases and occasionally disappears during these episodes, allowing

Table 1: Summary of temperature recordings at the four measurement stations calculated over three seasons. *SAT*= Mean surface air temperature. *GST* = mean ground surface temperature. *DDF* = freezing degree days. *DDT* = thawing degree days for air and surface (index *a* and *s*). n_T = thawing n-factor. n_F = freezing (nival) n-factor. *F* and *F+* are the frost number for air and surface. respectively. *TTOP* is *measured* mean temperature at the top of permafrost or the bottom of seasonal freezing.

subsequent cold penetration, resulting in higher n_F-factors. This is especially obvious at the Vopnafjörður station, where deep seasonal frost could develop late in the 2004/05 season after a strong melting episode. The Hágöngur station showed less strong melting episodes. At the Vopnafjörður station, temperature decreases with depth with values <0.4ºC at -20 m. This indicates possibly relic permafrost below 25 m or so (cf. Etzelmüller et al. 2007, Farbrot et al. 2007).

Simple TTOP modeling following Equations (1) and (2) indicate that at the three stations of Vopnafjörður, Gagnheiði, and Snæfell, permafrost persists above a nival factor of n_F >0.5, while the Hágöngur station would produce positive "TTOP" with n_F-factors <0.75 (Fig. 3), showing virtually no snow during the winter season. Etzelmüller et al. (2007) proposed a limit of *MAAT=-3ºC* (normal period 1961–1990) for the lower limit of widespread permafrost in Iceland and Scandinavia. Theoretical considerations based on the TTOP model indicate a minimum n_F-factor of ~0.3 for TTOP <0 and MAAT=-3ºC. Since temperatures during the normal period 1961–1990 were about 1º to 2ºC lower than during our study (Farbrot et al. 2007), the Vopnafjörður station possibly had permafrost during at least the major part of the last century. Measured TTOP temperatures were lowest on Snæfell, which seems to have the most stable permafrost (Table 1). The two other permafrost stations show TTOP-temperatures very close to 0ºC, and seem to be in a stage of degrading. When modeling TTOP temperatures according to Equation (3), the r_K values are close to unity, indicating mostly similar TTOP than GST. This is possibly because of water advection and the influence of unfrozen water content close to 0ºC.

Modeling of ground temperatures

To investigate the sensitivity of ground temperatures to changes in snow coverage, we employ a numerical 1-D heat conduction model. We use an n-factor approach to derive GST from SAT and change the values of n to represent situations of different snow coverage. Based on the results, we discuss possible changes that may have led to the recent deterioration of permafrost at Vopnafjörður

Heat-conduction modeling principles: A numerical 1-D model of heat conduction is used, which accounts for latent heat and is forced by annual, monthly or daily GST input values (cf. Farbrot et al. 2007). The model solves the heat conduction equations following:

$$\rho\, c\frac{\partial T}{\partial t} = -k\frac{\partial^2 T}{\partial z^2} \tag{4}$$

(e.g., Williams & Smith 1989). As boundary conditions, we prescribe time series of GST and the geothermal heat flux

$$Q_{geo} = -k \cdot \partial T / \partial z \tag{5}$$

at depth, Q_{geo} was sat to 0 for shallow modeling domains below 30 m. Values for Q_{geo} were obtained from Flóvenz & Sæmundsson (1993), and must be regarded as regionally applicable values rather than local estimates. The thermal properties of the ground are described in terms of density ρ, thermal conductivity *k* and heat capacity *c*. Typical values for Icelandic basalt were derived from the literature (Flóvenz & Sæmundsson, 1993). In our model, we consider the change of latent heat *L* due to phase changes of the pore water by describing a temperature-dependent heat capacity $c_{(T)}$. In a small temperature interval between T_1 (-0.1ºC) and T_2 (0ºC) around the freezing temperature, we add the effect of latent heat release to the heat capacity of the substrate c_0 (e.g., Wegmann et al. 1998).

$$c_{(T)} = c_0 + \frac{L}{(T_2 - T_1)} \tag{6}$$

Any effects of heat advection related to groundwater flow are neglected in this study. The heat conduction equation (Equation [4]) was discretized along the borehole depth using finite differences, and subsequently solved by applying the method of lines (Schiesser 1991).

Calibration run: For this study, the study sites of Vopnafjörður (no permfrost) and Gagnheiði (warm and shallow permafrost) were selected. The model was calibrated using measured ground temperatures, and the values of *w* (volumetric water content) and *k* were adjusted to match modeled and measured temperature distributions, annual amplitudes at a given depth, and modeled and measured thicknesses of the active layer (Fig. 4). Generally, the fit revealed R^2-values of *>0.9*. The model performance was lower during spring and fall, most probably due to advective processes which are not accounted for, or deficits of the modeling approach because of lacking prescription of important processes. Values for material properties are taken from literature. The calibration indicates relatively dry

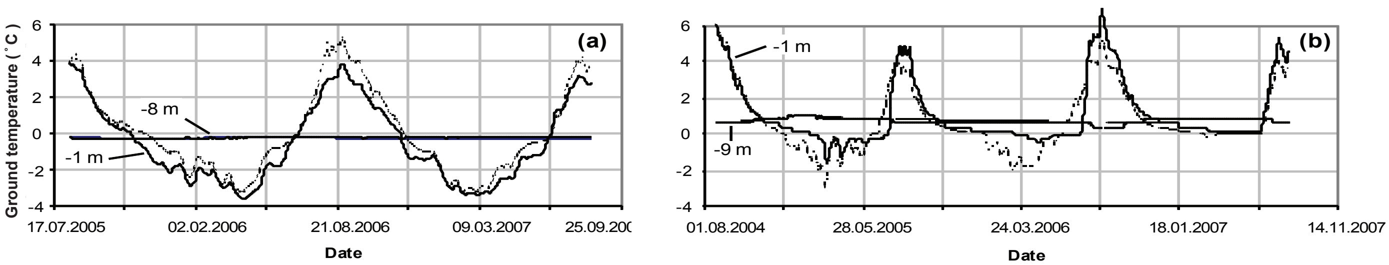

Figure 4: Examples of fit for modeled and measured ground temperatures in depth (8 and 9 m) and close to the surface (1 m). (a) Gagnheiði, (b) Vopnafjörður. Solid line is "modeled"; dashed line is "measured."

conditions at both sites, with volumetric water contents of below 5% (Farbrot et al. 2007).

Simulation run: To investigate the sensitivity of ground temperatures to changes in snow coverage, we use an n-factor linking GST to SAT and change the values of n_F to represent different situations. We prescribe SAT as a sinusoidal variation of specified amplitude around a specified annual mean temperature. Winter temperatures (defined as <0ºC) were damped using the n_F-factor.

Snow cover effect was simulated by changing n_F-factors, and SAT varies around a mean of *-1.6ºC* with amplitude of *9ºC* (Table 2). The n_F-factor was kept constant throughout the winter. For the Gagnheiði station, stable snow cover corresponding to n_F-factors <0.5 will lead to an almost instantaneous development of taliks. A smaller influence of snow coverage ($n_F>0.5$) is conserving the permafrost situation at Gagnheiði. This corresponds well with the TTOP analysis described previously, even if the TTOP approach produces errors especially close to 0ºC (Riseborough 2007). The same is valid for the Vopnafjörður station. Here, further warming of the ground is continued with $n_F<0.3$, while $n_F=0.4$ *to 0.6* results in a situation with no or very limited ground temperature trends, even after *40 years* of model run. This indicates that the measured n_F-factor (0.14) for the 2006/07 season at Vopnafjörður (Table 1) was exceptionally low. With $n_F=0.7$ permafrost aggregates after 7 years of model run. This is also in rough correspondence to Figure 3

In a second simulation, we evaluated the impact of changing SAT on ground temperatures, assuming a constant snow cover like that observed during the three years of recent monitoring. We introduced a step change of ~1ºC warming for Gagnheiði ($n_F=0.7$, *MAT=-0.6ºC)* and cooling for Vopnafjörður station ($n_F=0.45$, *-2.8ºC)*. For the Gagnheiði station, a talik appears after c. 8 years, and permafrost is degraded within 50 years. This is roughly in accordance to the analysis shown in Farbrot et al. (2007). For the Vopnafjörður station the model produces permafrost after c. *15 a* with instant cooling to *-2.8 ºC* and a $n_F=0.45$. The air temperature value corresponds roughly to MAAT during the last normal period 1961–1990 in eastern Iceland close to 900 m a.s.l. After 50 years, permafrost is modeled to be approximately 10 m thick. This clearly demonstrates that permafrost at Vopnafjörður most probably has been degrading during the last decades, and that there might still be relic permafrost. It seems certain that the site had permafrost conditions during the Little Ice Age, since there is plenty of geomorphological evidence, such as rock-glaciers and well-developed patterned ground features.

Table 2: Simulation for varying snow conditions. The model was forced with a sinusoidal curve, with MAT of -1.6ºC and air temperature amplitude of 9ºC. AL=active layer depth; SF=seasonal frost depth after 20 years; GT=ground temperature; T=Tallilk, PF=permafrost. The initial ground temperatures were sat to the measured temperatures from 1.6.2007.

	Gagnheiði		**Vopnafjörður**			
n_F	G T response	AL (m)	G T response	SF (m)	A L (m)	PF thick after 20 a

0.9	Stable	> 3.4	PF > 3 a		3.5	10 m

Summary and Conclusions

A three-year monitoring series of air and ground temperatures is presented for four permafrost stations in Iceland. Permafrost is warm, and in a degrading stage at two stations. At one, permafrost is absent, and this study indicates that permafrost may have existed at this station during some part of the last century. Snow is the decisive factor for permafrost distribution in elevation ranges between 800 m and 1000 m a.s.l. in Iceland, which corresponds to MAAT during the last normal (1961–1990) period of around -3*ºC*. A $n_F>0.6$ seems necessary to keep permafrost stable in the elevation ranges below 1000 m a.s.l. in Iceland. The study demonstrates the sensitivity of ground temperatures to small changes in air temperatures and snow cover in the maritime mountains of Iceland. As ground temperatures are major decisive factors for understanding a suite of geomorphological processes, the understanding of the impact of expected climate warming on this environment is crucial.

Abstract

The Gaissane Mountains, situated in northern Norway, reach elevations above 1000 m a.s.l. Our study area contains a range of active and relict periglacial features as well as numerous landforms related to the Pleistocene ice sheet. The distribution of permafrost in the mountains has been investigated through basal temperature of snow (BTS) measurements, continuous ground surface temperature (GST) measurements, and electrical resistivity tomography. Solar radiation and the presence or absence of coarse blocks are the two main factors controlling the thermal regime of regularly snow-covered ground. At fairly snow-free sites, the investigations indicate that mountain permafrost is common in the area above 350–450 m a.s.l. On the summits, about 1000 m a.s.l., geomorphic evidence combined with GST measurements suggest that the permafrost probably shows great antiquity, possibly prevailing since the last interglaciation.

Keywords: Gaissane Mountains; palaeopermafrost; permafrost mapping.

Introduction

In southern Norway, the lower regional altitudinal limit of mountain permafrost decreases eastwards with increasing continentality. The investigated sites in southern Norway have in common that the BTS variance to a great extent is explained by elevation, whereas the effect of solar radiation is secondary (Etzelmüller et al. 2003). Although Reusch (1901) a century ago recognized permafrost as a common phenomenon at high altitudes in northern Norway, few quantitative studies on mountain permafrost have been conducted in this area. Rather most investigations have focused on periglacial geomorphology and in particular palsas (Isaksen et al. 2008 and references therein). Gridded mean annual air temperature (MAAT) maps, however, indicate a similar altitudinal gradient for discontinuous permafrost limits also in northern Norway, decreasing from over 1000 m a.s.l. in coastal sites down to below 400 m a.s.l. in interior, more continental areas (Etzelmüller et al. 2008, Isaksen et al. 2008).

The aim of this study is to investigate occurrences of mountain permafrost in the Gaissane Mountains, northern Norway, by using measurements of ground surface temperature (BTS and Miniature Temperature Dataloggers [MTDs]) and electrical resistivity tomography (ERT). The factors controlling the distribution of permafrost are discussed. In addition, the distribution of paleopermafrost is briefly discussed based on geomorphic mapping.

Setting

The Gaissane Mountains are situated southwest of the Varanger Peninsula (70°N, 25°E) in the county of Finnmark, northern Norway (Fig. 1). The mountains reach elevations above 1000 m a.s.l. Western and southwestern parts of Norway are mostly influenced by western, Atlantic air flows bringing unstable weather patterns with high winter temperatures and moist air, whereas eastern parts of northern Norway are frequently dominated by Eurasian high-pressure systems involving stable air with high summer temperatures and low winter temperatures for long periods of time (Johannessen 1970). The official weather station closest to the field area is Banak (5 m a.s.l.), 20 km to the north. There, MAAT

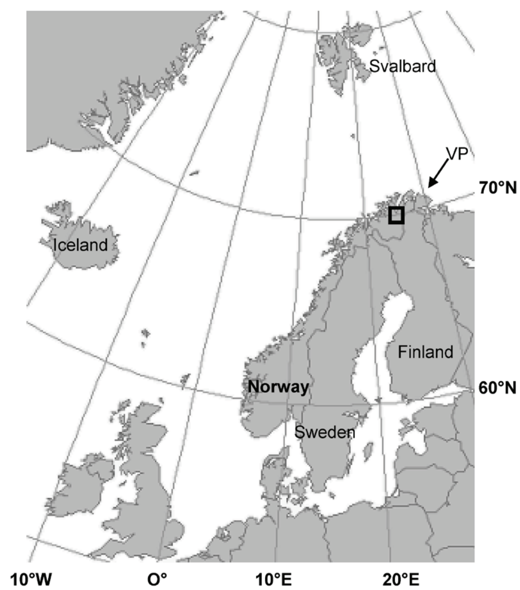

Figure 1. The Gaissane Mountains are situated in northern Norway, southwest of the Varanger Peninsula (VP).

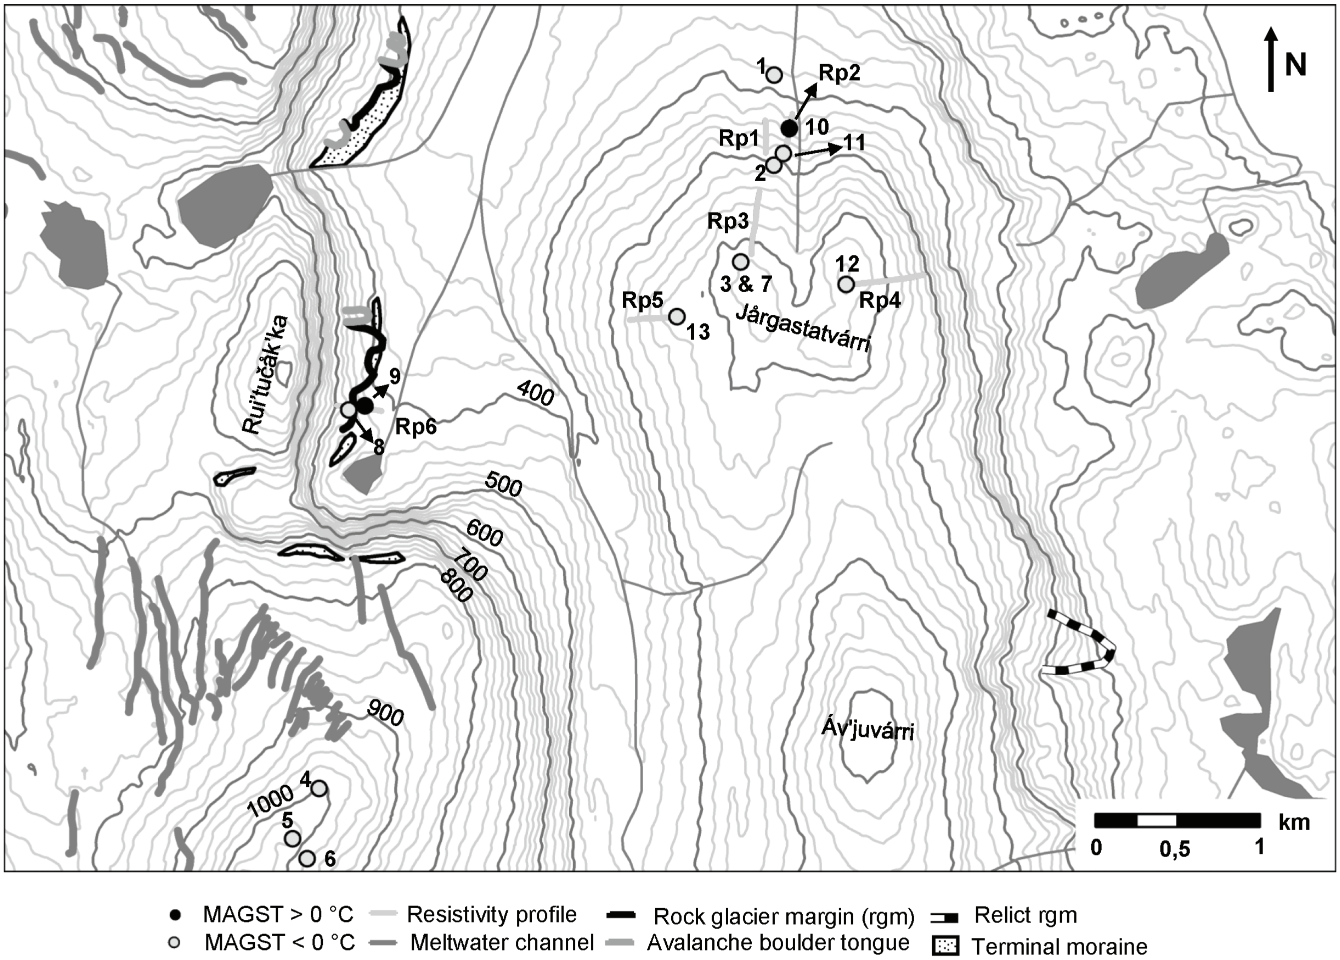

Figure 2. Map of the field area in Gaissane Mountains containing the positions of the ERT profiles (Rp1-6), MTDs and some geomorphic features. Letters refer to the MTDs in Table 1. The westernmost rock glaciers partly cover morainic ridges of presumable Preboreal age (Kellerer-Pirklbauer 2008).

(1961–1990) is 0.6°C and mean annual precipitation 345 mm. The winds are strong during winter, and above the forest line (250–300 m a.s.l.) extensive snow cover is commonly restricted to depressions.

The field area contains a range of active and relict periglacial features including rock glaciers, solifluction lobes, ploughing boulders, and patterned ground, as well as numerous landforms related to the Scandinavian ice sheet. The field area is situated well inside the glacial limit of the Younger Dryas ice; however, the summits were nunataks at that time (Marthinussen 1960).

Methods and Results

MTDs

13 UTL-1 MTDs were used during the period 2003–2006, 12 measuring ground surface temperatures and one measuring air temperature (Fig. 2, Table 1). The thermistors have a temperature range of −29° to +39°C, and the accuracy of the sensors are ±0.27°C (Hoelzle et al. 1999). The MTD data is probably not representative for long-term ground surface temperature conditions, since the observational period was characterized by considerably higher air temperatures than normal (1961–1990). By correlating the daily ground surface means with daily air temperature means from the weather station at Banak, a simple linear regression model was established. Using MAAT from Banak as independent variable, mean annual ground surface temperatures (MAGSTs) for the normal period 1961–1990 were estimated for the MTD sites. For these estimates to be reliable, we only used data from more or less snow-free sites, as indicated by the existence of high-frequency temperature fluctuations during winter (MTDs 1, 3-5, 8-13). The assumption is, thus, that these areas also remained snow free during the normal period 1961–1990 (cf., Farbrot et al. 2007). In general, a R^2 of > 0.70 (for all records: $p << 0.001$) was achieved in these analyses. Fitting a linear trend line through the estimated MAGST from the MTD sites indicate that the MAGST 0°C-isotherm of fairly snow-free sites is found at ~350 m a.s.l.

One year of air temperature measurements at an elevation of 614 m a.s.l. (MTD 7) combined with corresponding measurements from Banak weather station (5 m a.s.l.) reveal a mean altitudinal lapse rate of ~ -0.005°C m^{-1}. This fits well with investigations by Laaksonen (1976) indicating a similar mean vertical temperature gradient for Fennoscandia and in particular other investigations from northern Norway indicating comparable lapse rates (Isaksen et al., in prep.).

Table 1. Measured and estimated ground surface and air temperatures at the MTD sites in the Gaissane Mountains. MTD 10–13 were operating less than a year, but have been used for estimation of MAGST. MGST = Mean ground surface temperature, FDD = freezing degree days, TDD = Thawing degree days, MAAT = Mean annual air temperature, MAGST = Mean annual ground surface temperature, N = number of values in the statistical analyses, R^2 = Goodness-of-fit of a straight line fitted by least squares to the points.

Est. MAGST (°C)	-0.4	-	-2.2	-3.5	-3.6	-	-	-0.8	0.2	0.4	-1.1	-1.6	-1.7
N	313	1039	1039	1039	1039	1039	398	725	725	336	336	333	335
R^2	0.853	-	0.887	0.812	0.788	-	0.895	0.804	0.884	0.705	0.887	0.913	0.892
Est. MAAT (°C)	-1.3	-1.9	-2.5	-4.1	-4.5	-4.3	-2.5	-1.8	-1.7	-1.5	-1.7	-2.6	-2.3
Est. surface offset (°C)	0.9	-	0.3	0.6	1.0	-	-	0.9	1.9	1.9	0.5	1.0	0.6

Hence, the measured mean lapse rate is assumed fairly representative for the 1961–1990 period, and, thus, MAATs for this period can be estimated for the MTD sites (Table 1), thereby enabling estimates of the surface offset (i.e., MAGST–MAAT). Surface offsets are mainly less than 1°C at dry sites without pronounced snow cover (Table 1). This fits with investigations from southern and northern Norway (Isaksen et al. 2007, 2008) and Iceland (Farbrot et al. 2007). From this approach, permafrost should be common at locations with thin or no snow cover above the elevation of the –1°C-isotherm. Using the assumed mean altitudinal lapse rate of –0.005°C m^{-1}, the –1°C-isotherm is found at ~330 m a.s.l. in the field area.

BTS

Basal temperature of snow (BTS) measurements involve measuring temperatures at the bottom of the snow cover when the temperatures have stabilized before onset of melting. Under a thick, dry snow cover (>0.8–1.0 m) the ground surface temperature is mainly controlled by heat conduction from the subsurface, thereby reflecting the thermal regime of the ground. Permafrost is considered probable if BTS values <–3°C, possible if values are between –2° and –3 °C and improbable if values > –2°C (Haeberli 1973).

Table 2. Parametric (Pearsons r) correlation matrix for BTS as dependent variable and selected topographic attributes and presence and absence of coarse blocks at the ground surface expressed as a dummy variable. PR = Potential radiation, N = 163.

	Elevation	PR	Coarse blocks	Snow depth	Wetness index
BTS	-0.065	0.445*	-0.604*	0.289*	0.092

* Correlation is significant at the 0.01 level (2-tailed)

In March 2004, February 2005, and February 2006, a total of 334 BTS measurements were obtained. The measuring points' topographical characteristics such as elevation, slope, and aspect were estimated from a DEM with 25 m grid spacing (© Statens Kartverk). Further, the annual potential solar radiation (PR) was estimated based on the SRAD topographic model (Wilson & Gallant 2000). A potential topographic wetness index—defined as the quotient of the specific upstream area and the surface slope—was estimated based on Beven & Kirkby (1979). In addition, the surficial material type (presence or absence of coarse blocks) was recorded at each measuring

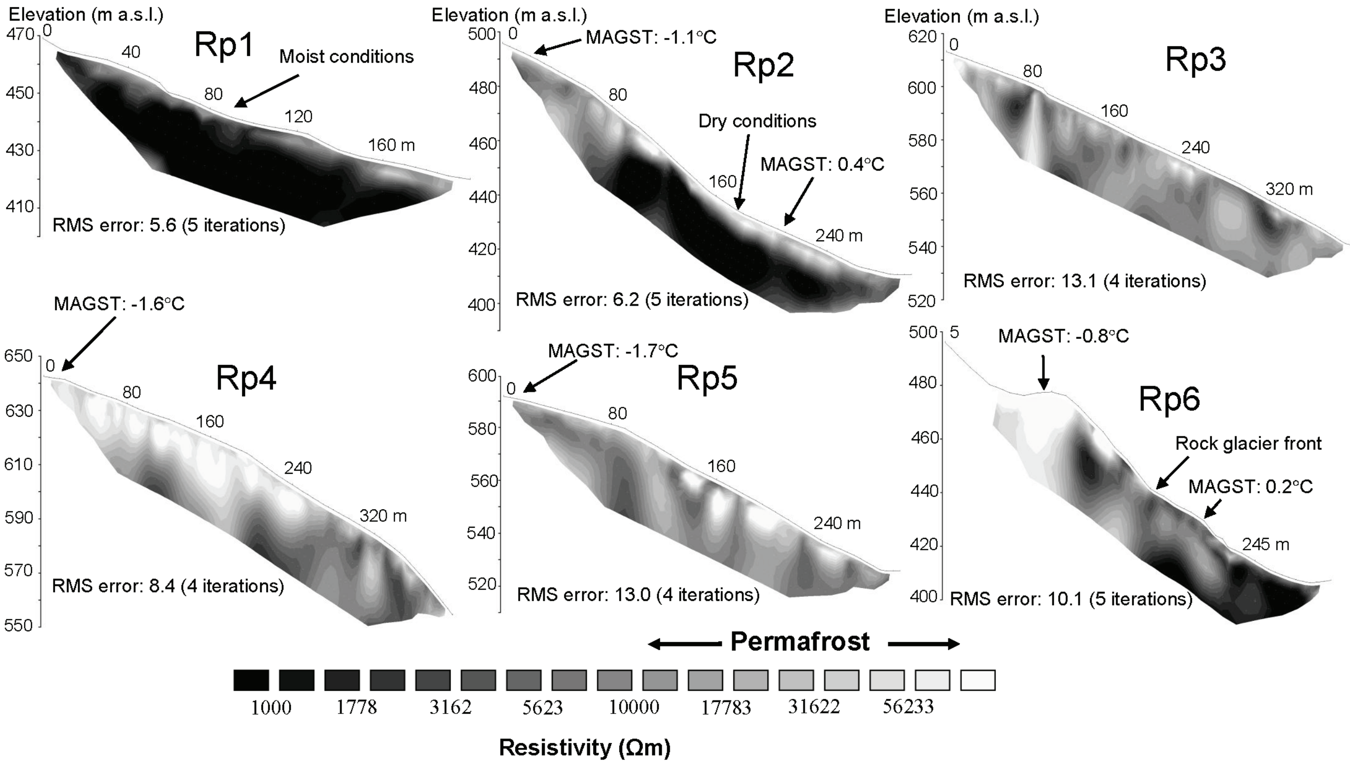

Figure 3. ERT profiles obtained in the Gaissane Mountains (for location, see Fig. 2). There is an overall increase in resistivity with elevation. The profiles indicate permafrost at elevations >450 m a.s.l., which corresponds well with estimated MAGSTs along the profiles.

site. Mean values were computed within diameters ≤10 m with consistent topographical and ground surface characteristics to try to overcome the problem of micro-scale variability and spatially clustered data (cf., Brenning et al. 2005), and these means (N=163) were used in the further analyses. From the correlation analysis, it is evident that PR and the presence or absence of coarse blocks, expressed as a dummy variable (1 means coarse material is present; 0 means coarse material is absent), are the major factors controlling BTS (Table 2). Mean BTS value for sites with coarse blocks is ~2.2°C lower than for sites without. However, the coarse-grained sites reveal less PR than the fine-grained sites. This effect is excluded by subtracting the assumed effect of lower PR on BTS values from the linear regression, thereby indicating that the effect of coarse blocks lowers the mean BTS value with 1.6°C. A linear regression model with the presence or absence of coarse blocks and PR as independent variables, explains 65% of the BTS variability. No significant correlation was found between BTS and elevation (at the 0.01 level [2-tailed]). Correlation between BTS and snow depth is significant but weak.

Electrical resistivity tomography

Electrical resistivity tomography (ERT) measurements are conducted by inserting an electrical current into the ground via two current electrodes. The resulting electrical potential between two other electrodes is measured, and from these measurements the true resistivity of the ground can be estimated. The existence of ice in the ground increases the resistivity markedly since the resistivity of ice is several orders of magnitude higher than water. Thus, resistivity measurements are highly valuable for detecting and characterizing ice-bearing permafrost (e.g,. Hauck & Vonder Mühll 2003). Six two-dimensional ERT profiles have been obtained in the field area (Fig. 3). Resistivity profile 1 (Rp1) is the lowermost profile (~400 m a.s.l.) across presumably permafrost free ground as indicated by BTS measurements. Hence, this profile presumably represents bedrock resistivities, thereby indicating that resistivity values >10 000 Ωm can serve as a conservative estimate for permafrost. This assumption corresponds well with the MTD measurements (Fig. 3). Generally, there is an overall increase in resistivity with elevation, and the profiles indicate permafrost above ~450 m a.s.l. Furthermore, Rp 6, a longitudinal profile along a rock glacier, indicates ice rich subsurface conditions within the rock glacier, although the possibility of air-filled cavities causing the high-resistive zone can not be excluded from the ERT measurements solely (cf., Hauck et al. 2004).

Discussion

BTS variability

The BTS measurements indicate that solar radiation and the presence or absence of coarse blocks are the two main factors controlling the thermal regime at snow covered sites (Table 2). The influence of PR is greater than what is found in southern Norway where ground thermal regime is highly correlated with elevation and to a lesser extent PR (Isaksen et al. 2002, Heggem et al. 2005). This difference seems plausible as the solar height is lower in northern Norway.

The occurrence of openwork blocky debris in the field area is clearly a cooling factor for ground surface temperatures. Similar results have been found in a range of studies (e.g., Harris & Pedersen 1998), and recently in southeastern Norway (Juliussen & Humlum 2007). This is presumably due to air circulation within the voids, which was indicated by several observations of air ventilation funnels through the snow cover in wintertime.

The lack of significant correlation between BTS and elevation probably reflects that the BTS points are mainly scattered between 300 and 600 m a.s.l., and a greater elevation span would have increased the correlation (cf., Brenning et al. 2005), as obtained for the MTDs. The mentioned elevation range obviously shows large snow cover, soil moisture and vegetation cover variations, covering the elevation signal in the statistical analysis (cf., Isaksen et al. 2002).

Present permafrost distribution

No borehole temperature measurements are available within the field area, so identification of mountain permafrost relies on indirect methods. Below the forest line of about 250–300 m a.s.l., winter snow cover is fairly extensively developed, so permafrost is presumably absent there due to the insulating effect of snow (cf., Johansson et al. 2006). The lowermost presumably active rock glaciers in the area have their margins at ~430 m a.s.l., and both BTS and ERT measurements indicate that these features contain permafrost at present.

The consistency of the independent indirect methods (Table 3) leads to the conclusion that mountain permafrost is common above 350–450 m a.s.l. As all BTS measurements rely on point measurements with a stable snow cover of a least 80 cm, this should imply that these points represent warmer ground conditions compared to areas with limited snow cover, due to the isolating effect of snow (cf., Jeckel 1988). Developed snow covers are limited in the field area due to low precipitation and strong winds. Thus, the aerial extent of permafrost is presumably greater than indicated by BTS measurements (cf., Sollid et al. 2003). The permafrost distribution pattern indicated fits generally well with Johansson et al. (2006), stating that permafrost is common in the tundra zone above the forest line in the Torneträsk region, northern Sweden. The pattern also agrees with investigations by King & Seppälä (1987) in north-western Finland which indicate a lower limit of discontinuous permafrost of 300–500 m a.s.l. based on geoelectrical soundings.

Past permafrost conditions

Several relict periglacial landforms in the field area point to a cooler environment in the past than at present. Such landforms include a rock glacier, terminating in the birch forest, with its fronts at 180 m a.s.l., presumably relict tundra polygons, ploughing boulders found in the birch forest, and extensive areas of vegetated patterned ground. The low-elevation rock glacier witnesses a past lower limit of permafrost at least 200 m below the present.

The past lower limit of mountain permafrost in the field area were obviously variable during the Holocene climate fluctuations

Table 3. Elevation of different environmental parameters and permafrost limits indicated by different indirect approaches. See text for details.

Environmental parameter/ permafrost limit	Elevation (m a.s.l.)
Tree line	250-300
Blockfield limit	~800
BTS	?
Estimated MAGST	350
ERT measurements	~450
-1°C isotherm	330
Active rock glacier	430

(cf., Kukkonen & Šafanda 2001). However, on the summits of about 1000 m a.s.l., a different picture emerges. The blockfields of the summit areas show no signs of Holocene modification. The lateral meltwater channels eroded into the blockfields together with the terminal moraines found on top (cf., Marthinussen 1960) indicate a pre-Late Glacial Maximum age of the blockfield and subsequent survival underneath cold-based, non-erosive ice. This interpretation is supported by investigations of blockfields on the Varanger Peninsula (Fjellanger et al. 2006). According to Heikkilä & Seppä (2003) maximum annual air temperatures in Fennoscandia were approximately 1.5–2.0°C higher during the mid-Holocene thermal optimum (HTO) than the reconstructed mean temperature of the last 200 years. Assuming a roughly equal coupling between air and ground surface temperatures, sub-zero MAGST probably still occurred in the summit areas of about 1000 m a.s.l. during HTO. This is based on the assumption that the summits have prevailed bare-blown, with limited influence of changes in the Holocene wind and precipitation patterns. Thus, although warm periods have occurred during the Holocene, affecting thermal regime and the permafrost thickness, permafrost conditions have presumably prevailed in the summit areas. This is supported by numerical modelling of permafrost in bedrock in northern Fennoscandia during the Holocene by Kukkonen & Šafanda (2001). Hence, assuming cold-based ice in the summit areas at least during the last glaciation, permafrost at these elevations probably is of considerable age, potentially spanning the Weichselian.

Conclusions

Based on these investigations the following conclusions concerning mountain permafrost in the Gaissane Mountains seem supported:

- At present permafrost is common above 350–450 m a.s.l.
- Coarse, openwork blocks tend to reduce ground surface temperatures significantly.
- The permafrost in the summit areas at about 1000 m a.s.l. is of considerable age, possibly prevailing since the last interglaciation.

Abstract

The main objective of this paper is to determine the state of permafrost landscapes in Central Yakutia under recent climate change. Air and ground temperature data from monitoring sites of the Melnikov Permafrost Institute and records from weather stations at Yakutsk, Churapcha, and Pokrovsk are used. Analysis of the data indicates that the Pokrovsk records are most suitable for evaluating long-term ground temperature variations in Central Yakutia. A good correlation has been found between the data from monitoring sites and the Pokrovsk weather station. During the last several decades, major increases in ground temperature occurred in the early to mid 1980s and the early 1990s. At present, some cooling of ground temperature is observed, although air temperature shows an increasing trend. However, there is a high risk for active development of cryogenic processes in forest-free areas that can cause permafrost degradation and terrain disturbance. Thermokarst is actively developing in some areas of Central Yakutia. Disturbed landscapes, primarily the deforested anthropogenic complexes affected by agriculture, tree removal, or burning, are most sensitive under the current climate change.

Keywords: climate change; cryogenic process; ground temperature; permafrost landscape; thermokarst.

Introduction

Ground temperature is an important cryoecological characteristic of permafrost-affected landscapes. Its influence on the state and dynamics of permafrost landscape is difficult to overestimate. Analyses of the recent data from thermal monitoring sites in Central Yakutia are presented in the Russian permafrost literature (Skryabin et al. 1998, Varlamov et al. 2002, Pavlov 2003, Konstantinov et al. 2006, Pavlov & Malkova 2005, and others). These studies document ground temperature and thaw depth variability and indicate that ground temperatures show both an increasing and decreasing trend in the region where air temperatures are increasing. However, observations at monitoring sites are too short and do not provide sufficient information to evaluate long-term trends in natural processes. Direct field observations of the ground temperature regime in Central Yakutia are available only for the period since 1980.

Weather station records have to be used, therefore, in order to understand the long-term dynamics of ground temperatures. Vasiliev & Torgovkin (1996), Gilichinsky et al. (2000), and Romanovsky et al. (2007) analyzed ground temperature records from Yakutian weather stations for various depths and various periods and determined trends. Most weather stations in Central Yakutia demonstrate a strong increasing trend in ground temperature. Vasiliev & Torgovkin (1996) examined the period 1967-1992 when the largest increase in air temperature was observed in Central Yakutia. The period 1951-1996 was analyzed in Gilichinsky et al. (2000) and the value of this work is in comparing temperature trends in different regions of the Russian permafrost zone. Romanovsky et al. (2007) calculated trends in ground temperature at 1.6 m depth along the Tiksi-Yakutsk-Nagorny transect in Yakutia. The authors analyzed the spatial variability of ground temperatures and found that temperatures were increasing at some sites and decreasing at others during the period from 1956 to 1990.

The paper discusses the results of long-term observations on permafrost terrain dynamics at the Yukechi, Neleger, Spasskaya Pad, and Umaibyt sites near Yakutsk, and the variations in meteorological elements based on Yakutsk and Pokrovsk weather station records (Fig. 1).

The main objective of this paper is to determine the state of permafrost landscapes in Central Yakutia under recent climate change. Retrospective analysis of ground temperatures provides a basis for assessing changes in the thermal state of cryogenic landscapes. However many factors make such assessment difficult, such as the differences in soil conditions between weather stations, the inhomogeneities in data records due to relocation, and the indirect effects of anthropogenic disturbance of surrounding

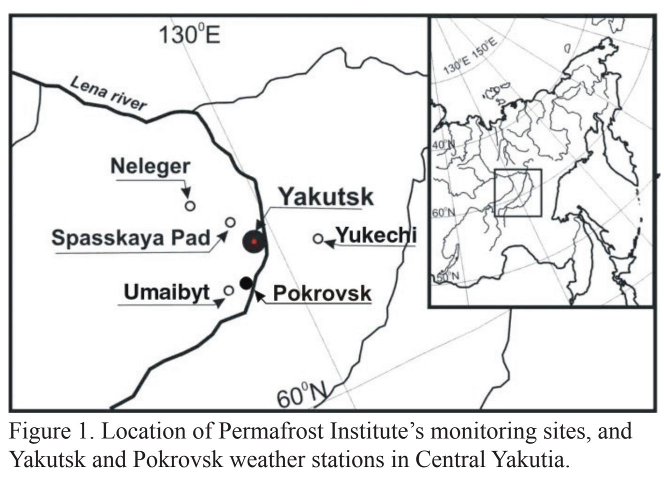

Figure 1. Location of Permafrost Institute's monitoring sites, and Yakutsk and Pokrovsk weather stations in Central Yakutia.

areas. Analysis of long-term ground temperature variations at weather stations during the entire period of instrumental observations will enable us to determine the development of cryoecological stresses in Central Yakutia, which is important for understanding the dynamics of cryogenic landscapes and for environmental protection planning.

Data Sources and Research Methods

Continuous ground temperature measurements in Central Yakutia have been made since 1931 (weather stations at Yakutsk and Pokrovsk). To determine representativeness of ground temperature records, data for depths of 1.6 and 3.2 m from the Yakutsk and Pokrovsk weather stations over the period 1931-2006 have been examined. The weather station data allow an assessment of both mean monthly and interannual variations in ground temperature. Based on the data analysis, Pokrovsk has been chosen as the most representative station for Central Yakutia. A measurement site at Pokrovsk was relocated in 1941. This move had little effect on the ground temperature record, because the new site was very similar to the older one in landscape and soil conditions. A site of the Yakutsk weather station was moved in 1964. The new and old sites differed greatly in landscape conditions, resulting in significant differences between the temperature series. Moreover, the Yakutsk data show virtually no variation after 1989 because of the change in the suprapermafrost water regime. This was a major reason for choosing the Pokrovsk records. Correlation coefficients between the mean annual ground temperatures at 1.6 and 3.2 m in Pokrovsk and Yakutsk are 0.85 and 0.88, respectively, at p=0.05 (during the period from 1965 to 1988 when the uniformity of measurement conditions was not disturbed by relocations or man-induced change in suprapermafrost water level).

Data obtained from the Yukechi, Umaibyt, Dyrgabai, and Tabaga monitoring sites, as well as the Neleger and Spasskaya Pad intensive observation sites, have been used to examine the effects of climate change on permafrost landscapes. These sites include measurements of ground temperature, thaw depth and active-layer moisture content, as well as observations of changes in microrelief and landscape at the facies level (Fedorov 1996, Fedorov et al. 1998, Konstantinov et al. 2001, Fedorov & Konstantinov 2003, Fedorov et al. 2003, Konstantinov et al. 2006). Ground temperatures at Spasskaya Pad and Neleger correlate well with the Pokrovsk weather station data. For example, the correlation coefficient of mean monthly temperatures at 3.2 m between Pokrovsk and the monitoring sites from October 2000 to September 2005 is 0.89 for Spasskaya Pad and 0.92 for Neleger. Such close relationship allows us to rely on the Pokrovsk records to analyze the long-term dynamics of ground temperatures and permafrost landscapes. We must also note that air temperature variations are relatively uniform across Central Yakutia. Correlation coefficients between locations are 0.89-0.98 (Skachkov 2001). In view of different record lengths and relocations of other weather stations, this fact allows us to use the Pokrovsk record as a basis for documenting long-term ground temperature variations (since 1931) in Central Yakutia.

Results

Interannual variations of ground temperature

A depth of 3.2 m was selected to analyze the long-term ground temperature variability, because materials at this level are perennially frozen. Temperature variations in the upper permafrost have a strong impact on the landscape and control degradation or recovery of the environmental conditions. An increase in temperature triggers cryogenic processes, while a decrease improves the stability of the upper permafrost.

The mean annual ground temperature at Pokrovsk for the period examined is -2.4°C and the standard deviation of the series is 0.44. The amplitude of annual means is 1.8°C, with a minimum of -3.3°C and a maximum of -1.5°C. The mean annual ground temperature has increased by 0.7°C over the period, with a trend of 0.1°C/decade (Fig. 2).

The time series of mean annual ground temperature shows a cyclic and progressive variation with an average period of 9.6 years. The maximum period is 12 years and the minimum is 8 years. Relatively high temperatures (the positive phase of the cycle) are observed in the mid 1930s, early 1940s, late 1940s-early 1950s, late 1950s-early 1960s, late 1960s-early 1970s, early 1980s-middle 1980s, early 1990s, and late 1990s-early 2000s. Two positive phases that occurred in the early 1940s and the late 1950s-early 1960s are less pronounced than the others. The temperatures series shows increasing values both for the positive and negative phases.

The most significant increases in ground temperature occurred in the early to mid 1980s and in the early 1990s, when the periods with maximum temperatures were longest and the periods with minimum temperatures were short. The temperature series before the 1980s can be characterized as stable, with alternating positive and negative phases.

Analysis of mean annual air temperature variations indicates that significant warming began in the late 1980s. Since then, the temperature series has changed from its normal pattern (Fig. 3). The mean annual air temperature at

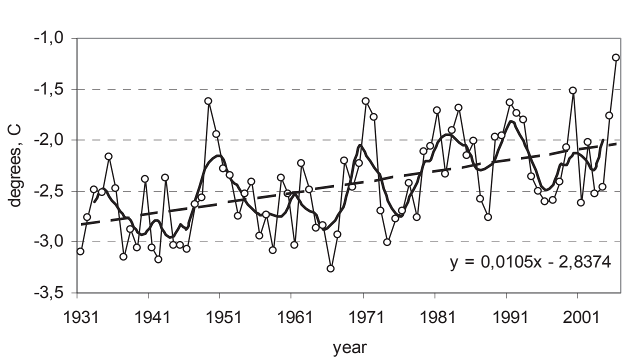

Figure 2. Interannual ground temperature variation at 3.2 m depth for the Pokrovsk weather station.

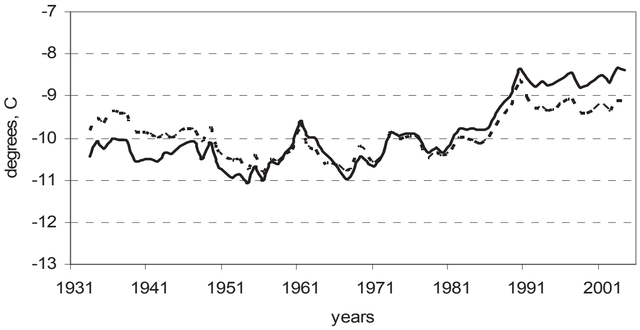

Figure 3. Variations in mean annual air temperature for Yakutsk (solid line) and Pokrovsk (dash line).

Yakutsk for the period from 1988–2005 was -8.5°C, while the long-term average had been -10.2°C (Handbook on the USSR Climate 1989). It is evident that the increase in ground temperatures from the early to mid 1980s was not due to a rise in air temperature. Being an integrating environmental parameter, ground temperature is not always consistent with variations of individual elements, such as mean annual air temperature or precipitation. We also note that air temperatures were higher at Pokrovsk than at Yakutsk until the mid 1950s, nearly identical between the mid 1950s and the mid 1970s, and colder since the mid 1970s to the present. This variation is likely due to circulation processes, since an anthropogenic factor has been ruled out by researchers (Skachkov 2001). However the increasing amplitudes of mean annual air temperature since the 1990s require a detailed analysis to determine the cause.

Of special interest is the change in ground temperature since 1980, with distinct cooling continuing to the present (Fig. 4a). Varlamov et al. (2002) attributed this cooling to the effect of snow cover. However the magnitude of the cooling is not so significant relative the entire series as to ameliorate the cryoecological stress (Fig. 2). There has been a steady increase in air temperature during this period in Central Yakutia (Fig. 4c), suggesting that Varlamov et al. are correct in relating the ground cooling to changes in snow cover. The variations in early winter (October, November and December) precipitation, which has an important effect on the permafrost temperature regime, provide some support to this view (Fig. 4b).

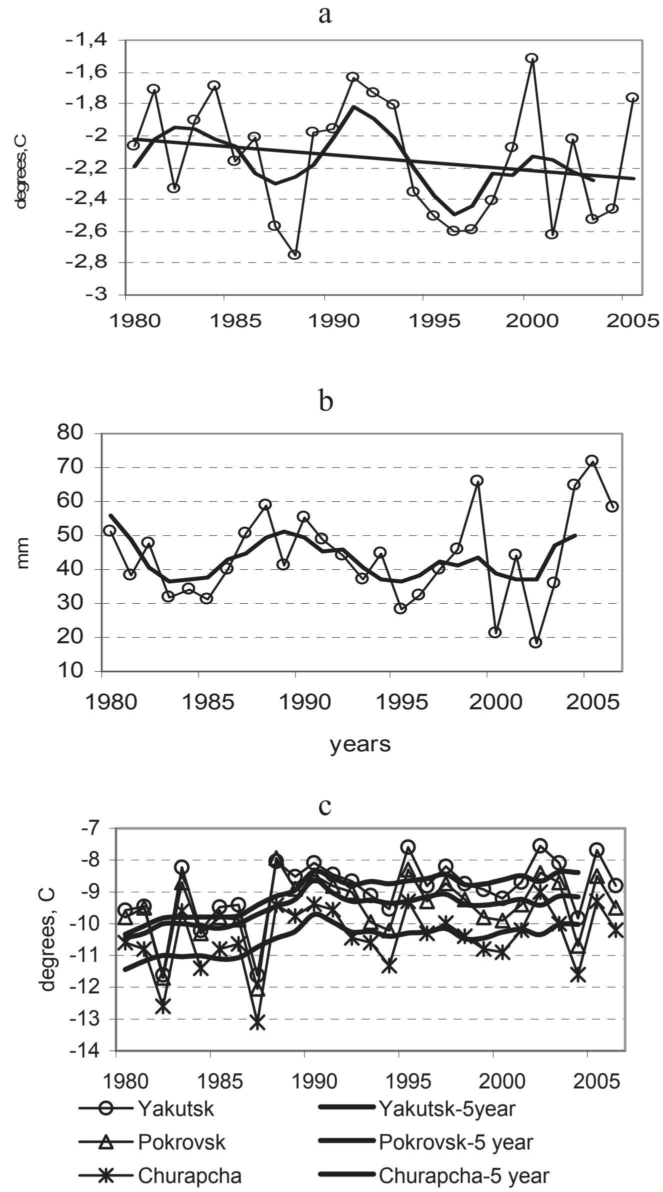

Figure 4. Ground temperature at 3.2 m for Pokrovsk (a) early winter precipitation for Yakutsk (b) and mean annual air temperature for Yakutsk, Pokrovsk and Churapcha (c) between 1980 and 2005. Thin lines – annual means, thick lines – 5-year running means.

Response of permafrost landscapes to impacts under present climatic conditions

Post-disturbance changes in permafrost and cryogenic landscapes have been studied during recent years as part of the Permafrost Institute's projects (Bosikov 1998, 2004, Fedorov et al. 1998, 2003, Gavriliev et al. 1999, 2005, Fedorov 2006). Thermokarst research is a major component in these investigations. Thermokarst studies are carried out at the Yukechi, Neleger, Spasskaya Pad and Umaibyt sites near Yakutsk.

The sites are heavily underlain by ground ice and contain numerous alases. Excess ice in permafrost is the main cause for thermokarst development. Central Yakutia, primarily between the Lena and Amga rivers, is dominated by ice-rich permafrost landscapes. The presence of wedge ice is readily identified by cemetery mounds on alas slopes and thaw depressions on the disturbed surfaces.

Generally, in Yakutia ice-rich permafrost landscapes are of limited distribution and occupy only near 10% of the region (Bosikov 1978), mainly within the densely populated areas such as the Lena-Amga watershed and the Viluy and Kolyma basins. However, thermokarst is not always active in ice-rich terrain. There are strong self-preservation forces in the landscapes that enable them to adjust and resist climate warming.

Climate plays a special role in thermokarst development. In Central Yakutia, thermokarst is actively developing in the previously disturbed areas since the 1990s when air temperatures began increasing throughout the region. The landscapes disturbed by fire, forest harvesting and land clearing for agriculture have become an indicator of the impact of recent climate change on permafrost. Ground ice at these sites occurs at shallow depths, on average within 2 to 2.2 m of the surface. The long existence of the landscapes in an artificial state cannot but leave a trace. The active layer becomes heavily desiccated, requiring more heat for thawing compared to wet soils in forest. As a result, seasonal thaw reaches the tops of ice wedges in critical years, causing ice melting and ground subsidence.

Gavriliev et al. (2001) obtained original data on thermokarst activity at the Kerdyugen site located near the village of Tabaga in the vicinity of Yakutsk. They observed rapid development of initial thermokarst forms in an abandoned farm field. In the field, which was little affected by thermokarst in 1987, shallow thaw pits covered about half of the field surface by 1993; currently the entire 100 ha field is disturbed by thermokarst. Recent monitoring studies have shown that, during the periods of notable climatic stresses, the ecological state of anthropogenic landscapes significantly degrades. This causes abandonment of agricultural lands.

We conducted detailed thermokarst investigations at the Yukechi site which is situated on the right bank of the Lena River 50 km east of Yakutsk. The area is characterized by extensive development of thermokarst landforms. Recent climate warming has intensified thermokarst activity in the existing thaw depressions and accelerated the rates of ground subsidence (Fig. 5). In central portions of young water-filled thermokarst depressions 2 to 2.5 m in depth, an average rate of surface subsidence is 5–10 cm/yr.

Interesting data were obtained from the areas that had not been affected by cryogenic processes previously. These are flat treeless interalas areas with no visible indications of thermokarst such as thaw troughs over ice wedges. Such sites are experiencing subsidence in response to climatic stress.

Our investigations since 1992 show that this process has a distinctive trend. At many observation points, the ground surface has subsided 20–30 cm between 1992 and 2006 (Fig. 6). This subsidence can be attributed primarily to climate warming. The treeless landscapes with the desiccated active layer are most sensitive to climatic warming and most threatened by further disturbances.

Analysis of the obtained data indicates that subsidence at these sites develops impulsively, showing some rhythm. For example, significant subsidence occurred in 1995–1996, 2000–2001 and then in 2004 and 2006. These settlements are more directly related to variations in precipitation rather than to changes in ground or air temperatures. The years when settlement was initiated (1995, 2000 and 2004) were characterized by lower precipitation following the previous rainy season, while subsidence in 2006 was related to anomalously high rainfall. Initiation of deep subsidence is also related to moisture content of the active layer, starting in the seasons with high soil moisture contents (1995, 2000 and 2006).

Thus, the last two decades with maximum increases in air

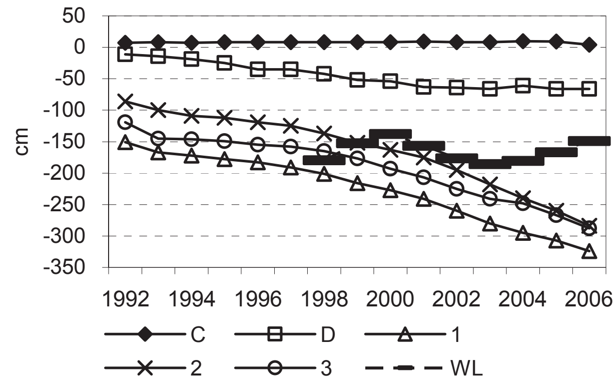

Figure 5. Surface subsidence at plot 2, Yukechi (well-drained inter-alas area). C – reference point, undisturbed inter-alas area, D – initial thaw depression, 1-3 – polygon centres within large thaw depressions, WL – water level.

and ground temperatures are very sensitive to changes in meteorological conditions. Thawing of the top of ice wedges and subsidence of the ground surface occur in 2–3 year intervals. This is apparently related to the general increase in annual air temperature from the average by up to +1.4°C and annual ground temperature from the average by up to +0.6°C which creates instability in the state of permafrost. The activation of subsidence on existing thermokarst depressions and directed subsidence of well-drained, flat interalas meadows are a dramatic indicator of current climatic changes in Central Yakutia.

The present response of disturbed areas underlain by ice-rich permafrost was investigated at the Neleger site in the vicinity of Yakutsk (Fig. 1).

It was found that cryogenic processes are most active during the first 5–6 years after disturbance, after which the processes stabilize and conditions develop for the recovery of permafrost terrain. If the forest cover is re-established over this period, the disturbed area is no longer the locus of ecological risk. At Kys-Alas (the Neleger site), which is underlain by ice-rich sediments, intensive thermokarst development with surface subsidence up to 10–15 cm began after the area was clear cut of trees in 1996. Subsidence continued to 2001, and then, between 2001 and 2004, the surface heaved due to refreezing of the thawed layer and exceeded the initial level. In 2004–2006, relative stability was observed (Fig. 7). The oversaturation of the active layer in the first few years after tree removal, as well as periodic strong cooling of the ground in early winter due to low snowfall in the winters of 2001/2002, 2002/2003 and 2003/2004, caused ground thawing to cease. An ice-rich layer formed at a depth of 110–180 cm which now acts as a protective layer.

The depth of thaw at this site has not exceeded 110 cm in recent years. Freezing of the oversaturated soils caused heaving and the relative surface levels have risen, on average, by 10–15 cm (Fig. 7). This mechanism of permafrost stabilization appears to be the main condition for recovery and optimization of the permafrost landscapes which are in a critical state.

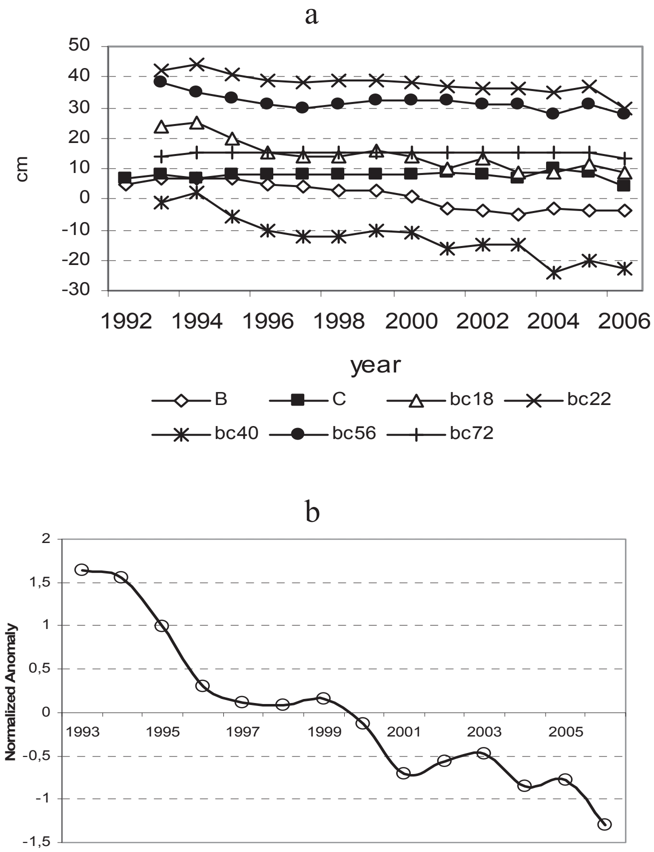

Figure 6. Surface subsidence in a well-drained inter-alas area, plot 2, Yukechi (a – observed values, b – averaged normalized anomalies) B and C – markers on stable flat surfaces; bc18, bc22, bc40, bc56 and bc72 – markers on relatively stable, flat surfaces near the slope of small thaw depressions. Normalized anomalies were calculated for each year as follows: $A = (i-i_{av})/\delta$ where i is the value for a given year; i_{av} is the long-term mean of a continuous series; δ is the root-mean-square deviation of a series.

Conclusion

In conclusion, recent variations in air and ground temperatures are reflected in the change of permafrost landscapes in Central Yakutia. A good correlation between the mean monthly ground temperatures at Spasskaya Pad and Neleger and the Pokrovsk records has allowed construction of a reliable retrospective scheme for ground temperature variations in Central Yakutia. It should be noted that ground temperature data from most other stations are inhomogeneous due to instrument relocations and human impacts. The ground temperature diagram shows that relatively high temperatures from the 1980s to present have been stressful for permafrost landscapes, resulting in fairly active development of cryogenic processes. Disturbed areas are most sensitive, particularly where trees have been removed for land use (croplands and cuts). Such permafrost landscapes are more vulnerable and sensitive to meteorological variations under the current climate warming. On the other hand, our results also indicate that permafrost landscapes are capable of self-stabilization. This mechanism is relatively strong, so thermokarst development is as yet limited.

Abstract

Slope stability of steep rock walls in glacierised and permafrost-affected high-mountain regions is influenced by a number of different factors and processes. For an integral assessment of slope stability, a better understanding of the predisposing factors is particularly important, especially in view of rapid climate-related changes. This study introduces a methodical design that includes suitable methods and techniques for investigations of different predisposing factors in high-mountain rock walls. Current state-of-the-art techniques are reviewed, and their potential application for in situ and remote studies is assessed. A comprehensive array of analyses and modeling tools is presented, including data-acquisition methods and subsequent stability analyses. Based on two case studies of recent slope instabilities in the European Alps, the effective application and coupling of measurements, analyses, and modeling methods are shown.

Keywords: climatic change; high-mountain rock walls; investigation techniques; predisposing factors; slope stability.

Introduction

Hazards related to rockfall, rock avalanches and combined rock/ice avalanches from steep glacierised and permafrost-affected rock walls pose a significant threat to people and infrastructure in high mountain regions. Due to ongoing climatic change, a widespread reduction in stability of formerly glacierised and perennially frozen slopes might occur and result in a shift of hazard zones (Haeberli et al. 1997, Harris et al. 2001, Fischer et al. 2006). A major problem is the possible increase in magnitude and frequency of slope failures.

Slope stability of steep rock walls in glacierised and permafrost-affected high-mountain regions is influenced by a number of different factors such as topography, geological and geomechanical characteristics, hydrology as well as glaciation, permafrost distribution, and thermal condition. Gradual or abrupt changes in one or more of these factors may reduce the slope stability and eventually lead to a rockfall event. Among these factors, permafrost and glaciers are particularly prone to rapid changes in relation to ongoing climate change. Although these two factors are, together with the hydrological regime, assigned a likely important role in current and future slope destabilization, the effects are not clearly understood. A better understanding of the factors and mechanisms determining the slope stability of steep rock walls is thus a key factor and needs basic research.

The complexity of slope stability problems requires a number of different investigation and modeling techniques to consider the relevant physical processes and factors. However, high-mountain rock walls are an extremely challenging environment for currently existing technology and related investigations for a number of reasons. Often, the hazard source areas are situated in remote high-mountain regions and the on-site access to steep rock walls is mostly very difficult or prohibitively dangerous due to existing slope instabilities. Furthermore, the steepness complicates applications of airborne investigation techniques.

This article provides a review of current local-scale investigation techniques and introduces a multidisciplinary methodical design for comprehensive, stability-directed investigations of predisposing factors in steep, high-mountain rock walls which adequately considers the particular difficulties of steep and partly inaccessible ground conditions, based on a combination of on-site and remote methods. The design presented here does not claim to provide a complete approach; rather it bases itself on investigation techniques and analyses that were applied and tested within past and ongoing projects. Also, the rapidly advancing technology may require extension and adaptation of the design in the future.

Factors Influencing Slope Stability

Predisposing and triggering factors can be distinguished with respect to slope stability of rock walls. In the following, a short definition of the two different types of factors is given. Proposed methodical design for slope stability assessment is mainly focused on the investigation of predisposing factors; analyses of triggering factors usually require permanent monitoring methods.

Predisposing factors are physically measurable processes and parameters that permanently affect stress and strain fields in a flank, also in the stable state. They can be broadly categorized in topographical, geomorphological, geological, hydrological, and several other physically-based factors. In high-mountain areas, permafrost and glaciers are two additional important factors (Fig. 1).

Triggering factors can vary in time, space, and magnitude and eventually provoke slope failure. They include, for example, earthquakes, rainfall and snowmelt events that can result in increased water pressure, and rather seldom in high-mountain areas, human interactions.

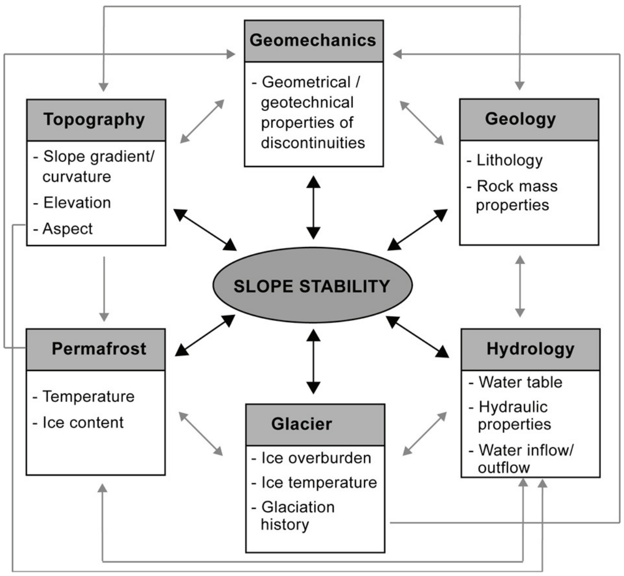

Figure 1. Predisposing factors influence the slope stability and have complex interactions among themselves which are represented by arrows.

Predisposing factors have complex interactions among themselves that influence slope stability (Fig. 1). Topography is a fundamental parameter for slope stability. Slope angle and morphology are important factors for the occurrence and spatial distribution of slope instabilities due to their strong influence on stress and strain fields within a flank. Topography is closely connected to the geological setting and the geomorphological history of a rock wall (erosion, glacial overburden), which, in turn, also effectively influence the geomechanical setting.

The geological setting is determined by the lithology and the geotechnical properties of the rock mass. The geological structures, i.e. discontinuities such as joints, bedding planes, schistosity, and fault zones are fundamental for slope stability, especially their geometrical and geotechnical characteristics. The shear strength as a major parameter for stability is directly related to the geotechnical properties such as cohesion, friction angle, aperture, infilling, and weathering.

Permafrost occurrence in a rock wall can strongly influence the geotechnical parameters of discontinuities, depending on ice content and temperature. The shear strength of ice-bonded discontinuities is strongly affected by the thermal regime in the sub-surface and may be reduced by a rise in temperature or finally the melting of ice-filled rock joints (Davies et al. 2001, Gruber & Haeberli 2007, Harris et al. 2001). This, in turn, also influences the hydrological regime, and may, for instance, result in an increase of the water pressure. The hydraulic setting in a steep rock wall is closely connected to the topography, geological setting, geomechanical characteristics, glaciation, and permafrost occurrence. Changes in water table and water pressure may significantly change the shear strength of the rock mass and therefore exert a strong influence on the slope stability.

Glacier ice may influence slopes differently. Hanging glaciers may have an impact on the thermal, hydraulic, and hydrologic regime in adjacent areas (Haeberli et al. 1997). The erosion by and retreat and down-waste of valley glaciers, in turn, may induce long-term change in the stress field inside the rock wall (Wegmann et al. 1998, Eberhardt et al. 2004).

Among the factors outlined in Figure 1, glaciation and permafrost are presently those subject to the most direct and rapid changes due to climatic change. Changes in these parameters can significantly influence other factors such as hydrology, geomechanical and geotechnical properties in particular. The response of steep high-mountain rock walls to changes in these predisposing factors is, at the same time, strongly conditioned by the topography and the geological setting, in particular by the geometrical and geotechnical characteristics of discontinuities (Ballantyne 2002).

Investigation Techniques and Methodology

Data acquisition

In this section, current state-of-the-art techniques for the investigation of the predisposing factors are illustrated, while in the following section subsequent analyses and processing methods are described (Fig. 2).

In situ field investigations are useful to obtain detailed data. Traditional geological in situ field studies are necessary to achieve data on geological and geomechanical characteristics of the rock mass. The lithological and geomorphological setting as well as geological structures can be mapped, and a preliminary assessment of the intact rock mass properties can be achieved, for example, using the Schmidt hammer method (Aydin & Basu 2005). The geomechanical and geotechnical properties of discontinuities can be assessed by measuring parameters such as orientation, frequency, spacing, aperture, and surface characteristics based on the application of rock mass classification systems (Hack 2002, Hoek & Brown 1997, Wyllie & Mah 2004). In case of inaccessible ground conditions, these types of investigations can also be conducted in the surrounding area with similar lithological and geomechanical settings. Limited observations of the hydrological regime can also be done in situ and from photographs; for instance, observations of water inflow or outflow in a mountain flank.

Point measurements of near-surface rock temperatures using temperature loggers installed a few cm to dm below the surface can constrain permafrost distribution and the prevailing thermal regime (Gruber et al. 2003). Nearby boreholes equipped with temperature loggers give an indication of temperature distribution at depth.

Geophysical techniques are powerful methods for the investigation of subsurface characteristics, but in steep rock walls difficult and complex in their application and therefore rarely exploited until now. Georadar, electrical resistivity tomography, and refraction seismic can be applied for the determination of subsurface structures and the distinction between frozen and thawing rock sections (Hauck et al. 2004, Heincke 2005, Krautblatter & Hauck 2007).

Remote sensing-based techniques are crucial due to the inaccessibility of wide areas of high-mountain walls.

Terrestrial and aerial imagery can be used for identifying

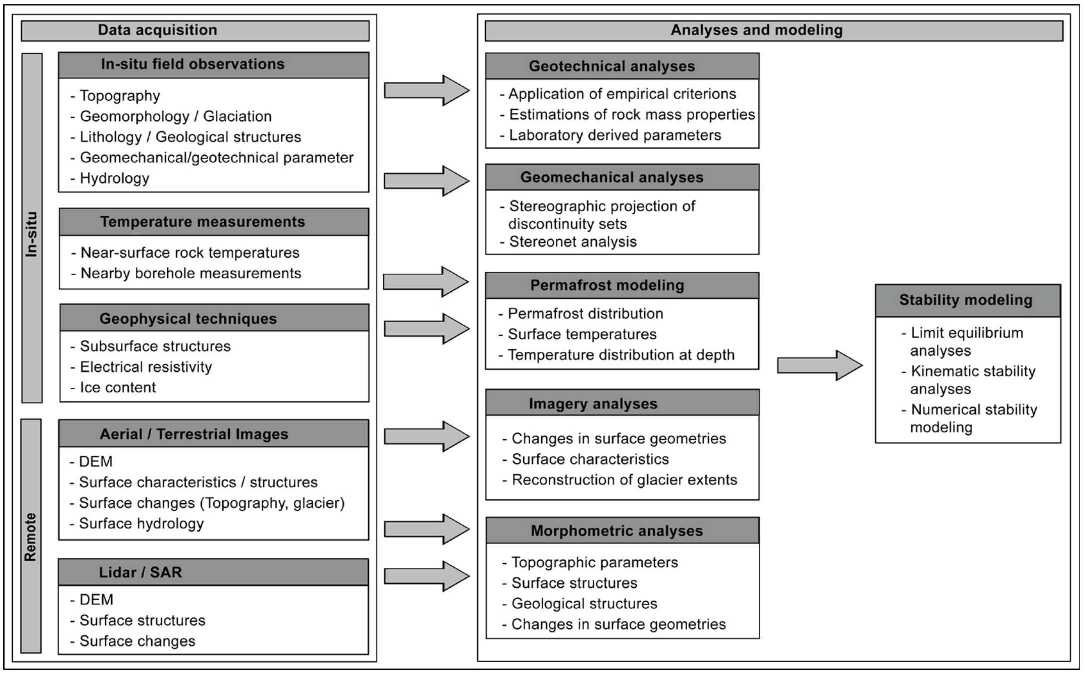

Figure 2. Methodical design for the assessment of slope stability in high-mountain areas containing different insitu and remote sensing-based methods. The upper part shows techniques for the data collection, the lower part processing and analyses of acquired data.

geological structures and surface changes with respect to ice cover and topography. Aerial photography can also be used for the generation of digital elevation models (DEMs), the measurement of terrain displacements and for detailed interpretations (Baltsavias et al. 2001). In some specific studies, terrestrial photography was used for identifying changes with respect to ice cover and slope instabilities on steep ice faces (Fischer et al. 2006, Kääb et al. 2005). These studies have shown the considerable potential of such image analyses which should be further exploited. Automatic cameras are a commonly applied tool for monitoring acute slope instabilities.

Airborne and terrestrial laser scanning (LiDAR) is a rapidly emerging and highly promising tool for acquiring very high-resolution DEMs for high-mountain areas, and thus for detecting small-scale topographic structures (Baltsavias et al. 2001, Janeras et al. 2004). Laser scanning applications from helicopter allow perpendicular recording of LiDAR data and simultaneous acquisition of digital photographs with little geometric distortion (Skaloud et al. 2005). Repeated measurements are the basis for deriving topographic changes. Ground-based synthetic aperture radar (SAR) technology is a capable tool for slope deformation studies (Atzeni et al. 2001, Singhroy & Molch 2004).

Analyses and modeling

Lithological and geomorphological data can be displayed on a map in a GIS for further applications or comparison with other parameters. The geomechanical and geotechnical data measured during fieldwork typically have to be processed to get required parameters for stability modeling by using empirical criteria and rock mass classification systems (Hack 2002, Hoek & Brown 1997) or with adequate laboratory tests. Geomechanical data such as the orientation of discontinuities can be displayed in stereographic projections and may be applied subsequently for kinematic analyses, limit equilibrium analyses, and numerical modeling (Stead et al. 2006).

For the modeling of permafrost distribution a number of models with varying levels of sophistication and at different spatio-temporal scales have been developed (Hoelzle et al. 2001, Gruber et al. 2003). The three-dimensional temperature distribution and its evolution with climatic change is an important component for rock slope stability considerations and has been assessed using numerical modeling by coupling a surface energy balance model with a subsurface heat conduction scheme (Noetzli et al. 2007). A modeling scheme that would directly include modeled permafrost distribution within slope stability models has yet to be developed, but it can be considered for the model assumptions.

Geophysical investigations can mainly be used as boundary conditions and reference values either for permafrost modeling or for analyses of the subsurface structures.

The most common application of remotely sensed image data consists of the interpretation and classification of the image content. Terrestrial and aerial imagery can be used for the identification and mapping of different surface features in steep rock walls and also their temporal changes. Digital aerial as well as terrestrial photos have considerable potential for quantitative analyses of geomorphic structures and changes in a rock wall by georeferencing or matching images based on a high-resolution DEM or photogrammetric techniques (Roncella et al. 2005).

DEMs represent the core of any morphometric investigation of predisposing factors. They can be obtained from stereo aerial and high-resolution terrestrial photos but also from LiDAR data (Kääb et al. 2005). From these DEMs, topographic parameters, large-scale morphotectonic features,

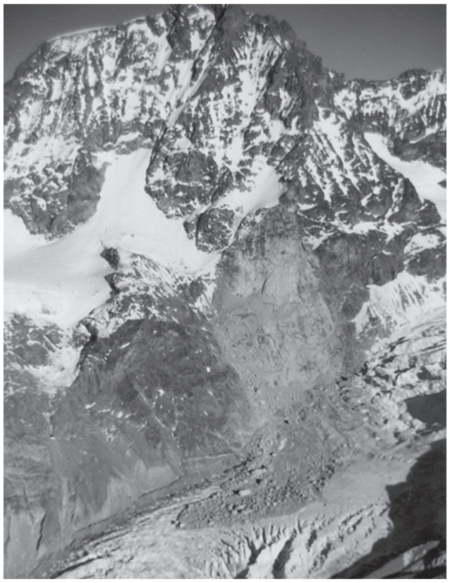

Figure 3. The western flank of the Piz Morteratsch with the Tschierva glacier in the foreground. Visible in the middle of the photo is the detachment zone of the 1988 rockfall and the deposits on the glacier (photo by A. Amstutz, 1988).

and geological structures can be extracted. A promising, yet not fully exploited method is the coupling of laser scanning data with photogrammetric analyses and terrestrial imagery analyses to extract important topographic and structural-geological parameters from DEMs. Main discontinuity sets can be distinguished and their geometrical pattern determined. Therefore, a preliminary assessment of potentially unstable areas may be performed based on geomechanical parameters with limit equilibrium and kinematic analyses using the data from in situ measurements or even only based on DEM analyses (Derron et al. 2005, Stead et al. 2001). Further structural and stability analysis with a DEM is made possible by the recent development of geologically oriented GIS tools (Günther 2003, Jaboyedoff et al. 2004).

For more complex slope stability assessments numerical methods are required. Numerical techniques used for rock slope analyses are generally divided into continuum and discontinuum approaches, or when combined, hybrid approaches (Barla & Barla 2001, Eberhardt et al. 2004, Stead et al. 2001, Stead et al. 2006). Numerical modeling is in fact a powerful tool for the assessment of failure mechanisms, but the level of topographic and geotechnical detail needed can limit the application.

Case Studies

Tschierva rock avalanche event

The Tschierva rock avalanche occurred on October 19, 1988, from the western flank of Piz Morteratsch (3751 m a.s.l., in the Engadin, Switzerland) on Tschierva glacier with an estimated volume of approximately $0.3x10^6$ m^3 (Fig. 3).

For the re-analyses of the Tschierva rock avalanche, detailed numerical slope stability modeling was proposed. Therefore, in situ fieldwork and subsequent geotechnical and morphometric analyses have been done to obtain required

Figure 4. The Monte Rosa east face with the Belvedere glacier in the foreground (photo by L. Fischer, 2004). The detachment zone of the ice avalanche (2005) is marked with a black circle, the one of the rock avalanche (2007) in white.

accurate data (Fischer et al. 2007). The steps described here generally follow the scheme from Figure 2.

The in situ field observations included:

- Preliminary analyses of rock mass properties (lithology, discontinuities, fault zones, water occurrence).
- Characterization of discontinuities (discontinuity sets, orientation, density, condition, aperture, filling).
- Surveying of detachment zone and adjacent area with manual rangefinder.

Subsequent complementary analyses included:

- Geotechnical and geomechanical analyses by using field data, stereographic plots, and empirical criterions.
- Photogrammetric analyses of aerial images for the evaluation of topographic changes.
- Analyses of aerial and terrestrial photos for detecting geological structures and water occurrence.
- Modeling of permafrost distribution.
- Reconstruction of glacier extents based on satellite images and historical topographic maps.

Numerical slope stability modeling was then performed with the 2-D distinct-element method model UDEC (by Itasca) to examine the possible failure mechanisms. Modeling of the unloading of the Pleistocene glacial overburden showed that subsequent redistribution of stress and strain fields in the flank had a strongly controlling influence on the geometry of the detachment zone. A sensitivity analysis of geotechnical parameters showed that the cohesion of the discontinuities was a fundamental parameter. The stability modeling for dry conditions also revealed that the failure mechanism was a combination of shear failure along preexisting discontinuities and development of brittle fractures propagation through the intact rock mass.

Coupled hydro-mechanical modeling demonstrated that slope stability was very sensitive to changes in water pressure. The existing fault zone crossing the rock slope induced an elevated water inflow due to the higher permeability and might therefore be, together with the long-lasting effects of ice unloading, a main factor for the slope instability.

Instabilities in the Monte Rosa east face

The Monte Rosa east face, Italian Alps, is one of the highest flanks in the Alps (2200–4600 m a.s.l.). Steep hanging glaciers and permafrost cover large parts of the wall (Fig. 4). Since the end of the Little Ice Age (~1850), hanging glaciers and firn fields have retreated continuously. During recent decades, the glaciers of the Monte Rosa east face experienced an accelerated and drastic loss. Some glaciers have completely disappeared. New slope instabilities and detachment zones developed and resulted in enhanced rockfall and debris flow activity (Kääb et al. 2004, Fischer et al. 2006). In August 2005, an ice avalanche with a volume of more than $1x10^6$ m^3 occurred, and in April 2007, a rock avalanche of about $0.3x10^6$ m^3 detached from the upper part of the flank.

The main focus of the investigations of the Monte Rosa east face was the assessment of the influence of glacier retreat and permafrost degradation on the current and possible future rockfall and ice avalanche activity (Fischer et al. 2006).

During field studies, the following data were compiled:

- Detailed geological and geomorphological mapping.
- Current glacier extents.
- Detailed map of the current detachment zones of mass movement activities.

Due to difficult and dangerous in situ access, this information was collected from distant ground-based and air-borne observations.

Further analyses included:

- Modeling of the permafrost distribution.
- Reconstruction of glacier extents since the early 20th century based on orthophotos and terrestrial photos.

The results were compiled in a GIS, and the overlay of each investigated factor revealed spatial as well as temporal linkages between investigated processes and their influence on the formation of new detachment zones.

The most important findings were that most detachment zones in the Monte Rosa east face are located in areas where surface ice has recently disappeared. In addition, many detachment zones are located at the altitude of the lower boundary of the estimated permafrost distribution, where presumably warm and degrading permafrost exists. A striking result is also that many detachment zones are situated in transition zones between orthogneiss and paragneiss. These findings demonstrate that the formation of detachment zones mostly seems to be caused by a combination of different factors.

Conclusion and Perspectives

The investigation of slope stability in steep, high-alpine rock walls is a major challenge, chiefly due to the difficulties in data acquisition and the complexity of the factors and processes influencing slope stability. In each case, the proceeding has to be adapted, and different methodologies have to be applied concerning the possibilities of data acquisition and the required stability modeling method.

The case study of the Tschierva rockfall shows that the appropriate method combination, including classic geological field investigation techniques, terrestrial and aerial image analyses, and permafrost modeling, allows the performance of detailed numerical slope stability modeling and the evaluation of possible failure mechanisms.

The much larger Monte Rosa east face, with surface and subsurface ice subject to extremely fast changes, represents the most challenging high-mountain conditions and required a more remote-based approach. However, local field surveys could be integrated for a comprehensive spatial and temporal analysis of predisposing factors and their interaction.

In the future, measurement, analytical, and modeling tools will be further advanced. For instance, ground-based SAR and helicopter-based LiDAR have only very recently been applied on large high-mountain walls and should be further developed. Advances are also expected with regard to a more comprehensive integration of high-technology data into slope stability assessment methods.

Permafrost in Marine Deposits at Ilulissat Airport in Greenland, Revisited

Niels Foged

Thomas Ingeman-Nielsen
Arctic Technology Centre, Department of Civil Engineering, Technical University of Denmark, DK-2800 Kgs. Lyngby, Denmark

Abstract

Ilulissat Airport was constructed in 1982 to 1984 after detailed geotechnical investigations as the construction site included up to 12 m thick basins of marine clay deposits. Despite soil temperatures of approximately -3°C the soil appeared unfrozen from 4 m to 5 m below ground surface due to a high residual salt content in the porewater. However, in the less saline top zone massive ice layers were found constituting up to 30% by volume. These formations, representing a typical example of saline permafrost, caused the planned position of the runway to be shifted towards the northwest and the layers to be removed and replaced with compacted blasted rock fill. However, a test fill of 2.5 m of rock fill and coarse gravel was constructed in the abandoned area in order to establish experiences for future constructions. Background, previous findings, and present activities are also topics in an accompanying paper, Ingeman-Nielsen et al. (2007).

Keywords: airport; construction; embankment; freezing point depression; saline permafrost; test fill.

Introduction

In Greenland it has been very difficult and costly to establish the traffic infrastructures necessary for the development of a modern society under the present physiographic and climatic conditions. The establishment of the airport in Ilulissat (Jakobshavn) was a milestone in a traffic project based on the aircraft type DASH-7, which could land on a short 700 m "Short Take Off and Landing" – STOL runway with an in-flight angle of 7.5° instead of the normal 3°. At present 7 airports of this type are operational and more will be established. Ilulissat Airport was the first to be constructed using rock fill on rock outcrops and marine clay under permafrost. Consequently, the geotechnical investigations started in 1978 were very detailed and led to new findings on saline clay permafrost published by Foged and Bæk-Madsen (1980).

Investigations in 1978–1982

Ilulissat Airport was constructed in 1980–1984 two km north of the town on a plain area with shallow rock outcrops surrounded by marine clay deposits. It is situated in discontinuous permafrost and project investigations from 1978 to 1985 focussed on the thermal state of these deposits and the geotechnical properties of frozen and unfrozen clay being the possible foundation for the runway embankment, taxiway, and terminal area. The soil investigations were carried out for Asiaq–Greenland Survey (Previously Grønlands Tekniske Organisation) by the Danish Geotechnical Institute with the senior author being responsible for special field and laboratory work.

Engineering geology

Ilulissat is located in the central bay of West Greenland, which was glaciated repeatedly during Quaternary but most soil formations relate to the last Weichselian-glaciation (Wisconsin) and to the late-glacial and Holocene deglaciation. Onshore, the most important deposits are local side moraines and glaciomarine clay and silt sediments overlain by Holocene solifluction deposits and topsoil in the form of only slightly decomposed peat. According to Bennike and Björck (2002) the innermost part of the bay near to Jakobshavn was not deglaciated before earliest 9600 years before present (BP). The glaciomarine sediments were deposited at a relative high sea level of >50 m above present. The saline pore water is maintained to a high degree as desalination due to freshwater percolation was not effective during the Holocene climatic optimum between 8000 and 5000 years BP (Weidick 1968, Foged 1979, and Foged & Bæk-Madsen 1980). After 5000 years BP it is assumed that the climate caused permafrost to develop as seen today.

Geotechnical investigations

The distribution of sediments, permafrost, and bedrock of gneiss was delineated using engineering geological field survey and aerial photos, Figure 1. This work was supplemented with geophysical investigation by means geoelectrical measurements using Wenner configurations for subsurface mapping of the marine clay basins and Schlumberger electrical soundings to delineate geological and permafrost boundaries. In connection with this more than 70 boreholes were carried out using a self-transportable rotary core drilling rig, indispensable in the very wet muskeg peat and solifluction soil top-layer. A number of boreholes were equipped with soil temperature PT-100 sensors sat down in PEL-tubes with an antifreeze liquid. The sensors were generally measured manually during the investigation and construction periods.

Borehole No.	Depth (m)	w (%)	Ca^{+} (g/l)	Mg^{++} (g/l)	K^{+} (g/l)	Na^{+} (g/l)	Cl^{-} (g/l)
79005	3.1	30.3	0.66	0.44	0.22	5.45	11.72
79011	5.0	34.1	0.65	0.36	0.30	4.84	10.26
79012	3.6	46.4	0.35	0.18	0.23	2.59	6.03
79012	8.0	63.4	0.35	0.25	0.24	3.94	8.52
Seawater			0.40	1.35	0.38	10.50	19.00

Collected soil specimens were stored in their frozen state and transported to the laboratories in Denmark for geotechnical classification properties as water content w (%), bulk density ρ_b (g/cm^3) using the Archimedes principle of volume determination with buoyancy in chilled trichlorethene, void ratio and saturation degrees of water and ice, S_r and $S_{r,ice}$ (%), using the specific soil particles density of ρ_s = 2.75 g/cm^3 and ρ_{ice} = 0.917 g/cm^3. The salinity variations in the pore water were established as the chloride content Cl^- (grams per liter = g/l or ‰) using $AgNO_3$–titration on diluted samples. Some additional tests on the cation-distribution by means of specific electrodes are shown in Table 1. Consequently, it was considered that Cl^- might be a useful indicator of the total ion content in the pore water as also shown by Foged (1979).

On intact core samples from the borings the freezing point depression ΔT_f was found by means of controlled, very slow thawing from the storage temperature. The results are shown together with the measured chloride content and the estimated minimum freezing-point depression as function of Cl^- in Figure 2.

Generally, the thawing showed a general transition over a wide temperature range, which also was seen in a series of consolidation tests carried out with well-controlled temperature steps of 1°C from -9°C to 0°C and continuous deformation registrations and further ordinary loadings shown in Figure 3. The example relates to borehole 78020 Lab.No. 156 from the depth of 3.2 m on frozen clay with a water content of 31.5% and Cl^-=13.0 g/l. From a geotechnical viewpoint it was very interesting that the test specimen after the controlled drained thawing, which caused 7.8% of deformation, showed an apparent preconsolidation of 210 kPa much higher than the in situ stress level of σ_o<55 kPa, due to desiccation of the clay structure by ice lenses. The sample appeared in thawed condition as a fissured silty clay. Another finding was that the drainage process takes place under partially frozen conditions, as seen from the step function of deformation in Figure 3.

Permafrost

The investigations showed the presence of saline marine clays in most depressions in bedrock, with sediment thicknesses up to 12 m. From a theoretical viewpoint this is a permafrost formation as temperatures below a thin active layer (0.2 m to 0.8 m at the time of drilling) were between

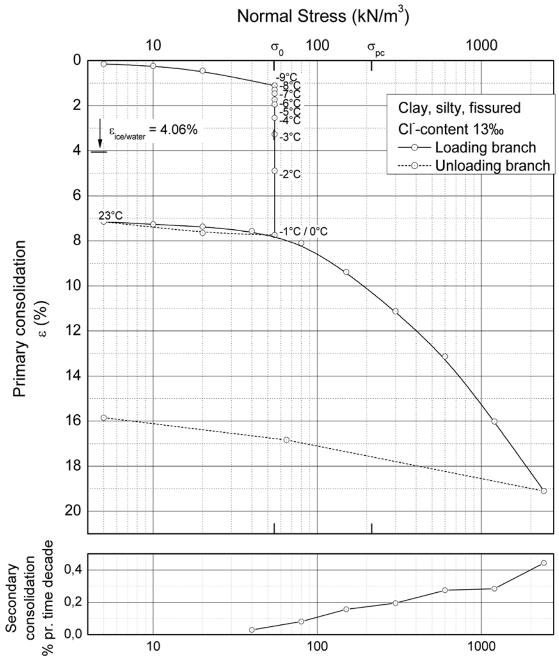

Figure 3. Sample deformation under controlled thawing followed by ordinary consolidation in a number of loading steps.

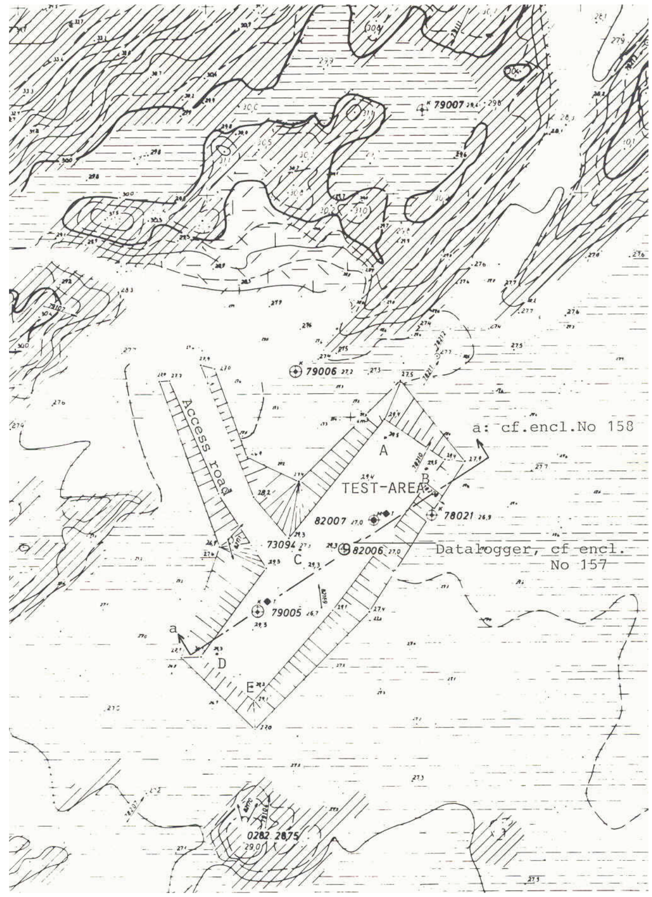

Figure 4. Test site at the south eastern corner of the present runway.

-1°C and -3.5°C. Technically however, it was obvious that the clay material was only partially frozen and often unfrozen below a depth of 4 m to 5 m b.g.s. The cause was also found by geoelectrical measurements showing extreme low electrical resistivity (<4 ohmm) and as previously shown by chemical analyses, which showed that the pore water changed gradually with depth from fresh water at the surface towards seawater at depths >5 m. The varying concentrations of pore water salinity give rise to various freezing-point depressions down through the deposits. Consequently, the thermal stability is very vulnerable to changes in the heat flux as the latent heat of soil layers may be limited. The clay formations showed variable freezing point depressions from -1°C to -3.5°C. Generally we found under 0.5 m active layer a 2 m to 4 m thick layer of frozen ice-rich clay was found underlain by unfrozen clay at soil temperatures of -3°C down to bedrock.

Furthermore, the geotechnical strength and deformation properties in such deposits must also vary with the thermal state from frozen deposits to unfrozen soil resulting in low shear and deformation properties. This would be of critical importance, when a runway is to be constructed on an embankment of up to 5 m of rock fill on top of such deposits.

Evaluations done related to the construction

Fine-grained deposits will always cause freezing point depression because of capillary tension in the pores, (Williams 1967, Pusch 1979, Tsytovich 1975) and parts of the water may remain unfrozen down to a temperature of -10°C. However, the combination with varying salinity in the pore water we found in literature only some results with the same tendency described by Young et al. (1979). It was characteristic for the area and other locations in Ilulissat (Olesen 2003), that a considerable part of the pore water is frozen at a depth of 4 m to 5 m below ground surface. The soil exhibits properties of unfrozen material in spite of temperatures of -2°C to -4°C. Consequently, only a limited heat capacity is available when temperature conditions change in the area due to constructions (and as seen today climatic changes). At that time we could not find practical experiences from the Arctic that could be directly applied.

The initial program showed major problems with two basins situated in the southeastern part of the area. The partly frozen and unfrozen sediments up to 12 m in thickness gave rise to latent risk of settlements caused by thawing and ordinary consolidation due to applied load from the construction. These conditions motivated the final choice of location for the runway as shown on Figure 1. Even with this choice, critical soil conditions were met to a minor extent along the runway and it was decided to excavate these small basins and to substitute the clay with compacted rock fill.

Test fill

With a view to future road construction, terminal area, and extensions of the runway, investigations were initiated in a test fill being placed in the critical area in combination with continuous recording of temperature in representative borings under and outside the test fill. The results have been

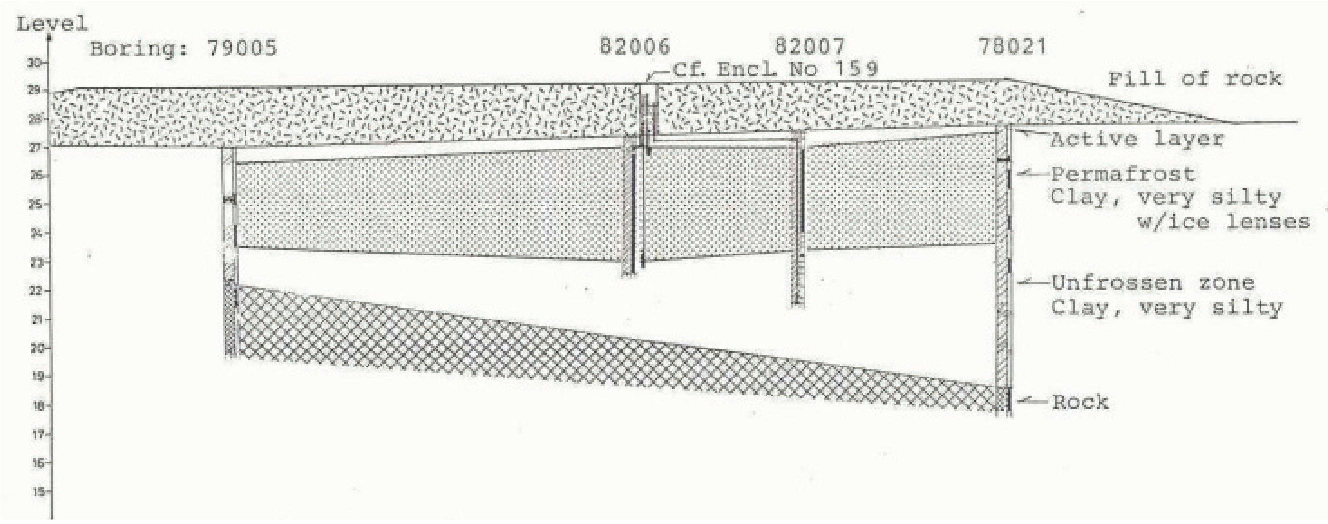

Figure 5. Cross section in the test fill along A-B.

the background for a M.S. project at the DTU Institute for Geology and Geotechnical Engineering in cooperation with the Danish Geotechnical Institute with the senior author as supervisor. The topic for the master thesis by Civil Engineer M.S. Søren Frederiksen (1993) was: "Foundation in Permafrozen Areas" reflecting construction methods of a fill area of compacted blasted rock fill. The technical details and the results through the initial observational period (approximately 5 years) and later on have never been published.

Ilulissat Airport and Test Fill

The test site was placed before construction of the runway as shown on Figure 4 and with a cross section as shown in Figure 5 in a typical basin of marine clay in the southeastern part of the airport area. The test fill was constructed along with some instrumented boreholes with deformation gauges and temperature sensors. The test fill was observed for 5 years during and after construction of the airport and in 2007 found intact and partly operational. The original technical findings are reported by the Danish Geotechnical Institute Geotechnical report No. 9 Jakobshavn Ilulissat. Temperaturmålinger. Prøvefelt. dated 1985-04-23 to Grønlands Tekniske Organisation (Asiaq-Greenland Survey).

The soil and permafrost conditions relate to boreholes 78021, 79005, 82006, and 82007 of which 78021 was selected for presentation in Figure 6. The soil formations consist of marine clay and silt deposits, being part of the marine Quaternary clay formation found up to approximately 50 m a.s.l. in Ilulissat. The profile shows diluted seawater content in the top zone and occurs presently partly permafrozen and unfrozen as previously discussed. The test site was established close to the present safety zone with a typical ca. 2.5 m thick layer of blasted rock fill overlain by some graded coarse gravel similar to the safety zone. For control of the changes in temperature in the test fill and the underlying marine clay a series of continuous temperature measurements were carried out in the boreholes 79005, 82006, and 82007. The deformation gauges were placed at the bottom and top of the real permafrost layer and at the original terrain surface under the test fill. Secured by a measuring well as seen in the cross section the settlement gauges were placed inside a lubricated tube to secure free motion. Furthermore 5 fixed measuring points were established on the top of the test fill in the graded gravel.

The boreholes outside the construction area show a slight tendency of temperature rise (1°C to 2°C) during the period until 1984. Below the test fill a yearly mean temperature of -4°C was found in 2 m depth rising to -3°C at 4 and 5.5 m of depth before filling up (1980 to 1982). After construction (1982 to 1984) values of -5.5°C to -3.5°C were found. The technical conclusion was that the 2.5 m rock fill and graded coarse gravel isolate against conductive heat during summer and allows enhanced convective heat transfer during winter resulting in approximately 1°C to 1.5°C lower yearly mean temperature. The settlement measurements show at all gauges and defined points less than 1 mm to 3 mm mainly reversible deformation, which are at the limit of the measuring resolution. Consequently, it must be stated that during the short control period the effect of filling up with 2.5 m of very coarse grained fill of blasted rock with a top layer of graded gravel must be considered positive.

In 1993 Søren Frederiksen visited the Ilulissat Airport area and downloaded from the data logger a full set of data from 1984 to 1987. He also collected a new series of measurements.

Below the test fill the original surface showed total settlements of 3 cm and the boundaries to top and bottom of originally permafrozen clay were unchanged. However, the top of the test fill showed continued settlements of up to 7 cm over the total period. The time series of the temperature sensors in boreholes B82006 and B82007 show that the upper limit of permafrost rises and a larger part of the original soil maintains permafrozen as expected.

Ilulissat Airport and test fill, revisited in 2007

In the NSF ARC-0612533 project "Recent and future permafrost variability, retreat and degradation in Greenland and Alaska: An integrated approach" this area was chosen as a type locality for permafrost studies in saline clay related to infrastructures. In June and August 2007 we revisited the area after 25 years of operation and found the constructions in very fine condition with only minor failures and deformations at the boundary of the test fill as seen on Figure 7. The slope of the test fill has moved horizontally due to a failure in the active layer which also turns the airport fence approximately 30°C. Søren Frederiksen showed some vertical deformation due to frost heaving of the pile.

In 1993 Søren Frederiksen observed somewhat less heave of the fence piles, however he did not observe any sliding. Consequently, it must be concluded that the present climate since 1993, which had the lowest registered temperatures since the construction of the airport, might have caused changes in the shear strength or changed the thickness of the active layer allowing for a failure to take place. We performed a levelling of the test fill surface in June 2007. The results for 4 sections A-D with a distance of 10 m perpendicular to the fence with station 0 at the safety zone boundary are shown in Figure 8. The failure zone in the test fill is found between St. 17 and 19 and in front of the test fill the sloping side and the soil layers in front of it show obvious horizontal displacement approximately 0.5 m away from the constructed test fill boundary. The fence is deformed similarly. In comparison to the levelling performed in the period of 1982 to 1987 and in 1993 the central part of the test fill shows only very little deformation as the level is found to a value of approximately +29 comparable to the earlier levelling results of +29.15 to +29.30 in July 1993.

Conclusions

The present contribution and an accompanying contribution, Ingeman-Nielsen et al. (2007), to NICOP 2008 present the new findings together with an overview of the project investigations done during the period of 1978 to 1984.

The geotechnical deformation and strength properties were studied in detail and influenced the final design and construction very distinctly. It was decided to keep the runway away from the deep basins of marine clay for stability and settlements reasons. Under the runway and taxiway and in the terminal area frost susceptible soils were substituted by rock fill.

These decisions led to a generally very stable runway, taxiway, and terminal area. According to interviews with the technical personnel at the airport only one repair has been performed of the asphalt concrete layer in an area where settlements occurred due to some natural silt and clay being left under the bearing layer during construction of compacted rock fill and coarse gravel fill.

The behavior of the test fill slope shows the present climatic change might explain a boundary failure and horizontal deformation in front of the test fill causing the Airport fence to tilt and heave.

Consequently, the detailed studies carried out in 1978 to 1985 have led to safe construction with very little need for repair and maintenance. We will continue the permafrost studies in the coming period as part of the present NSF ARC-0612533 project "Recent and future permafrost variability, retreat and degradation in Greenland and Alaska: An integrated approach." The locality is a well documented example on saline permafrost under discontinuous permafrost condition.

Acknowledgments

The original investigations were performed by the Danish Geotechnical Institute for Grønland Tekniske Organisation (now ASIAQ) on behalf of Grønlands Luftshavns Væsen GLV (now Mittarfeqarfiit). During design and construction of Jakobshavn Airport the senior author had a very close cooperation with Civil Engineer Poul Væver-Petersen from the Danish/Greenlandish consultant Nielsen & Rauschen-berger (now NIRAS). Permission to publish and valuable discussions with lead members and employers of the mentioned institutions are gratefully acknowledged. Furthermore, the work done in the M.S. Thesis by Civil Engineer Søren Frederiksen, INUPLAN, Nuuk, Greenland has been of great value.

The later part of this research was funded by the Polar Earth Science Program, Office of Polar Programs, National Science Foundation (ARC-0612533).

Abstract

Cryostratigraphic studies in the CRREL permafrost tunnel in Alaska revealed the presence of multi-directional ice veins in the permafrost which was described as reticulate-chaotic cryostructure. Our hypothesis relates the formation of this cryostructure to inward freezing of saturated sediments trapped in underground channels cut in the permafrost by thermo-erosion. The multi-directional reticulate ice veins were formed in the sediments deposited in the underground channels after the cessation of the underground water flow. This hypothesis was confirmed by laboratory experiments which reproduced reticulate-chaotic cryostructures and thaw unconformities in the sediments similar to those observed in the CRREL permafrost tunnel.

Keywords: CRREL tunnel; freezing cell; ground ice; ice segregation; reticulate cryostructure; underground thermo-erosion.

Introduction

The CRREL permafrost tunnel (≈ 64°57′N, 147°37′W) is located near Fairbanks, Alaska. In the 1960s, a 110-m long tunnel and an inclined winze were excavated in the ice-rich silt and the underlying fluvial gravel that locally form the permafrost. The geology, the cryostratigraphy, the chronology of the tunnel, and the properties of the permafrost were described in many publications (Sellmann 1967, 1972, Pettibone & Waddell 1973, Huang et al. 1986, Hamilton et al. 1988, Long and Pewe 1996, Shur et al. 2004, Bray et al. 2006). The stratigraphy of the permafrost exposed in the tunnel and in the winze consists of an ice-saturated gravel deposit unconformably covering weathered schist bedrock. Fluvial sandy silts overlay the gravelly unit and are covered by partially reworked eolian silts. The latter are syngenetic in nature, ice-rich, and characterized by a micro-lenticular cryostructure and, to a lesser extent, by layered and lenticular-layered cryostructures (Shur et al. 2004; Bray et al. 2006, Kanevskiy et al. 2008).

This paper focuses on the genesis of reticulate-chaotic cryostructures firstly described in the CRREL permafrost tunnel by Shur et al. (2004). The reticulate-chaotic cryostructures are associated with stratified sediments or massive ice bodies enclosed in the frozen ground or cross-cutting ice wedges. A reticulate cryostructure develops when ice crystals oriented in the direction of freezing and growing into the still unfrozen sediments are intersected by crystals of other orientation (Shumskii 1964a). Mackay (1974) proposed that the preferred growth of reticulate ice veins was linked to the restriction of an upward flow of water which prevented the maintenance of a stationary freezing plane and the growth of horizontal ice lenses. Murton and French (1994) mentioned that it is unclear why some reticulate cryostructures are regular and others are irregular. Our hypothesis is that reticulate-chaotic cryostructures observed in the CRREL permafrost tunnel were formed in a closed-system by inward freezing of saturated sediments deposited in underground thermo-erosion channels or gullies. The objective of this study was to reproduce in the laboratory inward freezing of saturated sediments in underground channels analogs in order to support our interpretations of reticulate-chaotic cryostructures genesis.

Methods

Field methods

Cryostratigraphic studies, performed in the CRREL permafrost tunnel in 2004–2006 (Shur et al. 2004, Bray et al. 2006), revealed the occurrence of a cryostructure named reticulate-chaotic. We logged and sketched the permafrost stratigraphy of exposures with reticulate-chaotic cryostructures enclosed in syngenetic permafrost. Samples were retrieved, described, and analyzed for their ice content. The grain size distribution of the sediments was obtained using sieves and an hydrometer (ASTM D422 2008). We studied the morphology and the density of reticulate ice veins and ice lenses within the sediments. Special attention was paid to the contact between the sediments with reticulate-chaotic cryostructure and the enclosing original syngenetic permafrost.

Laboratory methods

To reproduce reticulate-chaotic cryostructures, we conducted 20 laboratory experiments. We used a temperature-controlled environmental chamber to freeze sediments in PVC cells at temperature between -20°C and -25°C for at least six hours. Saturated sand or silt at room temperature were poured

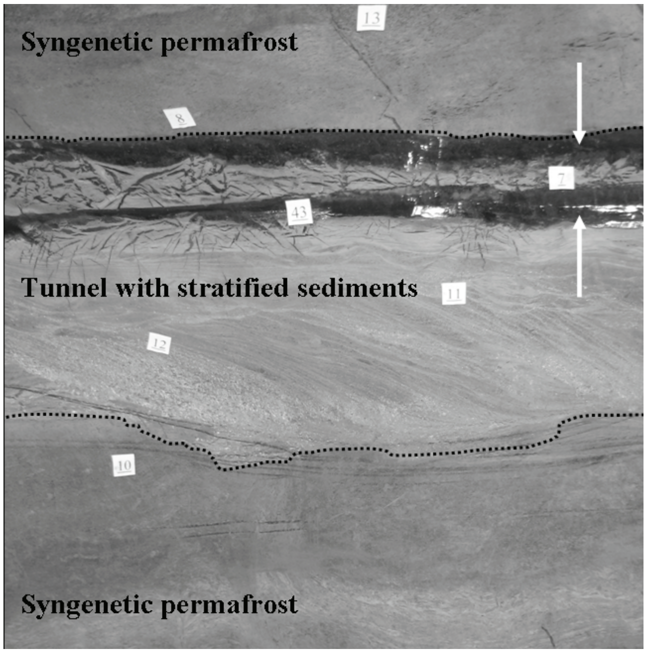

Figure 1. Underground channel filled with stratified sediments enclosed in syngenetic eolian silt. The erosion unconformities are outlined by dotted lines. The upper part of the underground channel contains layers of clear ice (arrows) underlain by stratified sediments dissected by reticulate-chaotic ice veins. The white paper scales are 2.5 x 2.5 cm.

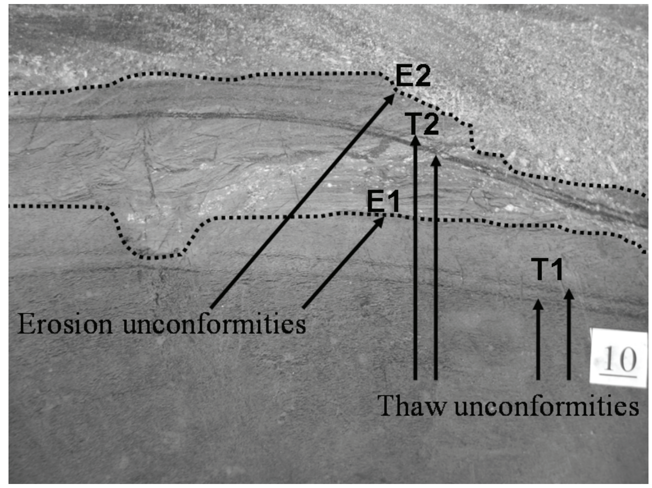

Figure 2. Close-up of erosion and thaw unconformities shown in Figure 1. The lowermost erosion unconformity (E1) is older and located at the bottom of the ice-poor stratified silts. Ice lenses located at the boundary with the underlying ice-rich syngenetic eolian silts mark the location of the thaw unconformity (T1) associated with E1. The uppermost erosion unconformity (E2) is younger and located at the bottom of the ice-poor stratified sand and gravel. The younger thaw unconformity T2 associated with this erosion boundary is marked by ice lenses located in the previously deposited sediments. The paper scale is 2.5 x 2.5 cm.

in the cells and allowed to freeze. After two days, a core was extracted from the central part of the frozen sediments to produce a cavity. A portable carbide and diamond crown drill was used for this procedure. The coring stopped at 5 cm to 10 cm above the bottom of the cells. The environmental chamber was then set to -5°C and kept at this temperature for one day to allow frozen soils to warm-up to this temperature. The cavity was used as an analog for underground thermo-erosion channels enclosed in permafrost. Cavities were filled with well-mixed supersaturated sediments previously kept at temperature between 1°C to 4°C. We used clay, silt, and sand sediments to test the effect of soil texture on the configuration of the cryostructures. We used soils with 80% and 150% gravimetric water content to test the effect of water content on the density of reticulate ice veins. Slices of frozen soil approximately 5 cm thick cut from the extracted cores and conditioned to -5°C were used as lids to close the underground channel analogs. The samples were allowed to freeze back in situ at a temperature of -5°C for 7 days to 14 days depending on the size of the freezing cells.

We used three different sizes of circular freezing cells to test the effect of underground channel size on the development of ground ice cryostructures. The first type of cell was 30 cm in diameter, 37 cm tall and covered by a 10 cm thick layer of mineral wool. The bottom and the top of the cell were covered by a 5 cm thick extruded polystyrene layer. The second type of cell was 17 cm in diameter, 75 cm tall and insulated by 5 cm thick extruded polystyrene rings. The third type of cell was 10 cm in diameter, 30 cm tall and covered by a 3 cm thick insulation layer. This cell was equipped with a consolidation device and cooled by thermal baths from the top and the bottom of the cell.

After the experiment, the frozen samples were extracted from the cells and cut into slices about 5 cm thick. The cryostructures were described. We analyzed the ice content of cores 2.5 cm in diameter extracted from the center and the side of the underground channel analogs slices. The geometric configuration of the ground ice formed and the contact with the enclosing sediments were described and compared to field observations in the CRREL permafrost tunnel.

Results

Field observations

Twenty ice wedge exposures can be observed in the adit of the CRREL permafrost tunnel. With the exception of one, all the observed ice wedges are showing signs of thermo-erosion. Remains of ice wedge with shapes atypical of syngenetic ice-wedge growth were observed at the erosion boundaries. Some ice wedges were cut by underground channels and gullies filled with sediments cutting across or enclosed in ice wedges. These underground channels are also enclosed in the syngenetic eolian silt surrounding the ice wedges (Fig. 1).

The syngenetic undisturbed permafrost comprises organic-rich fine eolian silts with abundant rootlets, oxydo-reduction stains, and millimeter-to-centimeter thick peat layers (Fig. 1). The permafrost is characterized by an ice-rich micro-lenticular cryostructure with gravimetric water contents usually above 100%.

Figure 3. Typical reticulate-chaotic cryostructure with multi-directional interconnected ice veins and ice lenses. The handle of the knife is about 6 cm long.

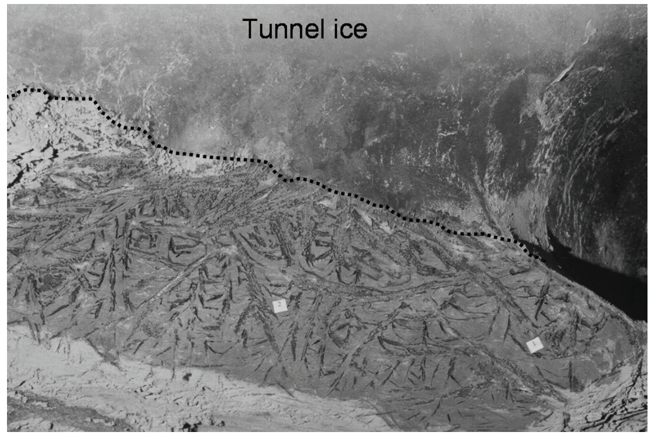

Figure 4. "Tunnel ice" underlain by sediments with high-density reticulate-chaotic cryostructure. The white paper scales are 2.5 x 2.5 cm.

The underground channels could often be traced over several meters. They had a slight inclination and flat to bowl-shape channel bottom. The channels were outlined by erosion unconformities at their contact with the syngenetic undisturbed permafrost (Fig. 2). In the underground channels, the sediments were mostly stratified and clearly different than the surrounding syngenetic eolian silt (Figs. 1, 2). For instance, in Figure 1, the underground channel is filled with ice and silty sands and gravels having oblique, cross, wavy, and horizontal stratifications (see also Fig. 2). The average gravimetric ice content of the cross-stratified sands in the underground channel is 44.6% (n = 8), whereas it is 107.7% (n =17) in the surrounding syngenetic permafrost.

In some cases the underground channels were only partially incised in the wedges and extended in the adjacent underground channels previously cut in the syngenetic permafrost. Among the observed channels, the grain-size fraction and the stratification patterns varied which suggests the occurrence of different sources of sediments and depositional modes, probably related to distinct thermo-erosion events along similar flow paths.

Along the boundaries of the underground channels, thaw unconformities were observed (Fig. 2). They were marked by a continuous ice lens a few millimeter-thick sub-parallel to the channel boundaries. The thaw unconformities were usually located a few millimeters to a few centimeters in the syngenetic permafrost surrounding the underground channels. The permafrost between the erosion boundary and the thaw unconformity did not have a micro-lenticular cryostructure. This indicates that after deposition of the saturated sediments, the release of heat from the water trapped in the underground channels melted the ground ice of the adjacent syngenetic permafrost. Freezeback of the thawed sediment created an ice lens marking the thaw unconformity. When underground channels were observed to cut through prior channels the thaw unconformities were located in the sediment of the eroded channels (Fig. 2). Thaw unconformities were also observed in the ice wedges cut by channels. Millimeter-thick ice lenses, often with elongated air bubbles aligned perpendicular to the thaw unconformity, were intercalated between the ice wedge and the sediments of the underground channels.

Usually, the sediments deposited in the underground channels were characterized by a reticulate-chaotic cryostructure made of multi-directional interconnected ice veins and ice lenses (Fig. 3).

Close to the underground channel boundaries, the ice veins were aligned perpendicular and the ice lenses parallel to the erosion unconformities. The concentration of ice veins and ice lenses were higher close to the channel boundaries, especially but non-exclusively at the bottom of the channels and decreased toward the center of the channel (Fig. 4). In the underground channels, the layers of sediments with reticulate-chaotic cryostructure were sometimes intercalated with centimeter-thick layers of clear ice with mineral or organic inclusions (Fig. 1).

About 60% of the underground channels cutting through the ice wedges and the enclosing syngenetic permafrost were partially or entirely filled by sub-horizontal non-foliated ice bodies (Fig. 4). The ice was clear to whitish, sometimes with orange to dark-brown bands in the central part and contained embedded organic matter. The ice had a columnar crystalline structure and bubble trains that suggested inward freezing. In the literature, this type of ice was previously called "thermokarst-cave ice" (Shumskii 1964b, Bray et al. 2006) or "pool ice" (Mackay 1988, 1997). We propose the term *tunnel ice* to describe massive ice bodies formed by inward refreezing of water trapped in underground thermo-erosion pipes, channels, and tunnels (Fortier et al. 2007). Usually at the bottom of these *tunnel ice* bodies we observed a sub-horizontal layer of sediment with a reticulate-chaotic cryostructure (Fig. 4).

Laboratory observations

The experiments in the laboratory reproduced reticulate-chaotic cryostructures similar to those observed in the field (Fig. 5). They were formed in the underground channel analogs during freezeback of the sediments.

The density of ice veins and ice lenses was always greater along the walls of the channel analogs than in the central part,

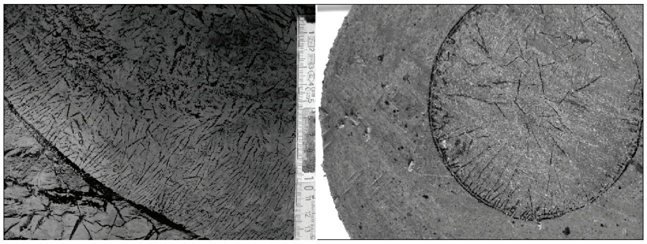

Figure 5. Comparison of field (A) and laboratory (B) observations. (A) Portion of an underground channel. The boundary (lower left corner) of the channel is outlined by a mm-thick ice lens. The sediments in the channel (right corner) are characterized by a reticulate-chaotic cryostructure (B) Channel analog 8 cm in diameter showing an ice lens at the channel boundary and reticulate-chaotic cryostructure similar to what was observed in the field (A).

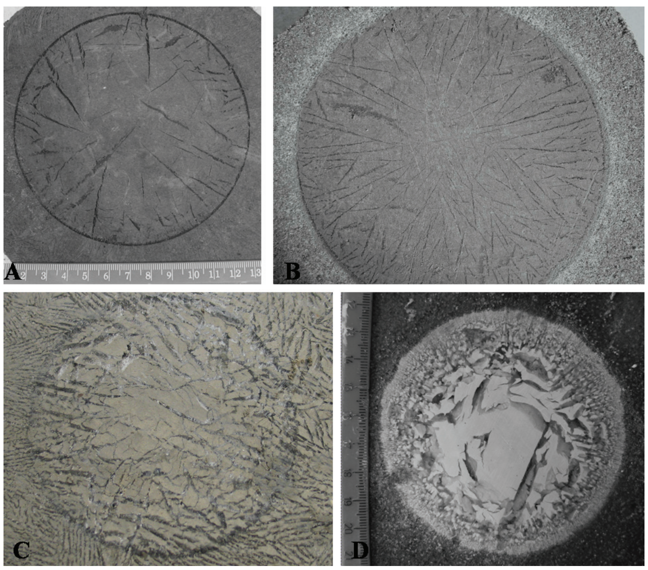

Figure 6. Cross-sections of channel analogs 8 cm in diameter with reticulate-chaotic cryostructures. (A) syngenetic eolian silt from the CRREL permafrost tunnel, 80% water content slurry; (B) fine silt <75µm, 80% water content, slurry; (C) fine silt <75µm and clay, 150% water content slurry; (D) clay, 150% water content slurry.

independent of grain-size and water content of the sediments (Fig. 6). Figures 6 and 7 show that the ice veins and ice lenses are often interconnected close to the boundary of the channel analog. In cross section, the ice veins were mostly aligned normal to the boundary. They extended toward the center with many ice lenses connected sub-perpendicular to them. The pattern of ice veins was more chaotic in the center of the channel analogs (Fig. 7). Consolidated sediments produced thin ice veins.

We observed thaw unconformities at the boundary of some underground channel analogs. On Figure 8, the ground ice in the frozen sediment enclosing the channel analog melted and secondary ice lenses were formed after freezeback.

Larger and thicker ice veins and ice lenses were formed in larger freezing cells. We used silt with a grain size fraction <75 µm and a water content of 150% for the slurry. Figure 9 shows that a thick ice lens was formed at the channel analog boundary. Large multi-directional ice veins were formed in the center of the channel analog.

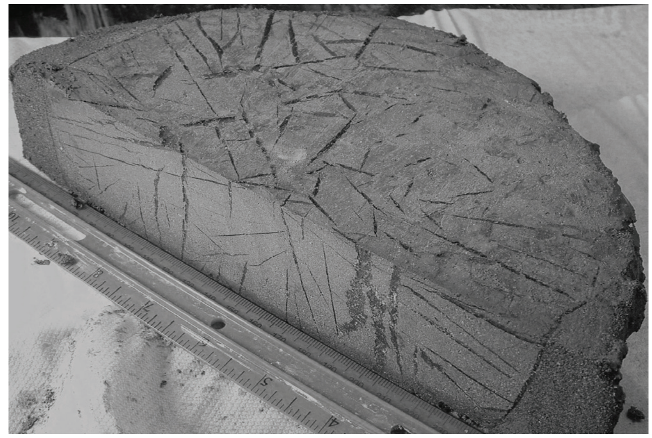

Figure 7. Cross-sections of a channel analog 25 cm in diameter (silt <75 µm, 150% water content slurry) with interconnected multi-directional ice veins and ice lenses. Note the similarity with reticulate ice veins of Figures 3 and 4.

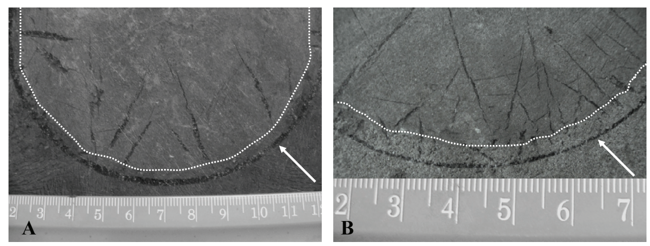

Figure 8. Cross-sections of channel analogs 8 cm in diameter showing thaw unconformities (arrows) located in the enclosing frozen ground. The dotted lines indicate the channel analog boundaries. (A) fine eolian silt from the CRREL permafrost tunnel with 80% water content. (B) coarse eolian silt from the CRREL permafrost tunnel with 80% water content.

We observed that fine-grained sediments produced more and larger ice veins and ice lenses than coarse-grained sediments. In Figures 6A and 6B, eolian silt from the CRREL tunnel was used for the experiment. In the experiment of Figure 6C, we used a mix of silt with a grain size fraction <75 µm and kaolinite clay. Experiments with clay soils are presented in Figures 6D and 10. The fine sediments produce a well-developed reticulate-chaotic cryostructure with a high density of ice veins and ice lenses. Figure 10 shows that the chaotic nature of the cryostructure and the formation of a thick ice lens at the channel analog boundary were better expressed in clay sediments.

In Figure 8A the gravimetric ice content of the sample after freezing was 122% at the channel boundary and 51% in the center whereas it was 58% at the channel boundary and 53% in the center in Figure 8B.

Discussion

Mechanism of reticulate-chaotic cryostructure formation

We observed in our experiments that saturated and super-saturated sediments trapped in frozen cavities (underground channel analogs) and submitted to slow inward freezing develop a reticulate-chaotic cryostructure. After deposition of the sediment, release of heat from water trapped in the

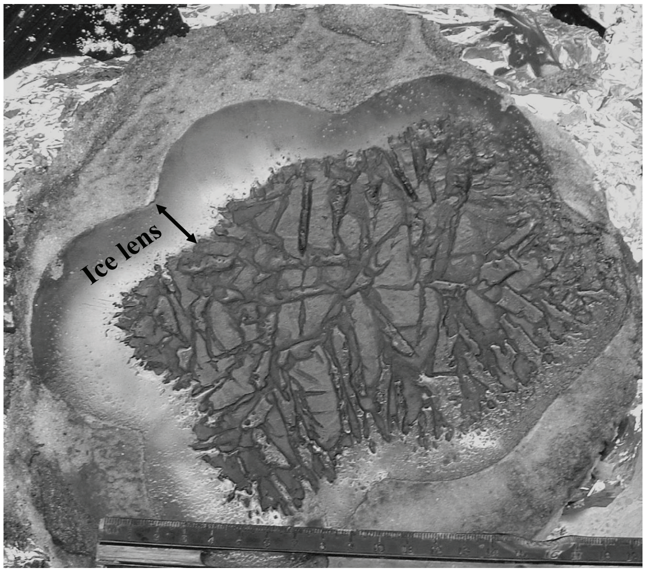

Figure 9. Cross section of a large channel analog formed in a large freezing-cell. A thick lens of pure ice was formed along the channel boundary between the coarse frozen sand and the fine silt (dark colored) in which large interconnected multidirectional reticulate ice veins were formed. The gravimetric ice content of the silt is 287%.

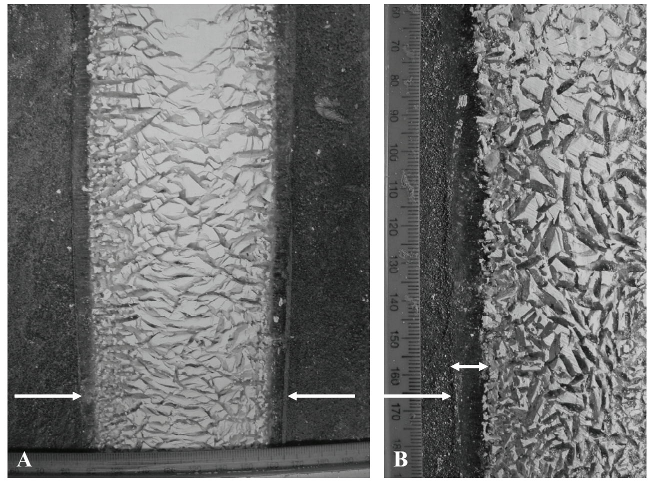

Figure 10. (A) longitudinal cross-section of a channel analog 8 cm in diameter. (B) Close-up of (A) showing a well-developed ice-rich reticulate-chaotic cryostructure in clay (150% water content slurry) with a thick ice lens (arrows) at the channel boundary.

sediment can melt the ground ice in the adjacent frozen sediments (Fig. 7). Inward freezing of the sediment creates one or more ice lenses at or close to the channel boundary (Figs. 6, 7, 8, 9, 10). Thicker ice lenses and larger reticulate ice veins were developed in: (1) slow freezeback scenarios (large freezing cells), (2) sediments with high water content, and (3) fine-grained sediments (fine silt and clay) (Figs. 6C, 6D, 9, 10). Due to redistribution of water in a closed system, the periphery of the underground channels analogs contained more ground ice than the center. At the beginning of freezing the uniform propagation of the freezing front inward created similarly aligned reticulate ice vein along the channel boundary. The chaotic nature of the reticulate ice veins is better expressed towards the center of the channels due to the slowing down and uneven inward propagation of the freezing front in sediments with lower water contents.

Formation of reticulate-chaotic cryostructures in the CRREL permafrost tunnel

Our experiments support the idea that reticulate-chaotic cryostructures were formed in relation to thermo-erosional events in the CRREL permafrost tunnel. A widespread network of underground channels was developed and buried during the syngenetic aggradation of the permafrost. The channels enclosed in the syngenetic eolian silt and cutting through the ice wedges were formed by underground thermo-erosion (Péwé 1982, Fortier et al. 2007). The stratified sediments in the tunnel were deposited by water flowing into the underground channels and after the cessation of the underground flow, either due to blockage or after the surface run-off period. The multi-directional ice veins observed in the sediments filling up the channels and at the base of the non-foliated *tunnel ice* bodies were formed after inward freezing of the sediments. Slow freezeback of supersaturated fine-grained silt developed dense reticulate-chaotic cryostructure patterns with thick ice veins.

Conclusion

Freezing of sediments trapped in underground channels cut by thermo-erosion in the permafrost that are submitted to inward freezing develops a reticulate-chaotic cryostructure. Availability of water, its ability to move through the sediments, and the rate of freezing can create thick ice lenses at the channel boundary and large multi-directional reticulate ice veins in the sediments. The irregular nature of the reticulate-chaotic cryostructure is linked to the uneven propagation of the freezing front in a closed-system with limited water supply. The reticulate-chaotic cryostructure is often observed close to or in contact with *tunnel ice* bodies. This type of ice is formed by inward freezing of water trapped in the underground channels. Our results help to identify ground ice associated with the process of underground thermo-erosion in permafrost exposures.

Acknowledgments

Special thanks are owed to the Fairbanks Office of the Cold Regions Research and Engineering Laboratory for access to the CRREL permafrost tunnel. Margaret Cysewski, Matthew Dillon, and Eva Stephani provided great assistance in field and in the laboratory. The reviewers and the associate editor are gratefully acknowledged for their suggestions to improve the manuscript. Abstract

The spatio-temporal evolution of lithalsas and thermokarst ponds near Umiujaq in Nunavik (Canada) was studied using time-lapse aerial photographs collected in 1957, 1983, and 2003, and IKONOS satellite images taken in 2005 to assess the permafrost degradation. Nine typical sectors located in valleys totalizing a survey area of 2.245 km^2 were selected. The areas occupied by the lithalsas and thermokarst ponds were respectively 0.421 and 0.024 km^2 in 1957 (18.8 and 1.1% of the survey area) and 0.251 and 0.066 km^2 in 2005 (11.2 and 3.0%). The permafrost extent decreased 40%, while the thermokarst one increased 175% in 48 years. According to the climate data from Environment Canada, the mean annual air temperature was quite variable over the study period but increased 3°C during the last 15 years. Climate warming is therefore the main driver of permafrost degradation, but other concurrent mechanisms affecting the thermal balance of permafrost exacerbate the observed degradation.

Keywords: climate warming; lithalsas; mapping; permafrost degradation; thermokarst ponds; time-lapse aerial photographs.

Introduction

Both palsas and lithalsas are cryogenic mounds formed in frost-susceptible marine sediments under a cold climate (Pissart 2002). They are important components of the periglacial landscape in the discontinuous permafrost zone in Nunavik (Canada). The tops of these periglacial features stand a few meters above the surrounding ground due to the accumulation of segregation ice; their mineral cores are ice-rich and they have a diameter of a few tens of meters making them easily recognizable on aerial photographs even at a scale as large as 1:40,000. They are an excellent indicator of the presence of ice-rich permafrost. While the palsas are covered by peat, the lithalsas are free of peat cover (Pissart 2002) and their surfaces are dotted with frost boils. Permafrost degradation due to climate warming and eventually the thawing of lithalsas leave ramparted thermokarst ponds (Luoto & Seppälä 2003, Pissart 2002).

Based on paleoecological studies of permafrost peatlands (Allard & Seguin 1987b), the inception of palsas occurred during cold periods of the Holocene with a maximum extent during the Little Ice Age (LIA), but they are now decaying in response to climate warming. The thawing of palsas and lithalsas located in the discontinuous permafrost zone along the east coast of Hudson Bay, Nunavik (Canada), was studied respectively by Payette et al. (2004) and Vallée & Payette (2007). Their results show continuous permafrost degradation during the 20th century. Between 1957 and the beginning of the 21st century the area occupied by ice-rich permafrost decreased by 84% and 23% respectively at the southern and northern limits of the discontinuous permafrost zone. Permafrost loss was compensated by a concurrent gain in thermokarst ponds. The subsidence of palsas surfaces due to the ground ice melting was of the order of 1 to 1.5 m from 1993 to 2003 (Payette et al. 2004). According to Payette et al. (2004), the main climatic driver for accelerated permafrost thawing was snow precipitation. The hydric conditions affect also the dynamics of lithalsas and control in part their decay (Vallée & Payette 2007).

The purpose of the present study is to map the spatial distribution of lithalsas and thermokarst ponds near Umiujaq in Nunavik (Canada) using time-lapse aerial photographs and satellite images to assess the permafrost degradation since 1957. The comparison of these photographs will allow the evaluation of the decrease of ice-rich permafrost extent. Since the thermal regime of the lithalsas is closely related to climate changes, the assumption of permafrost degradation due to climate warming recently observed in Nunavik (Chouinard et al. 2007) will be thus verified.

Study Area

The study area is located in the discontinuous permafrost zone close to the Inuit community of Umiujaq on the east coast of Hudson Bay, Nunavik, Canada (Figs. 1, 2). The deglaciation of the area took place 7600–7300 years ago. Marine sediments were then deposited in deep valleys. After emergence, the deposits were eroded and colonized by vegetation, and ice-rich permafrost aggraded. Large fields of lithalsas are found in the valleys.

Lithalsas and Thermokarst Ponds

An example of a recent collapse of a lithalsa due to climate warming and an expansion of a thermokarst pond to the detriment of the lithalsa is shown in Figure 3. According to field observations including deep temperature profiles

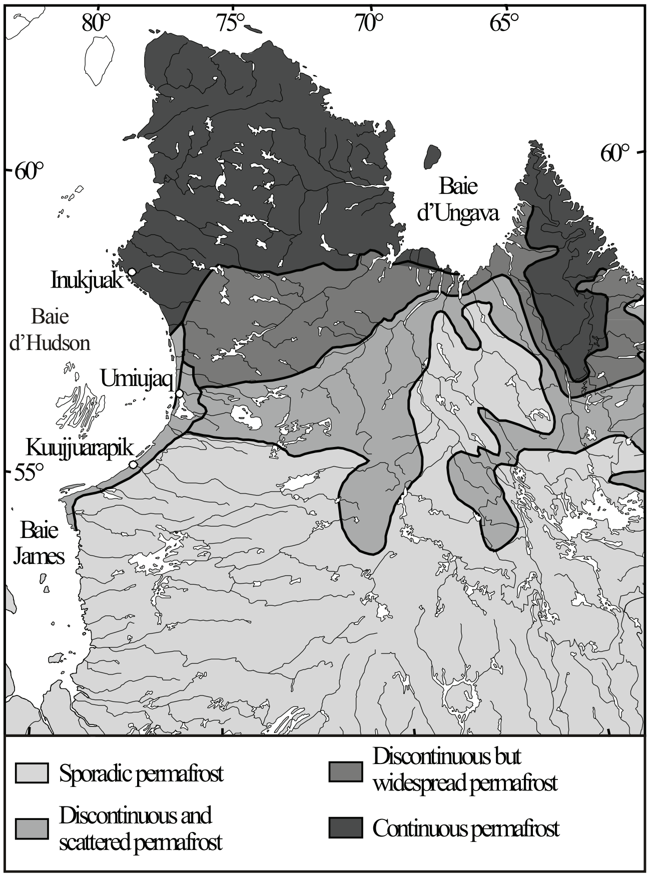

Figure 1. Map of permafrost distribution in Nunavik, Canada (modified from Allard & Seguin 1987a). Location of the Inuit communities of Kuujjuarapik, Umiujaq and Inukjuak along the east coast of Baie d'Hudson.

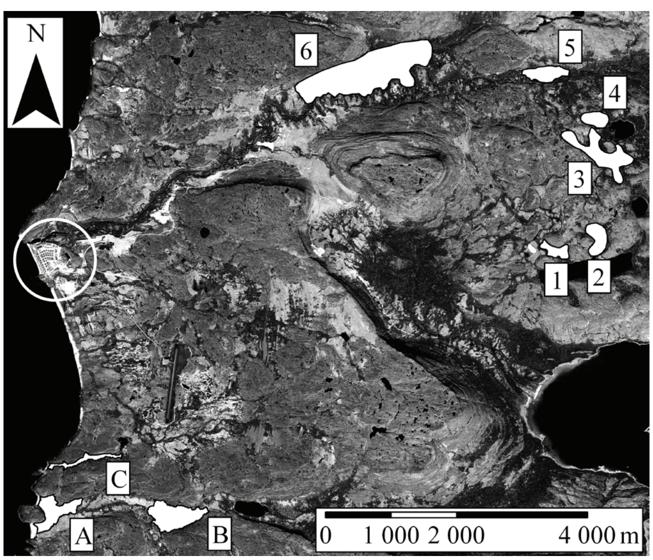

Figure 2. IKONOS satellite image of Umiujaq taken on July 26th 2005. Location of the Inuit community of Umiujaq (white circle) and the nine sectors (white areas identified with a number or a letter) mapped in the present study.

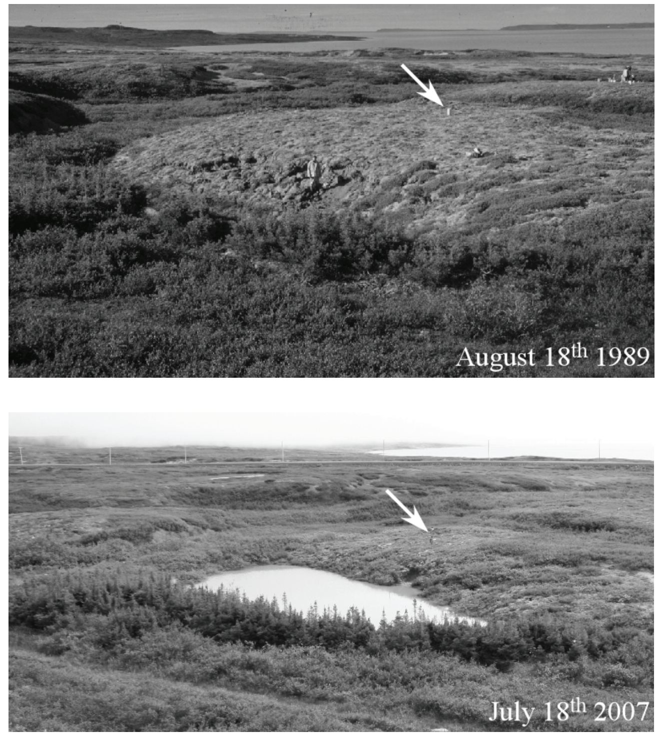

Figure 3. Example of permafrost degradation in 18 years from August 1989 to July 2007. The thermokarst pond on the left overruns progressively to the right the lithalsa. The arrow indicates the location of a thermistor cable. Note the man in the forefront near the small active layer detachment failure on August 18th 1989 for the scale. The road leading to the airport of Umiujaq in the background in 2007 was not yet built in 1989.

near Umiujaq, a typical lithalsa has a diameter of 40 m and a height of 2.5 m above the surrounding ground; the active layer is 1.5 m thick and the permafrost base is 12.5 m deep. The average volumetric ice content of the ice-rich core is 50%. For a permafrost thickness of 11 m, the total thickness of segregated ice lenses is then 5.5 m. The difference of 3 m between the frost heaving of the lithalsa surface and the ice accumulation is due to the irreversible over-consolidation of marine sediments occurring during freezing. These sediments were first deposited in a normally consolidated state before freezing. The formation of segregation ice fed by cryosuction can induce a decrease in void ratio as high as 30% of the saturated sediments in the freezing fringe (Konrad & Seto 1994). Therefore, after the permafrost thaws, a depression filled with water as deep as 3 m is left (2.5–5.5 m or 30% decrease in void ratio of a 10 m thick sediment layer). Due to solifluction on the lithalsa slopes there is an accumulation of materials on its sides explaining the remnant ring-shaped rampart left around the thermokarst pond (Fig. 3). Typically, a rampart is 3 m wide and 1 m high above the surrounding ground for an approximate volume of 350 m^3. This volume accounts for about 0.30 m (350 m^3 over a surface area of 1250 m^2) of the depression left. Following the water budget, drainage system and sediments permeability, the thermokarst pond can be more or less filled with water (Yoshikawa & Hinzman 2003).

Methods

Three series of aerial photographs collected in 1957 (series A-15618, Natural Resources Canada), 1983 (series Q83857 and Q83858, Ministère des Ressources naturelles et de la Faune, Québec) and 2003 (series Q03201, Ministère des Ressources naturelles et de la Faune, Québec), and one IKONOS satellite image taken in 2005 (Fig. 2) were used to map the spatio-temporal evolution of the lithalsas and thermokarst ponds. The snow cover was not totally melted in the series of aerial photographs taken on June 18, 1957 (Fig. 4A) making difficult the delineation of the thermokarst ponds. The aerial photographs in 1983 and 2003 cover only the west part of the satellite image including the village and airport infrastructures (Fig. 2). The satellite image was provided in a digital format, already orthorectified according to a digital elevation model of the world, and georeferenced.

Nine sectors typical of the lithalsas fields found in the study area and totaling a survey area of 2.245 km^2 were selected (Fig. 2). The mapping of permafrost degradation was carried out using ArcMap from ESRI. The satellite image allowed not only the delineation of the limits of lithalsas and thermokarst ponds in 2005 but also the georeferencing and rectification of the aerial photographs before mapping these periglacial features in 1957 and 1983. Based on numerous tie points selected and identified on both satellite image and aerial photographs, the georeferencing and rectification of the digitized aerial photographs were performed for each sector. The stereoscopic view of the aerial photographs in 1957, 1983, and 2003 allowed the delineation of the limits of lithalsas and thermokarst ponds. The lithalsas and thermokarst ponds look like heaved forms and ramparted depressions filled with water respectively and can be easily identified and mapped on the aerial photographs. However, only the water surface was mapped. These limits were then reported on different layers in ArcMap. Because the aerial photographs in 2003 and the satellite image in 2005 were so close in time, there was no real change in permafrost extent. However, the stereoscopic view of the photographs in 2003 was quite useful for delineating the lithalsas and thermokarst ponds on the satellite image in ArcMap.

Results

Spatial distribution of lithalsas and thermokarst ponds

An example of permafrost degradation mapping between 1957 and 2005 for Sector 1 (Fig. 2) is given in Figure 4. Permafrost degradation was already occurring in 1957 under the form of small thermokarst ponds mainly located along the northern valley wall and east of Sector 1 (Fig. 4E). The decrease in permafrost extent is major in the 48 years from 1957 to 2005. Most of the permafrost degradation visible in 2005 has taken place principally along the northern valley wall where the thermokarst ponds have replaced the lithalsas (Figs. 4G, 4H, 5).

The statistics on the areas occupied by the lithalsas and thermokarst ponds in 1957 and 2005, and the difference in areas between 1957 and 2005 appear in Table 1 not only for Sector 1 but also for the other sectors. The numbers of lithalsas or thermokarst ponds mapped in each sector and the numbers of vanished lithalsas or appeared thermokarst ponds between 1957 and 2005 are also given in Table 1.

The permafrost and thermokarst extents were also mapped on the aerial photographs taken in 1983 only for Sectors A, B, and C covered by this series of aerial photographs (Table 1). The rate of permafrost degradation increased in recent years from an annual loss rate of 380 m^2 or 0.8% between 1957 and 1983, to 640 m^2 or 1.6% between 1983 and 2005.

Spatial accuracy of the mapped areas

The spatial accuracy of the areas occupied by the lithalsas and thermokarst ponds is evaluated to 20% and 60% respectively. It depends on the spatial resolution of the aerial photographs and satellite image and the capability of the cartographer to delineate accurately the limits of the lithalsas and ponds. According to statistics drawn from the mapping, the average areas occupied by a lithalsa and a pond are 1200 m^2 and 130 m^2 respectively. If these areas are assumed to be perfect circles, the average radius is 20 m for a lithalsa and 6 m for a pond. The pixel side of the aerial photographs and satellite image is about 0.8 m. If an accuracy of ±2 m for the radius is supposed to take into account the spatial resolution and the error on the limit delineation, respective accuracies of ±250 and ±80 m^2 are found for the areas occupied by a lithalsa and a pond. For the photographs taken in 1957, the spatial accuracy of the areas occupied by the ponds is likely higher than 60% due to the snow cover still present at that time in the depressions between the lithalsas hiding the ponds (Fig. 4A).

Discussion

Climate variability

According to Chouinard et al. (2007), the surface temperature at the end of the LIA in Nunavik was colder of 1°C in comparison to the reference period 1961–1990.

Climatic data are available for the Inuit communities of Kuujjuarapik and Inukjuak respectively 160 km south and 250 km north of Umiujaq (Figs. 1, 6). No trend in snowfall is obvious over the record period (Fig. 6A). However, a marked trend to climate warming of at least 3°C is observed since 1992 (Figs. 6B, 6C). The mean annual air temperature is well above the average air temperature found for the reference period 1961–1990 plus one standard deviation since 1998 except for 2004.

Permafrost degradation

The thermal regime of permafrost is closely related to climate changes, and the main mechanism of permafrost decay is climate warming. Permafrost thawing is a long-term process due to the latent heat of fusion of ice delaying the impacts of climate warming on permafrost. The permafrost degradation already observed in 1957 (Figs. 4A and 4E) was therefore inherited from climate warming of 1°C since the LIA (Chouinard et al. 2007). In 1957 the lithalsas were probably not yet in equilibrium with the climate and permafrost degradation was still in progress.

The data in parentheses are the numbers of lithalsas or thermokarst ponds mapped in each sector.
The data in parentheses are the numbers of vanished lithalsas or appeared thermokarst ponds between 1957 and 2005 in each sector.
Difference relative to the area of each sector.
Difference relative to the area occupied by the lithalsas or thermokarst ponds in each sector in 1957.
Only Sectors A, B and C are covered by the aerial photographs taken in 1983.

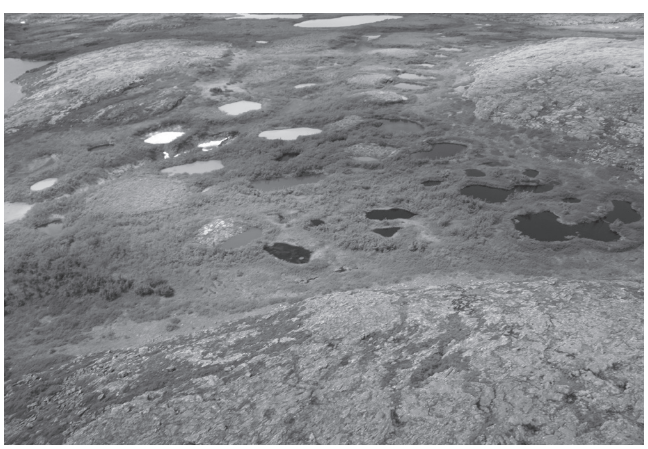

Figure 5. Aerial view of the sector no. 1 looking to the west taken on July 14, 2007. The presence of thermokarst ponds is more important close to the northern valley wall than in the middle of the sector.

From 1957 to 1983, the climate was more or less stable (Fig. 6), but the permafrost was still decaying at a loss rate of 0.8%/year for Sectors A, B, and C (Table 1). However, due to the trend of climate warming of 3°C over the last 15 years (Fig. 6), the rate of permafrost decay increased to a value of 1.6%/year between 1983 and 2005. The variability of annual snowfall without any trend (Fig. 6A) can be ruled out as a potential explanation of permafrost decay. Even if the actual climate stabilizes, permafrost decay will continue until a new thermal equilibrium is reached.

In addition to climate warming, other concurrent mechanisms affect the thermal balance of permafrost and exacerbate its degradation. The melting of ground ice in excess induces a differential thaw subsidence more important on the warmer sides of a lithalsa than its top. The subsidence is progressing from the sides to the top of the lithalsa (Fig. 3). Thaw subsidence allows the formation of a small thermokarst pond and the

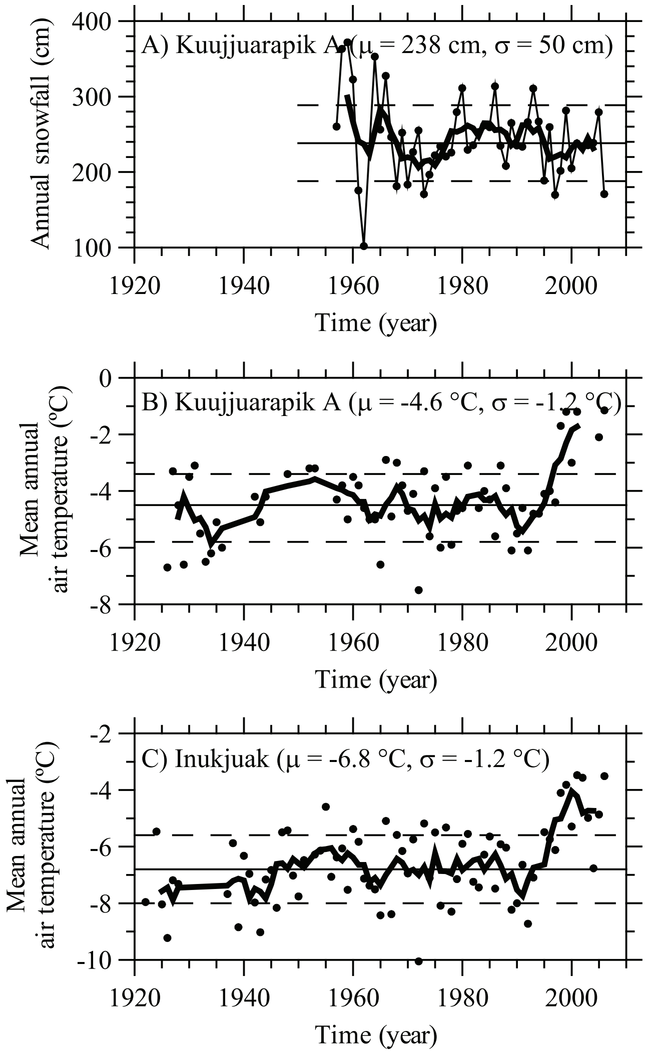

Figure 6. A) Annual snowfall at Kuujjuarapik A. Mean annual air temperature at Kuujjuarapik A (B) and Inukjuak (C). Climate data from Environment Canada. Thick lines correspond to a 5-year running average through mean annual snowfall or air temperature. Full and dotted horizontal lines are respectively the average and ±standard deviation (values in parentheses) of snowfall or air temperature over the reference period 1961-1990.

accumulation of snow. Freezing of the active layer underneath the thermokarst

pond is delayed the next winter due to the latent heat of freezing of water while the thermal insulation of thick snow cover also prevents further ground freezing. In addition, the vegetation growth under less severe climatic conditions favors the accumulation of snow in winter. These multiple degradation mechanisms have a snow ball effect. As soon as permafrost warming begins, these mechanisms operate and eventually can cause the lithalsa disappearance even if the climate is stabilized at some point. The warmest lithalsas, such as the ones close to the valley walls where the marine deposits are thinner and the heat flow is higher due to the high thermal conductivity of rock close to the surface are more susceptible to disappear first (Figs. 4A, 4B, and 5). The heat coming from running water on the valley walls can also contribute to permafrost warming.

Conclusions

Widespread and fast permafrost degradation is currently occurring at Umiujaq, Nunavik (Canada). These changes in the periglacial landscape were documented using time-lapse aerial photographs collected in 1957, 1983, and 2003, and satellite images taken in 2005. The rate of permafrost degradation increased over the last two decades due to a trend to climate warming of 3°C observed in Nunavik since 1992. At the annual loss rate of 1.6% found between 1983 and 2005, the disappearance of ice-rich permafrost will occur in this region through the next five to ten decades.
